ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—J. D. Barris and M. Donaldson: Acute Inversion of the Uterus. Treatment by Blood Transfusion and Late Replacement.—Drs. R. A. Hendry, A. Routh, and J. Adams: Latent Syphilis During Pregnancy.

FRIDAY, NOVEMBER 5.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science), at 2.30.—Prof. F. W. Oliver: The Reclamation of Waste Land by Botanical Means.—Dr. E. J. Russell: The Reclamation of Waste Land by Agricultural Means.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.

GEOPHYSICAL COMMITTEE (Royal Astronomical Society), at 5.—Discussion on the African Arc and Meridian, to be opened by Col. H. G. Lyons, and continued by Sir Charles Close, Col. E. M. Jack, A. R. Hinks, C. G. T. McCaw, and others.

NEWCOMEN SOCIETY FOR THE STUDY OF THE HISTORY OF ENGINEERING AND TECHNOLOGY (at the Patent Office Library), at 5.30.—E. W. Hulme: Introduction to the Literature of Historical Engineering.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Sir Richard T. Glazebrook: Limit Gauging (Thomas Hawksley Lecture).

JUNIOR INSTITUTION OF ENGINEERS (at Caxton Hall), at 8.—E. Cooper: Some Further Locomotive History.

ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—Dr. D. W. Buxton: The Psychology of Anæsthesia.

MONDAY, NOVEMBER 8.

BIOCHEMICAL SOCIETY (at Imperial College of Science).

ROYAL SOCIETY OF MEDICINE (War Section), at 5.30.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Meeting), at 7.—C. Poole: Electric and Hydraulic Elevators.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Annual Presidential Address.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street), at 8.—Dean W. R. Inge: Is the Time Series Reversible? (Presidential Address).

SURVEYORS' INSTITUTION, at 8.—J. Wilmot: Presidential Address.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Brig.-Gen. The Hon. C. G. Bruce: Mount Everest.

MEDICAL SOCIETY OF LONDON (at 11 Chandos Street, W.1), at 8.30.—Clinical Meeting.

TUESDAY, NOVEMBER 9.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. E. G. Browne: Arabian Medicine after Avicenna (FitzPatrick Lecture).

SOCIOLOGICAL SOCIETY (at 65 Belgrave Road, S.W.1), at 5.15.—Mrs. V. Branford: Theology and Sociology.

MINERALOGICAL SOCIETY (at Geological Society), at 5.30.—(Anniversary Meeting.)—Dr. E. S. Simpson: A Graphic Method for the Comparison of Minerals with Four Variable Components forming Two Isomorphous Pairs.—L. J. Spencer: Fibrolite (= Sillimanite) as a Gem-stone, from Burma and Ceylon.—Dr. J. W. Evans: The Origin of the Alkali Rocks.—A. F. Hallimond, with an analysis by J. H. Whiteley: Monticellite, from a Mixer Slag.—Dr. H. H. Thomas and A. F. Hallimond: A Refractometer for the Determination of Liquid Mixtures.

ROYAL PHOTOGRAPHIC SOCIETY, at 7.—Presidential Address.

OLD STUDENTS' ASSOCIATION OF THE ROYAL COLLEGE OF SCIENCE (at Imperial College Union, South Kensington), at 8.—Viscount Haldane: The Nationalisation of Universities.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Dr. W. H. R. Rivers: The Origin of Hypergamy.

ROYAL SOCIETY OF MEDICINE (Psychiatry Section), at 8.30.—Dr. E. F. Buzzard: Some Aspects of Mental Hygiene (Presidential Address).

WEDNESDAY, NOVEMBER 10.

ROYAL SOCIETY OF MEDICINE (Surgery: Proctology Sub-section), at 5.30.—E. Miles: Presidential Address.—L. Mummery: The Operative Treatment of the Prolapse of the Rectum in Adults.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Institution of Mechanical Engineers), at 8.—J. H. S. Dickenson: Some Notes on the Report of the Steel Research Committee.

THURSDAY, NOVEMBER 11.

ROYAL SOCIETY, at 4.30.—*Probable Papers*:—Dr. W. G. Ridewood: The Calcification of the Vertebral Centra in Sharks and Rays.—Dr. A. Compton: Studies in the Mechanism of Enzyme Action. I. *Rôle* of the Reaction of the Medium in fixing the Optimum Temperature of a Ferment.—C. H. Kellaway: The Effect of certain Dietary Deficiencies on the Suprarenal Glands.—E. J. Collins: The Genetics of Sex in *Funaria hygrometrica*.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—Annual General Meeting.

ROYAL SOCIETY OF MEDICINE, at 5.—Sir Almroth Wright: Medical Research.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. E. G. Browne: Arabian Medicine after Avicenna (FitzPatrick Lecture).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir D'Arcy Power: The Education of a Surgeon under Thomas Vicary (Thomas Vicary Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Ll. B. Atkinson: Inaugural Address.

OPTICAL SOCIETY, at 7.30.—Major E. O. Henrici: The Use of Internal Focussing Telescopes for Stadia Surveying.—Dr R. J. E. Hanson: Visual Fatigue and Eye Strain in the Use of Telescopes.

ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Dr. H. Head and Others: Discussion on Aphasia.

FRIDAY, NOVEMBER 12.

INSTITUTE OF CHEMISTRY, at 4.—To Receive Report of the Extraordinary General Meeting of October 28 and confirm the Resolutions and By-laws passed thereat.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—Dr. F. S. Goucher: Ionisation and Excitation of Radiation by Electron Impact in Helium.—J. Guild: Fringe Systems in Uncompensated Interferometers.—J. Guild: The Location of Interference Fringes.—Dr. G. Barr: A New Relay for Moderately Heavy Currents.

ROYAL ASTRONOMICAL SOCIETY, at 5.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.—Dr. F. Parkes Weber: Chronic Myeloid Leukæmia—Death from Acute Anæmia due to Massive Hæmorrhages (Hæmatomata). Simulation of Slight Pyuria by Leukæmic Oozing in the Urine.—Z. Cope: Diathragmatic Shoulder Pain.

INSTITUTION OF MECHANICAL ENGINEERS, at 7.—Informal Meeting.

ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30.—Dr. J. Taylor: Some Neurological Aspects of Ophthalmic Cases (Presidential Address).—P. Smith: The Blood-vessels in the Eye of the Ox.

Superannuation of University Teachers.

AN inquiry is being made by the Council of the Federated Superannuation System for Universities as to "what capital sums would be involved to place senior members of the staffs of university institutions in receipt of Treasury grants in a position comparable with that they would have enjoyed had the federated scheme been in operation during the tenure of their university appointments." This inquiry has been authorised by the Treasury through the University Grants Committee. It may not be generally known, however, that the suggestion arose in the Council of the Federated Superannuation System, and the authorisation simply means that the Treasury is paying the expenses involved in the inquiry. No doubt by this time the staffs of the various university institutions have received copies of the relative form of inquiry with a request to fill in certain particulars, and most of them will not require to be told that the simplicity of the questions has no obvious relation to the difficulty of answering them.

We fear that the services of the psycho-analyst will have to be requisitioned if retrospective particulars regarding salaries are to be given with any degree of accuracy. In point of fact, we seriously doubt whether these particulars can be given with the necessary degree of accuracy; if some other principle is not adopted, the inquiry might easily develop into a farce. Apart from this, however, two facts emerge—(1) the ambiguity in the use of the term *senior*, and (2) the restricted use of the term *service*. If we are to suppose that one section of university teachers is to be considered in respect of retrospective benefits, and another not, it is perfectly clear to anyone who really understands the temper of university teachers that the University Grants Committee and the Treasury are asking for trouble. Where is the line to be drawn? Why, indeed, should it be drawn? If retrospective benefits are to be given to one, they should be given to another. The School Teachers (Superannuation) Act makes no such distinction in respect of its beneficiaries. The framers of that Act had no desire to bring a hornet's nest about their ears! To draw any such line between one set of university teachers and another, or to limit the retrospective benefits to a certain number of years or to those in receipt of salaries above a certain figure, would be manifestly unjust, and will inevitably lead to criticism and provoke discontent.

Serious as this point is, however, it is not so serious as the question of service. The inquiry is being directed to ascertain the amount of service in universities, constituent colleges of universities, and university colleges, the implication being that no service outside such institutions is to count for retrospective benefits. If this is what is meant, and it is difficult to interpret the inquiry in any other sense, a grave injustice will be done to a not inconsiderable number of university teachers at the present moment, and a distinct injury will be inflicted upon the universities in the future. According to this interpretation, a university teacher who has at some time or other of his career seen service in a school—elementary or secondary—or in a college of non-university rank, will not be allowed to calculate such service as pensionable in respect of retrospective benefits. Surely this is a very absurd position of affairs. As for the future, if the same principle operates, one of the bridges, and a very important one, connecting the schools with the universities will be broken down. If, for example, a teacher spends the whole of his career in a school, or the whole of it in a university, he will receive full pension benefits; but if he is so unfortunate as to spend part of his career in a school or technical college of non-university rank before becoming a university teacher, he is to be mulcted of some portion of his pension benefits. This being so, a barrier is set up, and not only the schools suffer, but also the universities.

The position is quite indefensible. The Council of the Federated Superannuation System, the primary function of which should be the conservation and the extension of pension benefits to university teachers, ought to recognise this. If our understanding of the position is correct, the council may rest assured that university teachers will not be content to remain passive under such an anomalous scheme. We may remind our readers that the conference of representatives of universities and colleges which waited upon the Chancellor of the Exchequer on June 17 last presented the following resolution to him: "That this conference is of opinion that the interests of English and Welsh education as a whole demand the institution of a scheme of superannuation for university teachers and administrative officials conferring benefits not inferior to those granted under the School Teachers (Superannuation) Act, 1918, and of a like retrospective character." This, we understand, is the absolute minimum which university teachers demand; if anything beyond this is granted, they are willing to pay for the additional benefits. They believe that their services, to say the least, are no less valuable to the State than the services of those who benefit under the Act, and that they should receive treatment no whit inferior. Their treatment under existing conditions is enough to rouse the righteous indignation of every just citizen. We had before us recently the case of a university professor who was compelled to retire on account of ill-health, after having taught for more than thirty years. All that he can receive from the Federated Superannuation System is a lump sum of 780*l.*, whereas had he been a teacher eligible for a grant under the Superannuation Act he would be entitled to a superannuation allowance of five-eighths of his average salary for the last five years of service, which would amount to a pension of 240*l.* per annum, and in addition he would have a gratuity of 640*l.* This is a typical case, and it would be easy to give many similar examples of manifest injustice to university teachers.

The suggestion that by receiving equal benefits they will put the yoke of State control round their necks is unworthy of the acumen of the Chancellor of the Exchequer. Already the universities receive an annual grant of 1,500,000*l.* (the total Education Vote this year is about 52,000,000*l.*), and yet they are not State-controlled. Is it conceivable that a Government for an addition of one-twentieth of the university grant—for this is approximately the annual amount that would be required to give university teachers similar benefits to those under the Teachers (Superannuation) Act—will demand State control of the universities? Why has the Government not demanded it up to now? Simply because it has the prescience to recognise that State control of the universities would be fatal to the highest development—intellectual, social, and industrial—of the community. The Chancellor of the Exchequer himself in his remarks to the conference expresses a doubt as to whether "it is an exaggeration to say that what did as much for the ruining of Germany as anything was the lack of independence and the lack of independent power of speech and thought by the teachers of the youth of Germany through all the branches." Is it likely that the Government, as a *quid pro quo* for a comparatively small addition to the annual grant, would propose to deprive the universities of their freedom when highly placed statesmen speak such language? Most unlikely! Is it likely, indeed, that the universities would submit to State control? In our opinion, the bogey of State control of universities as conjured up by Mr. Chamberlain is unthinkable. We begin to wonder what other argument will be adduced to support an absolutely untenable position.

One other fact remains to be stated. The Association of University Teachers, comprising some fifteen hundred full-time teachers in the universities and institutions of university rank in England and Wales, co-operated in the conference referred to above, and supported it in its demand. As a result of the failure of the deputation to the Chancellor of the Exchequer, it immediately instituted a postcard vote amongst its members, setting forth three alternative proposals. Seventy per cent. of the voters declared in favour of the extension of the School Teachers (Superannuation) Act to university teachers, and in consequence the executive has decided to adopt this as its superannuation policy. Here we have a significant fact. If the Council of the Federated Superannuation System, the University Grants Committee, and the Treasury are wise, they will ponder carefully over this indication of the direction in which the university teachers are moving.

Biology of Endogamy and Exogamy.

Inbreeding and Outbreeding: Their Genetic and Sociological Significance. By Dr. E. M. East and Dr. D. F. Jones. (Monographs on Experimental Biology.) Pp. 285. (Philadelphia and London: J. B. Lippincott Co., 1919.) Price 10*s.* 6*d.* net.

IT has been shown that close inbreeding of good stock, if associated with the usual common-sense elimination of wasters, may be persisted in for several generations without any undesirable consequences. Many fine breeds of animals and races of plants have had very close inbreeding at their beginnings. It is said that there is habitual endogamy among bees and ants, and we know that in some formicaries the females are inseminated without an outside excursion. It seems then that "inbreeding is not in itself harmful." This is the first conclusion that the authors of this excellent monograph reach.

One can go further, however, and maintain that close mating is positively advantageous. It fixes desirable characters and leads towards the establishment of a uniform and stable herd. But it is well known that this is only half the truth; there is sometimes an advance, but there is often a disappointing regression—a reduction of vigour, resisting power, fecundity, and even size. Thus the authors tell us that in the case of grain there is a reduction of productivity to perhaps half of what it was, while in the case of maize there is a marked reduction in size and rate of growth. The problem then is to explain the deterioration that sometimes sets in, and to discover whether it is due to the consanguinity as such or to something else.

Drs. East and Jones point out that if there are, to begin with, in the inheritance of the herd, say, four distinct hereditary factors relative to a particular character, such as the colour of the pellage, the automatic effect of the inbreeding will be to isolate four types, each pure as regards the particular character. But some of the characters which are thus segregated may be undesirable "recessives," seldom seen in ordinary circumstances, because they are hidden by their "dominant" allelomorphs. "These recessives are the 'corrupt fruit' which give a bad name to inbreeding, for they are often—very often—undesirable characteristics." "Inbreeding tore aside the mask, and the undesirable characters were shown up in all their weakness, to stand or fall on their own merits." This is an interesting theoretical interpretation, and it immediately suggests a practical application. For if the inbreeding brings to the surface certain characters which were in the general inheritance of the stock, but were kept out of sight by more favourable characters which dominated them, it is open to the breeder to practise stern elimination, to get rid of the "isolated" types with undesirable characters, leaving the stock all the better for its purgation. It need scarcely be said that the authors back up their conclusion with a wealth of experimental data, and that they give it the fit and proper technical formulation.

It is often useful to stand back, as it were, from the realm of organisms and the age-long process of organic evolution, and ask ourselves what the great steps or trends have been. We mean such steps as getting out of the water, substituting sexual for asexual reproduction, and establishing viviparity. Another great trend is the securing of cross-fertilisation, though the range of the cross varies within wide limits. Parthenogenesis has been tried, and it seems to work well enough among Rotifers; autogamy or self-fertilisation has been tried, and it seems to work well enough in the liver-fluke; but the broad fact is that some form of cross-fertilisation is the rule. And if we ask for the deep reason justifying this, the probable answer is that the survival value of cross-fertilisation lies largely in the fact that it promotes variability. It brings about a greater variety of raw material on which selective agencies can operate. Now the authors bring forward experimental evidence to show that the wider ranges of cross-fertilisation which are called outbreeding are valuable in promoting variability, and they have an interesting discussion of the limits of profitable crossing. The strains crossed may easily be too unlike.

But there is another advantage in outbreeding, that it promotes the mysterious quality called "vigour." Darwin was strongly of opinion that the gain in constitution derived from an occasional crossing was a more important biological fact than the loss that sometimes follows close inbreeding; the authors confirm this shrewd judgment. What is the meaning of this "hybrid vigour," which may be associated with increase in resisting power, in size, and in other good qualities? It has been suggested that some physiological stimulus comes to the offspring because of the unlikeness or apartness of the parents, but that is not the authors' view. They think that the reason for "hybrid vigour" is to be found in the pooling of diverse hereditary resources of good quality. The crossing makes it more likely that a *minus* on one side may be made good by a *plus* on the other, or that desirable dominants may corroborate one another.

Sterility is such a puzzling phenomenon that any suggestion from competent biologists is very welcome. The authors point out the striking fact that both inbreeding and outbreeding may land the organism in sterility, and they suggest that there may be two quite different kinds of diverse origin. Inbreeding tends to sort out homogeneous pure strains in a stock, and in this sifting the ability to reproduce may be lost. On the other hand, outbreeding may bring together two germ-cells too incompatible in their chromosomal complex to allow of the continuance of the germ-cell lineage. Thus it may be that the number of chromosomes in horse and ass is too discrepant to allow of fertile progeny.

We have to thank the authors for a valuable monograph, embodying the results of many personal experiments and a critical utilisation of material previously available in the work of others. The book is marked at once by independence and by scholarship. Of great interest to many will be the application of the biological results to the particular case of man. There is a carefully selected bibliography, which might have included perhaps a useful work by Reibmayr, "Inzucht und Vermischung beim Menschen" (1897).

Einstein's Exposition of Relativity.

Relativity: The Special and the General Theory. A Popular Exposition. By Prof. Albert Einstein. Authorised translation by Dr. Robert W. Lawson. Pp. xiii+138. (London: Methuen and Co., Ltd., 1920.) Price 5s. net.

A POPULAR exposition of the doctrine of Relativity and what it implies: for this the world has been crying since the astronomers announced that the stars had proved it true. Here is an excellent translation of Einstein's own book; we hasten to it to know the whole truth and nothing but the truth. The reviewer on this occasion should be the man in the street, the man who, with thousands, has been asking, "What is Relativity?" "What is the matter with Euclid and with Newton?" "What is this message from the stars?" Whether it is possible for the prophet to make his message clear to the multitude, only history can prove. He must needs speak largely in parables, in incomplete similes; and he is subject, therefore, to inevitable misunderstanding.

The plain fact is that Einstein asks the world to give up preconceptions, and to change its point of view. Men jump at suggestions of the fourth dimension, which promise some amusement, and room for a play of fancy. But the fourth dimension does not call for a very high flight of imagination; it is not taken very seriously; it is even recognised as a commonplace and somewhat old-fashioned intellectual pastime. A much more serious trouble comes in with the simple concrete instance. A passenger sitting in a train finds himself hurrying towards the other side of the carriage. He remarks that the brakes have been put on and the train is stopping. We are told that he may also interpret his experience thus: "The carriage remains permanently at rest . . . during the period of application of the brakes, the railway embankment, together with the earth, moves non-uniformly in such a manner that their original velocity in the backwards direction is continuously reduced." This seems to upset all the mechanics we had ever learned. For while we had always been carefully taught that the real explanation of the phenomenon lies in the stopping of the train while we ourselves move on uniformly, it is now held to be indifferent whether we adopt this attitude or think of the pressure of the driver's hand on the brake lever as imparting a change of motion to the whole earth and to ourselves—to everything, in fact, except the train. But the plain man feels there is a very real difference, and the ardent mathematician must indeed be living in an abstract world if he does not feel it too.

Here, indeed, is the great virtue of mathematics, that in it one may escape from the tyranny of gross perception. As Prof. Eddington puts it, the mathematician is never so happy as when he does not know what he is talking about. The engine-driver applying the brake does not know what happens either to the train or to the earth; he does know that he has some control over their relative motion. The mathematician does not know, and does not wish to know, what happens to this or that individual thing. He takes that for granted. He asks only what are the relations between events, or rather what can the mind know about them. Here only the genius can make progress. An unshackled imagination and a keen logical sense must combine in the adventure. The human mind has dared to look upon all history in space and time as laid out before it, and having thus overstepped the limits of mortality, it must go back and ask how much of this vision it may, as mortal, know.

At this moment rain is falling, leaves are rust-ling, a motor hurries along the road, the clouds are drifting. All is change and motion. It seems that all history is change, and all is hurrying by us as we stand. But is it not a truer view, certainly a less egoistic one, to see history as one eternal whole, and ourselves as voyagers through it, our vision of it ever changing? All our experiments, our measurings and comparisons are themselves part of the great web; we ourselves are part and parcel of it, and must acknowledge our incapacity to put ourselves outside. All our pictures and conceptions of the universe in time and space are but pictures, and the painters are many. There are strange differences between their records of what they have perceived—more, indeed, of difference than of similarity. We go to a picture-gallery; there is so much of difference that at first there seems little in common. Yet gradually we become conscious that the pictures are all drawn from a common life. We begin to be able to analyse the painters, and see what kind of a mind is looking out upon it, to detect a point of view. In so doing we grow more clear as to the one reality behind all the pictures.

This is a true parable of the great change that has been consummated in physical thought by Einstein's work. It is the recognition of the relativity of our space-and-time pictures that has clarified our understanding of the universal phenomena. Gravitation has not been explained. The mystery of it is ten times greater than before. To Newton it was one among many properties of that fundamental mystery "matter." It is almost true now to reverse the order and say that matter is one of the manifestations of the fundamental mystery of gravitation.

The reader of Einstein's exposition will need to ponder hard if he is to get to the heart of the matter. For it is a spiritual adventure upon which he has to embark. The very clarity and simplicity of the book may hide this from the over-confident. The parable may be understood and its meaning lost. But to those who have the vision the world of physics will take on a new and wonderful life. The commonest phenomena become organic parts of the great plan. The rationality of the universe becomes an exciting romance, not a cold dogma. The thrill of a comprehensive understanding runs through us, and yet we find ourselves on the shores of the unknown. For this new doctrine, after all, is but a touchstone of truth. We must submit all our theories to the test of it; we must allow our deepest thoughts to be gauged by it. The metaphysician and he who speculates over the meaning of life cannot be indifferent.

The Cambridge British Flora.

The Cambridge British Flora. By Prof. C. E. Moss, assisted by specialists in certain genera. Illustrated from drawings by E. W. Hunnybun. Vol. iii. Portulacaceæ to Fumariaceæ. Text: Pp. xvi+200. Plates: Pp. vi+191. (Cambridge: At the University Press, 1920.) Price, two parts, *6l.* 15*s.* net; two parts in one volume, *7l.* net.

THE previous volume of "The Cambridge British Flora" was reviewed in NATURE of August 6, 1914. Since this review was written many things have happened. Dr. Moss has been appointed professor of botany at the University College, Johannesburg, and has been unable to give personal attention to the volume during its passage through the press. The syndics of the University Press acknowledge valuable assistance given by Mr. A. J. Wilmott, of the botanical department of the British Museum, in correcting proofs and in dealing with questions which are normally settled by an editor. In July, 1918, Mr. E. W. Hunnybun died. A sympathetic note by Mr. Wilmott, at the beginning of the present volume, gives an interesting account of his method of work in preparing the illustrations, which makes clear both its advantages and limitations. The character of the illustrations has been much discussed among British botanists, but it became evident that Mr. Hunnybun could work only on his own lines, the accurate delineation of an individual specimen, and was also unable to supply the botanical details of structure of flower and fruit which, in the opinion of many, would have enhanced the value of the illustrations. As permanence is a consideration in a work of such importance as a standard British Flora, it is surprising to find the plates printed on a chalk-faced paper. Other events have tended to delay the appearance of the present volume, and to cause the serious increase in cost of production, which has necessitated raising the price to nearly three times that of the previous volume. The syndics of the Cambridge University Press must view this addition to their difficulties with grave anxiety, and it is to be feared that many students of our British flora who would wish to possess the book will be unable to meet the increased cost. The critical elaboration of a number of families will be of considerable value should the work fail of completion; but British botanists will feel deeply disappointed if it cannot be carried through satisfactorily.

The families included in vol. iii. are Portulacaceæ, Illecebraceæ, Dianthaceæ (more generally known as Caryophyllaceæ), Nymphæaceæ, Ceratophyllaceæ, Ranunculaceæ, Actæaceæ (comprising the single genus Actæa), Berberidaceæ, Pæoniaceæ (limited to Pæonia), Papaveraceæ, and Fumariaceæ. The genera Montia and Cerastium have been elaborated by Dr. G. C. Druce, several genera of Dianthaceæ by Prof. R. H. Compton, and the genus Fumaria by Mr. H. W. Pugsley. In view of unavoidable delay in publication, it would be an advantage if the dates of completion of the monographs of the various families and genera were given; this would avoid the necessity for explanation in such cases, for instance, as Mr. Pugsley's account of Fumaria, which is antedated in publication by his recent complete monograph of the genus in the Linnean Society's journal, but was probably completed before the more important work was undertaken.

Dr. Moss has intercalated in the text notes on systematic arrangement, limitations of orders and families, and discussions of points of nomenclature, many of which are of considerable interest, though sometimes difficult of appreciation by the ordinary student of British botany, who may, perhaps, consider the elevation of Actæa and Pæonia to the rank of distinct families as puzzling and unnecessary. On the other hand, the student of the British flora will welcome the careful and critical treatment of the genera, species, and varieties of his plants, and appreciate the notes on their respective distribution in Great Britain and Europe, and the discussions as to their indigenousness in doubtful cases. The outline maps indicating distribution are a useful feature, and the information conveyed therein may be supplemented should occasion arise.

It is to be regretted that personal matters should have been introduced into a work of this kind. "The Cambridge British Flora" will, presumably, take rank as a standard work, a presentation of the knowledge and views of eminent British botanists at a certain period in the history of botany, and to perpetuate the differences of opinion which have arisen on matters of very secondary importance detracts from the dignity which such a work should possess. The syndics of the Cambridge University Press would have been well advised if they had exercised a fatherly censorship on several paragraphs in the introduction to the present volume. In conclusion, we would express the hope that the two succeeding volumes, which will carry the work to the end of the family Rosaceæ, will be published with as little delay as possible.

A. B. R.

Man and Matter.

Religion and Science: From Galileo to Bergson. By J. C. Hardwick. Pp. ix+148. (London: S.P.C.K.; New York: The Macmillan Co., 1920.) Price 8*s.* net.

BECAUSE we wish to give a very favourable impression of this little book, we propose to state our criticisms at once, leaving no "but" to the end which might suggest a reservation on the part of the reviewer. Mr. Hardwick has written a very clear account of some of the chief movements of philosophic thought since the Renaissance, in so far as these bear on the concepts of science and of religion, though he modestly disclaims so large a plan. We doubt if the title is well chosen, in spite of its excellent simplicity. "Religion and Science" suggests apologetic, possibly ill-balanced and ignorant, and this the book emphatically is not. Further, the author's definition of science is unduly wide in scope. "Systematic and accurate knowledge about everything there is to be known" (p. 2) really covers the whole of philosophy: science, as the term is commonly understood, deals with the facts of the physical universe alone. Thus the statement that "religion and science regard reality from different angles, but it is the same reality that is . . . the goal of their search" (p. 6), though true for the author's definition, is not true for Prof. Karl Pearson's (which he quotes) or for that of the ordinary man. The statements about radium on p. 126 are condensed to the verge of inaccuracy. Radium is *not* the only element which breaks down; it does *not* evaporate; nor are all the particles into which it disintegrates electrons, as the phrasing suggests. The statement that "electricity is a species of energy which can be expressed in terms of Will" (p. 128) conveys absolutely no meaning as it stands, and suggests that the author has not wholly escaped the plausible but dangerous idea that the dematerialisation of matter to which scientific investigation is tending necessarily brings matter nearer in nature to mind, thus confirming the idealist position.

Philosophers may here and there disagree with the author's emphasis. For example, the contribution of Hegel is generally held to be more important than is here allowed, or at least than is brought out; while the statement of the influence of Kant gives more finality to his work than is perhaps justifiable. But these are all minor blemishes—for the most part verbal—in a valuable book. Though it is far from faultless, we do not remember to have seen so clear, simple, and balanced a summary of the main trends of human thought about the relation between man and the matter amid which he lives and moves.

Few young students of science, and as few clergy, have any clear view of the history of the philosophic thought that bears on their work. We would suggest that the time spent in reading this little book would bring them lasting gain. It is so simple that it will interest those quite untrained in philosophy. It is not technical; it is neither dogmatic nor aggressive; it does not moralise or urge a doctrinal point of view. Furthermore, it is redeemed from the deadliness of most summaries by its admirable clarity and its firm adherence to one path where tempting by-ways cross it. The layman in science and theology will be almost equally attracted, and will rise with whetted appetite; for the defect, or merit, of the book is that one wishes it were longer and fuller. Nevertheless, we believe that Mr. Hardwick has done wisely in keeping his limits so narrow. He might have written a much bigger book, done it equally well, and yet have missed his mark. As it is, we believe that his shot will go home.

S. A. McDOWALL.

Our Bookshelf.

Mrs. Warren's Daughter: A Story of the Woman's Movement. By Sir Harry Johnston. Pp. xi+402. (London: Chatto and Windus, 1920.) Price 7*s.* 6*d.* net.

In writing "Mrs. Warren's Daughter," and more particularly in his first and very successful novel, "The Gay Dombeys," Sir Harry Johnston has sought to reproduce some aspects of the life led by men of science in London during the decades which stretch from last century into the present. Both novels are speculations regarding the influence of environment on human character and action; in "The Gay Dombeys" the author seeks to depict the influence of the post-Darwinian period on the descendants of the Dombey family created by Dickens, and in "Mrs. Warren's Daughter" he gauges the effect of the feminist movement of recent years on the daughter of that rather tarnished lady, Mrs. Warren, placed first on the stage of literature by Mr. George Bernard Shaw. Those, however, who knew the Zoological, Geographical, Anthropological, and other learned London societies some thirty or forty years ago will read these books with a double interest, for they will find that Sir Harry's characters resuscitate past chapters in the history of scientific life in London. The author, it is needless to say, uses a light and nimble pen to draw word-pictures seen from a highly individualistic Harry Johnstonian angle.

In "Mrs. Warren's Daughter" we are introduced to Prof. Michael Rossiter, F.R.S., "a really admirable and fluent lecturer on anthropology, chemistry, ethnology, hygiene, geography, economic botany, regional zoology, germ diseases, agriculture, etc., etc." Prof. Rossiter, whom we should suppose to be a character compounded from the late very distinguished surgeon, Sir Victor Horsley, and from the pioneer of modern physiology in England, the late Sir Michael Foster, is given qualifications as a lecturer beyond the wide capabilities of the combined originals. Even Sir Harry Johnston himself, who has first-hand acquaintance of more branches of knowledge than almost any man living, would hesitate to carry out the programme he assigns to Prof. Rossiter.

Der Aufbau der Materie: Drei Aufsätze über moderne Atomistik und Elektronentheorie. By Max Born. Pp. v+81. (Berlin: Julius Springer, 1920.) Price 8.60 marks.

In the form of three essays the author has given a clear and simple summary of the advances which have been made during the last few years in our knowledge of atomic structure. The first essay consists of a survey of the results obtained by purely physical investigations. It describes the measurement of the charge and mass of the electron, the Kelvin-Thomson model of the atom and the Rutherford-Bohr model which succeeded it, the discovery of the diffraction of X-rays by crystals, and Moseley's work on X-ray spectra and atomic number. A short account is given of Bohr's theory and its development by Sommerfelt, of the general relationships between the spectra of the elements, and of Kossel's work on electrovalency, which determines the number of electrons in the several shells surrounding the positively charged nucleus. In the second essay, the former attempts to obtain a mechanical model of the æther are contrasted with the modern conception of all mechanical forces as being electrical in their origin. Our knowledge of crystal structures has made possible a closer examination of the inter-atomic forces in solid bodies; quantitative relationships can be obtained—for instance, in the case of sodium chloride—between purely physical constants, such as the distances between the atoms, the ionic charges, and the compressibility of the solid on one hand and the heat of formation of the compound on the other. This is amplified in the third essay. Both chemistry and physics deal ultimately with the structure of the atom, for the constants which govern chemical reactions are to be explained in terms of the forces between electrons and nucleus in the atomic structure.

In so small a volume, the author cannot do more than indicate the results which have been obtained in each line of investigation, but very complete references are given to the original papers on the subject. So much work of fundamental importance has been done in the last three or four years that this book will be welcome, both as an introduction to the most recent researches, and for the useful references which it contains.

The Elements of Electro-Technics. By A. P. Young. Pp. viii + 348. (London: Sir Isaac Pitman and Sons, Ltd., 1920.) Price 7s. 6d. net.

THIS work is addressed as much to those connected with the electrical industry who are not directly associated with the technical side as to students about to embark upon an electrical career. The subject is looked at from the practical engineering point of view, but shows some departure from conventional lines. The elementary principles of currents and their effects are well set out, and of the later chapters those on the magnetisation of iron, measuring instruments, and insulating materials may be picked out as the best examples of well-selected information arranged with originality. In the last mentioned there is a good deal not found in the ordinary text-book, including a most useful summary of the composition, preparation, and properties of a number of insulating materials in common use. Another subject not always treated satisfactorily in elementary books is that of the magneto for ignition purposes, of which there is a brief but clear sketch.

The field covered is larger than would appear at first sight, and ranges over such diverse branches of electrical applications as Röntgen rays and electric furnaces. The continuous-current dynamo and motor are dealt with comparatively briefly, but alternating currents and their applications do not form part of the scheme. The student would be well advised to turn to Mr. Young for his introduction to the subject of measuring instruments.

Modern Explosives. By S. I. Levy. (Pitman's Common Commodities and Industries.) Pp. ix + 109. (London: Sir Isaac Pitman and Sons, Ltd., n.d.) Price 3s. net.

THIS book gives a popular and interesting account of the manufacture of explosives, with special reference to the work carried out during the Great War in the national factories in this country. Although avoiding technical details, the author has given a reasonable and well-balanced treatment of his subject in the space at his disposal. One or two slips may be noted. The oxidation of ammonia was not "discovered by the German chemist Ostwald" (p. 28), but by the English clergyman the Rev. A. Milner, although it is usually attributed to the French chemist Kuhlmann. The phrase "Haber-Ostwald process," mistakenly adopted by the Department of Explosives Supply during the war, has doubtless led the author astray. The statement that "the contact process . . . was not successful when first attempted in this country, and was first applied in Germany . . . by . . . Dr. Knecht [*sic*]" (p. 35), is inaccurate in view of Messel's work. The final chapter, on "Chemistry and National Welfare," although not directly connected with the subject, is very apposite at the present time, when many of the lessons taught by the war seem to be receding into obscurity.

An Introduction to Entomology. By Prof. J. H. Comstock. Part i. Second edition, entirely rewritten. Pp. xviii + 220. (Ithaca, N.Y.: The Comstock Publishing Co., 1920.) Price 2.50 dollars net.

WE have no hesitation in commending this book as a clear and thoroughly up-to-date elementary account of the general structure and metamorphosis of insects. It constitutes the first part of a treatise on entomology that the author has in preparation. The section devoted to the external anatomy of insects is particularly valuable.

The detailed studies of recent morphologists have left the terminology applicable to the various sclerites and regions in a very confused state; the nomenclature adopted in this book is well chosen, and should contribute towards establishing stability. With regard to the internal anatomy we are of opinion that the author should deal with the muscular system more fully in the final work. Rather more detailed reference to the adipose tissue and a mention at least of the corpora allata are also called for. These points are raised in a friendly spirit, and in response to Prof. Comstock's invitation for suggestions of any desirable changes to be made before the present part is incorporated in the complete work.

Throughout the book the author exhibits clear insight in the selection of the essentials of his subject, and the printing and illustrations are particularly good; there is also a useful and not too lengthy bibliography. A. D. IMMS.

Physiography. By Prof. Rollin D. Salisbury. Third edition, revised. (American Science Series, Advanced Course.) Pp. xv + 676 + xxvi plates. (New York: Henry Holt and Co., 1919.)

PROF. SALISBURY contrives to maintain the somewhat colourless subject of modern physiography as a study for the class-room by representing it as a description of the shaping of the present surface of the earth, and of the relations of air and water to the land. Questions of earth-history are left to geology, and of life on the globe to geography. His book might serve as an introduction to either of these sciences. Huxley's "Physiography" made a far wider appeal, and Prof. Salisbury has recently stated his own appreciation of geography as encouraging personal observation and verification.

We cannot help feeling that in the present work, the success of which is shown by its third edition, the author has been hampered by educational custom rather than by choice of subject. The small size of many of the illustrations of broad natural features is in keeping with the crispness of description. The use of parts of the maps of the U.S. Geological Survey as full-page plates is an admirable feature. The work has been brought up to date, with cautious references to the "upper air," and a description of the activity of Lassen Peak from 1914 onwards. May we suggest that the crystals shown on p. 71 should not be described as snowflakes? G. A. J. C.

Restoration of Energy.

CONCERNING the pressure of light, we may safely say that it was predicted by Maxwell, discovered by Lebedew of Moscow, and independently by Nichols and Hull in America; while it was elaborately discussed, clinched by further experiments, and its significance greatly extended by Poynting and by Poynting and Barlow. We now learn from Prof. Eddington's brilliant address to Section A of the British Association at Cardiff this year that radiation pressure has a cosmic significance beyond what had been thought possible; that it holds back or sustains the outer substance of the brighter and hotter stars, and is responsible for their huge size; while at the same time it has the effect of limiting the possible aggregation of masses of matter, so that the mass reasonably permissible to any star ranges from five times to one-half that of our sun—something of that order.

According to Prof. Eddington's calculations, the radiation from an exceedingly hot central nucleus, heated it may be by atomic disintegration, acts like a rushing mighty wind on the outer portions, and sustains them against gravitative attraction;—surely a remarkable example of the significance inevitably attaching to the most minute and barely detectable forces. So long as any given kind of force exists at all, it may under proper conditions have an overpowering and surprising effect.

I write to convey a verbal suggestion made by my assistant, Mr. Edward E. Robinson, a year or two ago, that light-pressure may afford an escape from some popular eschatological conclusions based on the doctrine of the dissipation of energy. Engineers like Prof. Osborne Reynolds and Sir William Siemens have deplored the waste of solar energy, of which so minute a fraction is caught by the earth or any planet, and have sought to circumvent and reconcentrate it somehow—by total reflection at an æthereal boundary or otherwise. And when we think of the vast store of power ceaselessly being radiated from every star, and apparently fruitlessly lost in the depths of space, it is natural to look either for some usefulness in the torrent or for some sort of compensating mechanism. So also, under the influences of gravitative attraction and the general law of dissipation of energy, it has seemed to some as if the cosmos was tending towards a cosmic tomb—consisting of one large cold or cooling lump of matter, with all the energy of its gravitative falling together wasted by radiation into the depths of space, and no recovery possible, nor any more generation of heat.

But what about the sweeping or propelling power of that apparently waste radiation? It exerts pressure on matter; particles of suitable small size must be swept along with it. Why should we not contemplate a constant sweeping of cosmic dust away towards infinity, with full power of return when sufficiently re-aggregated? Is there not some hope of restitution and restoration in this, so that gravitative fall can once more recur and the whole cycle begin again?

To estimate the amount of matter which can thus be repelled, taking into account diffraction effects, is rather complicated. It must not be enough at any one time to cause effective opacity; but, considering the speed generated by any small acceleration in free space and the length of time available, the total amount of repelled matter need not be inferior to the amount of disintegrated material which collisions and friction and eruptions and electrical repulsion are likely to provide. *Something* preserves the transparency of space; may it not be this constant sweeping away of dust? Far away from any source of radiation the particles would not be hot enough to repel each other, so there would be nothing to prevent their beginning to collect together, and so preparing to fall once more from practical infinity.

Electrified particles, ions and electrons, of which interplanetary space must contain myriads, are also propelled by light. But these seem to attain a terminal velocity, of value depending on the intensity of the radiation and the square of its wave-length. Long waves travelling in space would therefore be most effective, but short waves would act in the right direction; and the electrons thereby driven among the cosmic dust—exerting mutual forces much stronger than gravitation—might act as the cement to weld it together again.

So long as matter is being accelerated by radiation-pressure, and so long as fresh ions are being produced in its path, the energy of the radiation would tend to be consumed. Hence the ultimate result of all the otherwise waste radiation might be just that energy of gravitative separation which is required for a new Lucretian universe.

There are other possibilities, of too speculative a character, depending on the semi-material nature of light. The suggestions so far made may be negatived, but they seem worth putting forward in a tentative manner.

OLIVER LODGE.

British Laboratory and Scientific Glassware.

I HAVE no interest in the manufacture of scientific glassware, except in so far that as I devoted most of my time to the subject during the war I should like to know that my work would lead to permanent results. I may, therefore, be permitted to address a word to users and manufacturers of scientific glassware.

To users I say: Use only scientific hollow-ware which bears the maker's name; and if you find it faulty, send it straight back to the manufacturer, whom you will be assisting, and who will replace it at once. Even the famous Jena glass was often faulty, and while working in the laboratory in the autumn of 1914 it was not only once that Jena beakers were found to have cracked without apparent cause. On two occasions I actually heard beakers crack while they were standing on the table.

In the autumn of 1914 I worked out the resistance glass and lamp-working glass which have been spoken of as standing at the head of the list, and early in 1915 I began to manufacture these glasses, and continued to do so throughout the war, maintaining the original compositions, but modifying the batch formulæ as different materials became available. The glasses were worked out on the basis of analyses of a large number of foreign glasses and a study of their properties. The investigation was a perfectly straightforward one, and no particular difficulty attached to it, and I will even admit that luck came to the aid of judgment in arriving at the final conclusions.

I am making this statement because I wish it to be recognised that a misunderstanding exists as to the difficulties which had to be overcome in connection with the manufacture of scientific glassware, and not because I wish to lay claim to particular credit for carrying through a simple piece of work. The real difficulty lay in the working out of methods of manufacture, particularly the devising of mechanical methods, and in imposing them upon an industry which was rather unwilling to adopt them. The glassmaker's chair and tools had to be replaced by moulds, and even then the procedure adopted in mould-blowing as practised in the country had to be modified. Instead of employing men to finish such articles as beakers, machines had to be devised to carry out the processes which could be operated by girls. Drastic alterations in the methods of annealing had to be introduced. In some branches, such as the manufacture of graduated ware, the technical processes for production in mass had to be worked out from the commencement.

Now the fullest information as to the composition of German chemical glassware was at the disposal of anyone who had access to a chemical laboratory, such as Prof. Baker kindly placed at my disposal in October, 1914, and could make an analysis of glass. The reproduction of these glasses, on the basis of the analyses, called for some knowledge of commercial materials, and such information as was available as to the qualities of the glasses actually on the market made improvement a matter of no very great difficulty. If the chemical problems had been the essential ones the scientific public would have had every reason to complain if the manufacturers had not at the outbreak of war at once produced perfectly satisfactory scientific glassware, and had never failed to give them the most complete satisfaction. However, the actual fact is that the chemical difficulties were almost non-existent; but, on the other hand, the technical difficulties were very real, involving the expenditure of a vast amount of energy and money which had to be provided by the manufacturers themselves. I can say most definitely that all those who have been concerned in the industry have actually lost money in the venture, but that they do not grudge the cost.

During the war a vast amount of information was collected and shared between the various firms engaged in the industry, but it was often impossible to make use of it owing to the difficulties which stood in the way of obtaining machinery and plant. It would now be possible to make use of this information, to reorganise completely factories for mass production, and to install new plant, but the manufacturer is hampered by the stringency of the financial position, the enormous increase in the cost of machinery, etc., and the absolute uncertainty as to the policy of the Government. However, if the industry is doing its best to meet the situation, it deserves the support of the scientific public, which has also the right to demand guarantees. I suggest, therefore, that the manufacturers should invite the Institute of Chemistry and the Institute of Physics, which represent the professions most closely concerned, to investigate the position of the industry and to report upon it.

It must not be imagined that the cost of scientific glassware will ever approach the pre-war standard, and it does not appear that the increase in cost is in excess of the increase in cost of other commodities. During the war, while I had the opportunity of checking the figures, I know that our prices were lower than the pre-war prices relatively to the increase in the cost of production. Temporarily, owing to the rate of exchange, German glass is obtainable at a lower rate than English, but if this fact is taken advantage of now, the scientific public is likely to have to pay for its short-sighted policy so soon as the industry is once more completely in German hands.

M. W. TRAVERS.

November 6.

Negative Electron Curve.

THE elements are constructed, so it is now believed, of collections of hydrogen atoms bound together by negative electrons. The atomic weight of an element is not, as a rule, a whole number. I think the importance of this departure from integers is most significant.

If we can consider that the element is composed of a number of hydrogen atoms, then the departure from the simple sum of the weight of the hydrogen atoms composing the element must be due to the negative electrons. For example, the element vanadium has an atomic weight of 51·06. Suppose we consider it to be composed of 51 hydrogen atoms,

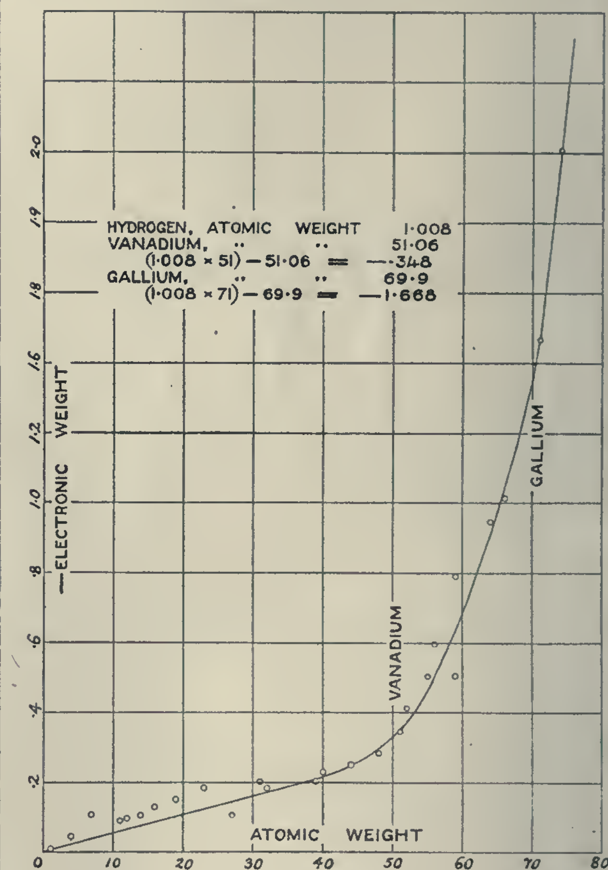

FIG. 1.

then its atomic weight should be $1·008 \times 51 = 51·408$; but its atomic weight is 51·06. The difference is $-0·348$, due, I take it, to the negative electrons which have entered into the composition of the element.

I have obtained *minus* quantities for a number of the elements, starting from hydrogen, atomic weight 1·008, and stopping at Ge, and I find that they space themselves along a regular curve, as shown in Fig. 1. That the *minus* quantities of the atomic weights should have arranged themselves in this regular way by pure accident I cannot believe, so I suggest that there is some natural law at work to account for it. The explanation is to be sought, I think, in the supposition that the hydrogen atoms attract each other, producing the force of gravity, while the negative electrons are repulsed by gravity; the elements are, therefore, lighter than the sum of the hydrogen atoms themselves.

Referring again to the curve, if the helium atom is composed of 4 hydrogen atoms and 2 negative electrons, then vanadium should have 51 hydrogen atoms and somewhere about 34 negative electrons.

The elements beryllium, neon, magnesium, silicon, chlorine, and argon do not seem to come properly in the curve. If their atomic weights have been correctly determined, then there must be something peculiar about these elements.

I have also drawn a curve from the atomic weights as given in Bloxam's "Chemistry," hydrogen being taken as 1, and have produced a similar curve to the one given here, except that the latter part does not rise so steeply.

S. G. BROWN.

52 Kensington Park Road, W.11.

Chemical Warfare and Scientific Workers.

LIKE Prof. Soddy (NATURE, November 4, p. 310), I have received an invitation from the War Office to become an associate member of the "peace" organisation which is to "develop to the utmost extent the offensive and defensive aspects of chemical warfare." I have had enough practical experience of the experimental side of chemical warfare to know what it involves, and I have without any hesitation refused to join the new Committee.

In the first place, the project is simply wicked. Education stands for something more than the acquisition of knowledge, and if at the present time I lent any support to the activities of the Committee I feel that I should necessarily be quite unfit to take any part in the training of young minds. To do what I can to promote in everyone the faith that war is done with has become part of my business because it is the world's business. In the second place, the project is futile. No real progress will be made in discovering new methods of offensive chemical warfare except by people who have their heart in it; perfunctory adhesion to an official organisation will discover nothing worth knowing.

Is any intelligent person—and only intelligent people would be of any use in this very complicated subject—at this point in the world's progress going really to put his heart into the search for methods of killing other people? I think not, even in the case of professional soldiers. Some may comfort themselves with the idea that they will escape the moral difficulty by engaging only with defensive methods. This will be equally futile, for adequate defence can only follow discoveries on the offensive side; it cannot precede them. It is impossible to devise protection against offensive agents which are unknown, just as on the medical side it is impossible to work out methods for the cure of lesions of an unknown nature. The only effective preventions and cures which can be prevised are ethical, and a War Office Committee is not quite the best atmosphere for that.

It may be extravagant to expect that all civilians will refuse to support this part of our "peace organisation," but I hope they will.

A. E. BOYCOTT.

University College, Gower Street, W.C.1,

Testing Einstein's Shift of Spectral Lines.

A WORD of caution may not be amiss in respect of the suggestion made by Sir Oliver Lodge in NATURE of October 28, p. 280. The rotational stresses in the disc, though very large, may not portend immediate dissolution in steel, but what of the glass (?) of the vacuum tubes? The stresses, like the gravitational effect, increase as the square of the angular velocity. The method would seem well calculated to develop pleochroic effects in glass.

CHARLES CHREE.

October 30.

Contractile Vacuoles.

CONTRACTILE vacuoles are found only in those cells which lack a continuous cell-wall. This appeared to suggest that the function of the contractile vacuole is to eliminate dissolved crystalloids and so to keep down the osmotic pressure distending the semi-permeable protoplasm. Otherwise the latter, lacking the support which a continuous cell-wall gives, would continue to stretch and would finally rupture.

There is, however, another, and possibly more plausible, point of view, namely, that the contractile vacuole is, in point of fact, this rupture. Suppose a small accumulation of a soluble crystalloid in a semi-permeable gel which exhibits slight elasticity and slight tenacity—qualities which the protoplasm of the cell appears to possess. The osmotic pressure of the crystalloid will push back the protoplasm, overcoming its rigidity. Thus a cavity is formed which enlarges as water flows into it. Expansion will proceed until but a very thin film of protoplasm separates the solution from the surrounding water. Later expansion causes continued thinning of the film until its tenacity suddenly gives way, and the solution contained in the vacuole becomes, through the rupture, continuous with the surrounding water. The elasticity of the protoplasm now asserts itself, and the walls of the cavity are driven together. The semi-fluid, viscid constituents of the protoplasm secure the healing up of the rupture and the obliteration of the cavity, while the viscosity of the surrounding substance leads to a delay in recovery marked by the appearance of the radiating canals.

Thus we may look upon a contractile vacuole, not as an organ of a cell, but rather as the effect of the local accumulation of any soluble substance. In fresh-water naked protoplasmic organisms the formation of a cavity surrounding this accumulation and the periodic forcible ejection of some of the solution are rendered inevitable by the physical properties of protoplasm. When once a cell acquires a complete cell-wall, the protoplasmic film receives sufficient support and the vacuoles become permanent.

HENRY H. DIXON.

School of Botany, Trinity College, Dublin,

Visibility of the Landscape during Rain.

ON a recent visit to the mountains of North Wales the writer was impressed with the variations in the visibility of the landscape when rain was falling. In the lower valleys a storm which may be sufficient to wet thick clothing through in a few moments may leave the contours of the mountains quite distinct at several miles distance. On the other hand, a mountain drizzle or "Scotch mist" may render everything invisible at a few yards. An elementary treatment of the subject brings out one or two points of interest.

Let it be assumed that the raindrops are perfectly opaque and that the atmosphere is otherwise perfectly transparent, both assumptions being, in general, close approximations to the actual state of affairs.

Consider a heavy rainstorm during which rain falls at the rate of 1 cm. per hour, or 0·00028 cm. per second. The raindrops appear to be most often of 1 to 2 mm. diameter. Taking the lower value (1 mm.), the volume of the drop is $0{\cdot}5\times10^{-3}$ c.c.

According to Stokes's law

$$v=\frac{2r^2(\rho-\rho_1)g}{9\eta},$$

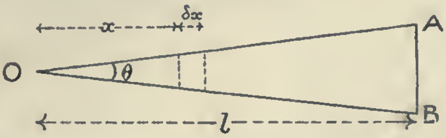
and at 15° C., η, the viscosity of air, is 181×10^{-6}, so that $v=3000$ cm. per sec.

Consequently, the depth of water which falls in one second (0·00028 cm.) is spread while falling over a vertical column of air 3000 cm. high.

There is, therefore, 1 c.c. of water in about 10^7 c.c. of air, or 1 raindrop in every 5 litres or so . . . . (1)

Now, in the state of maximum disorder (the "most probable" state) the raindrops will be spaced equally in all directions, vertically as well as horizontally, and the average distance between two spots will be

$$\sqrt[3]{5000}=17 \text{ cm.} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$



Consider a circle of landscape, of diameter AB, subtending an angle θ at the observer at O, distant l from AB. AB $=l.\theta$.

A spot of rain at x is projected against the background as a disc of diameter

$$\frac{l\,.\,d}{x}$$

(d being the diameter of the spot) and blots out an area

$$\frac{\pi}{4}\left(\frac{ld}{x}\right)^2.$$

If n denotes the number of rain spots in unit volume of air, then in the element ∂x of the cone in the figure there are

$$n\,.\,\frac{\pi}{4}(x\,.\,\theta)^2\partial x,$$

and these, projected on the background, blot out an area

$$n\left(\frac{\pi}{4}\frac{x\,.\,\theta\,.\,ld}{x}\right)^2\partial x,$$

or

$$n\frac{\pi}{4}\,.\,d^2\delta x\times\frac{\pi}{4}(l\,.\,\theta)^2,$$

or

$$n\frac{\pi}{4}\,.\,d^2\,.\,\partial x\times\text{Area of background} \quad . \quad (3)$$

Hence each element ∂x contributes the same amount of blotting-out of the landscape, the larger apparent diameter of the nearer spots being compensated by their smaller numbers, and the visibility of the landscape falls off as a linear function of the distance.

The total area blotted out is the integral of (3), *i.e.*

$$\frac{\text{Area of projected rain spots}}{\text{Area of landscape}}=nl\left(\frac{\pi}{4}d^2\right),$$

and the landscape is entirely blotted out when the above ratio equals unity.

Putting

$$n=\frac{\text{Depth of rain falling per sec. (D)}}{\frac{\pi}{6}\,.\,d^3\,.\,v}$$

in this equation, we get as the limiting distance at which the outlines of the landscape can be distinguished

$$l=\frac{2}{3}\frac{d\,.\,v}{\text{D}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

Using the values suggested above, $d=0·1$, $v=3000$, and $\text{D}=28\times10^{-5}$, the value of l comes out as 7 km., or $4\frac{1}{2}$ miles.

Thus a very heavy rainstorm may be remarkably transparent.

Let N = the number of spots falling per second on unit area (N $=n.v$), then, combining equation (4) with Stokes's law, and calling $\frac{1}{l}$ the obscuring power of the storm, we have

$$\frac{1}{l}=\frac{9\pi}{4g}\,.\,\eta\,.\,\text{N} \quad (\text{since } \rho-\rho_1=1) \quad . \quad . \quad (5)$$

That is, the obscuring power of a storm is simply proportional to the number of spots falling per second, or every raindrop has the same obscuring power, whether it be large or small and whether the total rainfall be heavy or light.

The very great obscuring power of a "Scotch mist" is thereby accounted for.

F. W. PRESTON.

90 Howard Road, Leicester, October 21.

Museums in Education.

IN NATURE of October 28 appeared a review of the Final Report of the Committee (British Association, Section L) on "Museums in Relation to Education," in which it was stated that "our great public schools have some excellent museums, but there is little or no evidence that they are used in school teaching." May I be allowed to point out that this sweeping indictment of incapacity or lack of imagination on the part of masters in public schools is not without exception?

The museum of natural history at Oundle School is, I suppose, fairly typical of such collections. It consists of specimens representative of zoology, botany, palæontology, and petrology. Owing to lack of space, not all the specimens can be exhibited with advantage, and the excess has been temporarily stored, so as to avoid detracting from the educational value of the exhibits, pending the erection of a more spacious building. The present museum, which is apart from the laboratories, is accessible at all times to all boys whether or not they are taking natural history subjects in the curriculum. The zoological collection forms an index to the animal kingdom; it consists of specimens representative of all the phyla and of a considerable number of classes. These are distinctly grouped and clearly labelled. In further amplification of this series a certain number of drawings, dissections, and skeletons, also clearly labelled, are interspersed among the types. This work has been carried out entirely by the boys, under supervision, and forms, therefore, an elementary introduction to research. There are also table-cases representative of protective coloration, insect pests, metamorphosis, etc. Owing to lack of time and space the botanical exhibition is not so far advanced, but there is a good collection of types of timber on view, while a collection representative of the dispersal of fruits and seeds is in the making. During the summer term the younger boys maintain a constant display of the flowering plants of the neighbourhood. (The lack of botanical exhibits in the museum is largely compensated for by a botanical garden comprising natural-order beds, a rock garden, a rose garden, marsh and aquatic flora, etc.) The palæontological collection consists of a series of wall-cases containing fossils arranged according to their strata. The petrological collection comprises table-cases illustrative of the more common rock-forming minerals, with a considerable number of good specimens clearly arranged and classified. For the two latter collections, as regards both material and arrangement, the school is indebted to the great kindness of Profs. Marr and Solly respectively.

More than three hundred boys (out of five hundred) are undergoing biological training at Oundle School in any one term. In teaching biology I have constant recourse to the school museum. For example, a class may be taken into the museum and a demonstration given of the general characters of the animal kingdom; or certain exhibits illustrative of one particular subject can be removed from the cases to the laboratory, where, after a short description, they can be sketched by the class. A similar use of the museum for practical education is made by my geological colleague. Further use of the collections has been made for popular demonstrations to members of a local society as well as to parents of boys who visit the school on Speech Day; on these occasions the boys themselves act as demonstrators. Such, in brief, are some of the uses to which a school museum is put in the service of education.

That the knowledge of such efforts in education has not come to the powers-that-be only emphasises the deplorable fact of the present lack of co-operation between the school and the university. As assistant in the zoological departments of Manchester and St. Andrews Universities I learnt the immense value of the museum as an aid to biological education. My experience of school work is confined to the brief period since the close of the war, but I cannot believe that no effort is being made similarly to use the museums of natural history in other schools where a biologist has been added to the staff of masters.

Mating Dances of Spiders.

I HAVE not, up to the present, found any account of anything approaching to a mating dance, such as is common among the Salticides, in the Lycosides. The following observations tend to show, I think, that some such dance must exist among certain members of this family. I should be glad to know if any readers of NATURE have met with similar experiences with these spiders.

The species observed was *Lycosa saccata* (Blackwall), which is exceedingly common in the spring. I was watching a number of these spiders at about 3 p.m. on April 29, 1919. They were sunning themselves on a vertical wooden board leaning against a cucumber frame. I first noticed a male, which was about 1 in. from a female, going through some most curious movements. He extended one palp downwards (at about 45°) and the other upwards, at the same sort of angle. He then withdrew them and extended them again in the same way, but with their positions reversed. Each time he withdrew them he usually took a step towards the female. He repeated this two or three times, and then brought the palps to their normal position with a curious quivering movement. The front legs were also caused to quiver, being held just off the ground. The front legs of the female were occasionally seen to quiver also.

When the male got up quite close to her (½–¼ in.) the female ran off, and the male searched about within 2 ft. of where he lost her, exploring crevices, etc., as though looking for her. At last he suddenly encountered her round a corner, and she ran away. He proceeded with his antics, however, without her being there.

A new male then appeared and began similar antics in front of the female, except that he merely extended each palp separately and returned them to their former position. The original male then came up and a fight ensued, in which both spiders fell off the board, leaving the female to continue her basking in the sun.

The Energy of Cyclones.

IN NATURE of October 28, p. 286, Lt.-Col. Gold refers to the theory of the late Dr. Margules, that storms would arise if two masses of air of different temperatures were in juxtaposition. The situation would be unstable, and in passing from this unstable situation to a stable one the potential energy would be reduced, part of it being converted into the kinetic energy of the ensuing "storm." The theory takes it for granted that the warm air rises and the cold air descends.

But storms are generally associated with cyclonic depressions, and of recent years the temperature distribution in cyclones has been carefully studied. Sir Napier Shaw (Meteorological Office Geophysical Memoir, No. 210*b*, p. 14) sums up the facts as follows: "The conclusions which we may draw are, first, that the pressure changes at the surface are a reproduction of the pressure changes at the 9-km. level, and that they must be regarded as produced, not by, but in spite of, differences of temperature in the air."

The theory of Dr. Margules, consequently, fails entirely to account for cyclones. On the other hand, his theory may play some part in the production of line squalls and some thunderstorms.

With regard to "polar fronts," the theory of Dr. Margules is also at fault in a great measure. The low-pressure areas over the polar regions produce the two great polar cyclones. The atmospheric columns over the poles must be relatively warmer than those over middle latitudes. As a result, the warm air is drawn polewards. But, although the atmospheric columns over the polar areas are relatively light, there are cold, dense layers of air resting on the earth's surface. These cold polar layers are pressing outwards, and where they meet the warm cyclonic inflows we have the "polar fronts."

The facts seem to point to the stratosphere as being the main source of energy of storms and trade winds.

R. M. DEELEY.

Tintagil, Kew Gardens Road, Kew, Surrey,
October 30.

DR. MARGULES wrote his paper mainly in connection with phenomena of the line-squall type, but he realised that it might have wider applications, and later investigations do indicate that discontinuity of temperature is the prime factor in the "birth" of cyclones. If one had an atmosphere with uniform pressure at sea-level, but with masses of warm and cold air, then at 9 km. pressure would necessarily be low in the mass of cold air, and a cyclonic circulation would ensue; but the energy of the motion would be derived from the potential energy of the initial state.

Differences of temperature originate in the lower atmosphere. The stratosphere may be able to draw upon a source of energy of which we are ignorant; it cannot of itself provide the energy of storms.

E. GOLD.

Luminosity by Attrition.

IN reference to the letter in NATURE of November 4, p. 310, by Sir E. Ray Lankester on the above phenomenon, it may be of interest to some to know that Thomas Wedgwood was the first to direct attention to the fact that light could be produced by the rubbing together of quartz or sugar. His paper on "Experiments and Observations on the Production of Light from Different Bodies by Heat and Attrition" may be found in Phil. Trans. Roy. Soc., 1792, part i.

November 6.

Industrial Research Associations.

I.—British Scientific Instrument Research Association.

By J. W. Williamson.

THE British Scientific Instrument Research Association is one of the earliest research associations formed under the scheme of the Committee of Privy Council for the promotion of scientific and industrial research. It was founded, as is stated in the third annual report of that Committee, "through the efforts of the optical industry, guided by the whole-hearted energy and zeal of Mr. Conrad Beck, the president of the British Optical Instrument Manufacturers' Association." The association was incorporated on May 30, 1918, and established on lines broad enough to include all scientific instrument makers. In November, 1918, a group of firms representative of the electrical scientific instrument, electro-medical, and X-ray industries joined the association, which may now claim to be what the above-named report of the Committee of Privy Council stated in August, 1918, it had every prospect of becoming—the representative industrial body dealing with the application of science to the manufacture of scientific instruments. The association was fortunate in securing from the outset as its director of research Sir Herbert Jackson, K.B.E., formerly Daniell professor of chemistry at King's College. Mr. J. W. Williamson was appointed secretary of the association, and, later, Mr. H. Moore assistant director of research, with special reference to the electrical and X-ray researches of the association.

The first task of the newly formed association was to secure suitable premises for offices and research laboratories, and in November, 1918, the remaining term of the lease of 26 Russell Square, W.C.1, was purchased, and the association entered into possession on Armistice Day, November 11, 1918. Steps were immediately taken to effect the necessary structural alterations and to equip the premises with laboratories and secretarial offices, and now, on the completion of its first two years of life, though more remains to be done, the association has a relatively well-equipped research institute, with a scientific staff of six research workers, all university graduates experienced in research, in addition to the director of research and the assistant director of research.

In the beginning the association suffered a grievous loss by the untimely death, in August, 1918, of its first chairman, Mr. A. S. Esslemont, on whose wisdom, zeal, and powers of organisation the members had confidently counted to guide the association in its early career. He was succeeded in the chairmanship by Sir Arthur Colefax, K.B.E., who rendered valuable service to the association, and when, owing to the pressure of other duties, he was compelled to resign the chair some months ago the association was fortunate in securing as chairman Mr. A. A. Campbell Swinton, whose high scientific attainments and wide experience will be of great benefit to the association.

The council of the association consists of fifteen elected members, five co-opted members, and five members appointed by the Department of Scientific and Industrial Research. The addition to the elected members of council of these Department representatives and co-opted members has been of great service to the association in enabling the council to view from a wide angle and to a far horizon the varied problems presented to it, without impairing the predominant interest of the members representing the industry or modifying the necessary bias of the association's activities towards practical results.

The main and immediate functions of the association, the council has agreed, are :—

(*a*) To prosecute research into the questions of pure and applied science arising out of the urgent needs of the scientific instrument industry.

(*b*) To take long views and to investigate those questions, whether of pure or applied science, upon which the future of the industry may be conceived largely to depend.

(*c*) To investigate systematically and continuously the field of application of scientific instruments.

Time and experience will show whether and how far these guiding principles need to be modified or amplified.

Just as the actor's art, however subtle, will fail if it does not get over the footlights, so will these associations for scientific and industrial research fail in one of their primary functions if they do not get the results of their researches over into the workshops of the industries. Two years is all too short a time for any association to accomplish much in this way. The first year is necessarily spent mainly in organisation and preliminary surveys of work under contemplation. But the British Scientific Instrument Research Association has, nevertheless, obtained results of research of immediate utility which have already found practical application in the workshops, and are of considerable benefit to the industry.

For example, as the result of an extensive research on polishing powders, a rouge was prepared for the hand and machine polishing of lenses, prisms, etc., which, tested by optical firms, has proved to be thoroughly successful in the workshop. It has been manufactured on an industrial scale, and is now standardised and in regular use by optical firms. This research has given rise to much investigation on the purely scientific side, and to further work of an applied nature with the view of decreasing substantially the time of polishing glass and similar materials. The comprehensive researches of Sir George Beilby on this subject, especially in connection with the flow of solids under mechanical disturbance, has been of great value.

Another line of investigation which has been occupying the association from the start is on abrasives. Much work has already been done both from the purely scientific point of view and on the production of abrasive powders. Materials made in the laboratory are being tested in workshops, and it is hoped soon to publish reports on the whole investigation and on the practical results.

Again, in response to a need expressed by the industry a solder was prepared in the association's laboratories capable of being used for all the ordinary metals, including aluminium, and of withstanding a temperature of approximately 350° C., so that it could be used when the later heating of joints made by it was necessary—*e.g.* in enamelling. This also has been manufactured on a large scale, and industrial firms are engaged on extended tests of it. The reports to hand are very promising. Another solder, fusing at a low temperature, for special use with aluminium, has also been made on the laboratory scale, as the outcome of the previous research, and is now being tested by certain firms.

The association has also been able to give immediate assistance in the matter of securing suitable and trustworthy liquids for level bubbles, and is now engaged on problems connected with standardising the glass for the bubbles and with methods of preparing the inside surface. In this connection it has been considered important that purely scientific research on the fundamental physical problems connected with this investigation should be prosecuted so that not only may the practice in manufacturing level bubbles be improved, but also the reasons underlying it may be fully elucidated. This is being done for the association, extramurally, in one of the London technical colleges.

An interesting investigation, apparently dealing only with a small detail brought to the attention of the association, led to a considerable amount of research work on the cause of the tarnishing which had been found with certain tissue papers used for wrapping up polished glass. A report on the whole research has been issued to members, and so far as the practical issue is concerned the position is apparently quite clear as to the properties which the paper must have and the method of testing whether it has them. Here, again, the research has given rise to problems which are of great interest in connection with physical and chemical questions about colloids, and would be suitable for further investigation on academic lines. It is under consideration what arrangements can be made for this work to be done elsewhere in some university or technical college.

Another research of immediate practical importance to the optical industry is the research on cements for prisms and lenses. A report on this subject has been issued to members, and in the important matter of obtaining cements which have no tendency to change either in the direction of crystallisation or in the gradual deposition of insoluble matter, and do not tend to break away from the glass surface, very considerable progress has been made. This investigation on cements has led to a large amount of relevant work in the matter of insulators, a subject of importance to the electrical members of the association, and is an example of the advantage of the wider outlook which is obtained in an association such as this where the needs of one of its departments are co-ordinated with those of another. There are, of course, many scientific problems raised here which might well prompt pure science research—*e.g.* into the causes and conditions of crystallisation or of other instability in resinous and similar substances.

Questions on the purity of chemical compounds and on the relation of purity to stability are raised by the research being undertaken by the association to study the durability of different types and meltings of optical glass under a variety of conditions. Similarly, another research of the association into the question of the production of a glass of truly neutral tint raises fundamental questions of the theory of colour in glass.

It is impossible in a short article to do more than take almost at random a few examples of the researches being undertaken by the association, but enough has been said, perhaps, to show that, even in those researches being prosecuted for immediate practical ends, fresh problems in pure science are raised, or wider vistas opened out, which may well be suggestive and stimulating to the workers in the laboratories of purely scientific institutions.

The programme of research of the association is, naturally, rather the private affair of the association, but it may be said that it ranges from problems in pure science involving the fundamentals of optical, electrical, or chemical theory to technological investigations on the methods and materials of manufacture, including, for example, such a practical problem as the best lacquer for making an instrument look well finished.

It may be well to point out that, besides the specific researches included in the programme of research, the association in its character as the scientific centre of the industry is called upon from time to time to assist the industry by contributing from a scientific point of view suggestions and criticisms to the appropriate Government and other quarters on such matters as the supplies of raw materials and the manufacture in this country of products essential to the development of the British scientific instrument industry. Much work in this direction has already been done. Moreover, users of scientific instruments have already brought to the notice of the association, and, as the association becomes better known, will doubtless tend increasingly to bring to its notice, their specific needs. In this way the association will perform a useful scientific *liaison* office between the users and the manufacturers. Already, by means of conferences and otherwise, the association has enabled the manufacturing members to become better acquainted with the scientific needs of the users, and the users to appreciate the limitations imposed on the manufacturers by design, material, or other conditions.

In the task of industrial reconstruction after a devastating war which the British scientific instrument industry, in common with other British industries, has now to face and accomplish, its most potent means must be the extension of scientific research to the varied problems of the industry. In this work the co-operative research of the association and the particular research of the individual firms are essential and complementary. The work of the association does not supersede, but emphasises the need for, and assists, the scientific research undertaken by individual firms. In the same way, the pure science research of the universities and kindred institutions is essential and complementary to all research carried out by the research associations or by industrial firms. The universities and their like are the great sources of purely scientific research, and to them we look for that fundamental work which, probably in many cases not of immediate applicability to industry, is bound to be the foundation of future guiding principles. Nowhere is this more fully recognised than in the British Scientific Instrument Research Association. Its work is also largely purely scientific, but to fulfil its purpose of immediate utility to its relevant industries it necessarily cannot always follow through to completion the numerous lines of investigation which arise out of the problems studied.

Microseisms.

By J. J. SHAW.

HOW often we use the term "terra firma"! It is used despite the fact that no square yard of the earth's surface is ever at rest; an unending train of waves, waxing and waning in amplitude, are unceasingly coursing along the earth's crust and to unknown depths. The wave period ranges between 4 and 8 secs.; the amplitude is between 1/50,000 and 1/2000 in., but with a wave-length of 8 to 16 miles. The speed of the waves is believed to be about 2 miles per sec. These microseisms have been known to seismologists for twenty years or more, and were originally thought to be air tremors. Later, the rocking of the observatory buildings in the wind was suggested as their origin, or the rocking of the ground due to the motion of trees in the vicinity; but it is now established that these disturbances are pure earth-movements travelling over long distances. With sensitive seismographs, microseisms are easily recorded, but whilst hypotheses have not been lacking, their origin and cause still remain unknown.

Prof. John Milne, in 1898, suggested ("Seismology," p. 285) that the cause may be twofold: (1) air currents and convection currents within the instrument cases; (2) a ground movement produced by rapid changes of barometric load. Before that time, Bertelli and Rossi had noted the connection of microseisms with barometric change.

In America, Burbank observed an increase in amplitude when a barometric load passed from land to sea, or *vice versa*. At the International Seismological Congress held in Manchester in 1911 funds were provided for the investigation of microseisms, and Prof. O. Hecker, of Strasbourg, was deputed to undertake the work.

Daily comparisons were made between the microseisms recorded and the state of the sea at Cape Grisnez, Heligoland, and Borkum, a connection between sea waves and these movements having long been suggested. The war intervened, and the conclusions do not appear to have been published.

In earthquake investigation observers are by this time fairly familiar with the easily recognisable chief phases, viz. "primary" and "secondary" waves, followed by "long waves" which rise to a "maximum"; hence it is comparatively simple to trace any particular phase around the globe, and by this means to determine the respective rates of propagation and to compile seismological tables for future guidance.

Microseisms do not lend themselves so readily to this kind of treatment. Fig. 1 illustrates a section of a record when microseisms are pronounced, and shows how similar one train of waves is to the next, thus defying identification of any particular wave at distant stations.

In May, 1917, the present writer was testing two similar seismographs in different buildings 60 ft. apart. The machines were arranged on the same electrical time circuit, and both oriented in the same azimuth. It was observed how closely similar were the microseisms on both records, showing that the air tremor hypothesis was untenable. A seismograph has two kinds of sensitivity—one to tilt, in which the period of the pendulum plays the more important part; the other to a horizontal thrust, where the ratio of the leverage, operating about the "steady-point," is the chief factor. These seismographs were constructed with the same sensitivity to horizontal thrusts, but, as an experiment, the period of one pendulum was raised until the sensitivity to tilt was four times that of the other. Under these conditions the recorded amplitude of the microseisms was approximately the same, whereas the large waves of an earthquake which were recorded were from three to seven times greater on the machine more sensitive to tilt. This seems to suggest that microseisms are principally a horizontal motion; but against this must be noted that seismographs designed for vertical motion record microseisms quite freely.

The fact that microseisms could be identified on instruments 60 ft. apart pointed to the advisability of attacking these waves on entirely new lines, viz. gradually to extend the distance between the observing stations so long as the identification of the individual waves remained possible. The use of a "dug-out" in a pit bank was secured, distant two miles from the home station, in a direction 17° west of north, and one of the instruments installed there. Both instruments were arranged in the same azimuth, with the same period, damping, and ratio of magnification. The clocks could be synchronised only by motoring between the two stations with a watch that varied about one-fifth of a second per hour. Comparisons were made

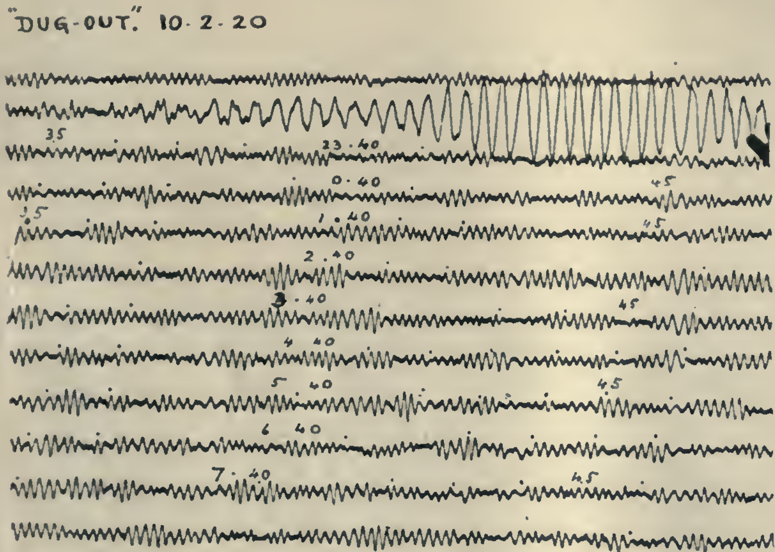

FIG. 1.—Earthquake and microseisms.

both ways, and the precision was calculated by interpolation. On favourable occasions the clocks were set alike within about one-tenth of a second.

It was at once seen that there would be no difficulty in identifying the waves at stations two miles apart (see Fig. 2). The films were timed by a short

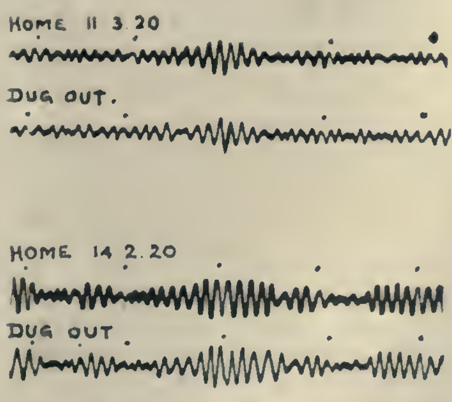

FIG. 2.—Comparative traces.

eclipse of the light every minute. In the first attempt the clocks were compared once daily, and the films timed by measuring from an eclipse to the nearest apex in the trace. By this method differences of as much as two seconds were noted, whereas one second was the maximum expected from the known rate of surface wave transmission. It was evident that a higher precision was necessary. The errors were chiefly traced to a lack of uniformity in the peripheral speeds of the recording drums. In a second series of observations the clocks were compared twice a day, and comparisons of the films limited to the point marked by the eclipse. For the success of this device it was necessary to obtain a record of the wave during the eclipse. This was achieved by cutting a fine slit across the shutter, so that whilst the beginning or end of the eclipse was still clearly defined, the leakage of light through the slit produced a "ghost" during the eclipse.

With the beginning and end of an excursion, and also the time-mark being defined, it remained only to resolve the harmonic motion to obtain the phase of the wave at each station at the instant the shutters closed, and so to deduce the time difference between the two observatories. By the first method there were readings ±1·13 sec. from the mean. By the second, this was reduced to ±0·3 sec.; but it is worthy of note that by either method the difference between the two means was only 0·04 sec. for the series.

It was noted that the wave period increased with the amplitude, and the amplitude increases generally with the daily movement of the air. There was, however, one marked exception on March 10, when a very moderate air movement coincided with nearly the maximum amplitude recorded. At this time rough weather was being experienced around the north of Scotland.

The chief objective in these proceedings was a comparison of wave direction with wind direction, and perhaps in its complete failure lies the greatest value of these observations, for it was discovered, it is believed for the first time, that there is practically no change in the wave direction, whatever the meteorological conditions may be. The microseisms always came, more or less, from the north—they always arrived at the "dug-out" first by about 0·8 sec. The small variations in time difference shown in column 2 of the table may or may not indicate a varying azimuth. It is equally probable that they are the result of personal or instrumental error.

To reduce the difficulties and shortcomings in the above experiments, it is proposed—with improved timing facilities and three machines placed at the corners of a 10-mile triangle—to continue this investigation, when it is hoped not only to obtain more precisely the rate of propagation, but also to determine to what extent the azimuth is constant. It would be of value if observers in other countries were to pursue the study of microseisms on this new system in order to determine whether this unidirectional character of the phenomenon is universal, and, if so, whether the direction is governed by the contour or physical features of the country.

The Tercentenary of Jean Picard.

By Dr. J. L. E. Dreyer.

AN article on "Le tricentenaire de l'abbé Picard," by M. E. Doublet, in the *Revue générale des Sciences* (September 15–30), directs attention to the tercentenary of the well-known French astronomer, Jean Picard, who was born on July 21, 1620. Very little is known about Picard's life, so that even the year of his death is uncertain (about 1683). He was a pupil of Gassendi, and took up the study of astronomy at latest in 1645, when he observed the eclipse of the sun on August 21 of that year, and it was as an observer that he was chiefly distinguished. Though he was not the first to apply telescopic sights to astronomical instruments, he was almost certainly not aware that this had many years before been done by William Gascoigne; but Picard was at any rate the first to make use of this invention in an extensive series of observations, when he, in 1669 and 1670, determined the size of the earth. This was done by a triangulation from Sourdon, near Amiens, to Malvoisine, south of Paris, on the plan first proposed and carried out by Snellius about fifty years earlier. Picard measured a base along a level and well-built road from Villejuive to Juvissy, 5663 toises long. It is deserving of special notice that he compared his standard toise with the length of the seconds pendulum, "lest the same should happen to it as had happened to all previous standards"; and that did indeed happen, for his toise is lost. The results of this, the first modern geodetic operation, were published in Picard's "Mesure de la terre" in 1671.

In 1669 Picard presented to the Academy a memoir on the most important astronomical observations which ought to be undertaken. Among these is a new determination of the right ascensions of stars by direct comparison with the sun; this had never been done before without observing an intermediary body (the moon or Venus) which could be seen in the daytime. But it was now possible, as Picard had found in the previous year, to observe stars in daylight with the telescope attached to his quadrant. Another desirable undertaking was the accurate determination of the position of Tycho Brahe's observatory. This he was able to carry out in 1671, when the Academy sent him to Denmark for that purpose. The results of his observations on the site of Uraniborg were published in 1680 in his "Voyage d'Uranibourg." This expedition became memorable in two ways. First, because Picard, in his account of it, describes certain apparent motions of the Pole-star towards or away from the pole, of which the period was a year, and which, he says, he had noticed for about ten years. From the details given, it is evident that Picard was the first to notice the effect of aberration on the apparent place of a fixed star; and when he adds that these irregularities were in some years smaller than in others, it shows that the effect of nutation was also beginning to be felt. But it was reserved for Bradley both to discover the laws governing these phenomena and to give the correct explanation of them.

The second valuable result of Picard's journey to Denmark was that he made the acquaintance of Römer at Copenhagen, and persuaded him to go to Paris with him. Römer stayed nine years in Paris, and it was there that he in 1675 announced his discovery of the gradual propagation of light. We know from his letters to Huygens that he at once realised that this must produce aberration. Considering that he and Picard lived together at the Paris Observatory, it is rather strange that they did not compare notes and remark how perfectly this agreed with Picard's observations of the Pole-star. But Römer scarcely ever published anything, so it is not impossible that he may have noticed the agreement, and did not care to publish it.

Picard from time to time carried out various geographical operations in France, the results of which are included in his "Ouvrages de Mathématique" (1736). He was a very active observer at the Paris Observatory from 1666 to 1682, and his observations, which were chiefly made with a 9-ft. quadrant, were finally printed in Le Monnier's "Histoire Céleste" (1741). Though his work was less showy than that of his colleague Cassini, Picard deserves an honourable place in the ranks of astronomers as one of the comparatively few observers with instruments of precision in the period between Tycho Brahe and Flamsteed, and as the pioneer in the application of the telescope to this work.

Robin's Water-music.

By PROF. W. GARSTANG.

SCARCE heard amid the choral throng
  That gave the Spring its greeting,
You triumph, Robin, when your song
  Marks Summer's joys retreating;
Then, while the green leaves flame to gold,
  And rain drips o'er their embers,
You raise, above the sodden mould,
  The song of all Septembers.

Erratic, wistful, sweet and shrill,
  The grave and gay you mingle,
As changeful as the trickling rill
  That voices glade and dingle,—
    From high to low,
    Now swift, now slow,
  Like water o'er the pebbles,
    Meandering here,
    And darting there,
  To sparkle in the trebles.

    Chir'ri-tew! Ir'ri-tew!
    Wis'-yoo, Wis'-yoo!
  Wee'!—Swee'!—Tew-ay'!
    Tew, tew', tew, Psee'!
    Chirri-wee'! Tyo-to'!
Se-Wis'sy-wissy, Wis'sy-wissy, Wee'!

Until, in soft soliloquy,
  You enter realms more tender,
And drop, from heights of ecstasy,
  A falling trail of splendour,—
    Brilliant gems no casket treasures,
    Crystal tones no music measures,—
A glittering, flickering, tinkling streamlet,
Fragile as a dream.

    See, See', See, TSEE'. . . !
Choo-it'ty, Tu-it'ty, Choo-it'ty, Tu-it'ty, Choo-ee'!
    Wee-chee'! Wee-tsee' . . . !
Che-wir'rio-ir'rio-wir'rio-ir'rio-ee'!
    As rockets soar
Aloft to fall in twinkling disarray,
    As fountains pour
To break adrift in showers of glistering spray.

* * *

Tit-it'! Tit-it-it-it'! Tit'! Tit'!
Yes, Robin, yes! I must admit
(*Tit-it'-it-it'! Tit-it'-it-it'!*)
  My actions were suspicious,—
For no true gardener stops his spade
To hear a little bird's cascade
  Of music, though delicious!
But when, enraptured, down the scale
  You dance by steps so slender,
    The Nightingale's *Tyo-tyo'-tyo-tew'*,
    The Throstle's *Tirra-lirra-loo*,
      Grow pale
  Before your rich chromatic splendour!

Notes.

THE following is a list of those recommended by the president and council of the Royal Society for election to the council at the anniversay meeting on November 30:—*President:* Prof. C. S. Sherrington. *Treasurer:* Sir David Prain. *Secretaries:* Mr. W. B. Hardy and Mr. J. H. Jeans. *Foreign Secretary:* Sir Arthur Schuster. *Other Members of Council:* Mr. J. Barcroft, Sir William Bragg, Dr. A. W. Crossley, Prof. J. B. Farmer, Sir Walter Fletcher, Prof. A. Fowler, Dr. A. C. Haddon, Sir Robert Hadfield, Sir Thomas Heath, Prof. J. Graham Kerr, Prof. H. Lamb, Sir William Leishman, Dr. S. H. C. Martin, Prof. J. W. Nicholson, Mr. R. D. Oldham, and Prof. W. P. Wynne. Prof. Sherrington, who is to succeed Sir Joseph Thomson as president, is the Waynflete professor of physiology in the University of Oxford, and was formerly professor of physiology in the University of Liverpool and Fullerian professor of physiology at the Royal Institution. He was elected F.R.S. in 1893, and was awarded a Royal medal in 1905 for his researches on the central nervous system.

DR. E. H. GRIFFITHS has been elected general treasurer of the British Association in succession to the late Prof. John Perry. The council of the Association has agreed to the formation of a separate Section of Psychology, as recommended by the Sections of Physiology and Educational Science at Cardiff, and approved by the general committee. Consideration of the number and scope of the various Sections is to be referred to a special committee. It has been decided to invite national Associations for the Advancement of Science to send representatives to annual meetings of the British Association in future.

THE council of the British Association has recently had before it the suggestion made by Prof. Herdman in his presidential address at Cardiff for a new *Challenger* expedition for the exploration of the great oceans of the globe with modern instruments and methods. It will be remembered that this proposal received the support of all the Sections of the Association by formal resolution, and the council was asked to appoint a committee to take the necessary steps to urge its need upon the Government and the nation. This committee has now been appointed, and the scientific world will follow its activities and their result with close attention. An oceanographical expedition along the lines contemplated, and equipped with the instruments which modern science can provide, would lead to a great increase of knowledge both for scientific study and for profitable development, and no nation could carry it out more appropriately than Great Britain in co-operation with our overseas Dominions. There will be an eclipse of the sun in September, 1922, with the line of totality crossing the Maldive Islands, and the expedition could very well include an astronomical party to observe it. It is believed that the Admiralty is favourably disposed towards the scheme, and every scientific man hopes that the necessary support will be forthcoming to carry out the enterprise on a scale worthy of the British Empire.

MR. H. G. WELLS, who has recently been in Russia, describes in the *Sunday Express* of November 7 the position of some leading men of science whom he met at Petersburg, by which name, and not Petrograd, this city is now called. He saw Pavlov, the physiologist, Karpinsky, the geologist, Belopolsky, the astronomer, Oldenburg, the Orientalist, and Radlov, the ethnologist, among others who have survived the complete social disruption which Russia has undergone since the catastrophe of 1917–18. Such privileges as are possible in the country under existing conditions appear to be extended to scientific workers; for Mr. Wells mentions that the ancient palace of the Archduchess Marie Pavlova is now a House of Science, where a special rationing system "provides as well as it can for the needs of four thousand scientific workers and their dependents—in all, perhaps, for ten thousand people." In spite of this, however, there are much privation and misery, and unless food and clothing are provided few are likely to survive the coming winter. What struck Mr. Wells more than anything else was that even under the present disordered conditions, and with physical vitality reduced almost to its lowest limits, a certain amount of scientific work is still carried on, and there is a burning desire to know what has been done for the advancement of natural knowledge in other parts of the world since the Russian collapse. "The House of Literature and Art," we are told, "talked of want and miseries, but not the scientific men. What they were all keen about was the possibility of getting scientific publications; they value knowledge more than bread." There would, we are sure, be no difficulty in obtaining the books and publications needed by, or funds for providing warm clothing for, the great survivors of the Russian scientific world, if their colleagues here were assured that the parcels would reach their destination. This specific aid is, however, a different matter from general provision for the physical and mental needs of the "four thousand" scientific workers to whom Mr. Wells refers. We should scarcely have placed so many men in that category even before the war, and the ranks of scientific forces in Russia must have been greatly reduced by the revolution.

A GOOD deal of uneasiness has recently been manifested with regard to the free importation of German dyes into this country, and in reply to questions on this subject the President of the Board of Trade stated on November 1 in the House of Commons that proposals to protect the industry for a time, so as to enable it to be placed on a secure foundation, will be embodied in a Bill relating to key industries which will be introduced and proceeded with as soon as possible. It appears that during the first nine months of this year 1574 tons of dyes were imported from Germany, of which 877 were consigned under the reparation clauses of the Peace Treaty. The value of the whole quantity was 1,399,027*l*., and as the average price per lb. is thus about 7*s*. 11*d*. it would not appear that there can be any question of dumping as alleged in some quarters. The amount imported is at the rate of about 2000 tons per annum, whilst in 1913 there were imported from Germany about 13,000 tons. It is evident that there is a demand in this country for certain dyes of German origin, and this is not surprising when it is considered that with one conspicuous exception British manufacturers at the commencement of the war, like the Americans, concentrated their attention on the production of those dyes which were most in demand, simple to make, and required readily obtainable intermediate products. It is high time, however, that a serious effort should be made to produce such important dyes as the rhodamines and others, for which special plant and intermediate products not easy to make are required; and it may be noted that the former, in consequence of the remarkable discovery of a new catalytic method of preparing phthalic anhydride at a very low cost, are already appearing in America. Until this can be done the introduction of legislation such as that foreshadowed by the President of the Board of Trade is quite essential.

IN view of the increasing population in England and the imperative necessity that this country should in the future be more self-supporting in the matter of food than in the past, few subjects are of more vital importance than that of the reclamation of waste lands. The Association of Economic Biologists, presided over by Sir David Prain, discussed this problem at its meeting in the Imperial College of Science on Friday, November 5. In addresses very fully illustrated by lantern-slides Prof. F. W. Oliver considered the question of reclamation by botanical means and Dr. E. J. Russell that of reclamation by agricultural means. The former devoted his attention primarily to the reclamation of salt marshes and other maritime tracts, showing the manner in which this process slowly occurs in Nature through the accreting activities of certain ordered successions of plants, and then indicating how such action might be accelerated and made of immediate practical value by the wise interference of skilled botanists. Knowledge of the ecology of maritime-strand plants is, however, very small, and the necessity was emphasised for the establishment of experimental stations where such problems could be studied. Dr. Russell considered the reclamation of inland tracts of country, such as moor and fen, sandy commons, etc., and lands deficient in particular mineral constituents. Each class of waste land was discussed in turn with illustrations drawn from a wealth of personal experience, and the different procedures required in the several cases were described. Prof. Farmer, Dr. Voelcker, Mr. Lobjoit, Dr. Salisbury, Mr. Bernard Davis, and Sir David Prain took part in the discussion.

"Our Wasteful Use of Coal and a Remedy" is the title of an article by Mr. W. O. Horsnaill appearing in the November issue of the *Fortnightly Review*. The author discusses in turn various recent publications, and concludes that "it is quite evident from the foregoing facts that coal should never be burnt direct for the production of heat if the greatest economy in its use is to be realised." He mentions the proposals made by Dr. Ferranti in 1910, according to which all coal would be consumed centrally for the generation of electricity, and points out once more the fundamental weakness of any such proposal, viz. that any attempt to deal with heating by such a scheme would mean an extravagant expenditure of fuel. The author finds that "the recommendations of the Coal Conservation Sub-Committee which was appointed by the Reconstruction Committee closely accord with the suggestions made" in his article, and goes on: "Put briefly, the Sub-Committee recommendations comprise the establishment of sixteen super-electric generating stations for supplying the whole country and the gradual suppression of the existing 600 undertakings. At these stations the coal would be so treated as to extract the tar, sulphate of ammonia, and gas, the latter, together with the coke, being utilised to produce the electricity. So far as practicable, the super-stations would be established near the coal-pits." There is a lack of precision about this paragraph which is observable in other parts of the article. The soundness of treating coal for by-products at the proposed super-stations was regarded by the Sub-Committee as requiring consideration. Moreover, the position of modern super-stations is of necessity determined by supplies of condenser water, and not by proximity to coal-pits. Mr. Horsnaill concludes: "Whether the use of electricity for heating and cooking is contemplated is not clear, but, in view of heavy losses already set forth as accruing from this practice, it is to be hoped that coke and gas will be employed for these purposes"—with which surely anybody who has looked into the subject at all carefully will agree.

We are glad to welcome a new contemporary in the *Mining Electrical Engineer*, of which the first issue is now before us. This publication is the official journal of the Association of Mining Electrical Engineers, a society which has been doing important work for the last eleven years in the spreading of knowledge regarding the use of electricity in mines. Such a journal is of particular interest at the present time, when the need for the application of scientific methods to the aid of labour in improving the output of the coal-mines is so urgent, and we are pleased to see this sign of vitality in a society which from its earliest days has worked hard to break down prejudice against the use of electricity in collieries, to facilitate the interchange of experience, and to encourage those researches which conduced so much to improved safety and trustworthiness in this field. Besides some sound common sense regarding the industrial situation, there are several interesting technical articles, including a discussion of the ventilation of enclosed motors by Mr. W. M. Landon, and a fully illustrated description of an electrically driven main shaft winding plant, employing a geared three-phase motor. A complete system of electrical signalling in collieries, worked out in great detail by one of the well-known electrical firms, is also described. The proceedings of the various branches of the association are recorded, and many interesting notes on matters of electrical interest appear.

The October issue of the *Scientific Worker*—the official organ of the National Union of Scientific Workers—contains the report of the Executive Committee on the policy and administration of the Government Department of Scientific and Industrial Research. After describing the present regulation for the formation of research associations under the Department, the report condemns the policy of assisting these close corporations with public funds, and would substitute for them the universities, colleges, and other national institutions at which research has been carried out so satisfactorily in the past. The report alleges that the faults of the present arrangements are due mainly to the constitution of the Advisory Council of the Research Department and to the absence of members with first-hand knowledge of the working of modern faculties of applied science at our universities and colleges. It is held that scientific eminence should not be the only qualification for membership of the Advisory Council, but aptitude for the conduct of affairs should be essential. These questions are to be discussed at the meeting of the council of the union on November 13.

Prof. F. Gowland Hopkins is to deliver the eleventh biennial Huxley lecture on "Recent Advances in Science in their Relation to Practical Medicine" at Charing Cross Hospital at 3 o'clock on Wednesday, November 24.

During the coming session the meetings of the Röntgen Society will be held in the physics lecture theatre, University College, Gower Street, W.C.1, on the Thursday before the third Friday of each month at 8.15 p.m.

The opening meeting of the new session of the Institution of Electrical Engineers will be held on Thursday, November 18, and not to-day (November 11), as originally announced, at the Institution of Civil Engineers at 6 p.m., when the president, Mr. Ll. B. Atkinson, will deliver his inaugural address.

THE Eugenics Education Society is organising a lecture to be given by Dean Inge on Tuesday, November 16, at 5.30 p.m., at the Wigmore Hall, Wigmore Street, W.1, entitled "Eugenics and Religion." The lecture will be free and open to the public.

THE annual Huxley memorial lecture of the Royal Anthropological Institute will be delivered by Dr. A. C. Haddon in the lecture-room of the Royal Society on Tuesday, November 23, at 8.30. The subject will be "Migrations of Cultures in British New Guinea."

THE New York correspondent of the *Times* states that the fifth quinquennial election to the American Hall of Fame has resulted in the choice, from among 177 names submitted, of six, which include James Buchanan Eads, a famous engineer, and William Thomas Greene Morton, the Boston dentist who introduced sulphuric ether as an anæsthetic. Of the 27 women nominated, one, Alice Freeman Palmer, the educationist, was chosen.

THE following have been elected officers of the Cambridge Philosophical Society for the session 1920–21:—*President:* Prof. Seward. *Vice-Presidents:* Sir E. Rutherford, Mr. C. T. R. Wilson, and Dr. E. H. Griffiths. *Treasurer:* Prof. Hobson. *Secretaries:* Mr. H. H. Brindley, Prof. Baker, and Mr. F. W. Aston. *New Members of the Council:* Prof. Marr, Mr. C. T. Heycock, Mr. H. Lamb, Prof. Hopkins, Dr. Bennett, and Dr. Hartridge.

MR. ARTHUR MACDONALD has reprinted from the *Medical Times* of July last an interesting paper on "The Anthropology of Modern Civilised Man." He describes the conclusions at which he has arrived after a long course of study. He dwells upon the importance of head measurements as a test of mental ability. The smaller circumference of the head among children of mixed nationalities in America is held to indicate an unfavourable result of race intermixture. One of the main objects of the study of humanity is to lessen pain through the knowledge gained by the study of pain itself. Investigations into sensibility give some interesting results. Coloured children are more sensitive to heat than white children, and bright children as compared with dull children. All children are more sensitive to heat and locality on the left than on the right wrist, probably because the greater use of the right hand causes obtuseness of feeling. Girls are less sensitive to heat and more sensitive to locality on the wrist than boys, and all children are more sensitive to heat and locality on the wrist before than after puberty.

IN the issue of *Man* for October Mr. L. W. G. Malcolm describes a settlement of Tasmanian half-castes on Cape Barren Island, included in the Furneaux group of islands in Bass Strait, between Tasmania and the Australian continent. The settlement dates from the latter half of the seventeenth century, when Bass demonstrated that Furneaux Land was a group of islands, and not, as was generally supposed, connected with the mainland. The sealers who visited it carried off aboriginal women from Tasmania, and from them the present population has sprung. Among them Mr. Malcolm found two old men who claimed descent from aboriginal Tasmanian mothers. There were only nine families on the island, comprising in all about one hundred persons. One noticeable fact about these people is the pronounced odour of their bodies, which was decidedly fishy owing to the character of their diet. Their chief industry is catching and salting mutton-birds, which are exported in casks to the mainland. The Government provides medical attendance, and a school has been established. This survival of half-castes derived from a race now extinct is of considerable interest to anthropologists.

THE *Museums Journal* for November contains a useful history of the Winchester City and Westgate Museums by Mr. R. W. Hooley, who as honorary curator has of late been devoting much time and labour to putting the collections in order. In the course of his inquiries Mr. Hooley has made the lamentable discovery that the original bushel measure deposited in the city by King Edgar, and still in its possession only fifty years ago, is now missing.

IT is an excellent custom of the Smithsonian Institution to print as an appendix to its annual report a selection of papers covering a wide range of sciences and each of some general interest. The volume for 1917, recently received, devotes 546 pages and 242 plates to twenty such papers, of which eleven are original. Except for one original memoir and two of the reprints, all are by American authors, and about half deal with American subjects. It is scarcely possible to abstract such an assemblage, but we would direct the special attention of British readers to two of the papers—in the first place to "The Correlation of the Quaternary Deposits of the British Isles with those of the Continent of Europe," a hundred-page memoir by Mr. C. E. P. Brooks. This does not reveal a first-hand acquaintance with the deposits, but it is a most useful summary of the voluminous literature. Dr. T. Wayland Vaughan has an intimate knowledge of "Corals and the Formation of Coral-reefs," and his paper should interest the countrymen of Darwin, whose atoll hypothesis Dr. Vaughan is unable to substantiate in fact. The advocates of a new *Challenger* expedition may note his conclusion that "further investigations of the phenomena associated with coral-reefs are among the pressing desiderata of geologic research."

AN account of the round-headed apple-tree borer (*Saperda candida*) and its control is given in Bulletin 847 (1920) of the U.S. Bureau of Entomology. This insect is a Longicorn beetle which is indigenous to the United States and Canada. Its larva bores into the bark and wood of apple, pear, and quince, thus causing a great deal of injury. Certain wild trees are also affected, including crab, hawthorn, mountain ash, etc. The complete life-cycle of the insect occupies, as a rule, two years, but the developmental period may be lengthened or shortened according to locality and other factors. No easier and cheaper method of control was found than the old method of removing the larvæ from the trees with the aid of a pocket-knife, a narrow chisel, and a piece of wire. It is claimed that two men, on an average, with an insignificant expenditure for tools and materials, should be able to "worm" 500 trees per diem. Ordinary white-lead paint is a cheap and effective method for preventing the females from ovipositing on the bark.

The important question of the control of the cotton-boll weevil by means of poison is dealt with by Messrs. B. R. Coad and T. P. Cassidy in Bulletin 857 (1920) of the U.S. Bureau of Entomology. Extermination of the species is not attempted, the result aimed at being a sufficient reduction of the weevil infestation to permit of the production of a full cotton crop. About 60 per cent. of the squares which appear on the cotton plant fail to mature as bolls, and are normally shed at some time during their development. It has been found that up to a certain point the first shedding due to boll-weevil attack merely takes the place of this perfectly normal shedding, which would be encountered even if the weevils were absent. The system of poisoning advocated is intended to keep the weevils controlled to such a degree that they will not be able to do more than offset the above-mentioned shedding. The authors advise dusting the plants with calcium arsenate at the rate of 5 lb. per acre. In order to avoid injury to the foliage the powder should not contain more than 0·75 per cent. of water-soluble arsenic oxide. It appears safe to assume that, with fertile soil and a fairly severe weevil infestation, average gains of 500 lb. or more of seed cotton per acre may be expected from the treatment advocated.

We have received a copy of the Mauritius Almanac for 1920, published by the Mauritius Stationery and Printing Co. It is a large volume containing a mass of statistical and descriptive matter on all aspects of the life of the colony. The account of the agriculture is particularly full and interesting. There is a general map of the whole island, and another showing the distribution of rainfall.

The results of some oceanographical researches on the coast of South-West Africa are published by the Deutsche Seewarte in *Archiv*, No. 1, vol. xxxviii., the first part of this publication which has appeared since 1915. The work, which was carried out by the *Möwe* so long ago as October, 1911, to July, 1912, includes the investigation of depths and sea temperatures along the coast between the Orange and Kunene Rivers seawards as far as the 200-metre contour. The results are discussed by Dr. A. Franz, and include charts of the depths, water, and air-temperatures. There is also a section dealing with the distribution of pressure and winds. The work is particularly interesting in relation to variation in the strength and temperature of the Benguela current.

The degree of inaccessibility of various parts of the Arctic regions has a direct bearing on future exploration. Mr. V. Stefansson has an article on this subject, accompanied by a map, in the September issue of the *Geographical Review* (vol. ix., No. 9). By measuring distances of 500 miles northward along the meridians from the more northerly points attained by various exploring ships, an area of comparative inaccessibility is found to remain. The distance of 500 miles is chosen, on the basis of Peary's journey from Cape Columbia to the Pole, as a fair maximum possible with dog-teams from the base of supplies. By these estimates the "pole of inaccessibility" is found to be at latitude 83° 50′ N., longitude 160° W. Various modifying factors must be borne in mind. Open leads or heavy pressure ridges are great impediments to sledge travelling in several parts of the Arctic basin, while the action of currents may nullify advance or, if known and taken advantage of, may greatly facilitate progress. The question of food supply, if the traveller is "living off the country," also influences the problem. Certain areas of Arctic ice are known to be almost devoid of seals. These deserts must be avoided or crossed hurriedly. But Mr. Stefansson believes that the well-known drift across the Pole carries to this region, least accessible to man, a certain number of seals from the Beaufort Sea, where they are abundant.

As previously recorded in Nature (August 23, 1917, p. 510), certain plant remains found in the wide tract of sandstones and conglomerates on the west coast of Norway led Nathorst to assign those rocks to the Middle Devonian. Some fish remains found since, and now described by Dr. Johan Kiaer (*Bergens Museums Aarbok*, 1917–18, 2 Hefte, 1920), fully confirm this conclusion, and, though incapable of specific determination, warrant a comparison of the Norwegian rocks with the upper part of the great Orcadian group as displayed in the north of Scotland, and particularly in the more closely adjacent Shetlands. There were at least two kinds of ganoid fishes (apparently Diplopterus and Tristichopterus) existing in large numbers, and, whether they fed on other fishes or not, their presence implies the existence of a large animal and plant life for their maintenance. Some of the plants are regarded by Nathorst as aquatic, and tracks of some crustacean have been observed. The present discoveries will doubtless lead to further investigation of these rather inaccessible Devonian regions, and we may hope that remains of other animals will before long be found.

Parts 1 and 2 of vol. vi. of the Proceedings of the Indian Association of Science contain together eight papers which extend to 112 pages. Although the papers cover most branches of physics, investigations connected with the behaviour of musical instruments are most popular. Amongst these one by Prof. Raman on the variation of the bowing pressure with the pitch of the note, with the part of the string bowed, and with the speed of bowing in a violin may be noted. The observations were made with a violin moved mechanically to and fro at a constant speed over an iron track, while above it was suspended a bow in a balanced frame which allowed the pressure on the string to be varied. If the position of the point bowed is changed, the bowing pressure must vary inversely as the square of the distance of the point from the bridge. If the speed of bowing is increased, the pressure must be increased, at first slowly, then more rapidly. If the pitch of the string is changed by stopping, the pressure varies with the frequency, and is a maximum at each of the resonance frequencies of the string.

IN the course of his presidential address to the North-East Coast Institution of Engineers and Shipbuilders, delivered on October 29, Mr. A. Ernest Doxford made reference to the educational functions of the institution. The promotion and maintenance of professional proficiency are among the chief duties accepted by the technical societies. Their policy is to increase the professional knowledge of their members by fostering the interchange of useful information by the members themselves, and there would seem to be no more useful method of attaining the end in view than that of the reading and discussion of thoroughly good papers. In the more scrupulous institutions no paper appears except from the pen of a practical expert, and the information provided has to be either quite new or sufficiently up-to-date to require further dissemination and discussion. If the engineering technical societies are truly representative of engineers in the particular territory to which they refer, they represent the only people who are able to provide new information on engineering questions, and it is the self-imposed responsibility of these societies to furnish such information. Strictly speaking, a society cannot *train*; it only finds the information with which its members must instruct themselves. Mr. Doxford puts the question as to whether the technical societies do, or can, fill a place in the educational system of this country, and considers that they are unique and indispensable factors in any complete national educational system. The institution is not endowed, and Mr. Doxford considers that the members, the local engineering and shipbuilding industries, and the shipowning businesses might find some opportunity of encouraging it by contributions to an endowment fund; he does not think that the institution should appeal to the State, particularly in these times when State generosity in some directions has become dangerous.

WE have received from Messrs. Dulau and Co., Ltd., of Margaret Street, Oxford Circus, W.1, two catalogues of books which they are offering for sale. One includes a number of old French and Italian books and a collection of some seventy volumes from the library of Adam Smith. There are also four volumes which belonged to Newton, two of which contain his autograph. The other catalogue contains a list of about one thousand books on mathematical and physical sciences, many of them very old copies. Among other important items we note that one set of the thirteen volumes in which the Paris Académie des Sciences published the works of Laplace is offered for sale. There are also some early works on sundials and a number of sets of the Proceedings of various British and American scientific societies and other scientific periodicals.

Our Astronomical Column.

THE DISTRIBUTION OF THE STARS IN SPACE.—The *Astrophysical Journal* for July contains an important paper by Prof. Kapteyn and P. J. Van Rhijn on star-density in different regions of the stellar system. The authors have lately accumulated from various sources much new material on star parallaxes and motions, and state that they could not resist the temptation to attempt a general solution of the problem of the universe, though they admit that it will need revision. They adopt the parsec as unit of distance, and the magnitude at unit distance as absolute magnitude. That of the sun is $-0{\cdot}2$, while the median magnitude of all stars is $+2{\cdot}7$. The expression for the logarithm of the number of stars of absolute magnitude M per 1000 cubic parsecs in the region near the sun is found to be $-2{\cdot}394+0{\cdot}1858\,M-0{\cdot}0345\,M^2$, indicating a parabolic curve when M is taken as abscissa. This gives 0·0451 stars per cubic parsec near the sun, or 23·6 within 5 parsecs of the sun. Observation gives some twenty-seven stars in this sphere—a satisfactory agreement.

The next step is to investigate the rapidity with which the stellar density falls off with increasing distance from the sun (provisionally assumed as the centre). Curves are drawn showing the lines of various densities on a plane drawn through the galactic polar axis. For example, the line of density 0·01 (the density near the sun being unity) is distant 1300 parsecs towards the galactic poles, and 8900 parsecs in the galactic plane. Density 0·063 is reached at about half these distances.

Prof. Kapteyn has re-investigated the formula connecting parallax and proper motion. The new formula is

$$\log \pi_{m,\mu} = -0{\cdot}690 - 0{\cdot}0713m + 0{\cdot}645 \log \mu,$$

m being the apparent magnitude and μ the annual proper motion in seconds.

THE MULTIPLE SYSTEM ξ URSÆ MAJORIS.—Dr. G. Abetti contributes a study of this system to *Mem. della Soc. degli Spett. Ital.* (vol. viii., Ott., Nov., Dic., 1919). He reminds us that it was this star which Sir W. Herschel, who discovered its duplicity in 1780, used to demonstrate the extension of the law of gravitation beyond our system. On plotting the numerous observations of the last sixty years a minor oscillation clearly appears superposed on the orbital motion. This was explained by the discovery made by Wright and Campbell at the Lick Observatory in 1900 and 1908 that each star of the visible pair is a spectroscopic binary. The period of the pair A, a is 1·82 years, and their respective masses are given as 0·52 and 0·16 of the sun. The joint mass of B, b is given as 0·49 of the sun, but there is scarcely enough material to assign the respective masses of B, b. The parallax of the system is assumed to be 0·156″. If the mass of a is correct, this is about equal to the companion of Krueger 60, these being the smallest stellar masses known.

CHARLIER'S CRITICAL SURFACE IN ORBIT DETERMINATION.—Prof. Charlier showed that a certain surface divides those regions in space where there is a dual solution of the orbit problem from three observations from those where there is only one. Herr A. Wilkens gives in *Astr. Nach.*, 5067, tables for laying out this surface accurately. It suffices to give the intersection with the plane of the ecliptic, the surface being one of revolution about the earth-sun line. The curve resembles a looped *limaçon*, the double point being at the earth, the inner loop extending to the sun, and the outer one to a point 1·7844 beyond the sun on the earth-sun line produced. The table includes some other auxiliary quantities of use to orbit computers.

Physics at the British Association.

THE programme of Section A included papers of wide and varied interest, ranging over the subjects of pure mathematics, experimental physics, geophysics, and astronomy. A great deal of the time of the Section was absorbed in atomic problems, and it was in relation to these that much interesting discussion arose.

Dr. Aston gave a concise and comprehensive account of his work on isotopes, starting from his original discovery of the complex nature of neon and chlorine, and he spoke of his early attempts to separate the components of these gases. He described his very elegant modification of Sir J. J. Thomson's method of positive-ray analysis, by which it has now become possible to obtain mass spectra of the rare gases and many other elements with high dispersion of the component lines. He showed how the spectra of various elements could be analysed into groups of lines due to the individual isotopes, and the results interpreted by examining the spectra of different orders produced by atoms carrying multiple charges. In this way it has been possible to eliminate uncertainties arising from radiations consisting of compound molecules and to determine the number of components due to each element. Thus it was shown that chlorine consisted of three isotopic components, krypton of as many as six, and xenon of five, corresponding with atomic weights represented by whole numbers, taking oxygen of atomic weight 16 as standard. Hydrogen alone gave an atomic weight of 1·008, differing from an integral value, and this discrepancy could be explained by considering that the spectrum of hydrogen was due to a hydrogen atom from which an electron had been withdrawn, and which from theoretical considerations should have a mass differing by the observed amount from that of the hydrogen atom. The results thus show that the elements may be considered as being composed of these hydrogen nuclei, or "protons" as Sir Ernest Rutherford would have us call them, and we thus return to Prout's conception of the constitution of matter, modified only by the recent discoveries and ideas of modern physics.

Sir Ernest Rutherford followed with an account of his researches on the structure of the atom, starting from the point of view of radio-activity. When α-particles pass through matter they are scattered, and when they pass sufficiently near to the atomic nucleus they may even be turned back upon themselves. In such cases, at any rate with the lighter elements, the forces involved are so enormous that the nucleus may suffer disruption and charged hydrogen atoms, or protons," be torn from the nucleus. Hydrogen atoms travelling with high velocities thus appear, and can be detected by their scintillations produced on a fluorescent screen. These have been found when nitrogen is bombarded with α-particles, as have elementary projected particles of atomic weight 3, probably an isotopic form of helium. The investigation has been extended to other elements, and it would appear that the nuclei of atoms of the lighter elements can be regarded as made up of suitable combinations of hydrogen and this new isotope of helium with electrons. In the heavier elements it would seem that a condensation occurs by which is formed the ordinary helium atom of mass 4. Models were shown illustrating the possible constitution of some of the lighter nuclei, but the complete elucidation of this suggestive and ingenious line of thought must await further experiments.

The discussion of the origin of spectra directed attention to other scarcely less important aspects of atomic phenomena. Prof. Fowler opened the discussion with a masterly description of the known phenomena of spectroscopy, referring to the latest results obtained in examining and classifying the different spectral series of the elements, leaving the consideration of the theories which have been devised to explain the observations to Prof. Nicholson, who described Bohr's well-known theory of atomic radiation. This simple view is, however, insufficient to explain the complicated structure of the lines composing the series, and Prof. Nicholson outlined the extension of Bohr's theory recently developed by Sommerfeld, in which the electronic orbits are considered as elliptical instead of circular. By this extension the relations obtained by Bohr are modified so as to explain the structure of the components of the various spectral series, and the predictions of theory have been strikingly verified by the work of Paschen, whose observations also indicate that the Zeeman and Stark effects are of the magnitude to be expected by theory. Prof. W. L. Bragg directed attention to the difficulty of reconciling the above theory with X-ray observations on crystals and with the chemical evidence leading to Langmuir and Lewis's theory of atoms containing stationary electrons; and Dr. Oxley in a separate paper pointed out the bearing on the question of the magnetic properties of the atom—a subject which has hitherto not received the attention it deserves. From the magnetic evidence Dr. Oxley postulates a binding of the atoms in the hydrogen molecule by a rotating electron system—a complication which, it is to be hoped, will find some simpler substitute.

The subject of relativity was represented by two papers, one by Mr. Evershed and the other by Sir Oliver Lodge. The former paper was concerned with the observations made during the last seventeen years at the Kodaikanal Observatory on the shift of the Fraunhofer lines in the solar spectrum. The conclusion is reached that the general shift of the lines at the centre of the sun's disc and at the limb is not due to pressure, and it is suggested that the increase of shift in passing from the centre of the disc to the limb may be explained by a constant shift towards red over the disc, which is partly compensated by a shift towards violet, due to a movement of ascent radial to the sun. A comparison was drawn between solar phenomena and the results of observations in the electric arc, and the experiments of Royds were quoted as showing that the vapour density in the sun is probably less than is found at the centre of an iron arc. Mr. St. John's measurements on band lines were discussed and compared with observations made at Kodaikanal, which give values at the sun's limb nearly in agreement with the Einstein theory. There are, however, difficulties involved in fully interpreting the results on this theory, and the alternative hypothesis that motion is the sole cause was considered. This view demands an earth effect and a general recession of the iron vapour from the earth. Mr. Evershed described his ingenious experiments in which the displacements were observed by examining the light reflected from Venus. When the angle Venus-sun-earth is about 90° such observations should be crucial, for in this case we should be observing the sun at right angles to the supposed movement. The results are regarded as being favourable to the motion hypothesis, but it cannot be considered that they are as yet decisive.

Sir Oliver Lodge discussed the assumed necessary constancy of the observed velocity of light in free space as contrasted with the universally admitted constancy of its true velocity. He contended that there is no experimental evidence for the dogma that wave-fronts are concentric with a travelling observer initially situated at the source. The Michelson-Morley experiment is consistent with such concentricity, but does not necessitate it. He argued that the Einstein equations exercise no physical discrimination, and are consistent either with this mode of expression or with the FitzGerald-Lorentz conception of the contraction of matter, which was a safer mode of expressing physical results than the attempt to impose complications upon time and space. The paper gave rise to some lively discussion from the supporters of the more modern views.

Mr. F. J. M. Stratton exhibited some spectrograms of Nova Aquilæ III. recently obtained at the Lick Observatory by Mr. Moore, which show important changes taking place in the distribution of radiation from the growing disc of Nova Aquilæ. It appears that the disc given by the $H\beta$ radiation is growing at only half the rate of that given by the nebular lines N_1, N_2, while the complex bands in the spectrum corresponding with all three lines give the same multiple of the wave-lengths for the displacement of separate maxima. Moreover, the separate maxima originate in different portions of the disc, and are inclined to the normal position of spectral lines. A complex combination of expansion, rotation, and vortex motion is needed to explain the effects in terms of the Doppler principle. While the maxima remain fixed in position, the most displaced ones are growing brighter as compared with the central ones.

A further paper on astrophysics was communicated by the Rev. A. L. Cortie, who drew some remarkable comparisons between observations on solar faculæ and photographs of calcium flocculi. The occurrence of magnetic storms on the earth was attributed to the emission of electrons from low, disturbed areas of the sun, giving rise to the formation of clouds into which the earth then passed.

The programme also included an interesting paper by Prof. S. Chapman, who gave an account of some recent extensions of his work on the subject of magnetic storms. Prof. Horton described the results which he had obtained on ionisation phenomena in neon; and Prof. Whiddington showed how he had been able to detect distances of molecular magnitude by observing the variations of frequency in a thermionic-valve circuit produced by the minute changes of capacity resulting from the displacement of one plate of a condenser included in the circuit.

The reports of the Committees on Tidal Observations and on Seismology were of more than usual interest; and in the latter report Mr. J. J. Shaw referred to his recent observations on microseisms. Both communications are being published in the reports of the Association. Much interest was added to the proceedings of the Section by the opportune appearance of the new star in Cygnus. The discovery was announced by the Astronomer Royal at the first session of the Section, and reports of later observations on the new star were received during the meeting.

Chemistry at the British Association.

THE meetings of Section B at Cardiff were fairly well attended, although the programme did not contain any remarkable novelties, and the war papers, which were so conspicuous a feature of the meeting at Bournemouth, were absent. Mr. Heycock's presidential address dealt with the development of metallography, a branch of physical chemistry which owes so much to the work of Heycock and Neville, whose investigations not only opened up important new lines of research, but also set a standard of accuracy which has had a most beneficial effect on later work in metallography, especially in this country. The lesson of the intimate connection between pure science and the advance of industry was well enforced by the address. The president was able to show lantern-slides made from the original photographs of Sorby taken just half a century ago, and members were enabled to appreciate the remarkable skill of the Sheffield amateur who was a pioneer in so many branches of science.

The Section held only one joint meeting for the purpose of hearing the papers in Section A on the subject of isotopic elements. There was a very large attendance at this meeting, and the latest discoveries concerning the isotopes of the commoner elements were described with admirable clearness by Dr. Aston. It is to be regretted that no chemist took part in the discussion. The doctrine of isotopes was founded on chemical evidence, and although recent developments have come chiefly from the physical side, the subject is one of intense chemical interest, and the conclusions which have been reached, inevitable as they appear to be, call for a drastic revision of conventional ideas regarding the elements. No chemist specially associated with the work of determining atomic weights was present, or it would have been interesting to learn whether accurate atomic-weight determinations have ever been made for a single element, other than those of the radio-active group, from materials of widely different origin and geological age; whether, for example, such differences as have been observed between specimens of lead from minerals containing thorium and uranium respectively could be found between chlorides of widely differing origin so as to indicate that the isotopes of chlorine were present in a different ratio from that which has led to the accepted atomic weight of that element. The later paper of Sir E. Rutherford on the structure of the atom was also of great chemical importance, and considerations of this kind have, in the hands of Langmuir and others, been brought into direct relation with chemical facts. It is to be hoped that by the time of the next meeting of the Association chemists will be prepared to join with physicists in the discussion of these questions.

The three subjects selected for discussion on the technical side were fuel, lubrication, and non-ferrous metallurgy. Capt. Desborough's paper on industrial alcohol gave an excellent review of the prospects of production of this fuel from vegetable sources in temperate regions, and showed that, whilst the present cost of root crops grown on cultivated land is too high to allow of their profitable utilisation as sources of alcohol, the possibility of growing suitable crops on reclaimed land is by no means excluded, and figures were given to show that artichokes, sugar-beet, and a South American tuberous plant are all deserving of consideration. The use of maize in certain climates and of waste cellulose is also being studied. The experiments now in progress at the Royal Naval Cordite Factory may be expected to throw some light on the question, and the Section took occasion to pass a resolution urging on the Government Departments concerned the desirability of continuing such experiments with existing plants. Some controversial matters arose in the discussion of the Third Report of the Fuel Economy Committee, which was presented by Prof. Bone. The report includes a memorandum by Prof. Louis urging improvements in the collection and presentation of mining statistics, and these recommendations have been adopted by the Committee. The Committee further disagreed with the policy of the Fuel Research Board in regard to the regulation of the quality of gas, and insisted on the importance of the limitation of inert constituents and sulphur. The hope was expressed that a further opportunity would be afforded to the Committee to submit its views to the Board of Trade before the matter was finally settled. The policy of the Fuel Research Board was defended by a later speaker, and references were made in the discussion to the use of colloidal fuel and to the recovery of ethylene from coke-oven gas. The Section asked for the reappointment of the Committee, which has done valuable work in directing public attention to the urgent national need for fuel economy. An allied subject was dealt with by Dr. Owens in his paper on the measurement of smoke pollution as carried out by a Committee of the Meteorological Office. The methods of determining acidity in air have been improved, but a good method of estimating the amount of acidity borne by the suspended solid particles is still lacking.

The discussion on lubrication covered similar ground to that of recent meetings of technical societies. Messrs. Wells and Southcombe described the influence of small quantities of free fatty acids in lubricating oils, and Dr. Dunstan directed attention to the present ignorance of the chemical nature of mineral oils. The mode of action of acids on these oils is almost completely unknown. Mr. Tizard regarded lubrication as dependent on the formation of an adsorbing layer on the surface of the metal bearing, and mentioned curious results obtained in determining surface tension between mercury and oils by the drop method. Castor oil and glycerol have about the same viscosity, but the former is a good lubricant and the latter worthless. Mercury drops falling through castor oil remain intact at the bottom of the vessel like lead shot, whilst in glycerol they coalesce immediately.

Mr. Vogel's paper on tungsten described the methods employed in the manufacture of the metal at Widnes, and included an interesting account of the steps taken by the steelmakers of this country, when the outbreak of war deprived them completely of supplies of this most essential metal, to meet the requirements of the industry, with such success that all the tungsten needed is now manufactured at home, whilst a surplus remains for export, the quality being superior to that of the metal used before the war. Prof. Desch gave an account of the preparation and properties of ductile tungsten, and directed attention to the remarkable properties of the metal in the drawn state, a complete theoretical explanation of which is still lacking. Mr. Field's paper claimed great advantages for the electrolytic method of extracting zinc over the usual distillation process, and urged its more widespread adoption. Two short analytical papers were presented by Dr. Stanford, and the last session closed with an exceedingly interesting account by Prof. Jaeger, of Groningen, of his determinations of the surface tension and electrical conductivity of organic liquids and fused salts over the remarkably wide range of $-100°$ C. to $+1600°$ C.

The report of the Committee on Absorption Spectra, which was taken as read and not discussed, consisted mainly of an exposition by Prof. Baly of his theory of absorption. This paper might have furnished the basis of a good discussion, as the physical theory involved is novel, and criticism from both the chemical and the physical sides should be expected. Whilst numerous papers on the use of atomic frequencies and of the idea of quanta have been published in recent years, there has been no thorough discussion of such views, and most chemists have allowed the communications to pass without submitting them to any rigorous scrutiny, so that it is uncertain how far the new ideas are likely to meet with acceptance.

Cardiff afforded many opportunities for the inspection of chemical industries of varied kinds, and the Sectional excursions, which were well attended, included visits to iron- and steel-works, copper-smelting works, tinplate works, gasworks, and a rubber factory.

The Lakher Head-hunters of Upper Burma.

AT the opening meeting of the session of the Royal Anthropological Institute, held on Tuesday, October 26, Prof. F. G. Parsons, vice-president, in the chair, Mr. Reginald A. Lorrain, of the Lakher Pioneer Mission, read a paper on "Lakherland, the Home of the Head-hunters."

Lakherland lies on the border of Upper Burma, and is some twenty days' march from civilisation. The Lakhers, who are practically unknown to the civilised world, are of the Mongolian type, and chocolate-coloured. While the men wear a small loincloth only, save for a large blanket thrown round them in the colder evenings, the women wear more clothing, their garments consisting of a piece of cloth for a skirt reaching down to the ankles, while a breast-jacket nearly covers the upper portion of the body. This jacket is open at the back in order that the heavy loads the women carry should not wear out the garment. The men allow their hair to grow long, but it is fastened in a large knot on the top of the head with long brass pins. A plume of horsehair is entwined in the head-cloth to show that the wearer has taken a head. The children run about in a nude condition up to the age of ten or twelve years.

The Lakhers are skilled smiths, although their tools and appliances are of the simplest character. The forge consists of three slabs of stone, and the bellows are hollowed trunks of trees in which is fitted a plunger consisting of a circular disc fitted to a handle, feathers being attached to the rim of the disc to make the plunger practically airtight. Pottery is made by the women without a wheel. The clay, which is obtained from the white-ant heaps, is moulded between a stone held inside the pot and a hammer with rope wound over the head.

An interesting feature in a dance described by Mr. Lorrain was that the ceremonial headdress of the chief for this occasion, which is handed down from father to son, was always worn by the chief's daughter.

The dead are buried in graves immediately outside the dwelling-houses. The grave consists of a hole about 4 ft. square, but the body is placed in a small, sloping trench or tunnel underground excavated from one side of this hole. The body is pushed into the tunnel feet first, the cavity then being closed with a stone. An ornamental wooden pole, with projections or ears which distinguish by their number the sex of the deceased, is erected over the grave. Outside the village decorated memorial poles are erected. In the example described by Mr. Lorrain, one of the poles bore the horsehair plume denoting that the deceased had taken heads and the tail-feather of a cock denoting that he had carried off another man's wife, while on another pole was the skull he had taken. A third small pole showed projecting points, each representing a slave he had carried off when making raids. The animals which had fallen to his spear in the chase were represented by stones round the foot of the poles. A large, flat stone was possibly a sacrificial slab. On one side was placed a row of flat staves representing the deceased's wives.

Great value is attached to the heads of animals taken in the chase and to the heads of human beings taken in tribal wars and raids, as the possession of such is believed to give the owner not only power over the victims in the "world to come," but also ensures a permit into Paradise after the death of the one who has obtained a full set of heads. Sometimes the marriage price of a maiden consisted in part of a number of such heads of human beings, and this led to young men entering into raids upon their near or distant neighbours.

By religion the Lakhers are animists, but it would be more correct to say that they appeased rather than worshipped these spirits, which are believed to be the authors of all evil. A large tree in the centre of the village was held to be the abiding place of the most powerful spirit. At the foot of this tree was the sacrificial stone upon which cocks and pigs were sacrificed.

In the discussion which followed the paper Mr. Lorrain, in replying to certain queries raised by Col. Shakespeare, stated further that there were well-marked social distinctions between the clans. The headship of the village could be held only by the members of about six clans. Next in grade to these were the aristocratic clans, also about six in number, who could not hold the headship of the village. The lower classes comprised two grades, an upper of ten to fifteen clans and a lower of about thirty clans. Below these were the slaves. The headship of the village descended from the father to the youngest son of the chief legitimate wife: other sons became headmen of outlying villages. Mr. Lorrain had not found any regular institution of feasts similar to those held among the neighbouring Lushai, which, when given in a certain progression in the number and character of the victims, bring the giver honour in this world and favour in the world to come. He had found, however, one instance of a house in which the door had a rounded instead of a square top. The exact significance of this he had not been able to ascertain beyond that it was a privilege connected in some way with a special sacrifice.

Meteors of the Season.

THE November meteors are due to return on November 14 and 15, and, though no abundant display may be expected, Mr. W. F. Denning thinks that the shower is likely to prove fairly conspicuous. The parent comet of the meteors must have been in aphelion in 1916, and is now situated between the orbits of Saturn and Uranus, so that whatever meteors may appear this year must be at a vast distance from the cometary nucleus of the shower. The whole orbit, however, contains meteoritic particles, and observations during last century prove that this system re-appears annually at the middle of November. It is fortunate that the moon will be absent from the sky after the rising of the Leonid radiant, which occurs at about 10.15 p.m. on November 15. Probably the meteors will be far more abundant after midnight, when the radiant at $150^\circ+23^\circ$ has attained a fairly good altitude.

These November meteors belong to the swift class, moving at the apparent velocity of 44 miles per second, and, like the Perseids of August, they include flashing fireballs of the largest kind intermingled with the smallest shooting stars.

An abundant shower of meteors was observed between October 30 and November 5, and quite a large number of fireballs were seen. The meteors belonged to a radiant point in Taurus and a few degrees south-west of the Hyades, at about $59^\circ+12^\circ$. There was also another shower situated in Aries at $43^\circ+22^\circ$, which furnished a considerable number of meteors. These were slow-moving, brilliant objects, and have usually traversed long flights.

Both these showers were well observed by Miss A. Grace Cook from Stowmarket during a series of careful and prolonged meteoric observations between October 30 and November 4. Mr. F. Sargent at the University Observatory, Durham, also witnessed the fall of a number of meteors on October 30 and November 5. At Bristol Mr. Denning saw some of the meteors, and one of them, on October 30, about 7.14, was also observed by Mr. F. Sargent. The real path of this object was from about 77 to 55 miles in height, and its luminous course 110 miles at a velocity of about 24 miles per second. The radiant point was at $60^\circ+14^\circ$.

A very brilliant member of the same shower appeared on November 4 at 6.11, and came under observation by Miss A. Grace Cook at Stowmarket and by others at Bristol and Ilford. It had an extremely long path, and afforded a grand spectacle to many observers in the south of England. This was also a Taurid, and it traversed a horizontal course of about 235 miles at a height of about 63 miles from over the sea, about 40 miles east of Southwold, to over Somerset about 20 miles south of Bath. This shower of Taurid meteors is well known, but its recent display, like that on November 2, 1886, was of a rather exceptional character.

Heredity and Social Fitness.

DR. WILHELMINE E. KEY has made (Carnegie Institution, Washington, Publication 296, 1920, pp. 102) a careful study of differential mating in a Pennsylvania family. The study comprises 1822 individuals, nearly half of whom are in the direct line of descent from two pairs of German immigrants of more than a century ago. The remainder were considered in connection with the strains into which the descendants of these couples married. The research began with four young people, patients at the Institution for the Feeble-minded of Western Pennsylvania, and was followed into intricate networks of stocks. Some of the general results may be outlined. (1) The behaviour in inheritance of such qualities as far-sightedness, perseverance, and push indicates that the occurrence of these traits is due to a segregation of their determiners. (2) There was a decided decrease in fecundity in all lines, but not more marked in the socially inefficient than in the efficient. On the other hand, the survival ratios increase for the successive generations of the efficient lines, while they decrease for the inefficient lines, thus illustrating Nature's method of eliminating the unfit. (3) In migration the more efficient push into new areas, the less efficient tend to settle down. (4) The reactions of the degenerate members show that the variations in efficiency are due not to adverse conditions, or to isolation, or to lack of opportunity, but to native inability and to the mating of defective with defective. (5) Individual immigrants of high potentiality tend to marry with the better native stocks, while those of low potentiality gravitate towards inferior native stocks. The whole history emphasises the usefulness (*a*) of segregating the markedly defective, (*b*) of some colonisation scheme, together with sterilisation, for certain types of the socially unfit, and (*c*) of some expert board of control with authority to prohibit marriages of a cacogenic sort. There is danger in ameliorative methods which allow the markedly unfit to multiply and counteract natural agencies for the selection of fit strains. More positively, public opinion requires to be educated towards a keener realisation of the possibilities of establishing strong strains of efficient citizens.

University and Educational Intelligence.

CAMBRIDGE.—Mr. R. A. Fisher and Mr. A. R. MacLeod have been elected to fellowships at Gonville and Caius College, and Mr. R. O. Street, Mr. W. H. Bruford, and Mr. G. E. Briggs to fellowships at St. John's College.

LONDON.—A course of nine lectures on "A Historical Review of Meteorological Theory" will be given at the Meteorological Office, South Kensington, S.W.7, by Sir Napier Shaw, reader in meteorology in the University, on Fridays at 3 p.m., beginning on January 21 next. The course is intended for advanced students of the University and others interested in the subject. Admission is free by ticket, to be obtained on application to the Meteorological Office, South Kensington, S.W.7.

The informal meetings at the Meteorological Office for the discussion of important current contributions to meteorology, chiefly in Colonial or foreign journals, began on Monday, November 1, and will be continued on alternate Mondays, with the exception of December 27, until March 21, 1921.

DR. A. FULTON, hitherto lecturer on engineering in Dundee University College, has been appointed to the chair of engineering in the same institution.

THE Cambridge University Calendar for 1920–21 has been published by the University Press, price 20*s*. The volume contains lists of University officials, professors, lecturers, etc., and the regulations for prescribed courses, degrees, and prizes. The Tripos lists from 1911–20 are given, and also the list of degrees conferred during the year 1919–20. Some three hundred pages are devoted to notes on the individual colleges, which give all the essential information about the constitution of these bodies, the regulations for admission, scholarships, etc., together with the lists of fellows, graduates, and undergraduates attached to them. The volume is supplied with a general index, and also with a complete index to members of the University.

THE Calendar for the session 1920–21 of University College, University of London, has been received. In it will be found complete details of all the faculties of which it is composed, together with time-tables for all the courses provided and lists of the scholarships, prizes, etc., available. There is also an account of the assembly held on July 2, when the American Ambassador, Mr. John W. Davis, took the chair. The Provost of the college made his report for the session 1919–20, and mentioned that during that period the college had been the recipient of two gifts from the United States: one of 1,250,000*l*. from the Rockefeller Foundation for the promotion of medical research, and another, a collection of books on American literature, history, and institutions, from the Carnegie Endowment for International Peace. Other benefactions which were mentioned included a gift of 10,000*l*. from Lord Cowdray for the extension of the engineering school, and a grant from the Carnegie United Kingdom Trust which had made it possible to institute a school of librarianship.

DETAILS of the French Budget for 1920 are given in the *Fortnightly Survey of French Economic Conditions* of September 1. For the Ministry of Public Instruction and Fine Arts a sum of 1,067,328,770 francs is provided which will be allotted in the following way: For public instruction, 994,335,476 francs; for the fine arts, 44,008,800 francs; and for technical instruction, scholarships, etc., 28,984,494 francs. Of a total of 3,280,247,620 francs provided for the Ministry of Public Works, 128,650,830 francs is devoted to section 11, which deals with aeronautics and aerial transportation. In the section of the Budget dealing with extraordinary expenditure which is not provided for by taxation the Ministry of Public Instruction and Fine Arts is credited with a further sum of 109,175,400 francs. The Ministry also receives 129,762,000 francs for the reconstruction of schools, etc., which will be recovered under various peace treaties which have been signed; while the Ministry of Agriculture will be credited with 5,812,000 francs from similar sources for the purposes of reafforestation and the reconstruction of fences protecting State forests.

TEACHERS' Leaflet No. 9 of the Bureau of Education, Washington, illustrates the earnest endeavours now being made in the United States to place instruction in civic rights and duties upon a firm foundation. The leaflet, prepared under the direction of the Bureau's specialist in civic education, describes a series of lessons in civics for the three primary grades of city schools. Each lesson is based upon some situation of civic significance in which the child is normally to be found. The typical situations include: Riding in public conveyances; visiting public places; an accident; a fire drill; arrival of a new pupil or visitor to the school; the walk to school; the arrival of the mail; and contact with a sick person. In conversation style the children are led to give their observations and experiences, and through the teacher's interpretation and enlargements the civic significance is induced. The syllabus is replete with suggestions, dramatisation without material being especially recommended. Similar situations are dealt with in each grade, the instruction being cumulative and concentric. The proposed enlargement of the syllabus and its adaptation to the requirements of the intermediate higher grade will constitute an interesting and important experiment in civic training.

THE Department of Aeronautics in the Imperial College of Science and Technology announces an extensive series of lectures for the year 1920–21. Two full-time courses have been arranged: (1) Design and Engineering and (2) Meteorology and Navigation. The former course includes lectures on aerodynamics by Prof. Bairstow, with practical classwork under his direction; a special course of mathematics for students of aerodynamics; design lectures and drawing-office work under Prof. Bairstow and Mr. F. T. Hill; and lectures on the construction and strength of aircraft by Mr. A. J. Sutton Pippard. Engine design is dealt with by Mr. A. T. Evans, the theory of the internal-combustion engine forming the subject of a series of lectures by the director of the department, Sir Richard Glazebrook. A special course of meteorology and navigation for students principally concerned with aerodynamics is being given by Sir Napier Shaw, while in the latter half of the session Wing-Comdr. Cave-Brown-Cave will lecture on airships. The full-time course on meteorology and navigation comprises a very detailed study of meteorology with special attention to its bearing on aeronautics. The work is under the control of Sir Napier Shaw, the late director of the Meteorological Office, with the assistance of Squadron-Leader Wimperis as lecturer on navigation. The whole programme for both courses is very well arranged, and as the services of such excellent lecturers have been obtained it is to be hoped that a sufficient number of students will be forthcoming to make the courses a success and to establish firmly this new department of the Imperial College.

Societies and Academies.

LONDON.

Royal Society, November 4.—Sir J. J. Thomson, president, in the chair.—Prof. H. **Lamb**: The vibrations of an elastic plate in contact with water. The chief problem considered is that of determining the gravest frequency of a thin elastic diaphragm filling an aperture in a plane rigid wall which is in contact on one side with an unlimited mass of water. This had an interest in connection with submarine signalling. An exact solution is not attempted, but a sufficient approximation for practical purposes is obtained by Rayleigh's method of an assumed type, which gives good results if the type be suitably chosen.—Prof. H. M. **Macdonald**: The transmission of electric waves around the earth's surface.—Lord **Rayleigh**: A re-examination of the light scattered by gases in respect of polarisation. II.: Experiments on helium and argon. The light scattered by helium and by argon is investigated. It is found in the case of helium that the total light scattered is in accordance with what would be expected from its refractivity. The polarisation in helium, contrary to what was found in 1918, is approximately complete. No intensity was detected in twenty-four hours of exposure in the component vibrating parallel to the exciting beam, and certainly this component was less than 6·5 per cent. of the other. Argon polarises much more completely than any other gas examined (with the possible exception of helium), the weak component being only 0·4 per cent. of the other.—Prof. C. F. **Jenkin**: Dilatation and compressibility of liquid carbonic acid. The paper describes the measurement of the dilatation and compressibility of carbonic acid between temperatures of $-37°$ C. and $+30°$ C. and up to pressures of 1400 lb. per square inch. The measurements were made to supply accurate data for determining the starting point for drawing the $\theta\phi$ and $I\phi$ diagrams and to replace the approximate results (known to be inaccurate) given in a former paper (Phil. Trans., A, vol. ccxiii., p. 76).—W. T. **David**: Radiation in explosions of hydrogen and air. This paper contains a record of the results of experiments on the emission of radiation during the explosion and later cooling of mixtures of hydrogen and air contained in a closed vessel. The results of experiments on the transparency of the exploded mixtures are also recorded. Some of the main conclusions arrived at are as follows: (1) The rate of emission is approximately proportional to the fourth power of the absolute mean gas temperature. (2) The maximum rate of emission occurs at the point of maximum temperature. (3) The exploded mixtures are very transparent throughout cooling to radiation of the same kind as they emit. (4) The intrinsic radiance increases both with the lateral dimensions and with the thickness of the radiating layer of gas. (5) The $2{\cdot}8\,\mu$ band of steam ceases to be emitted when the gas temperature has fallen to about 700° C.—Dr. R. E. **Slade** and G. I. **Higson**: Photochemical investigations of the photographic plate. (1) It has been shown that the silver halide grain is the photochemical unit in the photographic plate. (2) A method has been devised whereby the law of photochemical behaviour of these grains can be investigated free from the disturbing effects of development, etc., which occur in the photographic plate itself. (3) From experimental results obtained a formula has been deduced which shows the relation between the behaviour of the silver halide grains, the light intensity to which they have been exposed, and the time of exposure. (4) The results show that it is impossible for the mechanism of the process to be the absorption of light in discrete quanta, and that a given amount of light energy has a greater effect photographically when concentrated into a short range of wave-lengths than when it is distributed over a large range.—Dr. E. H. **Chapman**: The relationship between pressure and temperature at the same level in the free atmosphere. The paper deals with the exceptionally high values contained in the table of coefficients of correlation between changes of pressure and changes of temperature at different levels in the atmosphere included in Geophysical Memoir 13 of the Meteorological Office, by W. H. Dines. The coefficients are computed for observations taken at random, and arranged in four groups for the year of three months each. For the layers between 4 km. and 8 km. these coefficients range from 0·75 to 0·92. It is assumed that if the observations were freed entirely from errors of measurement the coefficients would be still higher. A method is therefore worked out for correction of coefficients of correlation for probable errors of observation in measurement.—Prof. J. C. **McLennan**: Note on vacuum grating spectroscopy.

PARIS.

Academy of Sciences, October 18.—M. Henri Deslandres in the chair.—M. **Mesnager**: The applications of the Pitot tube. Remarks on the note in the last issue of the *Comptes rendus* by the late Yves Delage. It is pointed out that the three problems stated by him—transmission to a distance, independence of the experimental indications and of the support, and registration of the velocities—have already been solved, and the first two in a simpler manner. An account is given of the methods hitherto proposed, all of which would be difficult to use at sea.—M. **Hamy**: The photography of stars in full daylight. An account of some experiments carried out at the Observatoire des Bosses (altitude 4350 metres) on Mont Blanc.—H. and F. **Le Chatelier**: The mechanical properties of plastic bodies: the importance of reactivity. From a study of the torsion of glass kept at 550° C. and of steel at 825° C., it is shown that there are three kinds of deformation: an instantaneous elastic strain, which disappears on removal of the stress; a sub-permanent deformation, produced slowly and disappearing equally slowly; and, finally, a viscous deformation, produced with a constant velocity and not vanishing after release from stress.—M. **Le Prieur**: A route corrector: a new method of aerial navigation by estimation.—J. L. **de Olivar**: Correction of the lunar coordinates deduced from observations made at Montevideo of the annular eclipse of the sun of December 3, 1918.—E. **Belot**: The law of distribution of masses in the solar system, and the origin of the smaller planets.—A. **Véronnet**: Time and temperature of formation of a collection of stars in an indefinite homogeneous nebula.—L. and E. **Bloch**: The spark spectra of some elements in the extreme ultra-violet. Details of the spark spectra of antimony, arsenic, bismuth, and tin between the limits 1850 and 1400 Ångström units.—G. **Bruhat**: The specific heat of saturated vapours at low temperatures. Reply to some criticisms of M. Ariès.—P. **Vaillant**: The existence of intermediate states in the phosphorescence of calcium sulphide deduced from its conductivity.—P. **Théodoridès**: The thermal variation of the coefficient of magnetisation in anhydrous sulphates, and the theory of the magneton. The results of magnetic measurements on the sulphates of manganese, cobalt, and iron at varying temperatures are given. These are in general agreement with the magneton theory.—A. **Dauvillier**: A new theory of photographic phenomena. In a recent communication the author developed a new theory of the chemical action of cathode, β, X, γ, and ultra-violet rays. The production of photographic images is considered from the same point of view.—L. **Dubreuil**: Determination of the number of independent constituents of a system of bodies.—R. **Fosse**: The micro-chemical qualitative analysis of cyanic acid. The method is based on the crystallisation of silver cyanate from hot water. After examining the forms of the crystals, they may be used for several colour reactions.—P. W. **Stuart-Menteath**: The tectonic of the Pyrenees.—G. F. **Dollfus**: The geological probabilities of discovering petroleum in France. A summary of the trial borings made in various parts of France for coal, potash, and oil. The outlook is generally unfavourable except in the valley of the Saône.—P. **Négris**: Considerations on the Glacial period. In an earlier communication the author was led to attribute the invasion by ice and its retreat to epirogenic movements. Further direct evidence of these movements is now given.—A. **Lepape**: The radio-active analysis of the thermal springs of Bagnères-de-Luchon. Some of the springs are rich in radium emanations, figures of 26·5, 31·6, and 41·5 millimicrocuries of emanation per litre of water being recorded.—H. **Ricôme**: The orientation of branches of plants in space.—L. **Emberger**: Cytological studies of the sexual organs of ferns.—M. and Mme. G. **Villedieu**: The non-toxicity of copper for moulds in general and for mildew in particular. Copper in the form of copper-ammonio-citrate does not interfere with the growth of the spores of Penicillium or mildew.—M. **Nicolle** and E. **Césari**: The effects and constitution of the antigens.—A. **Lumière** and J. **Chevrotier**: A simple and inoffensive method of avoiding anaphylactic shock. Starting with the hypothesis that anaphylactic shock is due to the formation of a solid precipitate in the blood plasma, experiments have been made *in vitro* on mixtures of sera capable of giving flocculent precipitates. Various reagents were added to these tubes with the view of discovering a substance capable of preventing the flocculation. Of the large number of reagents tested very few were found to possess the required property, and of these sodium hyposulphite was the most suitable. Experiments on animals showed that this substance was capable of preventing anaphylactic shock, and it was further proved that sodium hyposulphite did not appear to destroy, or even to attenuate, antitoxic sera.—G. **Bertrand** and R. **Vladesco**: The distribution of zinc in the horse. Twenty-three organs of the horse have been examined for zinc, the quantities found varying from 12·2 to 98 milligrams per 100 grams of dried material. Zinc was found in every organ examined, and the proportion varied not only from one organ to another, but also in the same organ or tissue in different individuals.—A. **Němec** and V. **Káš**: The favourable influence of selenium on some moulds arising from the cheese industry.—J. L. **Dantan**: The development of the Antipathella.—M. **Delphy**: The reproduction of *Enchytraeoides enchytraeoides* and *Clitellio arenarius*.—V. **Galippe**: Researches on the presence of living organisms in cretacean, ferruginous, pyritic, and siliceous fossils.—A. **Paillot**: Immunity in insects.

Diary of Societies.

THURSDAY, NOVEMBER 11.

ROYAL SOCIETY, at 4.30.—Dr. W. G. Ridewood: The Calcification of the Vertebral Centra in Sharks and Rays.—Dr. A. Compton: Studies in the Mechanism of Enzyme Action. I. *Rôle* of the Reaction of the Medium in fixing the Optimum Temperature of a Ferment.—C. H. Kellaway: The Effect of certain Dietary Deficiencies on the Suprarenal Glands.—E. J. Collins: The Genetics of Sex in *Funaria hygrometrica*.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5 (Annual General Meeting).—J. E. Campbell: Einstein's Theory of Gravitation as an Hypothesis in Differential Geometry (Presidential Address).—H. Bateman: The Conformal Transformations of a Space of Four Dimensions.—F. Bowman: (1) The Differentiation of the Complete Third Elliptic Integral with Respect to the Modulus; (2) Note on the Intersection of a Plane Curve and its Hessian at a Multiple Point.—T. S. Broderick: Dirichlet Multiplication of Infinite Series.—L. E. Dickson: Arithmetic of Quaternions.—P. J. Heawood: The Classification of Rational Approximations.—E. L. Ince: Integral Solutions of Ordinary Linear Differential Equations.—C. Jordan: The Series of Polynomials, every Partial Sum of which approximates *n* Values according to the Method of Least Squares.—H. J. Priestley: Some Solutions of the Wave Equation.—H. Steinhaus: An Example of a Thoroughly Divergent Orthogonal Development.—N. Wiener: The Group of the Linear Continuum.—G. S. Young: The Partial Derivates of a Function of Many Variables.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. E. G. Browne: Arabian Medicine after Avicenna (FitzPatrick Lecture).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir D'Arcy Power: The Education of a Surgeon under Thomas Vicary (Thomas Vicary Lecture).

ROYAL SOCIETY OF MEDICINE, at 6.30.—Sir Almroth Wright: Medical Research, and the conditions that are indispensable to the achievement of new knowledge.

OPTICAL SOCIETY, at 7.30.—Major E. O. Henrici: The Use of Internal Focussing Telescopes for Stadia Surveying.—Dr R. J. E. Hanson: Visual Fatigue and Eye Strain in the Use of Telescopes.

ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Dr. H. Head, Dr. J. Collier, and Others: Discussion on Aphasia.

FRIDAY, NOVEMBER 12.

INSTITUTE OF CHEMISTRY, at 4.—To Receive Report of the Extraordinary General Meeting of October 28 and confirm the Resolutions and By-laws passed thereat.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—Dr. F. S. Goucher: Ionisation and Excitation of Radiation by Electron Impact in Helium.—J. Guild: Fringe Systems in Uncompensated Interferometers.—J. Guild: The Location of Interference Fringes.—Dr. G. Barr: A New Relay for Moderately Heavy Currents.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Rev. J. G. Hagen: Differences between Long-period and Short-period Variables.—J. H. Reynolds: The Galactic Distribution of the large Spiral Nebulæ.—W. S. Franks: Micrometrical Measures of 202 Double Stars.—F. E. Baxandall: The Presence of Absorption Lines of Nitrogen and Oxygen in the Spectra of Nova Aquilæ III.—J. van der Bilt: Observations of Minor Planets made with the 10-in. Refractor of the University Observatory, Utrecht, Holland.—W. J. S. Lockyer and D. L. Edwards: Spectroscopic and Magnitude Observations of Nova Cygni III., 1920.—G. F. Dodwell: Note on the Longitude of Adelaide.—J. Evershed: Recent Work at Kodaikanal Observatory.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.—Dr. F. Parkes Weber: Chronic Myeloid Leukæmia—Death from Acute Anæmia due to Massive Hæmorrhages (Hæmatomata), Simulation of Slight Pyuria by Leukæmic Oozing in the Urine.—Z. Cope: Diaphragmatic Shoulder Pain.

INSTITUTION OF MECHANICAL ENGINEERS, at 7.—Informal Meeting.

JUNIOR INSTITUTION OF ENGINEERS (at Caxton Hall), at 8.—R. H. Squire: Hydraulic Sand Packing and Colliery Workings in India.

ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30.—Dr. J. Taylor: Some Neurological Aspects of Ophthalmic Cases (Presidential Address).—P. Smith: The Blood-vessels in the Eye of the Ox.

MONDAY, NOVEMBER 15.

ROYAL BOTANIC SOCIETY, at 3.—Prof. A. W. Bickerton: The Relations of Astronomy to Botany. (1) The Importance of Scientific Correlation.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge), at 5.—Prof. H. E. Schwarz: The Control of Climate by Lakes.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.—Ll. B. Atkinson and Others: Discussion.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—R. Dircks: The Library of the Royal Institute of British Architects.

TUESDAY, NOVEMBER 16.

ROYAL HORTICULTURAL SOCIETY, at 3.

ROYAL COLONIAL INSTITUTE (at Hotel Victoria), at 4.—G. Howell: Petroleum Resources of the British Empire.

ROYAL SOCIETY OF MEDICINE (Therapeutics and Pharmacology Section), at 4.30.—Major Acton: Pharmacological Actions of the Main Cinchona Alkaloids, illustrating their Isomeric Relationships.—Dr. W. E. Dixon: Quinine Derivatives as Local Anæsthetics.—Dr. W. Crowe: The Vaccine Treatment of Rheumatoid Arthritis.—Drs. W. E. Dixon and D. Cow: Pituitrin-like Body in the Cerebro-spinal Fluid, and Hormones which cause its appearance therein.

ROYAL STATISTICAL SOCIETY, at 5.15.—Sir B. Henry Rew: The Organisation of Statistics (Inaugural Presidential Address).

INSTITUTION OF CIVIL ENGINEERS, at 5.30.—F. W. Macaulay: Cross Connections on the Elan Aqueduct of the Birmingham Corporation Waterworks.

INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—L. W. Bates: Colloidal Fuel.—H. O'Neill: Properties and Characteristics of Colloidal Fuel.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. P. Chalmers Mitchell: Report on the Additions to the Society's Menagerie during the month of October.—Dr. W. A. Cunnington: The Fauna of the African Lakes: A Study in Comparative Limnology, with special reference to Tanganyika.—H. F. Carter: Description of the Adult, Larval, and Pupal Stages of a new Mosquito from Lord Howe Island, South Pacific.—Dr. C. L. Boulenger: Filariid Worms from Mammalia and Birds in the Society's Gardens, 1914-1915.

ROYAL SOCIETY OF MEDICINE (Pathology Section), at 8.30.—Dr. H. Schutze: Blood Grouping with Dried Material and its Medico-legal Bearing.—Dr. J. A. Murray: Autoplasty after Exposure to Hot Air.—Dr. A. Powell: A Flagellate Organism persisting for Six Years in otherwise Sterile Urine.

WEDNESDAY, NOVEMBER 17.

ROYAL SOCIETY OF MEDICINE (History of Medicine Section), at 5.—J. Berry: A Public Latrine of Roman Imperial Time.—Dr. M. Greenwood: Galen as an Epidemiologist.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.

ROYAL SOCIETY OF ARTS, at 8.—A. A. Campbell Swinton: Wireless Telegraphy and Telephony (Inaugural Address).

ROYAL METEOROLOGICAL SOCIETY, at 8.—C. E. P. Brooks and H. W. Braby: The Clash of the Trades in the Pacific.—Dr. W. H. Steavenson: Note on the Mirage, as observed in Egypt.

ROYAL MICROSCOPICAL SOCIETY, at 8.

THURSDAY, NOVEMBER 18.

ROYAL BOTANIC SOCIETY, at 3.—Prof. A. W. Bickerton: The Relations of Astronomy to Botany. (2) The Value of Basic Principles.

ROYAL SOCIETY, at 4.30.—*Probable Papers:* Sir Arthur Schuster: The Absorption and Scattering of Light.—Prof. O. W. Richardson: The Emission of Electrons under the Influence of Chemical Action.—Dr. A. E. Oxley: Magnetism and Atomic Structure. I.—Prof. A. O. Rankine: The Proximity of Atoms in Gaseous Molecules.—Prof. A. O. Rankine: The Similarity between Carbon Dioxide and Nitrous Oxide.—Dr. A. M. Williams: Forces in Surface Films. Part I., Theoretical Considerations; Part II., Experimental Observations and Calculations; Part III., The Charge on Colloids.

LINNEAN SOCIETY, at 5.—Prof. E. S. Goodrich: A New Type of Teleostean Cartilaginous Pectoral Girdle found in young Clupeids.—Dr. J. C. Willis: Endemic Genera and Species of Plants.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.—L. Dumblane: The Problem of the Helicopter.

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—J. Morrow Campbell: The Origin of Primary Ore Deposits (Adjourned Discussion).—H. C. Robson: Converting High-grade Matte in Magnesite-lined Converters.—C. Brackenbury: An Automatic Counting Machine for Checking Tram Wagons.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Ll. B. Atkinson: Inaugural Address.

INSTITUTION OF AUTOMOBILE ENGINEERS, at 8.—London Graduates' Meeting.

CHEMICAL SOCIETY, at 8.

RÖNTGEN SOCIETY (in Physics Lecture Theatre, University College, Gower Street), at 8.15.

FRIDAY, NOVEMBER 19.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.—Sir William Milligan: Chronic Catarrhal Otitis Media; Some Thoughts and Suggestions.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Capt. J. S. Arthur: Sterilisation of Water by Chlorine Gas.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Section) (at City and Guilds (Eng.) College, Exhibition Road), at 6.30.—C. C. Paterson: The Incandescent Electric Lamp from the Inside.

ROYAL SOCIETY OF MEDICINE (Electro-Therapeutics Sections), at 8.30.—Discussion: Radio-therapy; Prof. S. Russ: Physics.—Dr. Batten: Superficial Therapy.—Dr. Finzi: Deep Therapy.

SATURDAY, NOVEMBER 20.

PHYSIOLOGICAL SOCIETY (at St. Bartholomew's Hospital), at 4.

Science and the Cenotaph.

THE second anniversary of the Armistice of November 11, 1918, has come and gone, and the whole nation, united in a common impulse of pious and grateful remembrance, has done solemn homage to the memory of the glorious dead. King and people, leaders and comrades, have paid reverence to the remains of that unknown hero who has been laid to rest in our national shrine, and who typifies the humble and silent sacrifice of those many thousands to whom we owe the survival of civilisation.

To the soldiers of science, to whom duty and self-sacrifice are, or ought to be, ever-present ideals, the ceremony of last Thursday should have made a special appeal. In the great struggle which terminated two years ago they were not backward in taking their places in the fighting organisation of the nation. With very few exceptions they put their special gifts and training at the service of the State. The devotion and fearless courage of the medical branch of the scientific profession have earned universal recognition. Thousands of the younger students in all faculties, who had, before the war, patriotically joined the Officers Training Corps, came forward in 1914 as one man and filled the gap in the supply of officers until the new armies were ready. Of the older men of science a great number joined fighting units and shared with the rest the hardships and dangers of the trenches. Many valuable lives were thus sacrificed which a wiser distribution might have spent to better advantage: one remembers a mathematician of great ability who served as an infantry officer and was killed by the explosion of a bomb store, and the tragedy of Moseley, who fell at Gallipoli. Others, again, debarred from active service in the trenches, took up work behind the lines or in the technical services—work not without its perils, as is shown by the fate of Keith Lucas and Bertram Hopkinson, two distinguished fellows of the Royal Society, both killed in aeroplane accidents, who died a soldier's death as truly as if they had fallen in action. Another well-known scientific researcher spent weeks experimenting in a submarine in a highly dangerous zone. Such examples might be multiplied a hundredfold. In gas warfare, sound ranging, air work, submarine detection, etc., a vast number of men of science were to be found, and gave their labours and their lives unstintingly. Many made the supreme sacrifice, and, on the whole, men of science proved themselves to be capable leaders and efficient organisers and administrators even in fields widely separated from those of their peace-time activities.

Scientific workers may thus join in the universal homage to the fallen with a pure heart and the consciousness of duty done. They, at all events, are free from the reproach of having in any way profited by the general suffering, or of having exploited the war for selfish ends. Whilst the cost of living still soars, and salaries and wages, in industry, commerce, and administration, try to keep pace with it, the remuneration of scientific workers, poor already before 1914, is gradually being brought down to the starvation limit, the small nominal increase given in some cases being very far indeed from making up for the decreased purchasing power of the pound.

The question not unnaturally suggests itself: How many among those silent crowds that stood bareheaded last Thursday have given any effective help even to one of the millions of returned soldiers who, in the present jostle of selfish appetites, are asking for work and bread from those whose businesses and wages they have saved? And, in particular, how many have given a thought to those struggling scientific toilers who have put away their uniforms and strive vainly to exist on inadequate salaries, under crushing taxation and to meet an ever-rising cost of living? Yet the brains of these men were no mean factor in winning the war, and it should be increasingly obvious that the salvation of a modern State, both in peace and war, must depend nowadays upon trained observation and intelligence—that is, upon science. Only impartial observation and study, such as a scientifically trained mind alone can give, will bring us nearer to the solution of the tremendous problems in sociology and economics which confront this generation. Only science can find new sources of energy for an industrial system which is largely wasting its resources in coal and oil, and, for that reason alone, is doomed to bankruptcy: a strike of miners may be settled, but what politician will settle a strike of the coal itself? How is that new and marvellous roadway of the air to be opened up and made commercially available for future generations without not merely routine technical knowledge, but also that insight of genius which is the rare gift of selected souls? And how can the heritage preserved for us by the glorious dead be defended against the dangers which all history tells us are certain to arise again if the nation has not a reserve of trained and inventive intelligence at its service?

In those days, of which the memory now seems to be fading so quickly, when the whole Empire stood thrilled and tense it was commonly repeated that we had at last become conscious of the value of science, that the old mistakes would not recur, the old neglect would be a thing of the past. We look in vain in the public Press for a repetition of such statements nowadays. We have heard of a "land fit for heroes"—but perhaps the true meaning of the phrase may have been that it would take a hero to exist in the new world. Possibly the phrases about the nation's recognition of science may have been mere words, but human beings cannot live upon such diet. The multiplication of Government Departments supposed to foster research, or of highly paid research administrators (with or without scientific qualifications), will not really recruit the ranks of true scientific workers unless something is done, and done quickly, to make the existence of such workers tolerable. That these ranks are being depleted at the present time there is ample evidence; it is becoming increasingly difficult to find suitable candidates to fill university posts, and the more responsible the posts the more difficult it is to fill them. It is clear that the better brains are being gradually squeezed out of the scientific careers. If this process goes on much longer the nation will awake one day to find that it has effectually killed the goose which laid the golden eggs.

Most of us receive daily appeals for war memorials of various kinds. Would not the best, and, in the end, the cheapest, war memorial be a growing and efficient body of brain-workers, able and willing to solve the problems which the war has left in its train, and to help the nation in its hour of need? For leaders both in peace and war we must find and train men who will be competent to use the national resources in the most effective manner. Scientific workers are naturally marked out by their progressive instincts and severe training to serve not merely in an advisory capacity in the councils of the nation, but also as executive officers. Moseley and others of his type will not have died in vain if the Cenotaph reminds us that men of science must take an active part in the affairs of State, in guiding the development and thought of the nation, and in seeing that the bitter lessons learnt during the last six years are not forgotten.

This end will not be attained by service on committees, whether for chemical warfare or any other subject. If the War Office seeks to be scientific it should establish within itself, as the Admiralty has done, a research department with distinguished men of science as permanent members of the staff to suggest and supervise work on methods of modern warfare. It would be the business of such officers to make use of science for purposes of national security, and workers in university or other laboratories could please themselves whether they co-operated or not in particular researches or experiments. We can understand the objections offered by Prof. Soddy and others against men of science associating themselves as a body with problems of this type, but until human nature reaches a higher ethical plane than it occupies at present we must have a War Office, and an essential part of it should be an able scientific staff, the members of which would be responsible for making us strong enough to meet any crises which the future might bring. No committee of sixty or more associate members can do this, and none would be necessary if the War Office ranked a scientific service with the General Staff, as it should do, instead of inviting scientific workers to devote their time and knowledge to "offensive and defensive aspects of chemical warfare" for little more than out-of-pocket expenses.

We claim for science a much more responsible position, and a far higher appreciation of its worth, than our war leaders offer to it even now; and we do so because we remember that thousands of young lives were lost through its neglect. When we bow our heads before the Cenotaph we think of the highly trained men of science who were killed at Gallipoli or drowned in the mud of Flanders while Ministers turned for advice to alchemists and circle-squarers, or confused great chemists with dispensers of drugs, and we wonder whether even now anyone in power realises what civilisation has lost through the sacrifice of creators of knowledge. While we mourn their loss, let us work and pray for the scientific enlightenment of the leaders into whose hands the destinies of the nation are entrusted, so that we may be assured of strong and effective guidance whatever is before us.

The Newer Spiritualism.

Phenomena of Materialisation: A Contribution to the Investigation of Mediumistic Teleplastics. By Baron von Schrenck-Notzing. Translated by Dr. E. E. Fournier d'Albe. Pp. xii + 340. (London: Kegan Paul, Trench, Trubner, and Co., Ltd.; New York: E. P. Dutton and Co., 1920.) Price 35*s.* net.

"OF making many books" on spiritualism "there is no end," and study thereof "is a weariness of the flesh." Certainly such is the effect of reading a ponderous and repellent volume of 200,000 words conveying the story of séances the details of which are as like one another as peas in a pod. The author describes it as "really a monograph on materialisations," since it deals, in the main, not so much with communications from the dead as with exudations from the living. These, in pseudo-scientific jargon, are defined as "ideoplastic" or "teleplastic," taking the shape of fluidic threads or psychic discharges from the mouth, armpits, and other parts of the body, sometimes returning thereto, and often accompanied by blood. Both the author and translator agree in assigning them to "a new, or, rather, a hitherto unexplored, function of certain human organisms" which have "a spiritistic interpretation" as "conductors of psychic impulses."

The book made a considerable stir in Germany on its publication in 1913; here, it was the subject of a damaging review by Miss Verrall in the Proceedings of the Society for Psychical Research, July, 1914. The translation before us was made by Dr. Fournier d'Albe in consultation with Mme. Bisson, in whose house the medium lived, and whose reports on the sittings make up the substance of the book. It is to her that the medium has "lent her remarkable powers" in return for board and residence. The real name of the medium, whose pseudonym is "Eva C.," is said to be Marthe Béraud; and while Baron von Schrenck-Notzing says that he "is not justified in publishing details concerning her personal and family affairs," he withholds nothing in respect of detail about herself, both physically and mentally. As to the latter, she is described as abnormally emotional, subject to violent outbursts of anger, very amenable to influences, and nursing illusions that her charms lead the male sex easy captives. The numerous photographs of her which are sandwiched between faked spirit photographs show that physical beauty forms no part of her attractiveness. She is, in brief, a confirmed erotic and neurotic woman, who, according to information from an independent source, nurses the belief that she is an incarnation of Thaïs.

As already said, the record of the sittings, which extended from June, 1909, to July, 1913 (they were held chiefly in Paris), has a dreary uniformity. Mme. Bisson was always present; her watchful care over "Eva C." suggests more than friendship, and awakens suspicions as to collaboration in "materialisations." The appointments were as usual; the medium sat in a dark cabinet, Mme. Bisson hopping in and out, and then joining the other sitters, rarely more than three or four, in a room dimly lighted by a red lamp; a white light, as all spiritualists agree, "acting destructively on the pseudopods or psychic projections from the medium's body." Apart from M. Richet, a somewhat credulous savant, no prominent man of science was at the sittings, save one Dr. Specht, who, after three attendances, said that he had been "shown materialisations which do not exist." Baron von Schrenck-Notzing naïvely adds: "On account of this negative attitude, Dr. Specht was not invited to further sittings." Difficulty met attempts to secure teleplasma; "Eva C." was backed by Mme. Bisson in her objections, but of the two samples which Baron von Schrenck-Notzing secured one was recognisable as human skin, and the other, under microscopic examination, a mucus-like substance, showed "cell detritis, numerous microbes, and some wool (from dress)." Convinced as he is that the teleplasmic phenomena have a "spiritual interpretation," it is to the credit of Baron von Schrenck-Notzing that he admits explanations, if only to controvert them, such as are supplied by the facts of hysterical rumination, when the patients bring up matter which they have swallowed, and of excretions due to excitation.

The reviewer can deal only with such statements as fill this book at their face value. The *onus probandi* lies on those who make them. As Faraday said in a lecture delivered before the

Royal Institution in 1854: "I am not bound to explain how a table tilts any more than to indicate how, under the conjurer's hands, a pudding appears in a hat." Baron von Schrenck-Notzing and Dr. Fournier d'Albe have a clear course before them. Let them bring "Eva C." to London to exhibit her "materialisations" before a committee of which Sir Ray Lankester, Sir Bryan Donkin, and Mr. Nevil Maskelyne should be members. Then the matter would be put beyond doubt whether the so-called evidence, thus judicially sifted, is or is not based upon the collusive action of mediums and upon the bad, because prejudiced, observation of the sitters. The need to keep in mind what Hume says about occult phenomena was never more urgent than it is to-day. "As finite added to finite never approaches a hair's breadth nearer to infinite, so a fact [statement?] incredible in itself acquires not the smallest accession of probability by the accumulation of testimony."

Boltzmann's Lectures.

Ludwig Boltzmanns Vorlesungen über die Prinzipe der Mechanik. Dritter Teil. Elastizitätstheorie und Hydromechanik. Edited by Prof. Hugo Buchholz. Pp. xiii + 608–820. (Leipzig: Johann Ambrosius Barth, 1920.) Price 21.60 marks.

THE name of Ludwig Boltzmann will live on account of his great creative work, the study of which has happily been facilitated by the publication of his collected "Wissenschaftliche Abhandlungen" (3 vols., 1909, Barth), through the co-operation of the Academies of Berlin, Göttingen, Leipzig, Munich, and Vienna. But he was distinguished also as a teacher, and his power of exposition is shown in several volumes of lectures which have appeared in print. Perhaps the best of these are his "Vorlesungen über Gastheorie" (2 vols., 1895), based chiefly on Maxwell's and his own fundamental researches on the subject. Less well known are his lectures on Maxwell's theory of electricity and light, and those on the principles of mechanics, each occupying two volumes.

The book now under review comes from the same Leipzig press, and forms a third and final volume of the lectures on mechanics. Unlike the preceding volumes, it does not come direct from Boltzmann himself; it is written, on the basis of his lectures, by one of his pupils, Buchholz, to whom Boltzmann, and afterwards his widow, allotted the work of editorship. It first appeared in 1916 as an appendix to a larger volume of Boltzmann's lectures, also edited by Buchholz, entitled "Applied Mathematics: the Mechanical Potential and its Application to the Determination of the Figure of the Earth (Higher Geodesy)." It contains the theory of elasticity and hydrodynamics which was a necessary adjunct to the geodetic part of that treatise; but its separate publication as a third volume of the principles of mechanics fulfils Boltzmann's intentions regarding the latter course of lectures, and renders it readily available to those who do not wish to study the larger work from which it is reprinted.

Boltzmann's lectures on mathematical physics formed a "cycle" unified by his use of the conception of the potential—the mechanical, electrical, and electrodynamic potentials, as in the lectures previously published, and, in the present volume, the elastic and hydrodynamic potentials. One further set of lectures remains unpublished—namely, that on the general mechanical theory of heat; in this course the thermodynamic potential is introduced and illustrated by three important examples of its application, of which Gibbs's theory of chemical equilibrium is the chief. This final instalment is at present held up owing to financial difficulties; it is much to be hoped that these may be overcome, in order to complete Boltzmann's representation of mathematical physics and in view especially of the close relation of these lectures to his work on gas theory.

Although beyond a certain point the theories of elasticity and hydrodynamics diverge widely, their kinematical foundations are almost identical, while the theory of the stress ellipsoid is as necessary to hydrodynamics as it is to elasticity when the viscosity of liquids is taken into account (though in the present volume the latter is not done). It is therefore illuminating to consider the two subjects together, and their treatment in these lectures is admirable. The explanations of the kinematical and mechanical principles are simple and detailed, and the elastic potential is then introduced and applied to a few important general problems—in particular, to the proof of the Hamiltonian principle for elastic potential energy, to the determination of the potential for various forms of crystal, and to the propagation of waves of compression and distortion in an elastic solid. This is all done in comparatively little compass—a hundred pages—and a general grasp of the subject is rendered easy by the avoidance of individual problems, such as the theory of bending in beams, or the vibrations of rods, strings, and membranes, in which the potential plays no prominent part.

The second hundred pages are devoted, on similar lines, to the general equations of hydrodynamics, the velocity potential, and the theory of wave-motion and vortex-motion. Both water- and sound-waves are discussed, including the change of form of progressive waves on water. The analogies with other branches of science are pointed out from time to time, such as, for example, that between the magnetic field of an electric current and the irrotational motion round a vortex filament. The book should be valuable both to readers approaching electricity and hydrodynamics for the first time, and to those who have studied either alone in detail. S. C.

The Surveyor's Art.

Geodesy: Including Astronomical Observations, Gravity Measurements, and Method of Least Squares. By Prof. G. L. Hosmer. Pp. xi+368. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1919.) Price 18*s.* 6*d.* net.

PROF. HOSMER'S text-books on surveying and allied subjects are well known, and any further contribution from his pen is sure of a welcome from all those either actually engaged upon, or interested in, the art of mapping the earth. We here use the word "mapping" in its complete sense—namely, as including everything requisite to the most minute delineation of the earth's surface, and of such physical quantities dependent upon its interior constitution as can be determined by surface observations.

The present book, based upon the practice and researches of the United States Coast and Geodetic Survey, is designed as a text-book for students of the higher branches of the art. We can only lament that no such volume has yet appeared based upon British surveying practice, a deficiency due partly to the fact that the great survey work of a geodetic character recently in progress in the British Empire has been that carried out by the Indian Survey Department, a body which has always trained its own staff and never summarised its methods in a text-book, and partly to the complete non-existence of any school of geodesy in this country. Should such a school ever be established, and should we ever recognise that, taking the lowest point of view, it would pay us to put the survey of our African territories upon a scientific and permanent basis, and to discontinue the present fragmentary, haphazard, and unscientific methods, the experience gained by the United States Coast and Geodetic Survey, the system it has evolved, and the body of practice it has formulated will be worthy of the closest study. On some points of detail surveyors trained in other countries would doubtless depart from the American practice, while the latter would, in other points, possibly require supplementing; there has been, for example, little occasion to develop any procedure specially applicable to very dense forest country; but on the whole the experience and skill of the American surveyors may be safely taken as guides for any future work.

We do not quite follow Prof. Hosmer in his apparent support of the now rather out-of-date search for the "figure of the earth" in the form of the spheroid which most closely fits the true surface. For convenience of calculation some spheroid must be assumed, but, provided that this is approximately true, such an approximation as is furnished by any of the well-known figures, the exact spheroid selected is unimportant. The shape of the geoid, the ultimate objective of the surveyor, can be as well represented in relation to one spheroid as to another. Great practical convenience, however, accrues if all survey systems—in any case those which have, or possibly could have in the future, a land connection—are reduced to the same conventional figure. All the North American surveys from Canada to Mexico have now adopted the Clarke (1866) figure and no further knowledge of the earth's true shape will compel them to abandon this as the basis for their reductions.

As regards the system of levels we are doubtful whether the convention adopted in the United States of applying an orthometric correction and thus defining level so that two points on an undisturbed lake are at different levels is, on the whole, the best. We should prefer to treat any points on the same equipotential surface as being at the same level, and re-define height to mean the distance of the equipotential from the geoid at a selected latitude. This is a subject which might with propriety engage the attention of the International Geodetic Congress when that body is summoned. E. H. H.

Ronald Poulton.

The Life of Ronald Poulton. By his Father, Edward Bagnall Poulton. Pp. xi+410. (London: Sidgwick and Jackson, Ltd., 1919.) Price 16*s.* net.

NOT only those who were the intimate companions of Ronald Poulton, but likewise the rest—and they were legion—who admiringly witnessed his deeds of prowess in the field, were able to realise that behind all the brilliant qualities of the outer man, the vigour and sportsmanship and grace and sheer physical beauty, there lay as the inward source of all these things a beautiful nature. One of his friends has described his personality as "radiant," and perhaps no word is better suited to convey the secret of his shining manliness. He touched nothing that he did not strike fire from, and this was because something clean and strong, like fire, burned within him.

The story of his life is written with a simple directness that enables the unfolding of his character to be observed, as it were, objectively and in the light of the accessory conditions. Enough is said to reveal a happy and populous home as the most fundamental of such formative influences. Next we see him as one of that band of "dragons" who grow up at Oxford under the genial and wisely tolerant rule of Dr. C. C. Lynam, and note that his talent for games had already been discerned by sympathetic experts. Then he goes to Rugby. If life in the English public school needs sometimes to be painted in darker colours, it is at least certain that, wherever Ronald Poulton was, vice could not show its face. He found at Rugby what the normal healthy-minded boy may surely expect to find in any of our great schools—the opportunity for an education in which the physical, mental, and moral sides of young humanity are cultivated together. The threefold result is seen in his increasing skill as an athlete; in the winning of a science scholarship at Balliol; and in a capacity for helping others that at the university, in his various boy-clubs, in business at the factory, and finally in the Army, was destined to render him, unassuming as he was, a supreme leader of men. His subsequent career, from his Balliol days onwards, shows a steady maturing of many-sided powers of social usefulness that the word "leadership" serves best of all to sum up; and, indeed, the interest that one is led to take in this aspect of his development quite overshadows the stirring tale of his football, sketched as it is by Mr. A. C. M. Croome with many fine touches. One wonders how much he might have done for England had he been spared to give the full support not merely of his wealth, which was to be great, but of his lucid intellect and nobility of soul, to the public cause which he had most at heart—the provision of a liberal education for the masses.

Of a loss that touches so many it is hard to speak fittingly, but perhaps the following passage, taken from a story by Mr. G. F. Bradby, will seem not wholly beside the point: "We say to each other, and do, no doubt, in part believe, that it is not length of days, but service, that gives to life its value, and that to die cheerfully in a great cause is perhaps the noblest use to which any man can put the life that has been given him. And all the time we are conscious of the great blank that has fallen on our own."

R. R. MARETT.

Our Bookshelf.

An Ethno-geographical Analysis of the Material Culture of Two Indian Tribes in the Gran Chaco. By Erland Nordenskiöld. Pp. xi + 295. *The Changes in the Material Culture of Two Indian Tribes under the Influence of New Surroundings.* By Erland Nordenskiöld. Pp. xvi + 245. (Comparative Ethnographical Studies, Nos. 1 and 2.) (London: Humphrey Milford, Oxford University Press, n.d.) Price 20s. net two vols.

CONSUL-GENERAL AXEL JOHNSON, of Stockholm, managing director of the Johnson Line to South America, supports in every way Swedish exploration of that continent, recognising the advantages which are sure to result from purposely conducted commercial and scientific interchange between the peoples of the respective countries. In other words, systematically gained knowledge will benefit trade. Mr. Erland Nordenskiöld is by no means the first Swedish pioneer. The first volume comprises a sifting of the present economic conditions of two still primitive tribes, the Choroti and Ashluslay of the Gran Chaco. The second volume deals in a similar way with the Chiriguans of the great Guarani group, and with the Guaranised Arawaks, both on the border between Bolivia and Argentina. Many other tribes had also to be considered as the many implements, customs, games, etc., have been traced, sometimes all over the continent, their distribution being well shown by sixty maps. The more sporadic a certain tool, the older it is, and its discontinuous occurrence is generally caused by whole tribes having died out.

The less civilised tribes copy from the richer and more advanced, not *vice versa*. The very common practice of the rape of women is one of the main influences upon the adaptation and spreading of implements and industries, since the women naturally cling to what they have been brought up with.

The chapters on the influence of the whites contain some remarkable conclusions. The positive, advantageous effect of the white culture is greater where the Indians live far away from the whites —for instance, domestic animals and things connected with them. Direct contact brings loss of independence, which ultimately spells irretrievable poverty. There is an apparently exhaustive and critically consulted bibliography. An index may be forthcoming in the contemplated third volume.

Principles and Practice of Aerial Navigation. By Lieut. J. E. Dumbleton. Pp. vii + 172 + v plates. (London: Crosby Lockwood and Son, 1920.) Price 12*s.* 6*d.* net.

ORDINARY navigation may be broadly divided into two kinds: coastal navigation, in which, shaping his course by compass, the mariner verifies his position by cross-bearings of two terrestrial objects, by two objects in transit and the bearing of a third object, and by various other methods; and navigation of the open sea, with no lights or headlands available, so that he has to depend wholly upon celestial observations. With regard to long voyages of the second type, but little progress has been made in air matters, difficulties as to obtaining a satisfactory horizon having so far proved insuperable. It is upon the development of directional wireless that the hopes of the airmen are fixed in connection with long-distance aviation in the immediate future.

It is therefore to navigation of the coastal type that the airman has given special attention, and here it is evident that not only has he availed himself fully of methods already in use, but has also not failed to improve upon these processes.

On p. 90 we have an example of this in the course and distance indicator, an instrument which from a given course and an air speed calculates the course to steer and the ground speed. So also, on p. 64, we have a most useful problem, not to be found in navigation books, for finding by three bearings of the same object the course made over the ground. As presented in the book, to be done by protraction it would seem a little complicated for use in a heavier-than-air machine, but, reduced to the form of a table, it should be of very great utility by sea or air.

The book is clearly written and altogether a highly creditable production, and should prove attractive not only to airmen and seamen, but also to all who take an intelligent interest in the development of aviation on the scientific side.

Roses: Their History, Development, and Cultivation. By the Rev. Joseph H. Pemberton. Second edition. Pp. xxiv + 334 + 9 plates. (London: Longmans, Green, and Co., 1920.) Price 15*s.* net.

THE demand for a second edition of the Rev. J. H. Pemberton's useful book on roses is a welcome sign that there are still a considerable number of keen gardeners who are interested in the genus, not so much on account of its horticultural merits, but rather because of its botanical interest. The various species of the genus Rosa, unspoilt by the hybridiser and "improver," are well worthy of cultivation, and it is to be hoped that this book will turn many to the study of the wild species, as well as to the interesting hybrids that have been derived from them.

In garden catalogues of a hundred years ago the "old-fashioned" roses were the pride of the collections, and one would like to see such collections revived, difficult as it may be now to procure some of the earlier forms.

Few people to-day have seen *Rosa hemisphaerica* in all its glory, nor do they know the beauty of the various forms of the Scotch rose, or of *R. damascena* or *R. indica.* To most, probably, the charming little rose de Meaux (*R. centifolia Pomponia*), given in the list of grandmother's roses, is scarcely known, and the same may be said of the greater number given in this interesting list of old garden favourites.

This second edition does not differ on general lines from its excellent predecessor, but a good deal has been added on the perpetual flowering musk roses, which the author himself has done so much to popularise; and on the hybrid *lutea* roses. Some useful additions have been made to the section dealing with fungus pests and to the chapters on soils and manures.

The appendix, giving a list of selected roses, has been revised, and forms a valuable guide to those who wish to grow the best types of garden roses.

Pyrometry: A Practical Treatise on the Measurement of High Temperatures. By Chas. R. Darling. Second edition, revised and enlarged. Pp. xii + 224. (London: E. and F. N. Spon, Ltd.; New York: Spon and Chamberlain, 1920.) Price 10*s.* 6*d.* net.

THE publication of the first edition of Mr. Darling's book on pyrometry in 1911 filled a want in English technical literature at a time when the value of a more exact measurement of temperature in industrial operations was being appreciated. Mr. Darling points out in his preface to the new edition that since his book was first issued there has been a great extension in the use of pyrometers in industrial processes and laboratory work, and there can be little doubt that his book has contributed in no small measure to this desirable development. He further refers to the invaluable uses of pyrometers during the war, and it is pleasing to have his testimony that British makers were fully able to meet the demand for instruments. In his revision Mr. Darling has described several instruments of the more recent pattern, and added new material, bringing the book thoroughly up to date. The bulk of the new matter is to be found in the chapter dealing with thermo-electric pyrometry, and valuable and suggestive additions have been made, particularly on the use of base-metal junctions and on protecting sheaths for couples. In the chapter on optical pyrometers there has been considerable extension, especially of the section on colour extinction instruments, the simplicity of which is a strong point.

Co-education and its Part in a Complete Education. By J. H. Badley. Pp. 39. (Cambridge: W. Heffer and Sons, Ltd., 1920.) Price 2*s.* net.

THIS is an address delivered at Cambridge on February 22 of this year to a meeting of the "Socratic" Society by the headmaster of the well-known Bedales School, with the addition of some notes, which appear at length in the appendix, bearing upon points concerning which fuller information was desired. The address takes the form of a general survey of the present position and outlook of education in this country, and of the part that co-education may be expected to play in its development.

The author defines education as the training of life, for life, by life. We must think of the child as a living organism with immense and varied possibilities. The purpose is to give these possibilities the fullest opportunity of development quite irrespective of the child's future vocation, and concerned only with the point of view of his position as an actual and potential member of the community. Mr. Badley's contention is, as a result of twenty years' experience at the Bedales residential school for both sexes, that the full value of education in its widest aspect cannot be attained for either sex unless both be taught together during the whole period of school and student life with such differentiation as physical and psychical conditions demand. It is a carefully reasoned statement worthy of the serious attention of all educators. We are face to face with the making of a new world, in the fashioning of which men and women will share equally, and in the common educational training of both sexes the problem will find its most effective solution. Such is the view of the author of this most inspiring address.

A Text-book of Electrical Engineering. Translated from the German of Dr. Adolf Thomälen. By Prof. George W. O. Howe. Fifth English edition. Pp. xi+482. (London: Edward Arnold, 1920.) Price 28*s*. net.

A NUMBER of minor alterations which have been introduced into this edition increase its value. For instance, the symbols have been modified, when necessary, so as to bring them into line with the recommendations of the International Electrotechnical Commission, and descriptions of obsolete machines have been omitted. The theory of the single-phase commutator motor has been extended, and students will find the theorems given simple and instructive. We can recommend the book to those who want a general survey of the whole elementary theory of electrical machinery.

It is assumed throughout that the alternating-current waves follow the harmonic law; this greatly simplifies the analysis. We should like the author to have laid greater stress on the limitations of the theory due to the assumptions which have been made. Owing to hysteresis, for instance, the waves do not follow the harmonic law, and although the error introduced by the assumption may be small, it makes it difficult—if not impossible—to judge of the relative merits of some of the alternative diagrams given, as they are all affected to varying extents.

We notice that the translator defines the slip of an induction motor as the difference between the number of revolutions per second of the stator magnetic field and of the rotor. It is more customary now to define it as the ratio of this difference to the revolutions per second of the stator field. Defined in this way, the slip is a pure number, and the mathematical equations of the induction motor are simplified.

Governors and the Governing of Prime Movers. By Prof. W. Trinks. Pp. xviii+236. (London: Constable and Co., Ltd., 1920.) Price 22*s*. 6*d*. net.

THIS book is probably the only one in the English language which deals exclusively with governing, the subject being usually dealt with in text-books on prime movers. The author's aim has been to produce a book of essentials and principles, put in a form which will enable the reader to judge existing and future types of governors; there are no catalogue pictures. The author does not pretend to have covered the whole field of governing; thus the mathematical side has been restricted to the usual undergraduate standard; and he projects a further volume for the use of engineers who have to make governing a life study.

Among the other subjects treated in the volume will be found discussions on the governor as a motor and as a measuring instrument, promptness and traversing time, adjustment of equilibrium speed, shaft governors, natural period of vibration of governors, interaction of the governor and the prime mover, rate-of-flow, pressure and relay governors, governor troubles and remedies. There is also a very useful chapter on discarded types of governors. In all these the treatment is clear, and there is a large number of line drawings, which will be of assistance to the student. Since there are no makers' illustrations, the book is equally suitable for British and American students, and we can recommend it with confidence.

Portraits of Scientists. 11 in. by 14 in.+margin. (The Class-room Portrait Gallery, 7 Queen Square, W.C.1.) Price 6*s*. 6*d*. each, or 30*s*. the set of five.

THESE collotype portraits have been produced with the view of meeting the need for instructive decoration in classrooms, lecture halls, and laboratories. The publishers hope that, while helping to create an atmosphere of culture, the portraits will also supply a background for much solid instruction woven around the lives of great men.

The difficulties met with, at present, in the choice and provision of artistic, decorative, and educational pictures for secondary schools and other institutions are such that any attempt at improvement in this direction is welcome. However, the paper of the present issue and the artistic effect of the portraits leave much to be desired. The series includes Galileo, Sir Isaac Newton, Michael Faraday, J. Clerk-Maxwell, and Lord Kelvin; and it is proposed to prepare a further series, incuding chemists and other men of science of to-day.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Einstein's Shift of Spectral Lines.

REFERRING to my suggestion from Gullane on p. 280 in NATURE of October 28, Lord Rayleigh has recalled my attention to Prof. Eddington's admirable report on "The Relativity Theory of Gravitation," whereby I have been reminded that the predicted shift depends not on gravitational intensity, but on gravitational potential. This makes my revolving disc quite inefficient; it would seem that bodies of astronomical size are necessary for the test.

But since the shift is proportional to the square of peripheral velocity, instead of to the acceleration, it occurs to Lord Rayleigh that the high speed of positive rays curved in a magnetic field might facilitate its detection; for, as he points out, if their speed were 10^8 c.g.s., their radiation shift would be comparable to a fortieth of an Ångström unit.

But this same proportionality to u^2/c^2 raises the question whether, after all, the shift expected is anything more than the natural consequence of self-inductive increase of inertia due to speed. If a satellite suddenly gained a spurious inertia not subject to attractive force, its orbit would enlarge and its period lengthen. So it may be with electrons in a violently projected Bohr atom.

I appreciate Dr. Chree's friendly experimental caution in your issue of November 11.

November 12. OLIVER LODGE.

The British Association.

WE have been asked by the executive of the National Union of Scientific Workers to send a contribution to the discussion in NATURE on the cause of "the apathy of local people of the educated classes to the presence of the Association" in the centres where it meets.

The majority of those who have taken part in the discussion appear to assume that this apathy is due to the failure of the Association to interest the general public in the utilitarian applications of science and their contributions to the material benefits of civilised life. Only one or two writers seem to have attempted to follow up the lead given in your editorial of September 16, which attributes the public apathy to "the neglect of national bodies like the British Association to adjust themselves to changing national needs. . . . The Association makes little endeavour to show the bearing of scientific methods and principles upon most subjects of vital importance in national polity and industrial affairs."

Prof. Soddy strikes the same note in NATURE of September 23, where he says "the vast body of the general public, disillusioned by the war, looks to them [scientific men] to provide a way of escape from the evils that threaten our civilisation." He points out that "scientific synthesis and the direction of the unique mental attitude, induced only by the actual discovery of new knowledge, to the conduct of public affairs are the real and peculiar functions of the Association if it is to regain its national position."

The executive of the union would like to endorse these views, and to suggest that it is not necessary to invoke the outstanding genius of Huxley and his contemporaries and to hold them up in invidious comparison with the men of the present day in order to explain the apathy of the public. The explanation lies rather in the message which Huxley and his contemporaries had to give to the lay public. Their appeal was not based upon holding up to public admiration the utilitarian benefits offered by science, important as these undoubtedly are. Their message appealed to the deep-seated complex of ideas, experiences, beliefs, and emotions which conditions every man's outlook on life. It challenged the static view of man's relation to his environment which was the heritage of dogmatic theology, and offered in its place a dynamic view, which revealed man as himself a part of the great stream of natural causation. As such it tore old prejudices up by the roots, roused fierce resentment in those who could not free themselves from such prejudices, and an equally fierce exultation in others who were smarting under repressions imposed by the authority of theological dogma.

Science (or, we should rather say, the bulk of the institutions and men who claim to represent science) has no such message at the present day. As is shown by the Rev. A. L. Cortie in his letter in NATURE of September 30, the sections which discussed questions such as the constitution of the atom and relativity drew good and numerous attendances; we suggest this was because these subjects touch on ideas of the nature of matter, space, and time—ideas which find a place, however vague, in the philosophy of life of a large number of people.

We believe that if the British Association and other bodies representing organised science are to regain the place in the public estimation which they held in the latter half of last century they will have to come out with a new message which, like that of Huxley and his contemporaries, challenges old-established points of view. Where the Association is to find a field ripe for such a message is suggested in your editorial and amplified by Prof. Soddy. While Huxley's message forced people to revise their old-established ideas and prejudices as to man in his relations to his *natural* environment, the public is now ripe for a lead from science in the direction of a fundamental revision of that part of its outlook on life which concerns the relations of man to the *social and economic* environment which he has created.

JOHN W. EVANS,
President.
H. LYSTER JAMESON,
Member of Executive.
A. G. CHURCH,
Secretary.

National Union of Scientific Workers,
25 Victoria Street, Westminster,
London, S.W.1, November 12.

FROM the correspondence that has recently appeared in NATURE it is evident that there is a healthy determination on the part of scientific men in Great Britain that the British Association shall not be allowed to stagnate, but must exhibit progressive evolution as well as the solid dignity implied in its full title. One point that I have recently noticed in your columns with great satisfaction is that in future representatives from similar associations in other countries will be invited to attend each meeting. We who work in parts of the British Empire remote from its centre, and are content to do so, although perhaps our scientific atmosphere is not so rarefied as some maintain, are undoubtedly apt to get out of touch, if not out of sympathy, with the work of our colleagues at home, while they are equally apt to view our endeavours as something distinct from their own, on a different, if not precisely a lower, plane, or—shall I say?—on a stage such as that on which the dogs danced for Dr. Johnson's admiration. Such misconceptions are good for no one. They ignore two fundamental facts: that science is universal, and that, nevertheless, scientific work may be undertaken on different lines, and even in a somewhat different spirit, under different conditions.

I am convinced that the British Association might do a great deal to dispel the mirage by making a feature of discussions (of course, on quite general lines) on overseas work in different branches. There are always members present at the meetings from many parts of the Empire as well as from various foreign countries, but they are too often silent members from whom expression of opinion is neither encouraged nor invited. In zoology, at any rate, what we want nowadays is not so much isolated fragments of research, however accurate the observation may be, as syntheses of results. Zoology, indeed, and perhaps other branches of biology also, are in danger of destruction by the toxins produced in their own vital processes, such, for example, as nomenclature and purely museum taxonomy. Yet comparatively few of the subjects discussed at meetings of the British Association, to judge from reports, rise much above this level. What is wanted, so far as the scientific man from overseas is concerned, is more informal discussion on fundamental subjects, more expression of reasoned opinion and well-thought-out aims as opposed to details of observation, and less of the specialist atmosphere. At any rate, that is what *I* want on the rare occasions on which I am able to attend a meeting of the British Association.

N. ANNANDALE.

Indian Museum, Calcutta, October 19.

Chemical Warfare and Scientific Workers.

PROF. SODDY has directed the attention of readers of NATURE (November 4, p. 310) to the issue on the part of the War Office of a letter in which the active co-operation of men of science is invited towards the intensive development of chemical warfare. The list of ordinary associate members embraces more than sixty names of chemists, physicists, and medical men —a list apparently drawn up without consultation with the various members concerned. On receipt of the letter referred to, I replied at once with the request that my name should be removed from the list of associate members, and in this refusal to serve I was actuated by the following considerations:

The use of poisonous gases in warfare was a nefarious novelty introduced by the Germans in violation of the conventions prescribed for civilised belligerents, and the Entente Powers had no option but to undertake methods of retaliation. During the later period of the war I acted as an associate member of the Chemical Warfare Committee, and, like many other chemists, did all in my power to assist by scientific investigation the progress of gas warfare on the offensive side. At that time my services were given most willingly. But the position has entirely altered now that the war is over. My present point of view is that I do not think it right that men of science should, two years after the armistice, be approached with the request to undertake work on a method of conducting warfare which has not yet been recognised as legitimate.

If gas warfare is to be adopted in the future, one result follows of necessity: every nation will be compelled in self-defence to cultivate this form of devilry. Yet we have just listened to the earnest appeal of the Prime Minister for more goodwill amongst nations, amongst people, amongst the classes! The recognition of chemical warfare even on the basis of a peace organisation must certainly engender an atmosphere of suspicion. It will, however, be the hope of many that if nations will by mutual consent unite in the abolition of an instrument which adds so much to the horrors of war, they will also have the strength and the determination to make their decision effective.

The successful development of chemical warfare will obviously be dependent on scientific work, and it is easily understood that the authorities should look to the universities to give them some assistance in its prosecution. University teachers should be on their guard before they bind themselves to a policy in the framing of which their opinion as a body has never been taken. Surely the universities ought to have been asked their views. Why should a professor of chemistry by joining the Chemical Warfare Committee pledge his university to a course of action of which the university may not approve?

ALEX. MCKENZIE.

PROF. SODDY (NATURE, November 4, p. 310) seems to have overlooked some arguments. Lack of preparation for war is no guarantee against an aggressive policy. Recent British history shows a close correlation between Jingoism and military inefficiency. In this country Jingoes are seldom intelligent enough to provide against the risks they incur.

Again, the more scientific war becomes, the more difficult it will be to wage it without the consent of scientific workers. If they really desire a saner state of international relations, scientific workers should seek so to develop the engines of war that they alone can use them.

Lastly, if Prof. Soddy really wishes to stop the application of science to warlike purposes, he should surely welcome with open arms the War Office Committee. Can he suggest any means for discouraging the application of scientific study to war (or to any other problem) so entirely efficient as the placing of the matter in the hands of a large Governmental Committee composed exclusively of eminent persons?

NORMAN R. CAMPBELL.

British Laboratory and Scientific Glassware.

PROF. BAYLISS in his letter published in NATURE of November 4 appears to attribute the breakage of British laboratory glassware, when exposed to changes of temperature, to inadequate annealing, citing table glassware as an example of a commercially well-annealed article.

I have at different times examined many hundreds of pieces of table glass under the polariscope, and have never yet found one entirely free from strain. On the other hand, I have often found laboratory beakers, taken at random from average samples, in which no strain whatever can be detected. When strain does occur in beakers and flasks it is generally at the lip, and is caused by the flanging operation. In this connection it is interesting to note that beakers which contain bad striæ, and are, consequently, in a state of strain which cannot be removed by annealing, give figures for thermal endurance as high as those obtained from beakers free from striæ.

The difference in thermal endurance between German and English laboratory glassware is inherent in the composition of the glasses selected for their manufacture. The predominant factor controlling the variations in thermal endurance is the coefficient of expansion of the glass, since this property changes far more rapidly with a change of composition than do the other properties, diffusivity, tensile strength, and Young's modulus, which make up the thermal endurance of the glass. The coefficient of expansion of German laboratory glassware is something more than 10 per cent. lower than that of English, and this fact alone would account for the breakage of the English glass with drastic heat treatment.

There is no particular difficulty attached to the manufacture of glass having a low coefficient of expansion and high thermal endurance, and we may take it that the English manufacturers have decided that the maximum resistance to attack by reagents is to be desired, and have, accordingly, sacrificed thermal endurance to a small extent in order to obtain the encouraging results outlined in Mr. Jenkinson's letter in Nature of October 28.

The whole question is largely one of general policy. If the chemists of this country prefer to use a glass of higher thermal endurance but with less resistance to reagents, then I have little doubt that the British makers would supply it. E. A. Coad Pryor.

Milford, Park Road, Teddington, November 8.

The Separation of the Element Chlorine into Normal Chlorine and Meta-Chlorine, and the Positive Electron.

In commenting on a letter under the above heading from Prof. Harkins in Nature of April 22 last, I remarked that his assumption that "the hydrogen nucleus or the positive electron has, according to these papers, a weight, and presumably a mass, of 1·000, on the basis of oxygen as 16·000," was contradicted by experiment.

Prof. Harkins has pointed out to me that this assumption was made with the reservation "whenever the positive electron is combined in a complex atom," which I was careless enough to overlook. I wish, therefore, to apologise for my remark and withdraw it unreservedly.

I very much regret that this apology comes so late, but the delay is due to the fact that Prof. Harkins led me to understand that he was himself publishing a statement on the matter in Nature, to which I could reply. He now tells me he has decided not to do so. F. W. Aston.

Trinity College, Cambridge, November 9.

The Stereoscopic Appearance of Certain Pictures.

In going round a picture gallery it will be noticed that in certain pictures the objects delineated appear to stand out in a similar manner to those seen with a stereoscope. A picture of this kind has the effect of making those surrounding it appear very flat by comparison. This appearance is not the characteristic of a particular artist, because in an exhibition, all the paintings being by one man, only one or two may be found which have this stereoscopic appearance.

The majority of the pictures will be correct in drawing, perspective, light and shade, but it will be noticed that this will be correct only for one eye—that is to say, the picture is quite correct for either eye when the other is closed. Those pictures, however, which have a stereoscopic appearance are painted so that the representation is as nearly as possible a delineation as seen by the combined retinæ, any disturbing element which would do away with this illusion being eliminated. For instance, a revolver pointed straight at a person so that the centre of the barrel is pointing directly between the two eyes will be seen quite differently with the two eyes. When the right eye is closed the left-hand side of the barrel will be seen, the right-hand side being invisible. When the left eye is closed the right-hand side is seen, and the left-hand side of the barrel is invisible. When, therefore, the barrel of the revolver is foreshortened and both sides are visible, the muzzle being pointed directly at the observer, the appearance is such as could be seen only with both eyes. The stereoscopic appearance is then very striking, and the revolver appears to follow the observer and to be pointed directly at him, no matter what position he takes up with regard to the picture. In all the pictures or portions of them which present this stereoscopic appearance it will be noticed that the appearance as seen by both eyes is represented, the left-hand side of the picture being represented as seen by the left eye, the right-hand side as seen by the right eye.

In a demonstration which I gave before the Physiological Society (*Journal of Physiology*, vol. xlviii., 1914) I showed that the perception of binocular relief is independent of double images and the stimulation of disparate points, provided that the object presents images to the two retinæ similar to those which are presented by an object in the field of vision. This can be shown by taking a pair of stereoscopic photographs in which the point of sight is at the centre of each and cutting them vertically in two, and then, having pasted the left half of the left photograph on the left side and the right half of the right photograph on the right side on white or black cardboard at an appropriate distance, so that there is no overlapping when placed in the stereoscope, a picture in striking relief is obtained when combined together in the stereoscope. In this case it will be noticed that there is no portion common to both fields of view. In each case the overlapping portion is combined with white. It seems probable that this is how binocular vision takes place in ordinary circumstances. If an object in high relief—as, for instance, a vase or the face of a person—be viewed at a short distance and one particular point fixated, it will be noticed that the right eye dominates the right side of the field of vision and the left eye the left side. The image seen is almost entirely that of the right eye for the right side and that of the left eye for the left side, as may be proved by noticing the relation of surrounding objects, and closing first one eye and then the other alternately. F. W. Edridge-Green.

The Energy of Cyclones.

It does not seem to me as though any really satisfactory theory has yet been put forward to explain the genesis and maintenance of cyclones; I fully agree with Mr. Deeley (November 11, p. 345) that they are not due to contiguous masses of air at different temperatures, but, on the other hand, I do not see how they can originate in an inert and stable region like the stratosphere.

Were storms produced by contrasts of temperature —or, in other words, by the so-called polar front—surely they would be most violent where the contrast was most marked. The stormiest parts of the world are the great belt of the southern ocean from 40° to 60° S. lat. and that part of the Atlantic which lies north-west of Scotland, and neither of these regions shows any exceptionally steep gradient of temperature.

Observations in the upper air have shown a remarkable uniformity in the mean temperature (mean with regard to height) from 0 to 20 km. in every place where they have been obtained, and it follows as a corollary that there is a very uniform pressure at 20 km. height over the globe, for the pressure at 20 km. is almost independent of the surface pressure.

Observations over Europe, the only part of the world where they are numerous enough for the purpose, have also shown a most extraordinarily close correlation between the temperature and pressure of the air in the upper part of the troposphere, many of the coefficients exceeding 0·90. These facts must be reckoned with in any theory about the formation of cyclones.

My own belief is that pressure differences originate in the upper half of the troposphere from variations in the strength of the surrounding winds. Being given the means of originating and maintaining a difference of pressure at about the height of 9 km., the rest of the phenomena follow readily. The distribution of temperature, the high positive correlation below and the negative correlation above, and the rise and fall of the tropopause between cyclone and anticyclone are all explained by the vertical motion of the air that would naturally follow from the distribution of pressure. W. H. Dines.

Benson, November 12.

Physiological Method as a Key to the Causation of Isle of Wight Disease in Bees.

In the summer of 1918, while working with Prof. L. Hill and Mr. T. A. Webster on gas research, I advised Dr. John Rennie, of the natural history department of the University of Aberdeen, that a physiological study of metabolism in healthy bees and in bees known to be suffering from symptoms of Isle of Wight disease should be undertaken, making use of oxygen and carbon dioxide determinations. As a corollary, an investigation into the temperature of bees, healthy and unhealthy, was also indicated.

In the summer of 1919 it was found that apparently bees infected with Isle of Wight disease consumed in a given time much less oxygen than healthy controls. This observation was not reported to me until July, 1920, when I was able at once to draw the conclusion that the symptoms of Isle of Wight disease were due to blocking of tracheal tubes and anoxæmia. Loss of the power of flight was to be expected, as the co-ordinating nervous mechanism and the musculature involved were deprived of their proper oxygen supply.

Had I been made acquainted with the results of a research I had advised, or had the investigator been able to draw a very simple physiological conclusion from the data, whether the data were correct or erroneous, the discovery of a parasite as the blocking agent or disturbing factor in tracheal tubes would have been the natural consequence.

In 1920 this parasite was discovered by anatomical study, and its presence as the agent causing the disease is announced in the Press as the outcome of the researches of Dr. John Rennie, Mr. P. Bruce White, and Miss Elsie J. Harvey.

It will be noted that the physiological method of investigation could have led equally surely to the discovery of the parasite and to the interpretation of the symptoms. James M. McQueen.

Halesowen, November 5.

Luminosity by Attrition.

I am very glad that Sir Ray Lankester has again directed attention to this phenomenon. By a slip of the pen he says (November 4, p. 310) "quartz pebbles" in his first paragraph and in the heading. My object in writing is to say that these pebbles may be found on any shingle beach, and may be known by their translucent appearance under a "rotten" (or pitted) exterior. They are *pale* brown, and, when dry, look like lumps of derelict toffee. But on the shingle beaches of South Devon (notably the "Budleigh Salterton Pebbles"), the Chesil Beach, and the Suffolk coast (notably at Aldeburgh) practically every pebble on the beach will "flash."

It is much to be desired that some mineralogist should take up the intensive study of flint, chert, and quartzite. I may mention that for many years I have stored every "peculiar" flint pebble I have come across, and my entire collection is at the service (as a gift) of any museum worker who cares to undertake the study. Edward Heron-Allen.

Large Acres, Selsey Bill, Sussex,
November 12.

The recent letters in Nature from Lieut.-Comdr. Damant and Sir E. Ray Lankester recall some observations made in 1916 in collaboration with my friend and former headmaster, the late Mr. W. P. Workman, who first directed my attention to this interesting phenomenon. Specimens of translucent quartz from a quarry about three miles from Tintagel, North Cornwall, give the characteristic orange-coloured light in broad daylight and the peculiar smell. This *triboluminescence* of quartz was observed by Du Fay in 1735, and about 1748 Delius mentioned the sulphurous smell which accompanies the glow when quartz is rubbed against quartz (Kayser, Bd. iv., pp. 614, 617; Winkelmann, Bd. vi., p. 809).

The following observations present, I believe, some points of novelty: (1) Luminescence is produced when quartz is rubbed by any material, such as topaz or sapphire, which is harder than itself. Dr. Gordon, head of the geological department of King's College, London, kindly lent a number of minerals for the purpose of this test. Ordinary steel, which falls below quartz in the scale of hardness, does not cause the glow. (2) Fused quartz, as supplied by the Silica Syndicate, gives a very fine effect. I have on several occasions shown this as a lecture experiment by rubbing together two tubes of transparent fused silica. In this connection the observation of Lord Rayleigh (Nature, vol. civ., p. 153, 1919) that "silica glass" possesses a remarkable crystalline or quasi-crystalline structure is of special interest. (3) The tubes of fused quartz when rubbed together give the same peculiar odour as ordinary quartz pebbles.

It should, therefore, be possible to carry out an experiment of the kind suggested by Sir E. Ray Lankester by grinding the interior of a quartz vessel which might be highly evacuated or contain suitable liquid or gaseous reagents. According to Lord Rayleigh's experiments (Royal Society, February 27, 1919), the clearest and whitest quartz has some power of scattering light, though much less than that of glass or liquids. This small scattering is considered to be due to inclusions, as in the case of visibly smoky or yellow quartz. May not the presence of minute diffused metallic particles, or perhaps particles of silicon itself, be the cause of the various phenomena under discussion? H. S. Allen.

The University, Edinburgh.

Contractile Vacuoles.

There is no doubt that the explanation of the production of these vacuoles as given in Nature of November 11 by Prof. Henry H. Dixon is the correct one. It may perhaps be of interest to Prof. Dixon to refer to a paper by W. Stempell published in 1914 in *Zoolog. Jahrb., Abt. allg. Zool. u. Physiol. der Tiere* (Bd. 34, iii., p. 437), where the same view is put forward. I believe that this journal is not very accessible—a fact which doubtless accounts for its having been overlooked. I may say that it is my custom to teach this view, and a brief account will be found on p. 162 of my "Principles of General Physiology." W. M. Bayliss.

The Mechanics of Solidity.

THE subjoined table appears to indicate that the mechanical "hardness" of a solid is fairly closely related to its thermal expansion coefficient. There are exceptions like "invar," and for various reasons attention should be directed more to the scope of the relationship than to particular discordances between the hardness figures.

Comparison between Mean Linear Expansion and Three Scales of "Hardness."

It may, perhaps, be inferred that engineers would be well advised to scrutinise "solidity" more closely, and to make use of the simple physical constants of a metal as criteria of quality in preference to developing a chaos of complicated tests which bear as little relation to each other as they do to any practical service in which metals are employed.

The Brinell hardness measurements are taken from a paper by Prof. C. A. Edwards (Inst. of Metals, 1918); the others from Landolt-Börnstein's tables.

12 Edward's Road, Whitley Bay,
Northumberland, November 8.

The Protection of Animal and Bird Life in Australia.

I AM directed by the Hon. the Minister of Industry, who is the Minister controlling the Animal and Bird Protection Act in South Australia, to say that his attention has been directed to a note in NATURE of July 1 last, p. 558, in which the following quotation from a report from Mr. C. M. Hoy, of the Smithsonian Institution, appears: "There are very few game laws in Australia, and no one gives any attention to the ones that are in order." The Minister has communicated with the Smithsonian Institution, expressing regret that Mr. Hoy should have made such a statement, knowing, as he must, that so far as it applies to South Australia it is not correct that "no one gives any attention" to the laws that are in order.

We have an Animal and Bird Protection Act with very wide powers, and every effort is being made to carry out this law. We realise, of course, that in our out-back areas, where the population is very sparse, the law may not always be observed. At the same time, however, a special check is kept on persons dealing in skins and furs, and, generally, we have every reason to believe that the laws relating to the protection of animals and birds are fairly observed.

The very fact that Mr. Hoy was unable to collect a single protected animal or bird, or the nest or eggs of the protected birds, without a permit signed by the Minister of Industry, and that this permit was distinctly limited, inasmuch as it was issued subject to the condition that "no more than four examples of each totally protected species of native animal or bird are to be taken, excepting the common opossum, of which twelve (12) may be taken. No specimen of the Toolach wallaby (*Macropus Greyi*) is to be taken under any circumstances. Not more than twelve (12) examples of partially protected birds and animals," is ample evidence that Mr. Hoy knows that action is being taken in South Australia to compel the observance of these game laws. The Minister desires me to add that he trusts in the circumstances you will give publicity to his protest against Mr. Hoy's statements.

W. L. SUMMERS,
Secretary, Ministry of Industry.

Adelaide, South Australia, September 21.

New British Oligochæta.

IN revising my material and records of the Lumbriculidæ I find that two new species may now be placed on our list of indigenous annelids. These are *Rhynchelmis limosella*, Hoffm., and *Stylodrilus heringianus*, Clap. Respecting the former Beddard wrote in his "Monograph of the Order Oligochaeta" (1895, pp. 215–16): "I have seen a specimen from some part of England, but cannot give any details. There is every probability that it is a native of this country." It reached me some time ago from Ringwood, Hants.

Stylodrilus heringianus was first found near Brougham, in Cumberland, in March, 1911, but, being immature, there was an element of doubt as to its identity. In April, and again in November, of the same year I found it in two different localities near Swadlincote, Derbyshire. Our British list of Lumbriculidæ, therefore, now numbers seven species under four genera. These are *Lumbriculus variegatus*, O. F. M.; *Trichodrilus cantabrigensis*, Bedd.; *Stylodrilus Vejdovskyi*, Benh.; *S. gabretae*, Vejd.; *S. Hollissyi*, Southern; *S. heringianus*, Clap.; and *Rhynchelmis limosella*, Hoffm.

HILDERIC FRIEND.

"Cathay," Solihull.

Microscopy with Ultra-violet Light.

By J. E. BARNARD.

THE microscope is now so widely used in all branches of science and in industry that it is not surprising to find an increasing demand for greater optical efficiency. It must be admitted that in comparatively few cases is the instrument used under such conditions as to secure the best possible result; but this is due to lack of appreciation of the principles involved, and will be remedied only by a wide educational effort. Even when the greatest optical efficiency is secured, the limitations are soon felt. The chief need is for increased resolution, that factor on which the delineation of minute structure depends. Advances of great value have been made in methods of rendering visible minute objects, but it must be clearly realised that, while this greater visibility can be secured, no information as to the form or structure of objects which are below the resolution limits is to be obtained by this means. Increased magnification is by some workers still regarded as desirable, but unless this is accompanied by proportionally increased resolution, the results are worse than useless, and can lead only to serious errors of interpretation.

Two factors mainly govern resolution—namely, the numerical aperture of the objective, and the mean wave-length of the illuminant. No increase of numerical aperture has been obtained since the classic researches of Abbe, resulting in the production of apochromatic objectives; and in the present state of knowledge there appears little likelihood of any substantial advance in this direction. By using light of short wave-length, a promising field of research is at once opened up. An increase of resolution is obtained even with visible light if the violet or blue end of the spectrum is utilised, but the increase is much more definite if ultra-violet light is used, although the image is no longer a visual one.

The computation of microscope objectives for use with ultra-violet light presents considerable difficulties, as only two substances sufficiently transparent to these radiations are available—quartz and fluorite. So long ago as 1860 Spencer in America used fluorite for this purpose, and at a much later date Boys in this country suggested the possibility of using fused quartz. In 1904 Kohler, of Jena, succeeded in computing objectives entirely of fused quartz, some earlier ones which were fluorite-quartz combinations being thereby superseded. Ultra-violet light, therefore, became available for microscopic work, but the practical difficulties in the use of the apparatus are so considerable, calling for almost more knowledge of physical than of microscopical methods, that it has been used by few.

The results obtained, particularly in biological work, are in many cases of great interest, as, in addition to the advantages already indicated, there is the further important point that organisms are dealt with and photographs obtained of them in the living state. The classic researches of Hartley showed that organic substances which are perfectly transparent to ordinary light have very definite absorption regions or bands in the ultra-violet, and that their absorption is, in many instances, so characteristic that it constitutes an accurate method of identification. To a considerable extent, this fact is of value when using ultra-violet in microscopy. Objects that show little or no structure by transmitted light are seen to be highly organised when examined by ultra-violet radiations, and the structure seen is in part dependent on the wave-length of the light used. Objects for examination by this method must be dealt with in the living state, or at least in such a manner that no change takes place in their constitution. It follows that none of the ordinary methods of mounting such things as micro-organisms, in which staining, hardening, fixing, drying, or heating is resorted to, can be employed. The method is, in fact, its own staining process, differentiation of structure depending on the difference of absorption in ultra-violet, and not on complex staining processes, which are in some cases causing appearances not associated with the organism itself. Further, apart from the alteration that may take place in the tissues themselves as the result of such processes, their employment in the method under consideration would render them opaque to the radiations used, and, therefore, useless for the purpose. The organisms or tissues are simply mounted in any suitable fluid, such as water, normal saline, Ringer's solution, etc., which is transparent to ultra-violet light and the photograph is taken at once. The result is an image that, whether it shows more or less than a stained preparation, is a representation of the object in the living state, and with greater resolution than can be obtained in the microscope by any other process.

Such a method is obviously one to be tried to its utmost whatever practical difficulties may be involved, and there is little doubt that in time it will be recognised as what it really is—the only great advance in microscopic technique for a generation. The apparatus as used by the present writer is in its essentials the same as that devised by Dr. Kohler (Fig. 1), although in many points of detail improvements have been devised. The quartz objectives are three in number, their equivalent focal lengths being 6 mm., 2·5 mm., and 1·7 mm., their effective numerical aperture being respectively 2·50, 1·7, and 0·7. It will at once be appreciated that in cases where the full aperture can be utilised the two higher powers are of much greater N.A. when used with light of 275 $\mu\mu$ wave-length than any objective available for use with ordinary light. These two are glycerine immersion combinations, the refractive index of the immersion fluid being 1·447. As these systems are not homogeneous, the cover glasses are optically worked fused quartz of uniform thickness.

The slides are also of fused quartz, fitted into a carrier of a special type, which ensures that the surface of the slide is a constant distance from the objective, a point that in practice is of considerable importance. The quartz oculars are five in number, and range from an initial magnification of 5 to 20, giving camera magnifications of from 200 to 3600 diameters. The latter is a good deal too high for satisfactory results with most objects—in fact, it is doubtful, on theoretical grounds, whether such a magnification is justified. The quartz sub-stage condenser

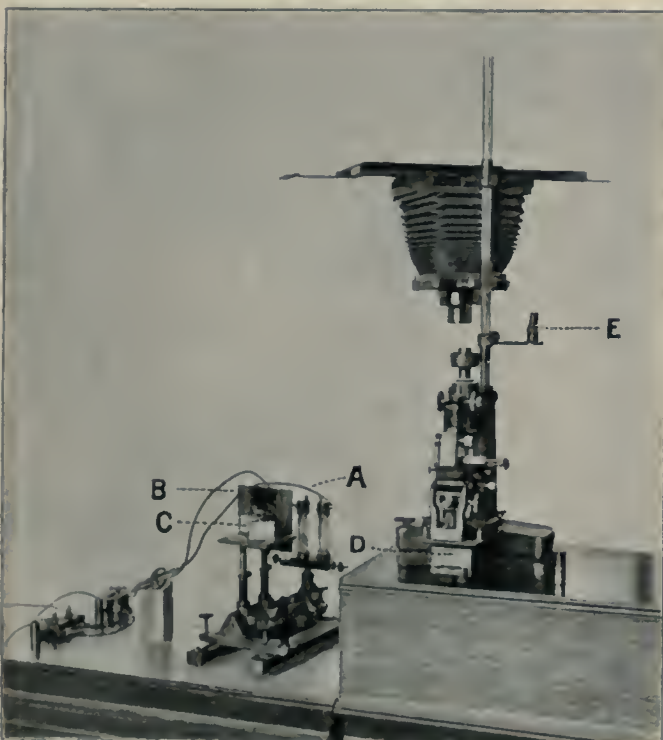

FIG. 1.—A, spark gap; B, quartz condensing lens; C, quartz prisms; D, box containing reflecting quartz prism; E, fluorescent ocular. The position of the other parts described will be evident to any microscopist.

is made with a duplex top, so that a combination is available for each objective to ensure that a suitable cone of illumination is used in each case. This is used as a glycerine immersion system with the two higher-power objectives, and as a dry system with the lowest one.

The source of light is produced by a high-tension discharge in air between metal electrodes, usually cadmium or magnesium, although other metals may be used if they produce a suitable line spectrum. There are obvious limitations in this respect, as the character of the spectrum emitted must be such that the principal lines in the ultra-violet region are sufficiently separated and of considerable intrinsic brilliancy. The spectrum of iron, for instance, is excluded, as, although it is rich in bright lines, these are so numerous and therefore so close together that the isolation of one line is impossible under the conditions realised in this method.

The spark is produced by means of an induction coil of special design giving a heavy discharge of relatively low potential, the equivalent spark-gap being about 5 cm. This is further reduced by placing a condenser immersed in oil in parallel with the spark-gap. The interrupter may be either an electrolytic one or a mercury break, the latter appearing to be more satisfactory. Special arrangements are made for accurately adjusting both the length of the spark and its position in relation to the optic axis of the microscope. The image of the spark is projected by means of a quartz lens, so that, after passing through a pair of quartz prisms of opposite rotation, an image of the spark in one wave-length is obtained approximately at the position of the iris diaphragm below the sub-stage condenser. To facilitate adjustment, a disc of uranium glass is placed at the latter position so that an image of the spark can be observed and focussed as required, after which the uranium glass in its carrier is swung aside. The direction of the illuminating beam is at right angles to the optic axis of the microscope; it has, therefore, to be reflected by a right-angled quartz prism along the axis in the same way that the mirror operates in an ordinary microscope.

The preparation being placed on the stage, the light adjusted, and the condenser accurately focussed on the object, the actual focussing of the image has to be carried out. This is effected by means of a fluorescent searcher eye-piece which is mounted above the quartz ocular, and by the use of which an image is seen on a fluorescent screen and focussed by means of an auxiliary magnifier. This operation is one of considerable difficulty, and only after long practice can success be assured. Its difficulty varies, too, according to the wave-length used; in some cases the fluorescent image is bright, but in others it is much more difficult to see. Some objects themselves fluoresce, with the result that a sharp visual image cannot be obtained. The method now largely adopted by the writer is to observe the object by monochromatic light as emitted by a quartz mercury vapour lamp. This illuminant has bright lines in the violet, blue, green, and orange regions, and by means of suitable screens any one of these can be transmitted.

The image having been focussed visually in one of these lines, the fine adjustment of the microscope is moved by a predetermined amount so that the image is in focus for any desired wave-length in the ultra-violet. This method is quite practicable provided that the fine adjustment of the microscope is of sufficient accuracy (the searcher eye-piece is not used in this case except to confirm the accuracy of the process). The focussing having been performed, the searcher eye-piece is removed, the camera placed in position, and the exposure made. The image is projected for a certain distance, so that it is in focus at the plane of the plate with a known length of camera. The exposures required are as short as two

seconds under favourable conditions, even at high magnifications.

There was considerable difficulty in obtaining a suitable photographic plate, as one was required of fine grain and with the smallest possible quantity of gelatine on its surface. Gelatine is itself opaque to ultra-violet light, so that the photographic action is confined to the surface of the gelatine, little or no penetration in depth taking place as with ordinary light. The result is that plates must be prepared with the smallest possible quantity of gelatine, but with the maximum quantity of sensitive silver salts that the gelatine can hold together. Such a plate has been prepared by the Kodak Co., and has proved satisfactory. Plates as prepared by Schumann for work in the far ultra-violet have also been experimented with, but for various reasons have not proved so satisfactory. The resulting negatives are at first glance somewhat disappointing if judged by ordinary photographic standards. They are always thin and lacking in violent contrasts, owing to the superficial action of the light, but the detail and fineness of lines due to the shorter wave-lengths used are evident to anyone having any knowledge of photomicrography. Whether the utmost resolution that theory demands can be achieved is at present unproved, not because the method has failed, but because of the difficulty of finding an object that can be regarded as a satisfactory test.

The accompanying illustrations give some idea of the comparative results obtained with living organisms. Figs. 2 and 4 are illuminated by a concentric dark-ground illuminator, the most satisfactory method available for observing living organisms by ordinary light, and Figs. 3 and 5 by a solid cone of ultra-violet light. The apparatus as figured is now in operation in the microscopical department at the National Institute for Medical Research.

Industrial Research Associations.

II.—British Non-Ferrous Metals Research Association.

By Ernest A. Smith.

The Research Association for the non-ferrous metals industry had its inception during the recent conflict, when manufacturers, under the stern necessity of war demands, began to realise the need for fuller knowledge respecting the metals and alloys with which they had to deal. Preliminary meetings were held at the end of 1918 and during 1919, the attendance being well representative of the non-ferrous metals and allied industries, and included smelters, founders, metal rollers, tube manufacturers, wire drawers, and makers of every class of industrial alloys, including the precious metals. After some unforeseen delay the association was formally incorporated in January, 1920, with headquarters in Birmingham, the centre of the British non-ferrous metals industry.

The association seeks the membership not only of firms engaged solely in the non-ferrous metals industries, but also of firms which are substantial users or workers of non-ferrous metals and alloys, such as engineers, shipbuilders, railway companies, etc. It will be obvious that if there is to be effective development of research in this important national industry, the whole-hearted co-operation of every manufacturer and user of non-ferrous metals is essential.

Whilst the main object of the association is to carry on research, it also seeks to disseminate technical and scientific information relative to the production, treatment, manufacture, and uses of the non-ferrous metals and alloys. To this end a bureau of information has been started, thus supplying a long-felt need experienced by many manufacturers in this industry. Attempts are being made to make the bureau as comprehensive as possible, and already good work has been done.

With regard to the scientific aspects of the research work to be undertaken, no definite programme of research has yet been arranged, owing to the comparatively recent date of incorporation, but the council is dealing fully with the matter in the near future. Technical committees, representative of the various sections of the non-ferrous industry, have been appointed to review the field of research in each particular sphere and to report to a full council in due course.

It may be well, however, to indicate briefly in which directions intensive research appears to be most necessary for the future development of the industry. It is now generally recognised that, important and necessary as improvements in smelting and other processes of metal production undoubtedly are, the most marked technical advance in the immediate future may be expected from a more complete study of the properties of metals and alloys, as influenced by thermal or mechanical treatment, and by the presence of foreign matter. This being so, the first duty of the association will be to initiate researches into the fundamental principles which underlie the working of metals and alloys. Whilst it is true that the past few decades have seen considerable progress in non-ferrous metallurgical research, a careful review of this work reveals the fact that existing knowledge respecting non-ferrous metals and alloys is far less exact and complete than that which is available in the case of iron and steel. This lack of more extensive knowledge was brought home to manufacturers by the claims made upon the industry during the war period, and has helped to emphasise the importance of systematic research to provide that new knowledge without which an industry cannot make progress.

More exact data are required in connection with the physical constants of most of the industrial metals, and the vexed problem of the cause of hardening under mechanical treatment still requires elucidation; also problems concerning the quality of hardness and methods of testing such.

Apart from the conduct of research into the constitution and properties of metals and alloys, the most pressing problems that await solution appear to be those connected with the melting, casting, and working of metals in works practice. Each stage of manufacture, from the raw material to the finished product, presents its own individual problems. Realising the importance of starting with a sound ingot, the Brass and Copper Tube Association, in co-operation with the Research Department, initiated in 1918 a research into the production of sound brass and copper castings, under the direction of Prof. Thos. Turner. This research, which was established in a temporary laboratory in Birmingham, has now been handed over to the British Non-Ferrous Metals Research Association. As the result of two years' work, results of practical value have been obtained, and a report will be issued to members shortly. Attention has been directed mainly to the important question of the inclusion of gases, a subject which has been brought more into prominence since the introduction of gas and oil melting furnaces.

The laboratory experiments have been repeated on a commercial scale, with the aid of an electric crucible furnace, which proved to be the most satisfactory method of melting for investigation purposes.

The growing importance of aluminium as a commercial metal has led to the formation of a committee, on which the association is represented, to deal with the corrosion of aluminium and its alloys, and research will be started shortly.

The atmospheric corrosion of non-ferrous metals is also receiving attention, the association having recently taken over this research, which was initiated by the Institute of Metals as one of the researches into the general question of corrosion of non-ferrous metals and alloys. The prominence now being given to aluminium alloys for aero-engines and motor-car construction opens up a wide field for research to gain more exact knowledge on alloys now in use and the introduction of new alloys. Particularly do the problems of ageing and disintegration need further research. The modern requirements of engineering practice call for more extensive information on the non-ferrous industrial alloys which are now produced in such large quantities. Modern research has considerably extended our knowledge of the constitution of the brasses and bronzes, but there is still scope for research into the factors which govern the machining and engineering properties of these alloys. More complete investigation is necessary into the composition of engineering alloys to withstand comparatively high temperatures, and chemical engineers are diligently seeking for non-ferrous alloys that will resist the action of acid solutions and vapours.

In this connection the use of chromium as a constituent metal appears to offer a promising field of investigation; its addition to nickel has produced some valuable industrial alloys, especially for electrical and for acid resistance purposes. but research in this direction is by no means exhausted.

The class of white alloys, including bearing metals and type metals, has so far received little attention at the hands of scientific investigators. Little is known respecting the exact constitution of the various series of alloys of which bearing and type metals are usually composed. There seems to be little doubt that a thorough investigation of this important class of alloys would result in many compositions now in use being discarded. The whole subject of bearing metals requires investigation in the light of modern scientific knowledge, as much information, based on practice, is contradictory.

Rapid advances in steel metallurgy have been made in recent years by the introduction of new alloys of remarkable properties, many of which include in their composition non-ferrous metals such as chromium, vanadium, molybdenum, titanium, tungsten, etc., which only a few years ago were regarded as rare metals. The success which has attended the use of these rarer metals in steel should stimulate investigation with a view to their wider use in the non-ferrous industry. At present practically nothing is known of the influence of these metals on the industrial non-ferrous alloys, with the exception, perhaps, of a few special alloys known as high-tenacity brasses and bronzes, which are very varied in composition and complex in character.

Research is also necessary in connection with the industrial alloys of the precious metals. Little work has yet been done on the mechanical properties of the various gold alloys of 9-carat standard, which constitute 50 per cent. of the jewelry manufactured at the present time. Further work is also required in connection with standard silver, especially on the exact cause and prevention of so-called fire-marks. Alloys to act as satisfactory substitutes for platinum are also required.

Such, in brief, are some of the problems that confront the non-ferrous metal industry, and will doubtless claim the early attention of its particular research association.

Research in connection with metal extraction processes will not, however, be neglected. The association is taking over the work of the Copper and Zinc Inquiry Committee which was especially appointed by the Research Department to review the field of research in relation to the production of these two important industrial metals. Other committees will doubtless be formed to deal with research in relation to the extraction processes of other non-ferrous metals of industrial importance.

The council of the association fully realises that the value of research work is often lost to the manufacturers because of its want of application; in the conduct of its research, therefore, every effort will be made to carry on the work in such a way as to enable the full value of its research investigations to be infused into works practice.

Another important matter which is claiming the attention of the association is the standardisation of non-ferrous alloys, a question which has been brought into some considerable prominence as the result of war conditions, and presents great possibilities of considerable import to the industry.

For the present the research work of the association will be carried out in the metallurgical laboratories of existing institutions and in the temporary laboratory of the association established at Birmingham. It is hoped, however, that when funds become available, permanent premises will be equipped for experimental work and research, and for the bureau and administrative purposes.

Each research decided upon by the council will probably be placed in charge of an expert in the particular subject chosen for investigation, whilst the general supervision of all the researches will be undertaken by the technical officer of the association, as required by the articles. This course appears to be the most satisfactory in view of the diversity of non-ferrous processes, metals, and alloys that require investigation.

Notes.

The King has been pleased to approve of the following awards this year by the president and council of the Royal Society:—A Royal medal to Mr. W. Bateson, for his contributions to biological science, especially his studies in genetics; and a Royal medal to Prof. G. H. Hardy, for his researches in pure mathematics, particularly in the analytic theory of numbers and allied subjects. The following awards have also been made by the president and council:—The Copley medal to Mr. H. T. Brown, for his work on the chemistry of carbohydrates, on the assimilation of atmospheric carbon dioxide by leaves, and on gaseous diffusion through small apertures; the Rumford medal to Lord Rayleigh, for researches into the properties of gases at high vacua; the Davy medal to Mr. C. T. Heycock, for his work in physical chemistry, especially on the composition and constitution of alloys; the Darwin medal to Prof. R. H. Biffen, for his work on scientific principles applied to the breeding of plants; and the Hughes medal to Prof. O. W. Richardson, for his work in experimental physics, especially thermionics.

Dr. H. Deslandres, president of the Paris Academy of Sciences, gave, at the meeting on October 4, an eloquent *éloge* on Sir Norman Lockyer, who was a correspondant of the Academy in the section of astronomy. He referred to Sir Norman as one of the founders of physical astronomy who approached science along untrodden paths and with whose name great discoveries are associated. Among the researches and conclusions to which Dr. Deslandres directed particular attention were those of the observation of solar prominences in broad daylight, the discovery of helium, the effect of variation of pressure on the width of hydrogen lines in prominences, the application of the Doppler-Fizeau principle to the spectroscopic determination of velocities in prominences, dissociation of chemical elements, the temperature relations of long, short, and enhanced lines in spectra, the correlation between solar and terrestrial meteorology, and stellar classification on an ascending as well as on a descending temperature scale as described in "The Meteoritic Hypothesis" and "Inorganic Evolution." Reference was also made to the Hill Observatory, Sidmouth, as "already one of the best provided in England," and Dr. Deslandres concluded his appreciative address with the words: "Dans son ensemble, l'œuvre est considérable et touche aux plus hautes questions de la Science. Sir Norman Lockyer est assurément un des plus grands savants de l'Angleterre, et un des plus grands astronomes de tous les temps. L'Académie s'honore de l'avoir compté parmi ses membres; elle adresse à sa veuve et à ses enfants ses plus vives condoléances."

A meeting of the International Commission for Weather Telegraphy, which was appointed by the International Meteorological Conference at Paris in October, 1919, will be held at the Air Ministry during the week November 22–27. The following delegates are expected to attend the meeting:—Lt.-Col. E. Gold (president), Meteorological Office, Air Ministry; M. A. Angot, Bureau Central Météorologique, Paris; Col. L. F. Blandy, Controller of Communications, Air Ministry; Dr. van Bemmelen, Meteorological Observatory, Batavia; Col. Delcambre, Service Météorologique Militaire, Paris; Prof. F. Eredia, Ufficio Central di Meteorologia, Rome; Prof. E. van Everdingen, Meteorologisch Instituut, De Bilt, Holland; Gen. Ferrié, Ministère de la Guerre, Paris; Capt. Franck, Service de la Navigation Aérienne, Paris; Señor José Galbis, Servicio Meteorologico Español, Madrid; Lieut. H. D. Grant, Meteorological Office, Air Ministry; Dr. Hesselberg, Meteorologiske Institut, Christiania; Col. Matteuzzi, Servizio Aerologico, Rome; Prof. A. de Quervain, Central Meteorological Office, Zurich; M. Rey, Ministère de l'Agriculture, Paris; Capt. C. Ryder, Meteorologische Institut, Copenhagen; Mr. T. Thorkelsson, Meteorological Service, Reykjavik; and Dr. A. Wallén, Meteorologiske Hydrografiske Anstalt, Stockholm. Since the war much progress has been made in different countries in the development of codes for telegraphic reports of the meteorological information which experience in the war and the needs of aerial navigation indicated as necessary. The main object of the Commission is to co-ordinate these developments in the revision and extension of the codes prepared at the last meeting of the Commission, which was held in London in September, 1912.

The Nobel prize for physics for 1920 has been awarded to Dr. C. E. Guillaume, director of the International Bureau of Weights and Measures at Sèvres. The prize for 1919 has been reserved.

The Chadwick Trustees announce that a public lecture will be given by Prof. J. B. Farmer, entitled "Some Biological Aspects of Disease," on Thursday, November 25, at 5.15 p.m. The lecture will be delivered in the lecture hall of the Medical Society of London, 11 Chandos Street, W.1.

The Woburn Fruit Farm, which was carried on from 1894 to 1918 by the Duke of Bedford, and since then by means of a grant from the Development Fund administered by the Committee of the Rothamsted Experimental Station, is to be closed at Christmas owing to the continued ill-health of Mr. Spencer U. Pickering, which renders him unable to continue his experimental work there.

The gold medal of the Institution of Mining and Metallurgy, the highest distinction in the power of the council to bestow, has been awarded to Sir Thomas Kirke Rose "in recognition of his eminent services in the advancement of metallurgical science, with special reference to the metallurgy of gold." The Consolidated Gold Fields of South Africa, Ltd., gold medal and premium of forty guineas have been awarded to Mr. H. Livingstone Sulman for his paper entitled "A Contribution to the Study of Flotation" (Transactions, vol. xxix., 1919–20).

At the anniversary meeting of the Mineralogical Society held on November 9 the following officers and members of council were elected:—*President:* Sir William P. Beale, Bart. *Vice-Presidents:* Prof. H. L. Bowman and Mr. A. Hutchinson. *Treasurer:* Dr. J. W. Evans. *General Secretary:* Dr. G. T. Prior. *Foreign Secretary:* Prof. W. W. Watts. *Editor of the Journal:* Mr. L. J. Spencer. *Ordinary Members of Council:* Dr. A. Holmes, Miss M. W. Porter, Mr. R. H. Rastall, Sir J. J. H. Teall, Mr. A. F. Hallimond, Dr. F. H. Hatch, Mr. J. A. Howe, Lt.-Col. W. Campbell Smith, Mr. T. V. Barker, Prof. C. G. Cullis, Mr. W. A. Richardson, and Dr. A. Scott.

MR. J. HARGREAVES presided over the annual meeting of the Chaldæan Society held at the Great Northern Hotel on November 13. Reports of astronomical work and progress were received from the local sections established at Luton and Tottenham, and the formation of new sections for Warwickshire and Hertfordshire was announced. Special attention was directed to the encouraging work of the society in the observation of the zodiacal light, variable stars, sun-spots, the moon, and photographic work. The secretary, Mr. S. S. Clerk-Maxwell, King's College, Cambridge, expressed a hope for further development and for the formation of local sections south of the Thames. *The Chaldaean* is now published for the society by Messrs. Geo. Philip and Son, Ltd., 32 Fleet Street, E.C.4.

A JOINT meeting of the Physical and Optical Societies for the discussion of "The Making of Reflecting Surfaces" will be held on Friday, November 26, at 7 p.m., at the Imperial College of Science and Technology, South Kensington, S.W.7. The programme will be divided into two parts: (*a*) Technical methods and processes, and (*b*) properties of reflecting surfaces (reflecting powers, etc.). Some demonstrations of actual processes will also be given. Mr. R. Kanthack is making a complete bibliography and *résumé* of previously published work on this subject, and will contribute a description of the results of his investigation to the discussion. Papers have been promised by representatives from manufacturing firms, astronomical observatories, and other scientific institutions. A complete programme will be issued during the week. Tickets may be obtained from the secretary of the Physical Society (Imperial College of Science) or of the Optical Society (39 Victoria Street, Westminster, S.W.1).

REPLYING to a question in the House of Commons on November 15, Mr. Lloyd George said: "The whole subject of chemical warfare has been under careful consideration by the Cabinet during the past year. It was decided on March 4 that the question should be raised at the Council of the League of Nations. It is, I am sure, obvious to the House that this is a question on which our action must depend on that of other nations. It was realised, therefore, that, as other countries have been continuing to develop this method of warfare, the safety of our fighting Services would be seriously jeopardised by lack of similar development in this country, and it was decided on May 12 that, pending a pronouncement on the subject by the League, the fighting Services should continue their researches and experiments. The War Office Committee has been constituted as part of the organisation necessary for the continuation of these studies. The whole subject will, of course, have to be reconsidered when the Council of the League of Nations has made its pronouncement."

REPRESENTATIVES of countries included in the League of Nations and of America met in Paris on October 17–21 for the purpose of forming an International Union against Tuberculosis, which would continue the work carried on by the old international association, the last conference of which was held in October, 1913, at Berlin. Great Britain's representatives were Sir Robert Philip, of the National Association for the Prevention of Tuberculosis and the Ministry of Pensions; Dr. Nathan Raw, also from the National Association; and Dr. Halliday Sutherland, of the Ministry of Pensions. The conference was presided over by M. Léon Bourgeois, and the principal subject raised was the necessity for the early diagnosis of tuberculosis and the methods which could be used for this purpose. The headquarters of the International Union against Tuberculosis will be at Geneva, and the next conference will be held in London in 1921.

MR. E. W. SHANN referred in his letter in NATURE of November 11 to the statement in the leading article in our issue of October 28 that there was "little or no evidence" that the museums of our public schools "are used in school teaching." This statement was based not only on the Report of the British Association Committee, but also on the confessions of public-school science masters in annual conference in 1916, and on personal inquiries from boys and masters while the article was being written. Oundle is a marked exception to the prevailing apathy, yet Mr. Shann in his long and interesting letter devotes only ten lines to the use of the museum in class-work. Such small evidence as there is, in addition to that from Oundle, comes, as in Mr. Shann's case, from the biological and geological sides. This is not because the subject or the material is more suited to the museum method, but because the teachers have had a scientific training and have some appreciation of a museum's usefulness. More might be done even here, but it is in the teaching of history, ancient and modern, and in the elucidation of ancient or foreign authors, that so much more use might be made of school museums.

IN a brochure entitled "A Proposal to Increase the Purchasing Power of the Penny" Mr. Harry Allcock puts forward the view that the value of the penny as 1/240th of the pound sterling has proved too low for post-war requirements, and that, in consequence, penny prices have been advanced by 50 per cent. in many cases where a smaller increase would have satisfied the seller had a single coin been available intermediate in value between 1*d.* and 1½*d.* As a result, two coins are now needed in millions of daily transactions where formerly only one was used, and this has led to a shortage of copper coins and much inconvenience to the public. The provision of either additional copper coins or new nickel coins would involve national expenditure, to obviate which Mr. Allcock suggests that the Government should now increase the token value of the penny by 20 per cent., thus making it represent one-tenth instead of one-twelfth of the shilling and increasing its purchasing power proportionately. The present value of the pound sterling and of all existing notes and silver coins relative to the pound would be unchanged, but the shilling would be divided into ten pence. The consequent loss to the Mint when the copper coins already in circulation became so worn as to need withdrawal would be insignificant, and the risk of the public hoarding copper coins in anticipation of the change could be avoided by imposing this without notice; while holders of large stocks of copper coins for business purposes might be called upon to surrender to the State the amount by which their holdings were increased in value.

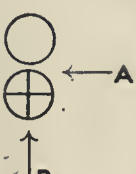
THERE can be no doubt that scientific progress in relation to agriculture has been seriously hampered in the past by the poor material prospects offered to the scientific worker, and the Ministry of Agriculture, in recognising the fact and in attempting to remove the defect, has shown a spirit of enlightened goodwill which is of hopeful augury. The provision of a grant earmarked to cover the salaries of workers in universities and in institutions such as the Rothamsted Experimental Station, in addition to, and separate from, a grant for laboratory and general research expenses, is a real effort to ensure that the workers shall have some security of tenure and some prospect of a settled career in the prosecution of research. The principle is sound, but the practical application is as yet not entirely successful. A system of grading the workers is perhaps inevitable, and the salaries allotted to the different grades are in some respects not unreasonable. But the annual increments are too small, especially during the years when the average worker is marrying and his expenses are increasing, and there is not sufficient range between the extremes of the scale, *e.g.* a worker recently graduated and beginning his career receives 450*l.*; the same man ten years later, with a wife, two or more children, and a position to maintain, receives only twice that amount, and is actually worse off than before. The total number of graded posts is much too small even to cover only those already working in agricultural research. That will, no doubt, be improved as time goes on, but meanwhile it leads to stagnant promotion and invidious selection. There must be something seriously at fault when (to take only one particular instance) a worker of more than thirteen years' experience in research, of acknowledged eminence and authority in an important subject, should be offered, and have in the meantime to accept, a post in the third grade (called "junior assistants"), and be classed along with those at the start of their career with no record of solid achievement behind them.

THE authorities of the New York Zoological Society are justly proud of the fact that a chimpanzee was born in the Gardens of the society on July 14. A very welcome account of this event is given in the Zoological Bulletin of the society for September (vol. xxiii., No. 5) by Mr. W. Reid Blair. The mother of this infant is about ten years old, and was taken in West Africa; the father is about eight years old, and was taken in what was German East Africa. The offspring of these two animals at birth weighed about 3 lb., and measured 16 in. in length. The body was but sparsely clothed with hair, save on the head, back, and arms. In its less prognathous jaws and in the great relative size and form of the ears it differs conspicuously from the adult chimpanzee. Unfortunately, the mother was unable to nurse it properly, so that it lived but a few days. During this time, however, some interesting observations were made upon the behaviour of the mother in regard to her treatment of her infant. Only once before has the chimpanzee bred in confinement. This was in Cuba in 1915.

IN Report No. 9 of the Industrial Fatigue Research Board Mr. P. M. Elton describes his investigations on output in the weaving-sheds of two silk mills. The observations lasted for a continuous period of fifteen weeks, and represent the output of forty-seven experienced weavers. At each mill it was found that the output steadily improved during the course of the experimental period. This was due mainly to the diminishing need of artificial light. In the latter half of February and the first week of March, when no artificial lighting whatever was necessary, the output during the first and last hours of the working day was 11 per cent. greater than at the same hours in January, when lighting was required, though the output in the middle hours of the day (when no artificial light was required in either instance) was practically the same. It might be thought that such a result argued inadequacy of the artificial lighting, but photometric measurements showed that the light was quite good. Another factor which influenced output was the temperature of the weaving-sheds. It was found that a rise of temperature from 59° F. to 65° F. caused a 10 per cent. improvement in output, but no definite relationship between output and humidity could be traced. The practical importance of Mr. Elton's investigations needs no comment. It is only by careful and accurate observations such as he has described that the conditions necessary for maximum efficiency can be ascertained.

IN Memoir No. 6 of the Entomological Series of the Agricultural Department of India, Ramachandra Rao gives a lengthy report of an inquiry into the efficiency of indigenous insect pests as a check on the spread of Lantana in India. This plant is a noxious weed in most parts of India and Burma; various other plants which have been introduced for ornamental purposes have also got, or are getting, out of hand, and are likely to prove sources of future trouble. A native of South and Central America, it has been introduced by man into many tropical countries, and in all suitable localities it is a scourge, displacing the native vegetation and often seriously interfering with the natural regeneration in forests. In the Hawaiian islands an Agromyzid fly introduced from Mexico, the larvæ of which live in the fruits of Lantana, has proved a valuable check, though it has not by any means exterminated the plant. In work of this nature it has to be considered whether the introduced species is likely to turn to plants of economic value and thus do more harm than good. It is necessary, therefore, to make quite sure of this vital point before introducing the Agromyzid into India. The author of this memoir has brought to light a number of insects attacking Lantana in India. The most efficient of these appears to be a small plume moth (*Platyptilia pusillidactyla*), the caterpillar of which feeds on the flower-heads and considerably reduces the number of seeds produced. Its efficiency, however, would be much greater were it not so subject to the attacks of Hymenopterous parasites. No insect is likely to do more than act as a check upon the reproductive capacity of the plant, and until such insects can be satisfactorily brought into operation, the eradication of the plant in (at present) lightly infested districts by cultural methods seems to be the only feasible course.

RECENT investigation into the irregularities of the heart illustrates the great value of researches which apparently have no practical application. The electrical phenomena of muscle and nerve were thought to be of merely academic interest, but after the perfection of the Einthoven galvanometer these electrical reactions became of great use in the study of the action of the heart. By placing pairs of electrodes on the surface of a muscle, as shown by the two circles of the accompanying diagram, it is found that a wave of excitation travelling in the direction of arrow A will reach both electrodes at the same time and the electrical response will be insignificant, but a wave of excitation travelling in the direction of arrow B will reach the electrode, marked with a cross, first, so that an appreciable electrical response will result, and the direction of the electrical current will indicate the direction in which the wave is travelling; the commencement of the electrical response shows the time at which the wave of excitation reaches the electrode. By this method Dr. T. Lewis and his co-workers have followed the path of the excitation in the disorder known as auricular fibrillation (see *Heart*, August, 1920, vol. vii., No. 4). The normal heart-beat starts at a locality known as the sino-auricular node, and spreads in all directions over the auricle. When the wave of excitation reaches the extremities of the auricle it cannot pass back because it is dammed by the refractory period of the contracting auricle. In auricular flutter the wave of excitation passes down one side and up the other, so that it reaches the starting point after the muscle has relaxed. Thus the wave can follow in the same direction and a "circus" movement becomes established. The result is that the auricle beats at a rate of more than 300 contractions per minute. It is not known why the auricle allows the wave of excitation to pass in one direction only, but once it is started it continues because the auricular muscle relaxes just before the wave of excitation reaches it, and the wave of excitation does not catch up to the refractory period of the contracting muscle.



DR. J. RUNNSTRÖM, of the Zootomical Institute, Stockholm, has long been occupied with experiments on Echinoderm larvæ. Among others, he has cut away portions of the larvæ and observed the further development either in those portions or in the individuals from which they have been removed. In *Bergens Museums Aarbok*, 1917–18 (1920), he tells us how he has removed from the larva of a sea-urchin (*Parechinus miliaris*) the sunken area that would in the normal course of metamorphosis produce the young urchin. This did not prevent the formation of a new sinking or infolded sac of similar character, though, owing to the regeneration of the hydrocœl (whence the characteristic water-vascular system develops), the formation of an actual echinoid did not proceed. Even a fragment removed from the same side (the left) of the larva displayed a like infolding, so that a single larva might thus be induced to form three sacs. These results show that in this case the laying down of an organ does not, as Driesch has supposed, limit the faculty of the remaining cells to form a corresponding organ, or perhaps one should say "of the neighbouring cells," for fragments removed from the right side of the larva produce, not an echinoid sac, but an infolding that seems to represent the formation of a new larval gut. In larvæ from which the echinoid rudiment has been removed further deviations from the normal process occur and resemble changes observed in some abnormal holothurian larvæ—an observation of much theoretical importance.

IN recent years dried blood has appeared frequently on the market as an animal food, and, considering the large quantities of this material which are available daily from the abattoirs of Great Britain and the increasing difficulties of obtaining nitrogenous food for animals, an inquiry was started as to the value and safety of utilising dried blood as a nitrogen-supplying food. Blood collected in small quantities and stored before drying is useful only as a manure, but blood which is dried immediately after collection may be used as animal food. Mr. L. F. Newman, in the *Journal of the Ministry of Agriculture* for June last, contributes the results of some feeding experiments with dried blood. He concludes that the addition of blood to an ordinary farm ration of wheat offals may cause considerable gain in weight compared with the results from a diet of offals only, while the addition of blood to plain maize-meal may give an increase equal to the results obtained from feeding offals only. Another material which has been suggested as animal food is the bracken rhizome, and a paper by Prof. James Hendrick on "Bracken Rhizomes and their Food Value" appears in the Transactions of the Highland and Agricultural Society of Scotland (1919). Prof. Hendrick carried out preliminary feeding experiments which indicated that bracken rhizomes are not rich enough in the more valuable food constituents to be of much use for anything but maintenance purposes, and even here their usefulness is limited because they are not palatable to certain classes of stock. During the last forty or fifty years, however, considerable damage has been caused by the spreading of bracken on good pasture lands, and it is possible that by utilising the rhizomes for animal food the infested areas can be cleared without incurring much loss.

THE October issue of the Journal of the American Chemical Society contains a long paper by Mr. W. D. Harkins on the structure of atoms. Evidence is given for the statement that atoms in which the ratio of negative to positive electrons in the nucleus is high are rare, both in meteorites and on the earth. Suggested constitutions are assigned to the nuclei of the more abundant light atoms. The constituents of atoms are regarded as α-particles, positive electrons (hydrogen nuclei), electrons, particles of mass 3 (ν-particles), and secondary structures of positive and negative electrons (μ-particles).

Engineering for November 5 contains an illustrated account of a large depôt to be used for the storage of wool, now approaching completion at Hull. This building is being constructed for the Ministry of Munitions by Messrs. Nissens, Ltd., of Birmingham, and is a development of the well-known Nissen hut, which proved its practical utility on a wide scale so successfully during the war. The area covered is approximately 10 acres, and construction was commenced only on June 16 last. The depôt consists of eighteen buildings of the Nissen type, each 552 ft. long by 40 ft. wide, all communicating. Each semicircular rib is made up of five segments joined by fish-plates; the ribs are held together by wood purlins. The buildings are double-skinned, with an air-space of 7 in. between the inner and outer linings of galvanised corrugated sheet, and are thus damp-proof and not affected by condensation. Only forty men, on piecework, have been employed, and the rate of building has been approximately one bay of 552 ft. completed per week. The form of construction has several advantages, and is suitable for many purposes. Buildings of practically any length can be made; they are absolutely weather-proof, are capable of erection by unskilled labour, and if lined with 2-in. plaster slabs will be found as cool as brick buildings.

Our Astronomical Column.

THE ECLIPSE OF 1922 IN AUSTRALIA.—Further details concerning this eclipse have come to hand. Mr. W. E. Cooke, the Government Astronomer of New South Wales, has visited various points on the Queensland railway within the totality track, and sends a pamphlet containing his experiences. The inhabitants of the villages are willing to give all possible help to observers. The weather prospects are distinctly hopeful, though the altitude of the sun in this region will not be great (26° at most). The most easterly and most accessible station is Stanthorpe, on the Dividing Range, 2656 ft. high, a favourite summer resort, having several good hotels. Those undertaking observations of a delicate nature should go further inland, to Coongoola or Goondiwindi. As there is a branch of the British Astronomical Association in New South Wales, there is reason to hope that all these stations will be occupied. The west coast of Australia in the neighbourhood of Condon or Wallal is favourable as regards height of sun and probability of a clear sky. Mr. H. A. Hunt, the Commonwealth Meteorologist, notes that Wallal, which is a telegraph station, might be reached from Port Hedland, 150 miles to the west-south-west by pearling lugger; a steamer visits Port Hedland about once a month. Mr. Hunt considers the weather prospects much more hopeful here than in Christmas Island. Another possible locality is in Central Australia, near the telegraph station of Charlotte Waters, which is 110 miles from the head of the railway at Codnadatta.

JUPITER'S SATELLITES.—Mr. R. T. A. Innes has carried out a regular series of observations of the eclipses of these satellites, especially of I. and II., since 1908; he gives the main results in Union Obs. Circ. No. 50. On comparing the observed duration of eclipse with the tabular value, there is a regular wave in the residuals with a six-year period, from which it is inferred that the tabular inclination of Jupiter's equator to its orbit needs a positive correction; it is indicated with less certainty that the node of the equator on the orbit needs a negative correction. The tabular values of mean longitude at epoch need the following corrections: I., $-0{\cdot}080°$; II., $-0{\cdot}031°$; and III., $-0{\cdot}006°$. These results are of interest, and they show that the idea, so generally held, that ordinary visual observations of these eclipses are no longer of use, is not correct.

Mr. Innes appeals to all observers to unite in observing the eclipses with special care for the period 1920 December 9 to 1921 May 31. The month February 18 to March 18 may be omitted, as eclipses then take place very near the primary. The disappearance of the last speck of light and the re-appearance of the first speck are the phenomena to which attention should be specially directed. The aperture and condition of seeing should be noted. Mr. Innes points out that observations of satellite I. afford a delicate test of the constancy or otherwise of the earth's rotation.

THE ORIGIN OF SPECTRA.—Dr. H. H. Plaskett contributes an interesting article on spectra to the Journal of the Royal Astronomical Society of Canada (vol. xiv., p. 7). The paper summarises Nicholson's work on the atom and that of Planck and Einstein on the quantum theory of light. It is pointed out that there are some serious difficulties in the quantum theory. "Interference can be obtained with a path-difference of more than a million wave-lengths. This seems to require that the quantum must have this length (several feet) in space. Further, the experimental fact that a 3-ft. O.G. has a higher resolving power than a 3-in. can only be interpreted as meaning that the quantum has a 3-ft. cross-section. It is difficult to see how a quantum of such dimensions is indivisible, and if it is, how any light gets into a 3-in. telescope." It is suggested that the facts seem to require some compromise between the undulatory and quantum theories; in fact, the author considers a satisfactory theory of radiation as the first desideratum of future progress, the second being a solution of the three-body problem as applied to the more complex atoms.

Dr. Silberstein's suggestion that the atomic nucleus may not be a homogeneous sphere of positive electricity, but a collection of point charges, is shown to remove some difficulties, but to create others, which have not yet been solved.

The Bulawayo Meeting of the South African Association.

THE eighteenth annual session of the South African Association for the Advancement of Science was held in Bulawayo, Southern Rhodesia, on July 14–17, with Dr. I. B. Pole Evans as president. There were the usual receptions and functions, together with visits to the Khami ruins, the Matoppos, the Victoria Falls, and Livingstone. A party, after the conclusion of the official meeting, visited the Great Zimbabwe.

More than sixty papers were read in the various Sections, and the attendance was a large one, more than 130 members proceeding by special train from the Transvaal, as well as some from the Cape Peninsula and Natal.

The president, Dr. I. B. Pole Evans, Chief of the Division of Botany and Director of the Botanical Survey of the Union, gave a most interesting address on "The Veld: Its Resources and Dangers," the address being illustrated by a series of beautiful lantern-slides. He reviewed recent progress in botanical knowledge, and outlined the notable advance that had been made by the members of the Botanical Survey in respect to systematic ecology, indigenous grasses, fungi, and poisonous plants. By "veld" is meant the natural vegetation of the country. The botanical regions correspond to a large extent with the geological formations, and nineteen types of veld, each with its own characteristic flora, can be identified. An outline was given of the geographical and geological features, climatic conditions, predominant flora, and plants of economic importance of each region. The grasses, poisonous plants, and those yielding drugs, fibres, oil, rubber, timber, and tanning materials, were noted. The need for co-operation among workers in different fields of research was strongly urged, and was illustrated by reference to the co-operation of botanists and veterinarians in the elucidation of certain stock diseases due to poisonous plants. The need for the closer association of the botanist and chemist for the investigation of various problems in animal nutrition was indicated. In conclusion, the president stated: "The investigation of such questions is of enormous importance from an economic point of view, and when such problems are scientifically and systematically attacked the veld will yield a hundredfold its present resources, and its dangers will correspondingly decrease and diminish."

Mr. H. E. Wood, of the Union Observatory, Johannesburg, as president of Section A, gave an address on "Recent Progress in Astronomy," noting that the present year was the centenary of the foundation of the Royal Observatory at the Cape. A very interesting comparison of the astronomical knowledge of a hundred years ago with that of the present day was given. The problem of the measurement of the distance of the stars by various methods was outlined, and the rapid progress due to the use of the blink microscope described. An account of the helium stars, of the behaviour of the variable stars, and of the important results accruing from the combined investigation of their absolute magnitude and spectroscopic constitution was given.

"Geology in Relation to Mining" was the subject of the presidential address to Section B, given by Mr. F. P. Mennell, who has seen all the later developments in the mining industry of Rhodesia. A detailed account was given of the ways in which the economic geologist could aid countries like the Union of South Africa and Rhodesia by showing that their internal resources were sufficient in kind and amount to form the basis of essential industries without overseas aid. Gold, chromite, coal, zinc, iron, and copper are present, and in the production of chromite Rhodesia leads the world. The structure of the Rhodesian gold-bearing rocks and its influence on the development of such reefs industrially were set forth. In conclusion, it was pointed out that the mining industry led to the manufacture of such products as pipes, wire, and chemicals on the spot, and so to the establishment of local industries.

Dr. T. R. Sim, late Government Forester in Natal, delivered the presidential address to Section C on "Causes Leading towards Progressive Evolution of the Flora of South Africa." He showed that change in the flora was continuously going on, and that there was an interaction between flora and climate. These interactions cause a definite trend, not necessarily in the direction of new species, but in the gradual disappearance of what were climax types. The influence of cultivation, bush-cutting, and climatology on flora was considered, while sun-spot cycles and rainfall cycles were described in considerable detail By the prevention of grass-burning, by forest maintenance, and by increasing the area under exotic trees the amount of moisture retained and reprecipitated could be vastly increased; thereby a more temperate method of rainfall would result, and consequently less erosion of the soil occur.

In Section D the presidential address was delivered by Mr. C. W. Mally, Cape Entomologist, whose subject was "Some Zoological Factors in the Economic Development of South Africa." The need for a zoological survey of the Union was mentioned, and the problem of the blending of white and coloured races was discussed and disapproved. The problem of "big game" was considered. Entomological research in relation to human and animal diseases and to agriculture was outlined, and the insect pests of maize, wheat, and olives were described. Fluctuations in the relative abundance of insects over various periods appeared to be more or less inexplicable. An account was given of some results achieved in combating insect pests of crops by the use of insecticides and natural enemies. A plea for adequately trained men for scientific research in South Africa concluded the address.

The Rev. H. A. Junod, president of Section E, gave a most interesting address on "The Magic Conception of Nature among Bantus." He outlined the peculiar difficulties in connection with the mentality of natives, and showed the necessity for a proper knowledge of their laws and customs by the dominant race. The Bantu mind does not concern itself with causes, but believes that any abnormal phenomena such as drought or disease are produced by spiritual agents who possess the power of witchcraft. Numerous interesting examples of the reasoning by analogy of the Bantu were given, and a demonstration of the native magic practice of "bone-throwing," together with a most interesting explanation of the symbolism, was presented. This ingrained magic conception was the stumbling-block to Bantu progress.

"Labour Conditions in South Africa" was the subject of Prof. R. Lehfeldt's presidential address to Section F. The problem is complicated by the presence of many natives. The sharp barrier between the races leads to the production of the "poor white" class, who become destitute and lazy while clinging to the remains of racial pride. The same condition prevents the more intelligent members of the native races from rising. Rural colonies failed for various reasons, and the great majority of the destitute cannot become independent farmers, but must work for wages. Native labour is cheap, and so forms an obstacle. A policy of segregation of the races in different parts of South Africa is almost impossible economically. The address closed with an aphorism: "A country will, in the end, belong to the people who do its work."

An evening lecture was delivered by Prof. J. A. Wilkinson on "The Nitrogen Problem." The South Africa medal and grant were awarded to Prof. E. Warren.

It is only possible to notice briefly a few of the many papers read before the various Sections, but most of them will be printed in the Journal of the Association.

In Section A, Prof. P. G. Gundry read an interesting paper on the effect of high temperature and the elevation of aerodromes in the taking-off of aeroplanes. Prof. W. N. Roseveare contributed a short note on Einstein's planetary equation. Father Goetz wrote on rainfall and barometric variation in Bulawayo.

Messrs. A. M. Macgregor, H. B. Maufe, and A. J. C. Molyneux contributed papers on the geology of Southern Rhodesia to Section B. Mr. G. N. Blackshaw investigated magnesia-impregnated soils, and concluded that the most economical treatment for them was liberal dressings of kraal manure. Such soils occur in the Great Dyke of Southern Rhodesia. Mr. E. V. Flack has analysed samples of bat guano deposits in Rhodesia. They vary in composition, but often the addition of sulphate of potash or nitrate of soda or superphosphate greatly adds to their value as fertilisers.

Dr. P. van der Bijl contributed a monograph on the Polyporeæ of South Africa to Section C. Prof. D. Thoday described the ericoid leaves of the Maquis of the Cape Peninsula, and Mrs. Thoday gave an account of the seed of *Gnetum gnemon*. Dr. E. Marion Delf discussed the distribution of accessory food-factors in plants, and Dr. T. R. Sim read a paper on South African ferns. Mr. A. O. D. Mogg described an interesting method of veld estimation by counting plants in transects, while Prof. S. Schonland discussed certain Crassulaceæ found in Rhodesia.

Papers on the causation of "lamziekte" were contributed to Section D by Sir Arnold Theiler, and from another point of view by Dr. E. R. Hartig. The former has found that bone-meal satisfies the abnormal craving exhibited by cattle suffering from the disease, and farmers in "lamziekte" areas, such as around Vryburg, are being advised to add bone-meal to the rations of their infected cattle. Dr. Annie Porter described the life-history of the African sheep and cattle fluke, *Fasciola gigantica*, and exhibited specimens. She has proved experimentally that the intermediate host is the snail, *Limnaea natalensis*, in which the young stage, *Cercaria pigmentosa*, occurs. Prof. H. B. Fantham gave an account of his continued observations on various parasitic protozoa found in South Africa. He has shown that there is a seasonal variation in the occurrence of the spores of *Sarcocystis tenella*. Mr. J. Sandground contributed an interesting paper on the economic importance of a study of Nematodes, mentioning his researches on *Heterodera radicicola*. Mr. S. H. Skaife described a Tachinid parasite of the honey-bee.

In Section E, Mr. N. H. Wilson, of the Rhodesian Native Affairs Department, gave a paper on the future of the native races there, and considers that it is necessary to allow both white and black to make full economic use of their abilities with the white man as a directing and predominant partner. The Rev. H. A. Junod, in describing some features in the religion of the Ba-Venda, mentioned that they have two sets of religious institutions, ancestor worship and a vague monotheistic notion. The Rev. W. A. Norton described some of his ethnological and linguistic studies in Bechuanaland.

A paper on agricultural economics by Prof. R. A. Lehfeldt, and one on geographical method by Mr. J. Hutcheon, were contributed to Section F.

Johannesburg is now the seat of the headquarters of the Association, and the next meeting will be held at Durban in July, 1921. H. B. F.

Geography at the British Association.

AFTER the presidential address by Mr. J. Macfarlane the proceedings of Section E began with a paper by Mr. D. Lleufer Thomas on some geographical aspects of the distribution of population on the South Wales coalfield. The main coalfield of South Wales comprises about 780 square miles. It is chiefly an elevated plateau with an average altitude of 1000 ft., rising in North Glamorganshire to some 2000 ft., and is deeply scored by narrow, declivitous valleys. These valleys open by narrow gaps to the coastal plain. The result of these conditions is that the population, which is mainly dependent on the coal outcrops, is pent up in the valleys and somewhat removed from the outer world. Another determining factor in the location of population was the occurrence near the coal of raw materials valuable in manufactures, such as iron, or sites offering special facilities for the assembling and treatment of imported materials, such as Swansea, which attracted the copper of Cornwall. Until nearly the middle of the nineteenth century coal-mining was entirely subsidiary to iron-making, and the development of the coalfield was therefore confined to its outer fringes, leaving the whole of the interior as sparsely populated as in the pastoral age. Development gradually spread southwards from the iron centres down the valleys. The present congestion of population is of comparatively recent date. The population is recruited mainly from the West Midland Counties, especially the British district, and to a less extent from the south-western counties. As a result, Monmouthshire and, to a less degree, East Glamorganshire have been anglicised in speech. In the discussion following the paper Mr. H. J. Randall emphasised the transitory nature of the population referred to and its complete dependence on coal production and demand.

Dr. A. E. Trueman read a paper on the iron industry of South Wales. The distribution of the industry was determined by the working of ironstone nodules, which are richest in the eastern part of the coalfield. Local hæmatitic ores have had little effect on the industry. The ironstone nodules were originally collected in stream-beds and worked chiefly along the northern outcrops, where the dip is less steep than in the south. With the deforestation of the country smelting declined, but revived in the nineteenth century with the use of coal. The phosphatic nature of the nodules rendered them unsuitable for the manufacture of steel by early processes, and the output of local ore gradually decreased. At present it is only a few thousand tons a year, most of which is sent to Staffordshire for smelting. The South Wales iron industry is now dependent on imported ores, chiefly hæmatite from Spain. While it persists in the north-eastern part of the coalfield, where it originated, there is some tendency to move the industry to the coast in order to save transport.

Mr. A. E. L. Hudson directed attention to an interesting scheme initiated by the Welsh Department of the Board of Education for the collection of rural lore by the schools of Wales. The scheme affords at the same time an excellent opportunity for the collection of regional survey material, and so introduces this important aspect of geographical teaching into the school curriculum.

Lt.-Col. W. J. Johnston described the methods employed for the production of small-scale Ordnance Survey maps. The introduction of colour in the one-inch maps in 1894 caused a decreased demand for the engraved form. Printing from copper plates is a slow process, and with the large editions necessitated nowadays is practically out of the question. At the best about 20 copies an hour can be printed in one colour from a copper plate, while a modern rotary machine can produce 2000 copies in the same time. Lithography is therefore superseding copper-plate printing in this and other countries. Col. Johnston discussed at length the various methods and showed numerous specimen sheets. He dwelt on the advantages of drawing on paper and then making direct zinc plates by means of photo-zincography. This is not only the quickest method and allows of rotary printing, but it also admits of fresh fundamental plates being made in a few hours without any risk of the subsidiary plates being out of register. For all practical purposes the glass negative is a permanent record, and has the advantage that corrections in detail can easily be made on it.

Capt. H. Allan Lloyd discussed the essentials of maps for aviators. Speaking from much experience on the Western Front, he considered that in order to be of value aerial maps must incorporate details of the outstanding features of town-planning and the nature and characteristics of the ground as seen from the aerial viewpoint. Opinion was far from unanimous as to the amount of detail necessary, but aviators were agreed that the topographical map made for land travel was not suited for their purposes. Natural and artificial features which attract the eye must be emphasised, and detail which is not distinctive, as well as most of the names, must be omitted. Capt. Lloyd believed that aerial maps should show the distinctive plan of each town exaggerated beyond the scale of the map in order that such prominent landmarks as towns might be recognisable by a fleeting glance through a rift in the clouds. Aerial maps of the future, in order to be widely useful, must meet the needs of the man half-trained or practically untrained in map-reading. Capt. Lloyd proposed also to distinguish between certain types of terrain, each characterised by shapes of fields, density of buildings, or other features, and to indicate these on the map, adding illustrations of the types in the margins.

The Section met jointly with Section L (Education) to hear Prof. W. L. Myres open a discussion on the place of geography in a reformed classical course. Recent decisions regarding "compulsory Greek" compel drastic revision of classical teaching. With the postponement and restriction of language courses the aim must be earlier acquaintance with ancient conduct and thought through a closer co-ordination between history, literature, and geography. The Mediterranean region forms a natural supplement to homeland geography, and is a unity bound together by the sea. A study of Mediterranean geography, with its emphasis on outdoor life, the outcome of its climate, and its dependence on woodland in place of grassland, is invaluable in giving a sense of proportion to the study of the geography of the British Isles. Prof. Myres regretted the lack of a good account of Mediterranean geography in English. The discussion was continued by Sir Robert Blair, Mr. G. G. Chisholm, Mr. H. O. Beckit, and the Rev. W. J. Barton. Mr. Beckit insisted that the study of geography saves history from becoming an abstraction and gives it reality. Mr. Chisholm pointed out the need for correlating history, geography, and literature with the adequate study of economics.

The Rev. W. J. Barton read a paper on the oases and shotts of Southern Tunis, and Dr. E. C. Jee contributed a paper on the movements of the sea to a joint meeting of Sections D and E. Dr. R. N. Rudmose Brown directed attention to the urgent scientific needs of the exploration of the oceans on a large scale with modern equipment and methods. In this connection the Section supported the movement initiated by Section D, urging the Government to undertake an oceanographical expedition at least comparable in scale with that of the *Challenger*.

Prof. E. H. L. Schwarz lectured on the Kalahari and the possibilities of its irrigation. In the 300,000 square miles which comprise the Kalahari Desert there are three great depressions which formerly held water. These are the Ovamboland, Etosha, and Great Ngami depressions. Prof. Schwarz outlined his scheme for a weir on the Kunene, by which the waters of that river could be turned into Ovamboland and restore the country to fertility, the surplus water finding its way to the Etosha. By weiring the Chobe its waters would be prevented from passing to the Zambezi, and could be made to flow to Ngami.

Dr. Vaughan Cornish, in a lecture on Imperial capitals, discussed the positions of the great capitals of ancient and modern times, particularly in reference to strategic considerations. Imperial capitals, as a rule, have not been, and are not, in the centre of their dominions, but in a position between this and the most important frontier. Such a position combines the best site for the administration of domestic affairs, which is the natural crossways of routes nearest to the centre, with the most suitable place for military headquarters and foreign relations, which is towards the principal frontier.

Dr. T. Ashby read a paper on the water-supply of ancient Rome. He dealt mainly with the four important aqueducts, the Anio Vetus and Anio Novus, which drew their supply from the Anio River, and the Aqua Marcia and Aqua Claudia, which made use of springs in the Anio Valley. These still form the most important source of supply for the modern city.

The work of the Section concluded with a paper by Principal E. H. Griffiths and Major E. O. Henrici on the urgent need for the creation within the Empire of a central institution for training and research in the science of surveying, hydrography, and geodesy. The work of such an institution would be to train surveyors by the most modern and exact methods and to turn out men suitable for the various Survey Departments of the Empire; to keep surveyors in touch with the activities and progress in all parts of the world; to give instruction in hydrographic surveying; and to conduct research in problems concerning the tides, terrestrial magnetism, and geophysics generally, particularly in the higher branches.

During the meeting of the Association a collection of maps illustrating various aspects of the geography of South Wales, arranged by the Cardiff branch of the Geographical Association, was exhibited in the reception-room in the City Hall.

National Union of Scientific Workers.

THE annual meeting of the council of the National Union of Scientific Workers was held at King's College on November 13. In his address Dr. J. W. Evans, the retiring president, dealt with the subject of "Research at the Universities." Dr. Evans paid a tribute to the achievements of scientific workers during the war, and pointed out that the task ahead of them was of even greater consequence and allowed of no relaxation of effort. After summarising the activities of the Department of Scientific and Industrial Research, he expressed dissatisfaction with the present attitude of this Department towards the scientific and technical faculties of our universities. Since the publication of its first report the Department appeared to have abandoned the more fruitful policy of encouraging to the utmost the research workers at the universities. The restrictive character of the present grants to individual workers at such institutions tended to divorce research from teaching. In his opinion this was a fundamental error, since the best results in research could be achieved only by those who devoted some time to teaching. Apparently the Department looked to the universities and technical colleges to maintain a supply of competent research workers for the State-aided research associations rather than to undertake industrial research for themselves. He considered that a teaching staff engaged in research work, both in pure science and in its applications to industry, was in a more favourable position to discover and develop new principles than research workers isolated and restricted in the laboratories of research associations or even Government research institutions. In conclusion, Dr. Evans urged the importance of universities including in any course in science some training in research methods. This he embodied in a resolution which was supported by Prof. Soddy, who stated that Prof. Perkin had already applied this principle to the chemistry courses at Oxford University. Chemistry students there had shown by their enthusiasm how much the change was appreciated.

Continuing, Prof. Soddy said that since the president had prepared his address there had been a complication brought about by a request from the War Office that the universities should undertake research into the development to the utmost extent of chemical warfare research for offensive and defensive purposes. He expressed the view that it was a matter that must inevitably be considered, sooner or later, by the union. It ought to be considered before rather than after the occasion arose. He was glad that the executive of the union had already decided to appoint a committee to go into the whole question.

The resolution disapproving of the policy of the Department of Scientific and Industrial Research, in establishing and financing research associations, which hands over to the private use of profit-seeking monopolies valuable knowledge obtained at the expense of the whole community, and places the research associations in a position to exploit the scientific workers of the country for their own benefit, was carried unanimously. Prof. Soddy stated that the Government had capitulated to the big business interests in politics and departed altogether from its original intentions. There was no greater example of unfair competition than in the chemical industries.

Mr. A. A. Griffith, in moving a resolution that for the present Advisory Council of the Department should be substituted a council elected on different principles, pointed out that there could be little effective criticism of the Department under the existing arrangement whereby the Government practically appointed its own critics. It was certain that a council part of which was elected by democratically constituted scientific organisations would result in more careful scrutiny and criticism of the acts of the Department.

A resolution by Mr. F. A. Potts to the effect that scientific workers employed as whole-time officials in Government Departments should enjoy status and pay not less than those enjoyed by the administrative class of Civil Servants was carried unanimously.

Prof. Leonard Bairstow was elected president for the ensuing year.

University College of Swansea.

THE University College of Swansea, which was incorporated in January of this year and made a constituent college of the University of Wales by a new University charter sealed as recently as August 13, opened its first session on October 5. The court of governors of the college held its annual meeting on Monday, November 15, and at the conclusion of the meeting the principal, Dr. T. Franklin Sibly, delivered an inaugural address.

After paying a tribute to the pioneers of the university movement in Wales, the principal recalled the fact that the local initiative and private benefactions which brought the college into being had their mainspring in the demand for scientific teaching and research which should benefit the great industries of the district. But no time was being lost in making provision for a faculty of arts, in willing response to the insistent local demand which arose from the conviction that a one-sided institution could possess no full title to university rank. It was, however, in the domain of science that the college would always discharge a large part of its mission; and Dr. Sibly laid emphasis upon the true humanity of the man of science and the nobility of the scientific ideals of a search for truth and of a disinterested co-operation with other workers.

The college was situated in the industrial heart of Wales. The leaders of local industry, headed by the president of the college, Mr. F. W. Gilbertson, were displaying a unique degree of enlightenment and generosity in their support of the college. To the original endowment fund of some 70,000*l.* they had already added donations amounting to more than 4000*l.* and subscriptions which totalled more than 6000*l.* per annum. The subscriptions, having been promised for a period of five years, were expected to earn an equivalent annual grant from the State. Dr. Sibly believed that the workpeople of the district would prove no less staunch as supporters.

The Municipality of Swansea, which had promoted the college, had already given a magnificent site of forty-five acres in Singleton Park, offered the use of Singleton House, and promised further support. The college set the highest store on all grounds by its close association with the town.

There were, however, some serious material disadvantages. The adverse factors of inflated prices and depreciated currency were all the more serious in view of the relatively heavy cost of staffing and equipping technological departments. The measure of State aid in sight was quite inadequate.

Outlining the range of their activities and the spirit in which they entered upon them, the principal laid stress upon their work in applied science on one hand, and upon the extra-mural field open to them on the other. They possessed the means of building up a great school of metallurgy which would work in the closest co-operation with industries at its very doors. A strong department of mining and fuel technology would be essential to the future development of the college, but the funds needed for its inception were not yet forthcoming. They realised the vital importance of research in these fields as in others. Adult education was one of the greatest problems of the modern universities, and they sought to take the university to the people in the fullest possible measure.

It was a duty and an essential of success to associate themselves as closely as possible with local needs and national aspirations, but they had also to play their part in the world-mission of the universities. They were laying the foundations of a great institution which would exist and work in order to enrich the life of the people.

University and Educational Intelligence.

BIRMINGHAM.—The Huxley lecture is to be delivered in the Mason College on Friday, November 26, by Prof. C. S. Sherrington, who has chosen as his subject "The Gateways of Sense." The lecture is open to all members and friends of the University.

EDINBURGH.—Dr. John Stephenson, until recently professor of zoology in Government College, Lahore, has been appointed lecturer in zoology in the University.

OXFORD.—On November 16 Convocation passed a cordial vote of thanks to Prof. James Mark Baldwin for his offer to pay for the present, in honour of his friend, Prof. Poulton, an annual sum of 100*l.* into a fund to be called "The Edward Bagnall Poulton Fund," to be applied at the discretion of the Hope professor of zoology for the time being in the promotion of the study of evolution, organic and social. Prof. Baldwin has also announced his intention of leaving by will moneys for the sustentation of such a fund.

The nomination by the Council of the Royal Society of Prof. C. S. Sherrington, Waynflete professor of physiology, to the presidency of the society has given great satisfaction throughout the University.

MR. G. S. ROBERTSON has been appointed lecturer on agricultural chemistry in the newly founded department of agriculture of the Queen's University of Belfast.

LORD ATHOLSTAN has given 100,000 dollars (more than 25,000*l.* at the current rate of exchange) to the special fund now being raised by McGill University, Montreal.

THE Toronto correspondent of the *Times*, in illustration of the liberal attitude of the Quebec Government towards education, states that the Legislature will be asked to vote 1,000,000 dollars (approximately 250,000*l.*) to McGill University.

COL. S. L. CUMMINS, who in 1913 succeeded Sir William Leishman as professor of pathology of the Royal Army Medical College, Millbank, has been appointed to the new chair of tuberculosis at the Welsh National Medical School, founded by Major David Davies, M.P.

WE learn from the *Times* that the Government of Burma has decided to establish a university at Rangoon. The administration will be in the hands of a council, with an executive committee, comprising representatives of such bodies as the Burma Chamber of Commerce and the Rangoon Trades Association, while matters connected with teaching will be in charge of a Senate composed almost exclusively of professors and lecturers.

DR. RUSSELL WELLS, Vice-Chancellor of the University, was entertained at a house dinner at the University of London Club on November 10. Lord Moulton, who presided, paid a high tribute to Dr. Wells's work for the University, referring particularly to his success in raising 300,000*l.* for degrees in commerce, mainly from men of business. Work of this kind tended, he said, to break down the isolation which was so frequently the bane of universities. Dr. Wells said that their object was to make the University of London in the educational world what the City of London was in the world of commerce.

THE first Congress of Universities, which was held in London in 1912, was a conspicuous success. All the universities of the Empire, to the number of fifty-three, were represented, in most cases by their executive heads, together with several of their professors. The report of the proceedings, an imposing volume of some 460 pages, is a valuable contribution to the politics of education. The Universities Bureau was an outcome of this congress. To it was entrusted the summoning of future congresses at intervals of five years. The war prevented this intention from being carried into effect, and, since hostilities ceased, the great pressure under which the universities have been working has made it impossible for their representatives to gather from the four corners of the Empire earlier than next summer. It has now been arranged that the second congress shall be held in 1921. Dr. Alex Hill, who organised the first congress and has acted as secretary to the Bureau since its institution, is engaged in its promotion. The number of universities in the Empire has now increased to fifty-eight. It is hoped and anticipated that all will make a point of sending delegates to this great council on higher education. With great generosity the University of Oxford has invited all members of the congress to be its guests on July 5–8. The Chancellor of the University, Lord Curzon, will preside over the morning session on July 5, and Mr. A. J. Balfour, Chancellor of the University of Cambridge, will preside in the afternoon. On the preceding day the congress will assemble in London for certain ceremonial functions and entertainments, of which the programme will be announced at a later date. During the fortnight preceding the meeting of the congress members from overseas will visit the various universities of the United Kingdom in turn, in order that they may become acquainted with their methods and resources.

Societies and Academies.

LONDON.

Royal Society, November 11.—Sir J. J. Thomson, president, in the chair.—Dr. W. G. **Ridewood**: The calcification of the vertebral centra in sharks and rays. In the course of the inquiry 150 sharks and rays, belonging to 68 species and 44 genera, were examined. The investigation largely resolved itself into ascertaining the limits of the three component cartilages of the definitive centrum, namely, the sheath-cartilage, the arch-cartilage, and the perichondrially produced cartilage, and studying the relations of the calcified lamellæ to these parts. Similarity in pattern of the calcified lamellæ is shown in certain cases to be homoplastic, the lamellæ being developed in sheath-cartilage in some genera and in perichondrial cartilage in others. In some cases the similarity may be accounted for by convergent degeneration from ancestral types which there is reason to believe were themselves different in their mode of calcification. The distribution and proportions of the three kinds of cartilage composing the centrum are of greater morphological importance than the disposition of the calcified lamellæ in them, and the difference between chorda-centra and arco-centra is relative rather than absolute. In some cases (Lamnidæ) the centra possess so little sheath-cartilage that they approach the arco-centra of Esox and Amia.—Dr. A. **Compton**: Studies in the mechanism of enzyme action. I.: *Rôle* of the reaction of the medium in fixing the optimum temperature of a ferment.—C. H. **Kellaway**: The effect of certain dietary deficiencies on the suprarenal glands. Changes in the size and adrenalin content of the suprarenal glands of pigeons were found constantly when the diet consisted of polished rice alone, or when an adequate ration of protein or of fat was added to the dietary, and were associated with the appearance of polyneuritis. The daily administration of a sufficient amount of "Marmite" to the diet of polished rice prevented these changes from occurring. An attempt was made to explain the enlargement of the adrenals as being due partly to congestion and œdema of the gland-tissues, and partly to the storage in the cortex of the gland of lipoids set free by the breaking down of body-tissues. The investigation of the cholesterol content of the adrenals of normal and polyneuritic birds did not support this theory of lipoid storage. The increased residual content of adrenalin was attributed to diminished output of adrenalin, as a result of the greatly lowered metabolism in birds fed on deficiency dietaries. The histological appearances of the glands suggested obstruction of the venous outflow from the medulla by cortical hypertropy as an additional cause. Œdema in birds fed on deficient diets was of infrequent occurrence, and could not be produced by the daily administration of large doses of adrenalin. It does not appear to be causally related to an increased output of adrenalin.—E. J. **Collins**: The genetics of sex in *Funaria hygrometrica*. Cultures of *F. hygrometrica* from spores reproduced the normal monœcious plants; vegetative cultures derived from the antheridia and the surrounding "perigonial" leaves of the male "inflorescence" produced male plants only, pointing to the probability that a separation takes place such that the element upon which the monœcious condition depends is dropped out of those cells from which the male organ with its surrounding leaves is formed. Vegetative cultures from the archegonium and the surrounding "perichætial" leaves have been made, and have produced typical monœcious plants. The conclusion is that up to the point of the formation of the female organ the cells of the haploid gametophytic phase retain the power to produce monœcious plants, whereas the leaves surrounding the male organ have lost this power. Sex-segregation here occurs in a haploid tissue.

Geological Society, November 3.—Mr. R. D. Oldham, president, in the chair.—Miss M. E. J. **Chandler**: The Arctic flora of the Cam Valley at Barnwell, Cambridge. The Pleistocene loams and gravels at Barnwell, Cambridge, contain peat-seams showing variations in character which are probably dependent on the ordinary laws of transport by water. These seams have added numerous new plants to the small flora previously known to occur therein, so that the floral list now includes about eighty-nine species. The plants identified were grouped as follows: (1) The Arctic element. (2) The plants of wider distribution. (3) The southern element. (4) The calcareous-soil element. (5) The estuarine element. Attention is directed to the complexity of the flora because of its bearing on the whole question of peat deposits in river-gravels. The Arctic floras of the Lea and Cam Valley differ in the occurrence, to a great extent, of different plants and plant-families in the two cases, and in the more pronounced Arctic character, exotic element, and calcareous-soil element in the Barnwell flora. If the floras lived during different cold periods, their discrepancies could be explained by an appeal to the interval of time which separated them; if, as seems more probable from stratigraphical evidence, they lived during the same cold period and were approximately contemporary, the gradual oncoming or decline of the cold, together with the respective geographical situations in the two cases, would probably be a sufficient explanation of their points of dissimilarity.

Aristotelian Society, November 8.—The Very Rev. W. R. Inge, Dean of St. Paul's, president, in the chair.—W. R. **Inge**: Inaugural presidential address on "Is the Time Series Reversible?" The kinematograph has illustrated the possibility of observing events in a reversed time order; is it possible that we might actually move through time in a reversed order so that effects would be thought of as causes? If the positions of earlier and later and of past and future belong to appearance, and not to reality, the real order will be a series, but a series without change and without time. The psychological theory of the "specious present" was criticised, and also the scientific concept of cause. In regard to the first, it was suggested that our consciousness of the present is our point of contact with supra-temporal existence, and that our tendency to identify this experience with the moving line which divides past from future is an error. Immediacy belongs only to a supra-temporal mode of intuition. With regard to the conception of causation, it had been almost driven out of natural science, and it would be a good thing if it were driven out of philosophy too. Time-succession seems to belong to a half-real world and to share its self-contradictions. We are partly in this half-real world and partly out of it. We are enough out of it to know that we are blind on one side, which we should never know if time were real, and we inside it.

CAMBRIDGE.

Philosophical Society, October 25.—Mr. C. T. R. Wilson, president, in the chair.—K. **Tamaki** and W. J. **Harrison**: The stability of the steady motion of viscous liquid contained between two rotating co-axial circular cylinders. It is shown that the steady motion is unstable for one particular type of disturbance, and that a considerable degree of viscosity is needed to give stability in the case of some other modes of disturbance. It is not possible to discriminate on a theoretical basis between the relative stabilities when the inner cylinder is rotating and the outer fixed, and *vice versa*. A criterion suggested by Prof. Lamb is discussed. Further, an explanation is given of the apparent discrepancy between the conclusion of Reynolds that a certain degree of viscosity is necessary for stability and the conclusion of Lord Rayleigh that certain steady motions of an inviscid liquid are stable, without making the assumption that there is a finite difference in behaviour between a viscous and a non-viscous liquid.—M. M. **Riesz** and Prof. G. H. **Hardy**: Le principe de Phragmén-Lindelöf.—G. P. **Thomson**: A note on the nature of the carriers of the anode rays.—M. H. **Cramér**: The distribution of primes.—Prof. G. H. **Hardy**: Note on Ramanujan's trigonometrical function $c_q(n)$, and certain series of arithmetical functions.—L. J. **Mordell**: The representation of an algebraic number as a sum of four squares.—Major P. A. **MacMahon**: The parity of the number which enumerates the partitions of a number.

MANCHESTER.

Literary and Philosophical Society, October 19.—Sir Henry A. Miers, president, in the chair.—C. E. **Stromeyer**: An attempt to explain the real nature of time, space, and other dimensions. The author said that in the remote past doubts seem to have been entertained about the reality of time and space, and of matter it seems always to have been believed that it could be made to appear and disappear. Kant and Schopenhauer were converts to the new belief in the indestructibility of matter, but asserted of time and space that they were functions of the brain. They may, therefore, be looked upon as being the innocent originators of the modern idea that the world is mind and matter. In their days energy and its conservation or indestructibility had not been discovered, but they suspected that besides matter there was another reality which they respectively called "das Ding an sich"—the real thing—and "der Wille zum Leben"—the will to live. They did not explain what they meant by reality, and the author pointed out that they should have said that time and space were relatively unreal to matter and to the "real thing," in the same way that length, breadth, and depth are relatively unreal to space, if this be taken as the standard of reality. The author then said that dimensions, using the term in its widest sense so as to include time, space, velocity, work, pressure, and all the electric, thermometric, and chemical dimensions, were unquestionably factors of energy. Energy always appears as a product of these factors, never as a factor. It stands in marked contrast to every one of its factors in being indivisible quantitatively until it has been divided qualitatively. It cannot be located in the same sense that length may be said to be located in space or a volt in an ampere. Energy, in contrast to its factors or dimensions, seems to be the only "real thing"; all its factors, our world, are relatively unreal, but amongst each other they appear relatively real. Thus, contrary to Kant's and Schopenhauer's views, matter is both as real and as unreal as are time and space. The author also dealt with the fourth dimension, and showed that it was not a real one.

EDINBURGH.

Royal Society, October 25.—Prof. F. O. Bower, president, in the chair.—The president delivered an address on "Size: A Neglected Factor in Stelar Morphology." The purpose of the address was the application of the principle of similar structures to certain internal tissues of plants. The principle had been used by zoologists to explain certain peculiarities of the animal body, both external and internal. Botanists had been slower to use it in relation to plants, though it had been pointed out that the limit of size of trees is imposed by the fact that the strength of the trunk increases only as the square, while the weight increases as the cube, of the dimensions. The same relation holds for the limiting surface of internal tissues in proportion to their bulk; as the size increases the surface varies as the square, while the bulk of the tissues enclosed varies as the cube. If, then, interchange of soluble substances through the limiting surface be proportinnal to its area, as the size is increased there will come a limit beyond which further increase is impossible unless the form be altered. This general position was used to explain the very complicated vascular system in certain plants, especially the ferns. The breaking up of their vascular tracts into curiously elaborate masses was held to be a necessary consequence of the need for increased proportion of surface to bulk in the larger forms. It was also exemplified in certain roots of palms and other plants. The reason why the difficulty did not arise in ordinary tree-trunks was that after the early stages the strict limitation of the conducting tracks was broken down. But in fern-stems and palm-roots it was strictly maintained in the adult, and this was what raised the difficulty and accounted for the peculiar structure which they showed.

PARIS.

Academy of Sciences, October 26.—M. Henri Deslandres in the chair.—P. **Appell**: The ellipsoidal oscillations of a liquid sphere.—P. **Termier** and W. **Kilian**: The tectonic signification of the fragments of mica schists, various crystalline rocks, and green rocks which crop out here and there near Briançon in or at the surface of strata of Briançon facies.—C. **Nicolle** and E. **Conseil**: The preventive vaccination of man against Mediterranean fever. Experiments on human subjects showed that it is easy to vaccinate preventively by subcutaneous inoculations of dead cultures. The duration of the immunity has yet to be determined.—R. **Birkeland**: Resolution of the trinomial algebraical equation by higher hypergeometrical functions.—M. **Zervos**: Some transformations of partial differential equations of the second order.—C. **Camichel**, D. **Eydoux**, and A. **Foch**: The transmission of energy by vibrations of liquids in pipes. M. Constantinescu has recently described his researches on the transmission of energy by means of vibratory waves in a pipe full of liquid. As the methods of calculation have not been published, the author develops the theoretical side of the question by the general method given by Allievi.—A. **Buhl**: The symmetries of the gravific field and the Lorentzian extension of Hamilton's principle.—E. **Jouguet**: The variation of entropy in waves of shock of elastic bodies. The variation of entropy is of the third order at least, and hence for small discontinuities the dynamic adiabatic law of Hugoniot is very near the ordinary adiabatic law.—P. **Dejean**: The Ar_3 point of steels and of martensite. In a recent paper by L. Guillet a diagram by M. Chevenard was given relating to iron-nickel alloys practically free from carbon. For alloys between 0 and 25 per cent. of nickel the curve of the Ar_3 points showed no discontinuity, and this appeared to contradict some earlier results of the authors on the critical points of nickel steels containing 0·2 per cent. of carbon. In the present communication it is proved that the two series of results are not contradictory.—M. **Barlot**: Combinations of the halogen derivatives of lead and thallium. A study of the electrical conductivity of aqueous centinormal solutions of $PbCl_2$ and TlCl indicated the existence of a compound $TlCl.PbCl_2$, and this was isolated by cooling a boiling aqueous solution containing the two chlorides in equimolecular proportions. The crystals separating are of a definite form, but after keeping for some time at the boiling point in presence of a quantity of water insufficient to dissolve it, they decompose into the two constituents, readily identifiable under the microscope. Similarly constituted double bromides and iodides were also prepared.—M. **Godchot**: The systematic degradation of dibasic saturated acids of high molecular weight. The method of Bouvet has been successfully extended to suberic, azelaic, and sebacic acids.—A. **Damiens**: The estimation of traces of bromine in organic materials.—G. **Denigès**: An extremely sensitive colour reaction for phosphates and arsenates: its applications. Traces of phosphates treated with an acid solution of ammonium molybdate and a little stannous chloride develop a blue coloration. Arsenates behave similarly.—M. **Marion**: The action of hydrogen peroxide on flour. Solutions of hydrogen peroxide allowed to react with flour under definite conditions (concentration of hydrogen, peroxide, temperature, and acidity) give off oxygen, and this can serve as a measure of the grade of the flour.—J. **Savornin**: The continental Aquitanian in South Morocco.—P. **Bonnet**: The structure of the Caucasian isthmus and its relations with the oil-fields.—S. **Stefanescu**: The phylogeny of *Elephas meridionalis*.—A. **Danjon** and G. **Rougier**: The spectrum and theory of the green ray. Photographs of the spectrum of the green ray show that the theory of anomalous dispersion is untenable; the results are clearly in favour of the theory of normal dispersion, with absorption of the orange by the moisture in the atmosphere.—C. **Dufraisse** and J. C. **Bongrand**: The measurement of the tear-producing power of irritating substances by the *méthode du seuil*. The "*concentration de seuil*" is the lowest concentration which can be detected by its action on the eye in 30 seconds. This concentration for benzyl bromide is taken as unity in the measurements, and, although observers differ in sensibility, the comparative results expressed in this manner are independent of the observer. Figures are given for the principal lacrymogenic substances utilised in the war.—R. **Wurmser**: The action of radiations of different wave-lengths on the chlorophyll assimilation.—L. **Destouches**: Physiological observations on *Convoluta roscoffensis*.—A. **Krempf**: The larval development of *Coeloplana gonoctena*.—P. **Wintrebert**: The embryonic functions of the apparatus of relation in the anamniotic vertebrates.

NAPLES.

R. Accademia delle Scienze fisiche e matematiche, April 3.—Prof. Monticelli, president, in the chair.—G. **d'Erasmo**: Miocene ichthyolites from Syracuse. A description of four species of Teleostomi new to the fossil fish fauna of the calcareous Miocene deposits of the province of Syracuse, of which one (*Pagellus siracusanus*) is new to science, and also one representative of the Elasmobranchi of the genus Carcharias. The paper is accompanied by a plate of *Sparnodus vulgaris*, *Pagellus siracusanus*, and *Callipterix spinosus*.—M. **Picone**: Riemann's integral and its relation to that of Lebesgue.—E. **Pantanelli**: Elective absorption of ions in equilibrated solutions. This is a sequel to the author's investigations on the absorption of ions by plants, in which he employs new experimental methods to elucidate the complex process of absorption of ions in equilibrated solutions, whether modified by the addition of salts with the object of maintaining the same osmotic pressure as that of solutions in which marine or terrestrial plants live, or in experiments with pure salt solutions.

April 10.—M. **Cipolla**: Hardy's criterion of convergence, ii.

SYDNEY.

Royal Society of New South Wales, September 1.—Mr. J. Nangle, president, in the chair.—G. D. **Osborne**: The volcanic neck at the basin, Nepean River. The general geological features of the neck are discussed and a detailed account of the petrology of the rocks occurring there is given. The neck, which breaks through the Triassic rocks at its surface outcrop, is filled with a fine-grained breccia which is intruded by basalt dykes and plugs. The formation of the neck with the production of a long, narrow vent has been effected by explosive action concentrated upon a weak fissure structure lying transverse to the monoclinal fold in that locality. It has played an important part in the physiographic history of the Warragamba and Nepean river systems in Cainozoic times, the present junction of these two rivers being within it. In the breccia there occur fragments of the peridotites cognate with the basalt, and foreign xenoliths of rhyolite, gneissic granite, and sandy limestone. The basalt contains only cognate inclusions of norites, hyperite, harzburgites, lherzolites, dunites, pyroxenites, and troctolite, the last-named recorded for the first time in New South Wales. The cognate inclusions represent fragments of a differentiate which solidified under plutonic conditions. The rhyolite inclusions may have come from the southward extension of the Kuttung series, the granitic rocks from ancient terrains and the calcareous clastic rocks from a now denuded roof of Upper Wianamatta rocks. Chief among petrographical features are the occurrences of two mineral intergrowths, a granophyric one of pleonaste and diopside and a graphic intergrowth of augite and picotite.—R. H. **Cambage**: Acacia seedlings, part vi. The seedlings of seven Acacia species are described. The author stated that one seed-pod of *Acacia farnesiana* had floated in sea-water for more than eleven weeks and another for more than twelve weeks, and as he had previously demonstrated that a seed of that species would germinate after having been immersed in sea-water for three and three-quarter years, he considered the likelihood of the distribution of this species being sometimes effected by ocean currents was strengthened. The twinning of seedlings of *Acacia asparagoides* was recorded, several seeds having produced twin plants.—J. H. **Maiden**: A box-tree from New South Wales and Queensland. This tree, which is described as a new species, seems to deserve the name of "narrow-leaved box" better than all the boxes, its juvenile leaves being narrow-lanceolate and its mature foliage almost as narrow. The fruits are small and the timber pale brown. It is one of the trees known as "mallee box." It differs from *Eucalyptus bicolor*, which has narrow juvenile foliage, in the red timber and thick bark of the latter, and is widely different from *E. Woollsiana*, R. T. Baker, which has broad juvenile foliage. It has been collected from Gilgandra, New South Wales, to Southern Queensland, and is particularly abundant in the Pilliga scrub. The type comes from Narrabri, New South Wales.

Diary of Societies.

THURSDAY, NOVEMBER 18.

ROYAL BOTANIC SOCIETY, at 3.—Prof. A. W. Bickerton: The Relations of Astronomy to Botany. (2) The Value of Basic Principles.
ROYAL SOCIETY, at 4.30.—Sir Arthur Schuster: The Absorption and Scattering of Light.—Prof. O. W. Richardson: The Emission of Electrons under the Influence of Chemical Action.—Dr. A. E. Oxley: Magnetism and Atomic Structure. I.—Prof. A. O. Rankine: The Proximity of Atoms in Gaseous Molecules.—Prof. A. O. Rankine: The Similarity between Carbon Dioxide and Nitrous Oxide.—Dr. A. M. Williams: Forces in Surface Films. Part I., Theoretical Considerations; Part II., Experimental Observations and Calculations; Part III., The Charge on Colloids.
LINNEAN SOCIETY, at 5.—Prof. E. S. Goodrich: A New Type of Teleostean Cartilaginous Pectoral Girdle found in young Clupeids.—Dr. J. C. Willis: Endemic Genera and Species of Plants.
ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.—L. Damblanc: The Problem of the Helicopter.
ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.
INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—J. Morrow Campbell: The Origin of Primary Ore Deposits (Adjourned Discussion).—H. C. Robson: Converting High-grade Matte in Magnesite-lined Converters.—C. Brackenbury: An Automatic Counting Machine for Checking Tram Wagons.
CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. F. G. Crookshank: The Anthropological Study of the Feeble-minded, or Imbeciles and Apes.
INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Ll. B. Atkinson: Inaugural Address.
INSTITUTION OF AUTOMOBILE ENGINEERS, at 8.—London Graduates' Meeting.
CHEMICAL SOCIETY, at 8.
WIRELESS SOCIETY (at Royal Society of Arts), at 8.—A. A. Campbell Swinton: Address.
RÖNTGEN SOCIETY (in Physics Lecture Theatre, University College, Gower Street), at 8.15.—Dr. R. Knox: Presidential Address.

FRIDAY, NOVEMBER 19.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.—Sir William Milligan: Chronic Catarrhal Otitis Media; Some Thoughts and Suggestions.
INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Capt. J. S. Arthur: Sterilisation of Water by Chlorine Gas.
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Section) (at City and Guilds (Eng.) College, Exhibition Road), at 6.30.—C. C. Paterson: The Incandescent Electric Lamp from the Inside.
JUNIOR INSTITUTION OF ENGINEERS, at 7.—G. H. Ayres and Others: Discussion on Economical Transmission of Power.
ROYAL SOCIETY OF MEDICINE (Electro-Therapeutics Sections), at 8.30.—Discussion: Radio-therapy; Prof. S. Russ: Physics.—Dr. Batten: Superficial Therapy.—Dr. Finzi: Deep Therapy.

SATURDAY, NOVEMBER 20.

PHYSIOLOGICAL SOCIETY (at St. Bartholomew's Hospital), at 4.

MONDAY, NOVEMBER 22.

ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.
ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Major F. M. Bailey: A Visit to Bokhara in 1919.
MEDICAL SOCIETY OF LONDON (at 11 Chandos Street, W.1), at 8.30.—Dr. F. J. Poynton, Dr. D. H. Paterson, and Dr. J. C. Spence: A Study of an Outbreak of Acute Rheumatism in Children under 12 Years.—Dr. G. E. S. Ward: Some Disorders of the Myocardium (illustrated by the electro-cardiograph).

TUESDAY, NOVEMBER 23.

ROYAL BOTANIC SOCIETY, at 3.—Prof. A. W. Bickerton: The Relations of Astronomy to Botany. (3) Complex Changes of Season and Climate.
SOCIOLOGICAL SOCIETY (at 65 Belgrave Road), at 5.15.—C. R. Enock: Suggestions towards a Science of Corporate Life.
ROYAL SOCIETY OF MEDICINE (Medicine Section), at 5.30.
INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—Short Chemical Papers.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Technical Meeting), at 7.—W. T. Wilkinson: The Wet Collodion Process Demonstrated, and an Incursion into Litho-Photography.
ROYAL ANTHROPOLOGICAL INSTITUTE (at Royal Society), at 8.30.—Dr. A. C. Haddon: Migrations of Cultures in British New Guinea. (Huxley Memorial Lecture.)

WEDNESDAY, NOVEMBER 24.

INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section) (at Institution of Civil Engineers), at 6.—Dr. W. H. Eccles: Address.
ROYAL SOCIETY OF ARTS, at 8.—Dr. F. W. Edridge-Green: Colour Vision and Colour Blindness.
INSTITUTE OF CHEMISTRY (in Chemical Theatre, University College, Gower Street), at 8.—J. Turney Wood: Some Scientific Aspects of Tanning.

THURSDAY, NOVEMBER 25.

ROYAL SOCIETY, at 4.—Special General Meeting to consider the Annual Report of Council.—At 4.30.—*Probable Papers.*—Prof. L. Hill: The Growth of Seedlings in Wind.—Prof. P. T. Herring: The Effect of Thyroid-feeding and of Thyro-parathyroidectomy upon the Pituitrin Content of the Posterior Lobe of the Pituitary, the Cerebro-spinal Fluid, and Blood.—W. A. Jolly: Reflex Times in the South African Clawed Frog.—Prof. J. A. Gunn and R. St. A. Heathcote: Cellular Immunity. Observations on Natural and Acquired Immunity to Cobra Venom.—L. T. Hogben: Studies on Synapsis. III. The Nuclear Organisation of the Germ Cells in *Libellula depressa*.
CHADWICK PUBLIC LECTURES (at the Medical Society of London), at 5.15.—Prof. J. B. Farmer: Some Biological Aspects of Disease.
INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—W. B. Woodhouse: The Distribution of Electricity.—R. O. Kapp: Some Economic Aspects of E.H.T. Distribution by Underground Cables.
EGYPT EXPLORATION SOCIETY (at Royal Society), at 8.30.—Prof. G. Elliot Smith: The Royal Mummies.
ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.

FRIDAY, NOVEMBER 26.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 5.
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Section) (at the City and Guilds Technical College, Leonard Street, E.C.), at 6.30.—A. J. C. Watts: Electricity and the Paper-making Industry.
OPTICAL SOCIETY AND PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 7.—The Making of Reflecting Surfaces. (*a*) Technical Methods and Process. (*b*) Properties of Reflecting Surfaces (Reflecting Powers, etc.).
ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.30.—Dr. A. Chaplin: Measures for Preserving the Health of Seamen on Board Ship.

British Dyes.

In view of the present large importation of German dyes into this country, a strong appeal for the protection of the British dye industry is made by Dr. Herbert Levinstein in the *Morning Post* of November 19. Dr. Levinstein points out that the pledge given by Sir Albert Stanley, President of the Board of Trade, on May 15, 1918—namely, that the importation of all foreign dyestuffs should be controlled for a period of not less than ten years after the end of the war—has never been redeemed, and adds: "Nobody suggests that a prohibition of imports except under licence should be permanent. Ultimately, the industry must flourish on its own merits, prosper by its efficiency, by the originality of its inventions, and by the scale of its operations."

It would seem to be a simple matter for the Government to allow imports under licence of such dyes as are required, but not yet manufactured, in this country, and to exclude those which can be shown to be produced here in adequate amount. That the position is not quite so simple as would appear from this is shown by the statement of the Prime Minister so recently as November 11, to the effect that no guarantee could be given that this measure would be brought in before Christmas unless it could be shown that the measure was non-contentious, and by Dr. Levinstein's own very serious and alarming statement that since July last, owing to the large importation of German dyes which has taken place, a great injury has already been inflicted on the dye industry, and consequently on the textile industries. Progress has been arrested, developments brought to a standstill, great plants closed down, and large numbers of workmen thrown out of employment. At the same time, whilst in July, 1914, the German supplies were above 80 per cent. of the dyes used in this country, in July last the output of the British Dyestuffs Corporation, Ltd., was greater in quantity, though less in variety, than the total quantity of dyes imported from Germany in July, 1914.

The only conclusion that can be drawn from the Prime Minister's statement is that opposition exists to the apparently logical measure which the dye manufacturers desire to see introduced, and this can come only from the dye users. Dr. Levinstein's statement shows, further, that German dyes, of the same kind as are being manufactured here, are being bought on the large scale in preference to the dyes made at Huddersfield and Manchester. Evidently the dye users have a very strong preference for German dyes, even of the commoner kind. It was to be expected that the more complicated dyes which the Germans produce, but which are not yet made in this country, would be eagerly acquired by the dye users when available, but that the British Dyestuffs Corporation would be compelled to close down great plants and discharge large numbers of workmen immediately following importation from Germany was not anticipated, and is a matter of most serious moment.

There can be only two reasons for this: either the products made by the British Dyestuffs Corporation are not of the same quality as the German, or they are of the same quality, but must be sold at a higher price. Dr. Levinstein suggests that the latter is the case, for he says: "Owing to the depreciation of the mark, they [the Germans] can undersell any English makers, and yet make large profits." Whatever may be the depreciation in the value of the mark, it does not appear that the Germans are underselling the English manufacturers. As was stated recently in these columns, the average price of the 1500 tons of German dyes mentioned in the House of Commons as having been imported during the first nine months of this year was 7*s.* 11*d.* per lb. Even supposing that part of this quantity consisted of very highly priced dyes, presumably not manufactured here, yet the quantity of the cheaper class of dyes must have been large if, as we may presume, they were at least partly responsible for the collapse referred to by Dr. Levinstein, and, therefore, their average price could not have been very much less than 7*s.* 11*d.* When it is considered that the average pre-war price of the majority of dyes advertised at present by the British Dyestuffs Corporation was very much nearer 1*s.* than 8*s.*, it is difficult to imagine that there can be such underselling as is suggested.

On the other hand, will the dye users say that the quality of the dyes made at Huddersfield and Manchester is equal in every respect to that of the pre-war (and present) German product? Although the shade of the dyes is probably the same—and there is no doubt that the product made by the chemist in the works is fully equal to the German—this product must necessarily be reduced, by adding salt or other inert material, to a given standard. Precision and exactness in seeing that all deliveries conform to this standard of strength are of vital importance to the dyer, and divergence from this may well lead him to seek his supplies elsewhere.

Antarctic Research.

(1) *Scottish National Antarctic Expedition: Report on the Scientific Results of the voyage of S.Y. "Scotia," during the years* 1902, 1903, *and* 1904, *under the Leadership of Dr. William S. Bruce.* Vol. vii., Zoology; parts i.–xiii., Invertebrates; pp. viii+323+15 plates. (Edinburgh: The Scottish Oceanographical Laboratory, 1920.) Price 50*s.*

(2) *British Museum (Natural History). British Antarctic ("Terra Nova") Expedition,* 1910. *Natural History Report. Zoology.* Vol. xi., No. 9. Mollusca. Part iii., Eupteropoda (Pteropoda Thecosomata) and Pterota (Pteropoda Gymnosomata). By Anne L. Massey. Pp. 203–232: No. 10. Mollusca. Part iv., Anatomy of Pelecypoda. By R. H. Burne. Pp. 233–256+4 plates: vol. iv., No. 3. Echinoderma (part xi.) and Enteropneusta. Larvæ of Echinoderma and Enteropneusta. By Prof. E. W. MacBride. Pp. 83–94+2 plates. (London: British Museum (Natural History), 1920.) Prices 7*s.* 6*d.* and 8*s.* 6*d.*

(1) THE seventh volume of the results of the successful voyage of the *Scotia,* under the able leadership of Dr. W. S. Bruce, contains a series of interesting memoirs. Mr. Pearcey identifies 267 species of Foraminifera, eleven of which are new. He thinks the group richer south of 70° than north of it, and that the Foraminiferal fauna of the arctic and antarctic regions is strikingly similar, from the generally uniform conditions of temperature extending over the bottom of the deep sea (*more* Sir J. Murray). The collection was especially rich in Sponges, which are ably described, with excellent figures, by Prof. Topsent. Ten Hexactinellids were obtained, including new species of Malacosaccus, Acæocalyx, Docosaccus, and Caulophacus, the size of the first and last being remarkable, whilst the wonderful megascleres and microscleres enhance the interest of the group.

The antarctic seas abound in Tetractinellids, though the *Scotia* procured only three known forms. The Monaxonida are grouped as antarctic and subantarctic. Amongst the striking forms is *Cladorhiza thomsoni*, a relation of the interesting little Cladorhiza of the *Challenger,* which was sent as an Alcyonarian to Prof. Arthur Thomson, of Aberdeen. The author repeats his antagonism to the bipolarity theory by pointing out the richness of the antarctic region in Hexactinellids and their paucity in the arctic seas. The wide distribution of the Siphonophores Porpita, Velella, Physalia, and the Diphyidæ is shown by J. H. Koeppern. An elaborate memoir on the structure and relationships of the Hexactinian Porponia, Hertwig, is given by Prof. Carlgren, of Lund, showing, amongst other things, its close connection with Halcuria, mesenteries in both occurring regularly in the endocœls. The new species is *P. antarctica.*

Five species of stony corals are dealt with by Prof. Stanley Gardiner, the most important being a new species, *Madracis scotiae,* from the Abrolhos Bank. Mr. Laidlaw notices the pelagic Polyclad Turbellarian, *Planocera pellucida,* from St. Paul's Rocks; whilst Mr. Pringle Jameson describes the Chætognaths, the wide distribution of which, and the large size of *Sagitta gazellae,* are noteworthy. Mr. L. N. G. Ramsay again takes up the Nereids (Polychæts), of which there were six known forms and one new—*N. falklandica.* The peculiar genus Sclerocheilus receives important treatment from Prof. Ashworth, and a new form, *S. antarcticus,* is described. Miss Helen Pixell (Mrs. Goodrich) gives a careful account of the four Sabellids and the six Serpulids. The resemblance in certain respects of Ehlers' Sabellid genus Potamis to the genus Jasmineira, St. Joseph, merits further attention.

Mr. Tattersall deals with the Schizopods, Stomatopods, and non-antarctic Isopods, together with a few Schizopods collected by the *Discovery* in the tropical Atlantic. A new Boreomysis and the re-discovery of *Exosphaeroma tristense,* Leach, are interesting. The occurrence of a new species of the primitive Dorid, Bathydoris, has enabled

Mr. J. T. Evans to give an account of its anatomy, which is in the main Doridiform, though the length of the nerve-collar, the position of the cerebral ganglia, and the absence of separate gastro-œsophageals diverge, and point to a condition earlier than that in the Pleurobranchids and Tritonia. The fusion of the ganglia of the visceral loop, again, is a modern feature, like the loss of the eyes in deep water.

(2) The three parts of the zoology of the *Terra Nova* antarctic expedition published by the British Museum comprise the anatomy of the Pelecypoda by Mr. R. M. Burne, viz. the structure of the Filibranchiate Arcidæ, Pectinidæ, and Limidæ, that of the Eulamellibranchiate Carditidæ, Veneridæ, and Anatinidæ, and traverse much of the ground worked by Pelsener. A curious feature is the occurrence of a finger-shaped glandular cæcum on each side behind the mouth in Lissarca, Adacnarca, and Philobrya, in connection with a ridge of modified epithelium between the body and the gill-axis. The presence of vestigial cephalic eyes in these and in Barbatia is also noteworthy, and the author thinks that at 250 fathoms their function may be other than that connected with light. The incubation of eggs in the mantle cavity in Adacnarca, in the supra-branchial chamber of Anatina, and in the interlamellar space in Venericardia is rare in marine Lamellibranchs, and may be an antarctic habit.

In her report on the Pteropods, Miss A. L. Massey adopts the terms of Boas, viz. Eupteropoda and Pterota for the older Thecosomata and Gymnosomata, since they are really not closely related, except for the presence of fins. All the seventeen specimens are known forms. If Bonnevie's view is correct, some species frequent the surface and others occur in the deeper water, so that surface-netting only might explain the absence of the latter. Miss Massey, however, does not allude to possible changes of vertical distribution from temperature, storms, light, or darkness. The materials have been worked out most carefully, structurally and otherwise. The wide distribution of Limacina and Clione suggests the possibility that several species of the former may yet be reduced to varieties, as Vayssière holds, and the same may be said with respect to *Clione limacina* and *C. antarctica*.

Prof. MacBride's description of the Larvæ of Echinoderma and Enteropneusta includes four species of the former, two of which, a Bipinnaria and an Auricularia, are new, whilst the latter is represented by a species of Tornaria. It is noteworthy that he was enabled, by the examination of *Auricularia antarctica*, to confirm H. Bury's original view that the anterior division of the cœlomic sac does not become directly converted into the hydrocœle. The latter grows out as a bud from its hinder aspect. Interesting points in the structure of *Auricularia nudibranchiata* are given, demonstrating that Chun's interpretations of the hydrocœle were erroneous; and what he thought to be a median pouch of the intestine is really double, so that the larva cannot belong to the Elasipoda, in which the diverticulum is single. Two examples of Tornaria furnished the author with stages in the development of the so-called "glomerulus," or "proboscis gland." He terms the glandular tissue around the blood-space "heart-gland," which he thinks an organ of internal secretion. All the three memoirs are illustrated by excellent figures.

W. C. M.

The Physiology of Pregnancy.

Radiant Motherhood: A Book for Those who are Creating the Future. By Dr. Marie C. Stopes. Pp. 246. (London: G. P. Putnam's Sons, Ltd., 1920.) Price 6*s*. net.

THE publication of the report of the Royal Commission on Venereal Diseases in 1916, and of two reports by the National Birth-rate Commission in 1916 and 1920, if it did not in itself bring in a new era of frank, open discussion of what had been regarded as the secrets of *la vie intime*, at any rate gave to that era official recognition, and perhaps something also of the nature of a benison. When, further, it became evident that civilised mankind (including womankind) had begun to show its intense interest in its own reproduction by experimenting upon it, and even by attempting to control it, it followed with an almost gravitational certainty that individuals would in separate volumes set forth the hitherto unrevealed aspects of such subjects, and would each try to outdistance competitors in what may be called a race to lay bare all the phenomena of the sexual relations which precede and of the obstetrical results which follow (when they are permitted) the cohabitation of man and woman.

Dr. Marie C. Stopes is one of the authors who have trodden this path in literature in her earlier works, entitled "Married Love" and "Wise Parenthood," and now in her latest book, which she has named "Radiant Motherhood." She is a doctor of science, London, a doctor of philosophy, Munich, a fellow and lecturer in palæobotany in University College, London, and she was a member of the National Birth-rate Commission when it was preparing its second report; but she lays no claim on her title-pages to the possession of any medical qualification or obstetrical diploma. These restrictions may not to the author seem to matter much, but they inevitably lessen the value to be assigned to the more strictly medical and obstetrical portions of her work.

For example, on p. 34 Dr. Stopes writes of the tendency for the head of civilised man to get larger and so to make the birth of the babies of the future through "the gateway of pain" (*i.e.* the mother's pelvis) almost impossible unless Cæsarean section, which may have become a racial necessity by that time, is perfected; but on p. 155 she ascribes the survival of more girl than boy babies to the strength of the former, apparently forgetting her conclusions about "the gateway of pain," for surely the heads of the boy babies (who weigh on an average more than the girl babies) are more likely to be compressed injuriously in their exit.

A careful reading of the whole book leaves the reviewer in two minds whether to praise it on account of the many beautiful and far-seeing thoughts in it and the practical suggestions it contains for the relief of the distresses and difficulties of expectant mothers and fathers, or to censure it for the impracticability of many of its recommendations and for the lack of distinction between matters which have been fairly well established and those which are little more than speculations. It is only fair, however, constantly to bear in mind that the appeal of the book is pre-eminently to the "young happy and physically well-conditioned pair who, mating beautifully on all the planes of their existence, are living in married love" (p. 13), and to "middle- and upper-class women" (p. 168). With this group as audience it is less surprising to read that for the man who "desires to have a child who may become one of the *master* minds" it is wise "to mate himself with the long-young late-maturing type of woman and let her bear that child some time between the age of thirty-five and forty-five." At the same time, even that type of woman within these years is likely to have rigidity of the "gateway of pain" just as any other elderly primipara has, so the expected "master mind" may come to be a still-birth. All the way through her book Dr. Stopes is impeded by the confusion of thought which reigns when one group of parents is being advised and another is being scolded. The radiant motherhood which is written about is for the few. This becomes clear when we read (p. 50) that "the ideal way of spending the earlier months of coming parenthood is in the form of an extended honeymoon, in which the couple, travelling slowly, should follow the guide of seasonal beauty," etc.; that the fertilising union should take place "on a holiday into wild and inspiring solitudes"; and that after giving birth to her child the mother "should lie about for the whole of six weeks" (p. 174).

With two very difficult subjects Dr. Stopes deals in her own way. In the chapter which she calls "The Weakest Link in the Human Chain," she tries to decide the best way of answering the child when he or she asks about sexual and reproductive matters. She cuts the Gordian knot by recommending that "the child's first instruction in its attitude towards its sex-organs, its first account of the generation of human beings, should be given when it is two or three years old"; and she adds: "A child so tiny will usually not remember one word of what was said to it, but the effects on his outlook will be deep." The other difficult question is that of sexual connection during pregnancy. Several of the chapters contain very useful advice, and that (the tenth) on the physical difficulties of the expectant mother is full of such; but is Dr. Stopes aware that at antenatal clinics these things are being commonly taught to all expectant mothers, sometimes with quite usefully irradiating effects? Not a few obstetricians believe that morning sickness and some of the other impedimenta of pregnancy are preventable.

In other chapters, as has been hinted already, the author reveals a rather extraordinary readiness to consider strange stories, such as that Oscar Wilde's character was determined by thoughts which his mother cherished about him whilst she was carrying him in her womb. Some of her suggested remedies for existing evils are sound, although difficult of accomplishment, such as the endowment of motherhood; but the sterilisation of the unfit by Acts of Parliament might tend to do what she herself condemns so much—the manufacturing of revolutionaries. Her suggestion of a safe method of controlling parenthood by preventing conception is taken for granted in this volume; it was described in detail in an earlier one.

Roscoe and Schorlemmer's Chemistry.

A Treatise on Chemistry. By the Rt. Hon. Sir H. E. Roscoe and C. Schorlemmer. Vol. i., *The Non-metallic Elements.* Fifth edition, completely revised by Dr. J. C. Cain. Pp. xv+968. (London: Macmillan and Co., Ltd., 1920.) Price 30*s.* net.

IT is forty-three years since the first edition of Roscoe and Schorlemmer's "Treatise on Chemistry" appeared. The volumes on Organic Chemistry have now passed out of general use, but those on Inorganic Chemistry show no sign of any decline in popularity, and maintain their position almost unchallenged as the standard work on chemistry in the English language. It is not easy at the first attempt to discover what are the special qualities that give to Roscoe's book this attribute of perpetual youth and long-sustained utility, but the refusal of the author to sacrifice either clearness of exposition or scholarly writing in order to reduce the size of the treatise, or to overcrowd its pages with detail, has perhaps been one of the most important factors in securing these enviable attributes. Thus it is still possible to turn to the work for the detailed story of the investigation of the fixed or variable oxygen-content of the atmosphere, or of the composition of the distillate from hydrochloric acid, without finding that the narrative has been so abbreviated as to be valueless except as a guide to the original papers. The editors of successive editions must have exercised considerable restraint in order to allow a full account to be preserved of experiments which were becoming too old to be modern, but were still too modern to be classical.

In bringing out the new edition, Dr. Cain has been handicapped by the fact that he has no longer been able to refer his work to Roscoe himself for approval; but, having been associated with Roscoe in the preparation of the preceding edition, he has had special advantages in striving to preserve the character and style of the book, and has succeeded so well in his task that the later dates which now appear in the footnotes are the most conspicuous marks of modernity. Here and there a paragraph remains which shows signs of obsolescence, and in an occasional instance (*e.g.* the electrical method of making carbon disulphide) modern work has escaped notice; but the new edition is a worthy successor to those that have gone before, and will contribute its share to the long life of the treatise.

One fault which was formerly characteristic of Roscoe's "Chemistry" has almost disappeared in the new edition—namely, the conversion of classical apparatus into a modern form, without any indication in the text of the transformation that had been effected. Only one example of this curious process appears to have survived—namely, the introduction of a gas furnace with a row of Bunsen burners in the figure illustrating the experiments on the composition of air carried out by Dumas and Boussingault in 1841, although the joints of the apparatus are still shown with the original rubber bandages instead of rubber tubing. This last link with an old tradition will perhaps be broken when the time comes for a sixth edition to appear.

It is some satisfaction that the printing and paper show no sign of deterioration, so that the appearance of the book is as attractive as in former years. Roscoe's "Chemistry" has never stooped to the use of black type as a means of emphasis, nor to the use of smaller type for matter of less importance. Even the conventional division of the text into chapters is missing. These features have given to the book a character of its own, which clearly appeals to the more scholarly type of reader, even if the student finds that he is obliged to read the book instead of skimming through it from one key-word to another. The student will still find, however, that he has in Roscoe the best available guide to the literature of inorganic chemistry, directing his attention to all the more important papers, and passing lightly over the mass of detail which has converted so many of the larger works from text-books into dictionaries. Roscoe's "Chemistry," in spite of its increasing size, still possesses all the essential qualities of a book rather than of a catalogue, and this is perhaps the principal reason why its approaching jubilee is unaccompanied by any marks of old age.

T. M. L.

Archimedes.

Archimedes. By Sir Thomas Heath. Pp. ii+58. (Pioneers of Progress Series.) (London: S.P.C.K.; New York: The Macmillan Co., 1920.) Price 2*s.* net.

BY the general consent of all competent judges Archimedes is one of the greatest mathematicians the world has ever seen. It is not easy to justify this opinion to a popular audience, most members of which know little and care less about mathematics; but Sir Thomas Heath's book ought to succeed in making the ordinary reader understand to some extent the nature of Archimedes' discoveries, and in arousing interest in the achievements of Greek mathematicians.

Chap. i. gives such fragmentary (and often legendary) notes as we have on Archimedes' personal career; chap. ii. is an excellent account of Greek geometry before Archimedes' time; chaps. iii.–vii. give analyses of Archimedes' extant works. Special attention may be directed to the paragraphs (pp. 31–35) on the "Method," discovered by J. L. Heiberg so lately as 1906 in a palimpsest at Constantinople. This work shows how Archimedes was led to some of his theorems by quasi-mechanical considerations. It should be observed that Archimedes does not give a so-called "statical proof" of any purely geometrical theorem; this would be contrary to Greek ideas of mathematical propriety. But the theorem having suggested itself as probable from mechanical (or other) considerations, strict methods were applied to test it—such, for instance, as the process of "exhaustion." In connection with this exhaustion method it is properly pointed out that the Greeks virtually laid the foundations of the integral calculus, much in the same way as Apollonius, in his "Conics," virtually anticipates the results of modern analytical geometry.

Scattered about the book there are numerous references to Greek discoveries and speculations which are not so well known as they ought to be. Thus Archimedes determined the angular diameter of the sun to a comparatively close degree of accuracy (p. 47); Aristarchus of Samos enunciated the Copernican hypothesis (p. 46); and, of course, all mathematicians of the time assumed the earth to be a sphere, and had a very fair idea of its dimensions.

The book is well printed and attractive in appearance; it is adorned by a frontispiece which is a reduced facsimile of that in Torelli's edition of Archimedes' works. The original is a good example of eighteenth-century copper-plate—amusing in one respect, because, although the landscape is put into proper perspective, two mathematical diagrams supposed to be drawn on the sand are drawn in their proper shape in the plane of the paper. The process reproduction appears to be very satisfactory, considering the amount of reduction involved. G. B. M.

Australian Meteorology.

Australian Meteorology: A Text-book, including Sections on Aviation and Climatology. By Dr. Griffith Taylor. Pp. xi + 312. (Oxford: At the Clarendon Press, 1920.) Price 12*s*. 6*d*. net.

THIS text-book of meteorology is written for readers in the southern hemisphere, where, as the author truly points out, European and American text-books are to some extent inapplicable by reason of the fundamental difference in the wind circulation around centres of high and low pressure in the two hemispheres. The examples introduced for purposes of illustration in the present work are mainly drawn from Australian conditions, though the author's wide knowledge of world climatology is also freely used. The 300 or so pages of the book are divided into twenty-six chapters, which cover the practical work at observing stations, as well as the more theoretical aspects of dynamical meteorology and climatology. The author has achieved his object in producing a work which will give the reader of fair intelligence, but without advanced knowledge of mathematics or physics, a good general grounding in the subject. In this connection the pages devoted to pressure gradient and Ferrel's law may be particularly commended. One or two parts are less satisfactory, and in particular the reviewer suggests that in a future edition the chapter devoted to upper-air research might be recast, giving less space to the methods employed, and more to the very important results which have been obtained during the past few years in this field. At the same time, a little more attention might be devoted throughout the book to defining the technical terms used, and to explaining in more detail a few of the less obvious types of diagram, which do not at first glance convey much meaning to the unaccustomed reader.

In chap. xviii. a novel theory is put forward to account for the origin of the tropical lows which form over Australia and drift away to the south-eastward. The theory postulates that domes of warm ascending air are formed over the hottest inland regions in summer, and that the upper north-westerly current, striking these fixed domes, forms gigantic eddies which pass away to the south-eastward, being marked at the surface by a low-pressure centre and often by falls of rain. Any theory of the formation of depressions will be received with interest. The one here put forward is certainly not lacking in originality. It is surprising to learn that the words "backing" and "veering" are used in Australia in the sense of turning against and with the sun respectively instead of with the meanings counter-clockwise and clockwise as recommended by the International Meteorological Committee in 1905. In a modern text-book of meteorology one misses any reference to G. I. Taylor's eddy conductivity. In dealing with the diurnal change of wind at the surface and in the lower layers the simple convection theory of Espy is referred to, but no reference is made to the more complete explanation put forward by G. I. Taylor, in which the observed facts are well accounted for on the reasonable assumption of a diurnal variation of "K."

In his preface the author offers a half apology for the roughness of the diagrams with which the book is illustrated, but this seems scarcely necessary, as the numerous figures form one of its most valuable features, being mainly of small size, and yet showing just the details required to illustrate the point under discussion. J. S. D.

Our Bookshelf.

Elementary Practical Biochemistry. By Prof. W. A. Osborne. Pp. v+184. (Melbourne: W. Ramsay, 1920.)

This book represents the course of elementary instruction in practical biochemistry which the author has found suitable for large classes. The conception of biochemistry is, however, limited to the chemistry of the animal body, so that the title may prove misleading. The work actually comprises a course of elementary physiological chemistry, and is divided into twenty-six lessons, each representing a period of laboratory work. A short statement on the theory of the subject of the exercise is given, followed by directions for the practical work. The latter is almost wholly qualitative in nature, and consists of the usual test-tube experiments on the properties of the chief constituents of the animal body. This mode of treatment is always open to the criticism that the theoretical discussions are too short to be of real value, and it is, indeed, difficult to imagine that the small amount of space allotted, *e.g.*, to the carbohydrates will be of much teaching value. On the other hand, they serve a useful purpose in refreshing the student's memory, so that the tests are more intelligently performed.

We note that the author still uses the term "lipoid," and includes the sterols under this head, in spite of the recent suggestion for the abolition of this term. The question of hydrogen-ion concentration is not touched upon, and this constitutes a serious defect, as this conception is of great importance, even for elementary students, and the work on ferments, proteins, and colloids suffers greatly from its omission.

Dietetics receives a good share of attention, and a useful appendix is given containing an elaborate table of food values. Within the limitations of the author's scheme the treatment is quite adequate, but it is to be regretted that more attention is not paid to quantitative and preparative work. A. H.

Monograph of the Lacertidae. By Dr. George Albert Boulenger. Vol. i. Pp. x+352. (London: British Museum (Natural History), 1920.) Price 2*l.*

This volume comprises only forty species, but it contains the important genus Lacerta, and this has been submitted to an intensive study of the individual variations of the species and their many varieties. The author rightly calls the available material unique in its vastness, due, we may add, to his untiring, purposeful exertions during the many years he has been in charge of the cold-blooded vertebrates in the national collection. He deemed it important to ascertain the extent of variation of which a given form is susceptible and in what direction a given variation trends, and then to decide what characters have been modified, or lost, and what new ones produced.

The way in which certain combinations of orthogenetic and adaptive modifications have, by their recurrence, led to various parallel series is of prime importance. Ten characters, mostly concerning the scaling, have been selected to show from what each has arisen, whither it trends, and how the resulting combinations have produced thereby those recognisable varieties of the several species, and then in turn the genera, which have been evolved from the more central or older genus Lacerta. To trace all this required immense study of the numerical variations in the Lepidosis, as attested by the tens of thousands of measurements.

Lastly, "if the interpretation of these evolutionary series of lizards is at all sound, a step will have been made in the advance of our knowledge, and a more rational basis laid down for the discussion of the probable mode of geographical dispersion of the genera, species, and varieties."

The Centenary Volume of Charles Griffin and Co., Ltd., Publishers, 1820–1920. With Foreword by Lord Moulton. Pp. xx+290+plates. (London: Charles Griffin and Co., Ltd., 1920.)

As a member of the council of trustees of a public library, the present writer has often smiled when the name of Messrs. Charles Griffin and Co. has been accepted as the guarantee of a book rather than that of the less known but aspiring author. He well remembers an interview with Miss Elizabeth Eaves Griffin, who selected him, after the manner recorded on p. 8 of this memorial volume, to prepare a very dry and formal text-book, because she had read a sketch of midnight travel written by him in a school magazine. No wonder, then, that he joins with many others in applauding the perspicacity of the firm. It was a happy thought to bring together its history, told by writers who understand what scientific progress means. Prof. Beare thus deals with engineering, Sir W. Abell with naval architecture, Prof. Gowland with metallurgy, and Prof. Louis with mining. In each case the works published in Exeter Street are mentioned in connection with researches and technological developments that have affected the world at large, and the excellent portraits of authors, such as those of Sir W. Roberts-Austen, Sir Edward Reed, and Mr. Alfred Brothers, are a pleasing record in themselves. The founders and directors of the house are also happily represented, and Mr. F. J. Blight is revealed to us in a welcome moment when he is not called upon to write his well-known signature. The book rightly characterises many of the works issued as "pioneers." It is edited with as much good taste as is shown in its technical production.

Rudiments of Electrical Engineering. By Philip Kemp. Pp. viii+255. (London: Macmillan and Co., Ltd., 1920.) Price 6*s.*

This book is intended for those with practically no electrical knowledge, but whose daily work brings them into touch with electrical apparatus. The recent rush of students to join classes in elementary electrical engineering in technical schools shows that there is a demand for this knowledge. We think, however, the author has included too much in the scope of the work. We read about magnetism, primary batteries, electric bells, and kinema sets. We also read about three-core cables, rotary converters, boosters, interpoles, etc. The book would have been more useful if the description and elementary theory of the more intricate apparatus had been excluded. It does not advance our technical knowledge of what is meant by "candle-power" to be told that "a source of light is said to possess candle-power." It is also not very instructive to be told that the back E.M.F. of a motor can be obtained by Fleming's right-hand rule. We failed to follow the theory given for the action of the balancers in a three-wire system of distribution (p. 246). The reader ought to be told why the difference of pressure between the two ends of a circuit is called the "potential difference." The introduction of the word "potential" must strike him as mysterious. In electrical science, more almost than in any other, it is impossible to be perfectly exact "at once," but a beginning at precision should be made early, even although the author should run the risk of being called "academic."

The Nomenclature of Petrology: With References to Selected Literature. By Dr. Arthur Holmes. Pp. v+284. (London: Thomas Murby and Co., 1920.) Price 12*s.* 6*d.* net.

THERE is probably no department of science in which the nomenclature is in such a state of confusion as in petrology. The rocks that form the earth's crust include an innumerable variety of types which pass by imperceptible degrees into one another, so it is not surprising that rock names have been multiplied to an extraordinary degree, and that there has been considerable variation in their application. The student of petrological literature, therefore, frequently finds himself faced with unfamiliar terms or those which are used in a sense different from that with which he is acquainted, and he will owe a debt of gratitude to Dr. Holmes for the labour expended in compiling this invaluable work of reference. He will no longer be dismayed when he meets in the pages of geological publications with "lavialites," "ledmorites," "leeuwfonteinites," and "leidleites," all of which are explained in a single page. The book deals not only with the names of rock types, but also with those indicating their structures and other characters, and we shall know now what is meant when a rock is referred to as being "lepidoblastic" or "glomeroplasmatic."

A useful feature is a list of the commoner prefixes and suffixes and the meanings usually attached to them by petrologists, and there is a glossary of French and German terms. A tabular classification of rocks, including ore deposits, follows, and presents many novel and interesting features. It is based partly on fundamental principles of rock genesis, and so far it is likely to hold its own in the future; and partly on arbitrary numerical criteria, and must to that extent be considered only a provisional stage in the evolution of a scientific classification. There is an instructive synopsis of processes of alteration due to igneous exudations, and of their products; and the classification of metamorphic rocks according to their structure into maculose, schistose, gneissose, and granulose appears to be distinctly useful.

J. W. E.

Liquid Air and the Liquefaction of Gases. By Dr. T. O'Conor Sloane. Third edition, revised and much enlarged. Pp. 394. (London: Constable and Co., Ltd., 1920.) Price 21*s.*

IT must be confessed that the *raison d'être* of this book is not easy to discover. From its sub-title ("A Practical Work," etc.)—and, we may remark, from its price—one might expect an authoritative book of reference for the engineer. It is, however, intended as a popular exposition of the history of the liquefaction of gases.

An introduction to the elementary facts of physics is followed by a series of chapters on the personalities, methods, and apparatus of some leading experimenters, beginning with the work of Faraday, and culminating in the achievements of Mr. Charles E. Tripler. An outline is given of the Linde, Hampson, and Claude processes. Numerous experiments, such as that of pouring liquid air on the floor, or boiling it on a block of ice, are described and illustrated. Indications are given of some applications of liquid air.

The author has evidently read with care much of the historical literature, and his digests of some of the early work are well told. He would probably not lay claim to a first-hand acquaintance with the scientific and industrial cryogenic developments of the twenty years which have elapsed since the book was first written; and it may be doubted whether the information imparted is of a kind to satisfy any but the most superficially minded of readers.

George Stephenson. By Ruth Maxwell. (Heroes of All Time.) Pp. 192. (London: George G. Harrap and Co., Ltd., 1920.) Price 3*s.* 6*d.* net.

AN account is given in this book of the more important events which marked the career of George Stephenson. A few pages are devoted to a brief account of his childhood and early struggles. Then comes an account of the invention of the "Geordie" safety lamp for use in mines, which was brought out simultaneously with Sir Humphry Davy's famous lamp. The remainder of the book records in detail the more interesting points in the history of the great engineer from the time when he built the Stockton and Darlington Railway onward, and it is amusing to read of the struggles he had from time to time to secure the requisite Parliamentary authority for building railways on which traffic would travel at ten miles an hour! Nine excellent full-page illustrations showing some features of British railways in Stephenson's time make an agreeable addition to an interesting book.

Heredity.

MAY I bring the following considerations before readers of NATURE interested in the study of heredity and evolution? I daresay I am wrong, but I should be glad to learn just how I am wrong.

The multicellular individual springs from a germ-cell. Presumably he inherits solely through that cell. In the germ are none of the characters which he afterwards develops—limbs, scars, instincts, knowledge, and the like. These are characters not of a cell, but of a cell-community—the soma. The germ contains nothing but potentialities (powers, capacities, diatheses, tendencies) for producing in its massed cell-descendants these communal characters in response to fitting influences (stimuli)—food, internal secretions, heat, light, moisture, functional activity (use), injury, and the like. Strictly speaking, therefore, nothing is inherited save potentialities—powers to develop in this way and that in response to this and that stimulus. Lacking the right influences, an individual may not reproduce all that he inherits, but he can reproduce nothing that he did not inherit. Reproduction is inheritance *plus* development. In the case of variations development occurs without inheritance; the individual does not then reproduce; he merely produces. Such colloquialisms as "The son has inherited his father's muscles" do no harm so long as the real truth be borne in mind; but if the truth be forgotten, endless loose thinking, confusion, and futile discussion may result, and often has resulted, as we shall see presently. Problems concerning potentialities are, of course, matters for the student of heredity. Problems concerning reproduction (as to what influences cause development) are equally, of course, matters not for the student of heredity, but for the student of physiology.

The sum of the potentialities in the germ whence the individual springs is his nature; the sum of the influences which play on him and cause, or prevent, or change his development is his nurture. Both nature and nurture are necessary and equal factors in the development of all characters. The query as to whether nature or nurture is the stronger is akin to a query as to whether the steam or the engine is the more potent in moving the train. Nature and nurture are never warring, but always co-operating, factors.

Individuals differ by nature and by nurture. They vary, and then their differences are *innate* or *germinal*. They are modified, and then their differences are *acquired* or *somatic*. Obviously, the words in italics are used intelligibly when employed to describe likenesses and differences between *individuals*. Thus we know what is meant when we are told that one man is by nature or by nurture darker than another. But, obviously again, they are used incorrectly and unintelligibly when employed to describe likenesses and differences between characters. How, for example, is a head more innate and germinal and less acquired and somatic than a scar? Can anyone tell us in precise language? The scar is as much founded on germinal potentiality as is the head; the head is as much a product of nurture and as much situated in the soma as is the scar. Evolution has so fashioned the race whence the individual sprang (has conferred on it such a nature) that, given a certain kind of nurture, he produces a head, and given another kind of nurture, he produces a scar. Plainly, all characters are both innate and acquired, germinal and somatic, in precisely the same sense and degree. Plainly, also, inheritance (*e.g.* of latent ancestral traits) is one thing, while reproduction is another and quite a different thing.

Of course, we may, if we please, give arbitrary, limited, unusual meanings to our words. But we shall then, with the multiplicity of meanings, risk confused thinking. As Bacon said, "Men believe that their reason rules over words; but it is also the case that words react, and in their turn use their influence on the intellect." Thus we may limit the terms "acquired" and "somatic" to those characters which develop in response to use and injury, while reserving the terms "innate" and "germinal" for all other characters. This, indeed, is commonly done. Thus the abnormal musculature of the blacksmith is termed "acquired," while the normal development of the ordinary man is supposed to be innate. But the result is confusion worse confounded, for the muscles of the ordinary man also develop from birth forwards in response to use. Like most human structures, unused muscles, even in childhood, do not develop; they atrophy; they owe not only their development, but even their maintenance to use. If, then, we give these meanings to our words, we must apply the term "acquired" to vastly more than we do now, and we must go back to the infant, or beyond him, to find the natural man. Or, again, the word "innate" may be limited to the "normal," and "acquired" to the "uncommon." In that case we should have to term variations "acquirements," and call the English language germinal in England and acquired in France. In fact, no matter what arbitrary meanings we take, the moment we embark on them we are swamped in a sea of confusion.

Darwin founded his theory of natural selection on the supposition that innate likenesses and differences between individuals were transmissible. However he expressed himself at times, his meaning was usually clear. Lamarck founded his theory on the supposition that acquired likenesses and differences between individuals were transmissible; but he expressed himself in terms of characters, and his meaning, as we shall see immediately, was never clear. Gradually, especially after the advent of Weismann, discussion centred more and more on characters, some of which were termed "germinal" and others "somatic." At present most biologists hold that "acquired characters are not transmissible." But here again, can anyone explain precisely what he means? So far as I am able to judge, that pronouncement is neither true nor untrue; it is purely nonsensical.

Consider the following, which I think most biologists will consider true, and, I suppose, all will consider intelligible: "Heads, being germinal characters, are inheritable; but scars, being somatic, not germinal, are not inheritable." But since only potentialities are present in the germ, all we can mean by the statement that heads are transmissible is that offspring, inheriting like natures from their progenitors, reproduce, under like conditions, like heads. If we gave our words the same meanings, we should say that a scar is inherited when a child reproduces it under the same conditions as the parent did (*i.e.* in response to the nurture of injury). The child would then be like, both by nature and by nurture, to the parent. But no biologist regards a scar so reproduced as inherited. It would be regarded as inherited only if the child reproduced it in a way in which the parent did not, and could not, have produced it, *i.e.* only if the child became profoundly different by nature from the parent, *only if it varied.* It follows that the word "inherit" (because often used as synonymous with "reproduce") is employed, commonly but quite unconsciously, with two directly opposite meanings. When applied to "germinal" characters it is given its ordinary meaning; it then means *inherit* (in the only sense in which anything can be said to be inherited). When applied to "acquired" characters it means *vary.* All this loose use and misuse of words—innate, germinal, acquired, somatic, inherit, reproduce—is a legacy from the days, before the discovery of cells, when students of heredity thought in terms, not of the germ-tract, but of the whole individual, the soma. "Germinal" and "somatic" are modern terms, but they reproduce ancient, inaccurate, popular ideas. The result has been half a century of futile labour, discussion, and confusion. If it be thought that I am mistaken as to all this, can anyone tell us in precise terms what in the world the Lamarckian controversy was *about*; or what is meant when it is said that some characters have "representatives in the germ-plasm" while others are merely due to "light, heat, moisture, and the like"; or what is intended when an inquirer seeks to ascertain to what categories (germinal or somatic) certain characters belong, and so on?

Is not the following universally and indisputably true? Does it not cover the whole Neo-Darwinian-Lamarckian field, and much besides? *The sole antecedent of non-inheritance is variation. Apart from variation, like exactly begets like when parent and child develop under like conditions.* But if this general statement be true, the study of heredity is relatively simple. Its difficulties have resulted not so much from the complexities and obscurities of reality as from those of language.

The natural inference from the discovery of cells and their mode of origin is that heritage travels down the germ-tract. The *necessary* inference from this, in turn, is that all the characters of the individual are innate, acquired, and inheritable in exactly the same sense and degree. The inference which Weismann, hypnotised by words, drew was that acquired characters are not transmissible. If we give our words their natural meanings (which is not the meaning the Lamarckians gave), there is sense in the statement that acquired characters are transmissible. *Of course,* acquired characters are transmissible in exactly the same sense and degree that any characters are transmissible. But there is absolutely no meaning in the Neo-Darwinian statement that acquired characters are not transmissible. It is like a declaration that five miles weigh five pounds.

Squalodont Remains from the Tertiary Strata of Tasmania.

During a recent visit to the north-west coast of Tasmania I was fortunate enough to discover in the Tertiary beds at Wynyard—usually regarded as Miocene—the skull and a good proportion of the skeleton of a Squalodont whale. The fossil is in a particularly good state of perservation, and has been removed to the biological department of the University of Tasmania.

The remains so far discovered in Australia which can be assigned definitely either to the Archæoceti or to the primitive Odontoceti comprise in all some six or seven teeth, so that the present discovery is of more than passing interest. A detailed description of this specimen will be published later, but I have thought that a preliminary notice might be of interest to British naturalists.

The following is a short summary of the characters of the skull of this fossil:

Measurements.—Total length, 56 cm.; zygomatic breadth, 37·6 cm.; snout length (from bottom of antorbital notch), 25·5 cm. Whole skull, dolphin-like; snout shorter in proportion to skull than in Squalodon, longer than in Prosqualodon or Patriocetus; shape of snout triangular, but slightly concave on each side. Nasal bones similar to those of Prosqualodon. External nares not so far back as in Squalodon. Supra-orbital plate of frontal not entirely covered by the supra-orbital process of the maxilla. Supra-occipital strongly developed, meeting frontals anteriorly, and so preventing the parietals from entering into the formation of the skull-roof. Symphysis

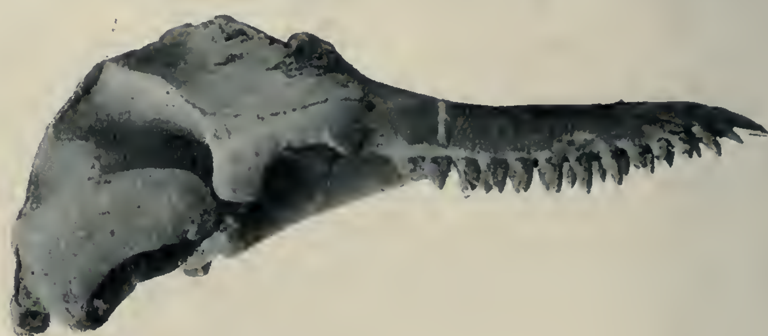

Fig. 1.

of mandible extends to posterior edge of first molar.

Dental formula: I 3/3, C 1/1, P 4/4, M 6/6 (Van Beneden's notation).

Posterior molar in each jaw degenerate. All molars two-rooted, with indications of disappearing third root. Roots of molars connected by an isthmus as in Prosqualodon; roots of premolars coalesced, though separated by a groove in some cases. All teeth closely packed in jaw, sometimes overlapping. Molars with three cusps on each edge, making, with the primary cusp, seven cusps in all. Pattern of surface of molar teeth can be seen from Fig. 2, (B) and (C).

The arrangement of the bones of the skull-roof marks this skull as being that of a Squalodont, but there are features in which the specimen closely approaches the Archæoceti, *e.g.* in the form of nasals, the position of the external nares, and the shortness of the rostrum. The problems centring round the dentition need not be discussed here.

It is possible that these remains might be referred to one of the genera Parasqualodon and Metasqualodon founded by Hall on an examination of the Australian teeth referred to above.

This is a point on which a definite opinion can be given only after a detailed examination of the teeth in the National Museum, Melbourne. I have refrained, therefore, from referring the specimen to any genus.

With regard to the figures accompanying this letter, Fig. 1 shows the skull from the right side, and Fig. 2 (A) the posterior premolar, (B) the fourth molar, and (C) the posterior molar, all of the left ramus of the mandible. In (B) and (C) can be seen the isthmus joining the roots of the molars and the traces of the original third root. The peculiar cusp-like pattern on the face of the teeth is also well shown.

It should be mentioned that the knob which is apparent in front of the nasal region of the skull in Fig. 1 is merely a concretion difficult to remove without damage to the skull.

The Energy of Cyclones.

I do not find that people in general are aware of an important source of energy for the maintenance and intensification of cyclones, nor am I acquainted with a clear exposition by a meteorologist that the condensation of aqueous vapour will suffice.

Atmospheric pressure being a ton weight per square foot, the disappearance or collapse of a cubic foot of ordinary air would yield a foot-ton of work. The disappearance, by complete condensation, of the aqueous vapour in 760/12·7, say 60, cubic feet of atmosphere would yield the same amount.

If, then, the temperature of saturated air fell from 18° to 12° C. by reason of condensation and rainfall, so that the vapour-pressure diminished from 15·36 to 10·46 mm. of mercury, a foot-ton would be generated in each 155 cubic feet of that region of the atmosphere. Incidentally, the corresponding deposit of liquid would be 5 grams per cubic metre, or a rainfall of $\frac{1}{5}$ in. from a vertical mile of air.

Assuming that the above fall of temperature in the central region of a travelling cyclone is not excessive, the energy available in each cubic mile of it would be nearly a thousand million foot-tons.

Oliver Lodge.

With reference to Mr. R. M. Deeley's letter on the above subject in Nature of November 11, may I suggest that the energy of a cyclone is derived from the heat-energy of the earth's surface? If we assume that the air which ascends in the centre of the vortex is less dense on the whole than the air which is at the same temperature outside the vortex, then, since the ascending current must be compensated by a descending current elsewhere, the air will go through a thermodynamic cycle in which positive work will be done at the expense of the heat communicated at the earth's surface.

The process may be compared roughly to a Carnot's cycle, in which the inflowing air at the earth's surface is isothermally raised in temperature, expands adiabatically as it ascends, cools isothermally by radiation at the higher levels as it flows outwards, and contracts adiabatically in descending again. The work done would appear as increased vortical motion if the conditions were favourable, and the mechanical forces causing the motion would be due to the differences of hydrostatic pressure within and without the cyclone.

Molecular and Cosmical Magnetism.

Recent researches on magnetism tend to suggest that the negative electron may be a magneton or unitary electromagnet as well as a unitary electric charge, consisting, that is, of an anchor-ring of negative electricity in rotation about its axis of symmetry. Such a magneton would behave mechanically like a gyroscope; magneto-gyroscopic effects have been previously considered and observed in relation to ferromagnetic bodies on the assumption that the ferromagnetism is due to electrons in orbital motion as a whole. Wider conclusions can be drawn, however, if the magneton hypothesis is adopted, and the deductions are of importance, not only in the theory of atomic and crystal structure, but also in relation to cosmical magnetism. The following notes describe a few of the more important consequences; a detailed account of the theory and of some experiments designed to test its validity will be published shortly.

A magneton rotating with any kind of matter will tend to align its axis parallel with the axis of rotation. Since the electricity of the magneton is negative, the direction of magnetisation will be related to that of rotation, as is the direction of translation to that of rotation in a left-handed screw. This is the right direction in order to account for the general magnetic fields of the earth and sun as due simply to their rotation. The explanation of the observed magnitudes of these fields seems to present no difficulty; numerical details will be given in the forthcoming paper, where also a theory will be suggested to account for the rapid radial diminution of intensity in the sun's general magnetic field.

Mr. S. J. Barnett has shown by delicate experiments on ferro-magnetic bodies that they become magnetised slightly on being rapidly rotated, and has propounded a theory according to which such bodies should acquire magnetisation of amount proportional to the angular velocity, the factor being a universal constant depending on the ratio (mass/charge) for an electron. The fields observed and calculated (on this theory) agree as to order of magnitude, but are quite inadequate to account for solar and terrestrial magnetism. The theory, however, apart from the fact that it is based on the hypothesis of electrons in orbital motion, seems to require serious modification.

On the present theory, magnetisation by rotation should be shown by dia- and para-magnetic bodies as well as by ferro-magnetic substances, and the intensity should be proportional to the angular velocity only when the substance is in such a state that the constraints exerted on the magneton by neighbouring nuclei and electrons are strictly elastic. In this case, moreover, the factor of proportionality will not be a universal constant, but will vary with the nature of the constraints, and in particular with temperature; in hot bodies the intensity of magnetisation should be greater than in cold ones. An extreme case is that in which the temperature is so high as to produce general dissociation of the electrons from the nuclei, as appears to occur in the interior of stars. Apart from the disturbance produced by collisions, the magnetons are then free to set their axes parallel to the axis of rotation, and a large proportion of them would seem to do this in certain cases (*vide infra*). The upper limit of magnetisation is reached when all the magnetons are set parallel to the axis; this limit can be calculated in some cases, it being possible to estimate the number of electrons in electrostatically neutral matter of given kind and density. Other things being equal, the maximum magnetisation will be proportional to the density and independent of the speed of rotation.

The magnetic fields of the earth and sun can thus be accounted for on the present theory because these bodies are at a high temperature (in the case of the earth this is so except for the parts near the surface); what has hitherto been an obstacle in framing theories of their magnetic fields is here regarded as probably the determining factor as regards magnitude.

The same explanation applies to sun-spots. These occur in pairs of opposite magnetic polarity, and it has been pointed out that the polarities are such as would be accounted for by negative electricity in rotatory motion such as is observed (with opposite directions) in the members of a sun-spot pair. The sun-spot pair is thus regarded as the surface portion of a "line"-vortex continuously connecting the ends beneath the surface. The difficulty has been that no Stark effect is observable, such as would accompany rotating charges of the required amount; it has therefore been suggested that the magnetism of sun-spots is due to galvanic currents, *i.e.* electrons in translatory motion through electrostatically neutral matter. This hypothesis is unnecessary; it seems possible to account for the observed fields, of order 3000 gauss, simply by the observed rotation of the matter composing the vortex, on the above magneton hypothesis.

The obliquity of the magnetic axes of the earth and sun requires some additional hypothesis for its explanation, since an unsymmetrical condition cannot be accounted for by a cause, like rotation, symmetrical about an axis. The obliquity being present, however, it seems possible to explain the secular variations of the solar and terrestrial magnetic fields as due to precessional motion of the magnetons. A magnetic field applied obliquely to a magneton will tend to cause it to precess round the lines of external magnetic force. The magnetic fields of the earth and sun, due mainly to rotation, will exert this effect on any magnetons the axes of which are inclined to them; the speed of precession depends solely on the strength of the applied field if the magnetons are free, and the direction of precession agrees with the direction of rotation of the magnetic axes of the earth and sun.

Physiological Effects of Alcohol.

DURING recent years a good deal of work has been done and a great many results have been published on the above subject. Some of these have been very recently reported in the general Press. In most, if not in all, of the researches which have been made on the physiological effects of moderate doses of alcohol, taken in the form of beer, spirits, or other alcoholic beverages, but little attention has been paid to the very important disturbing influence of what may be called "secondary products"—whether extractive matters normal to the beverages in question or volatile by-products of the alcoholic fermentation process itself. Most people are aware that there is no *definite* relationship between the intoxicating effects of certain wines and the amounts of alcohol which they contain, and the marked difference in the physiological effects of new whisky on one hand, and of well-matured spirit *of the same alcoholic strength* on the other, is a matter of common experience.

In the case of beer the soporific effect depends not a little on the hop and other extractives, and consequently there is no scientific justification for drawing any definite conclusions of a quantitative character as to the physiological effects of small doses of alcohol unless the beer used in the whole series of experiments had been of precisely the same character throughout, and even then the "personal equation" would introduce a further serious difficulty. Most beer-drinkers of middle age are well aware that the physiological effects of bitter beer on one hand, and of mild ale or lager (which are less heavily hopped) on the other, are not by any means the same, even for equal percentages of alcohol. The investigation of the effects of these various "secondary" constituents undoubtedly presents great experimental difficulties, but until their physiological significance is better understood there must always be an element of uncertainty in any conclusions arrived at in regard to the physiological effects of small doses of alcohol taken in the form of the usual alcoholic beverages.

A. CHASTON CHAPMAN.

London, November 15.

Atomic Structure.

THE arrangement of the non-nuclear electrons in the atom is being determined by work along two lines: first, from the Bohr-Sommerfeld theory of characteristic frequencies, and, secondly, from the Lewis-Langmuir or Born-Lande theory of the structure of molecules, supported by Prof. W. L. Bragg's work on atomic radii in crystals. It has been stated several times recently that the conclusions drawn from the two sources are mutually inconsistent, in that the first indicates that the electrons are revolving in planetary orbits, and the second that they are fixed in constant positions. The essential truth of the first theory is now beyond doubt; the second is extremely plausible. If they are really inconsistent the position would be intolerable.

But they are not really inconsistent. The Bohr-Sommerfeld theory does not make explicit use of the assumption that the electrons in their stable states are moving; it assumes only that in those states they have the energy, calculated by Hamiltonian (relativity) dynamics, which they would have if they were moving in certain orbits. It is not logically impossible to maintain that they have that energy and are yet at rest. Nor is it physically impossible if we accept Bohr's principle of "correspondence," which has been so astoundingly successful in explaining the Stark effect and in predicting the number of components in lines of the hydrogen and helium spectra. According to that principle, the intensity and polarisation of components can be predicted by the application of classical dynamics to certain assumed orbits, although it must be assumed at the same time that the electrons are *not* moving in those orbits. If intensity and polarisation can be predicted from orbits that are wholly fictitious, why not energy?

Of course, the adoption of Bohr's principle in this extreme form would sever the last connection between classical dynamics and the real structure of the atom. But we are surely now all convinced that we must abandon part of that connection. Is there any reason but mere conservatism that makes us hesitate to abandon all of it, and to admit that, even in respect of energy, a fixed electron can have the properties which classical dynamics attributes to a moving electron? Classical dynamics, it is clear, is only "statistical"; what are the principles of the elements of the statistical group is the main problem of the physics of the future. NORMAN R. CAMPBELL.

November 16.

The Testing of Balloon Fabrics.

ON p. 130 of the Report of the National Physical Laboratory for 1919 reference is made to the testing and experimental work carried out in connection with the manufacture of balloon fabrics for war purposes, and in connection with this we wish to place on record this company's work in the manufacture of materials, especially hydrogen-proof fabric, for lighter-than-air craft.

The North British Rubber Co., Ltd., first took up the manufacture of this material in 1908, and, realising that the problems involved in manufacture necessitated scientific control, as a preliminary installed in its laboratory an apparatus for measuring the permeability of rubber to hydrogen, and thereafter initiated research into the factors responsible for the deterioration of rubber under the influence of light.

When the Admiralty installed its test station at Manchester we were requested by the officer in charge to furnish drawings of the special type of hydrogen diffusion apparatus which had been designed at Castle Mills, and one of its staff received a course of instruction in the company's laboratories on the procedure to be followed in testing balloon fabric. At a later period of the war this department was taken over by the newly formed War Office Aircraft Fabrics Department, which installed an extended testing plant, and another member of that staff also received his training in this work in our aeronautical laboratories.

The Aeronautical Inspection Department was also indebted to the laboratory of the North British Rubber Co., Ltd., for the training of some of its scientific staff, and its testing equipment was in many respects also based on the results of this experience.

During the course of the war our output was steadily increased, and at the armistice we were manufacturing more than 35,000 yards of balloon fabric per week, every piece of which was tested in our aeronautical laboratories for weight, strength, and hydrogen leakage.

The investigation of the research laboratory into the action of light on rubber resulted, moreover, amongst other things, in a discovery which, without any increase in weight, permitted the production of a fabric of vastly enhanced durability specially suitable for use in the tropical theatre of the war.

Our reason for asking for the publication of this communication is only for the purpose of stating that at least one manufacturer was sufficiently well equipped, not only in the manufacture, but also in their scientific staff and laboratories, to carry on without outside help, and it is not intended to detract in any way from the very useful and great assistance which the National Physical Laboratory gave to Government Departments and others starting out in what was probably new ground to them.

W. A. WILLIAMS,
Works Manager.

The North British Rubber Co., Ltd., Castle Mills, Edinburgh, November 12.

Luminosity by Attrition.

WITH reference to Sir Ray Lankester's suggestion in NATURE of November 4 that chemists should endeavour to ascertain the cause of the "empyreumatic" odour which accompanies the flashes of light produced by rubbing two quartz pebbles together, may I suggest also that the inquiry might be extended to include other substances which possess this property of triboluminescence?

The property is not confined to *crystallised* silica; it is displayed also by the amorphous varieties (opal, etc.) and by flint and chert.

Felspars possess the property in varying degrees; in general, it is more pronounced in the alkali felspars than in the lime-soda species. Fused albite displays the property.

Certain types of igneous rocks, both crystalline and glassy, behave in the same way. The property is most marked in the acid types; in the basic types (*e.g.* picrites, etc.) it is feeble or wanting.

Among the sedimentaries, sandstones, arkose, etc., and among the metamorphics, gneiss and some crystalline schists, display the property. The empyreumatic odour is a general accompaniment in the cases referred to above.

Saccharin and certain varieties of sugar possess the property in a moderate degree, and Dr. Lawson (Newcastle) has observed it in uranium nitrate when crystals of the salt are shaken up in a bottle.

I have investigated a large number of other substances (artificial glasses, rocks, and minerals); in the main, the results are negative.

Luminescence occurs between any pair of the "active" rock or mineral substances mentioned, and it would seem that the property is not dependent on crystallinity or wholly on chemical composition, but its relation to silica content (in silicates, etc.) is as yet obscure.

As regards the crystalline substances, the idea prevalent on the Continent is that during the process of crystallisation some of the outer electrons of the atom-system become detached, as it were, from the rest, but can recombine, with accompanying luminescence, under the stimulus of violent vibration. On the other hand, it may be a piezo-electric phenomenon; strain and deformation may induce positive and negative electrical charges on neighbouring particles, discharge being accompanied by luminescence. As the investigation is incomplete, further discussion would be out of place. A. BRAMMALL.

Imperial College of Science and Technology (Royal School of Mines), South Kensington, S.W.7, November 13.

Spiranthes autumnalis.

IN NATURE of September 16, p. 79, I reported the occurrence of this orchis, new to Scotland, in Lower Strathspey. As I can find no record of the species growing on soil other than cretaceous, and as there is no lime in the soil where I found the plants, I suspect that I may have been deceived by the superficial resemblance between Spiranthes and *Goodyera repens*. The point, of course, might have been decided at once by lifting a root; but, being very unwilling to disturb rare plants, I refrained from doing so. I hope to return to the place next summer to verify the species; until then I must ask botanists to dismiss my note as *non avenue*. If it should prove that I have erred, I have done so in good company, for was not Sir Joseph Hooker deceived by the decussate, scale-like leaves of *Veronica cupressoides* into pronouncing that plant to be coniferous from specimens sent from New Zealand? HERBERT MAXWELL.

Monreith.

Negro Life in South Central Africa.[1]

By SIR H. H. JOHNSTON, G.C.M.G., K.C.B.

THERE have been very few books like the two volumes before us published about any people of arrested development, even in Germany, where, before the war, a certain standard of perfection was reached in ethnological treatises. It is difficult to find any fault with the work, in regard to either what has been put in or what left out. The authors are the Rev. Edwin W. Smith, an honorary chaplain to the Forces and a Church of England missionary to the Ba-ila, and Capt. Andrew Murray Dale, a magistrate in the British South Africa Company's administration. Capt. Dale died (unhappily) last year of blackwater fever, worn out with much war service. The Rev. E. W. Smith, if I mistake not, saw considerable war service in Italy and elsewhere, and his work with the Forces kept this remarkable book back from publication for some little time. Incidentally, I might mention him as well known to students of Bantu. He was the author of a handbook of the Ila language, and an important contributor to the information on South-west African languages in my "Comparative Study of the Bantu."

The Ila people inhabit the central part of Northern Rhodesia, especially the region through which flows the great river Kafue. (This name seems to be a corrupted and abbreviated form of Kavuvu or Kafubwe, which means "Hippopotamus.") They have evidently been a conquering race of invaders from the north-east which has imposed its language and customs on less courageous tribes of inferior physique. The true Mu-ila is—for a pure Bantu negro—rather a handsome type, at any rate in beautifully formed and proportioned body and limbs; but other tribes speaking the Chila language to-day are of different stocks; some may even go back for their ancestry to Bushmen or to Congo pygmies, and in remembrance of this they are called "Batwa" (dwarfs) to this day. Others, again, belong to the Luba group, the men of which have almost an Arab cast of features and a full beard.

This most noteworthy work deals with the history, the physical characteristics, clothing (often lacking in the males), building operations, food, domestic animals (their cattle are straight-backed, and seem to have come to them from the west and south, the old Damara-Ngami breed and Portuguese), hunting, warfare, medicine, iron-work, pottery, social organisation, terms of relationship, religious beliefs, relations of the sexes, folk-lore—and what perhaps is most interesting and novel, their ideas about psychology, astronomy, biology, the undefined external forces of Nature, thaumaturgy, and therapeutics. The chapter on etiquette brings home to one how minutely these seemingly savage men and women may order their lives by prescribed custom, and what slaves they can be to convention. No newly enriched person in our own land, wishing to move

FIG. 1.—A Baluba type. From "The Ila-speaking Peoples of Northern Rhodesia."

[1] "The Ila-speaking Peoples of Northern Rhodesia." By the Rev. Edwin W. Smith and Capt. Andrew Murray Dale. In two vols. Vol. i., pp. xxvii+423; Vol. ii., pp. xiv+433. (London: Macmillan and Co., Ltd., 1920.) Price 50s. net two vols.

without attrition in the highest circles, need undergo such a tax on the memory as the stranger who would desire neither to offend nor to shock a Mu-ila man or woman. The language is full of pitfalls, because it is as rich in double meanings as any European tongue. You may be grossly indecent in alluding to common objects of the house or garden implements.

The Ba-ila are so sensual that the relations between the sexes are nearly promiscuous. Yet here again everything must be governed by custom. One man may be fined lightly for a gross act of immorality, while another will be mulcted severely for merely alluding to an indecent proposition. Many of the dances and a number of the songs—especially those sung at funeral ceremonies—are termed by the authors "phallic," and here very sensibly they quote the actual words and deeds, lest imagination should exaggerate. The authors conclude that this condition of immorality, especially among quite young people—children not fully mature—is leading to a seriously diminishing birth-rate.

FIG 2.—Young Ba-ila fresh from the hairdresser. From "The Ila-speaking Peoples of Northern Rhodesia."

In some writings on Africa missionary work is still sneered at; but one result—especially in South and East Africa—has been to raise the birth-rate amongst the negroes by discouraging polygamy, and, above all, by strenuously urging the abolition of the depraving initiation ceremonies and all immodest behaviour amongst young girls and boys. The worst feature in Ila-land is the abuse of quite young girl-children by adult men.

But the study of these primitive people as a whole leaves one with a very pleasant mental impression, alike of them and of their two interpreters, Mr. Smith and Capt. Dale. The absolute truth is told about them, but it is told so tersely, with so much humour, sympathy, and insight, that the discriminating reader, the ethnologist above all, rises from the reading of "The Ila-speaking Peoples" with a sense of gratitude to the authors and with a wonderfully vivid impression of negro life in South Central Africa—a life in that particular region very little influenced as yet by the white man. One hopes sincerely that the Ila people may turn the corner under wise administration and missionary teaching, and become in time a flourishing race, playing a considerable part in the development of Northern Zambezia.

Industrial Research Associations.

III.—THE BRITISH COTTON INDUSTRY RESEARCH ASSOCIATION.

By DR. A. W. CROSSLEY, C.M.G., F.R.S.

THIS association was incorporated in June, 1919, but much valuable work had been done previously by a Provisional Committee appointed by the Department of Scientific and Industrial Research towards the end of 1916. The Committee was presided over by Mr. J. W. McConnel, to whose efforts it is largely due that more than 90 per cent. of all the spinners, doublers, manufacturers, bleachers, dyers, calico printers, and finishers engaged in the cotton industry have given their support to the association, which now numbers 1461 members, including representatives of the lacemaking and hosiery trade. The first chairman of the association was

Mr. H. R. Armitage, of the Bradford Dyers' Association, who was most unfortunately compelled to resign owing to ill-health after a few months' activity. His place has been taken by Mr. Kenneth Lee, of the Tootal Broadhurst, Lee Co., Ltd. The council of the association is composed of men representing all sections of the industry, and is strengthened by the inclusion of some men of science and leaders of the following great operatives' organisations: the Amalgamated Association of Operative Cotton Spinners, the Card and Blowing Room and Ring Frame Operatives' Association, the Amalgamated Weavers' Association, and the Operative Bleachers', Dyers', and Finishers' Association.

In November, 1919, the council appointed the present writer, then Daniell professor of chemistry in King's College, University of London, director of research. He was unable to take up his full duties until April of the present year, and in the meantime plans for the future development of the association's activities were discussed. It was decided that individual scientific effort would not give the desired results, which could only be obtained by establishing an institute worthy of the great cotton industry, where all the sciences involved in that industry would be found represented and working in the closest co-operation. Apart, therefore, from the annual income of the association, the council has decided to raise a special building fund of 250,000*l*. A property with more than 13 acres of ground has been purchased in Didsbury, and the existing house adapted to serve as the administrative block, with accommodation for offices, library, council room, etc., as well as dining rooms, rest rooms, and some living rooms for the research workers. Owing to the housing difficulty, it has also been decided to build a certain number of houses in the grounds, where the first portion of the laboratories and workshops is also in course of construction. The whole will be known as the Shirley Institute.

The heads of the following departments have been appointed: Information and records bureau; botany; colloid chemistry and physics; general chemistry; organic chemistry; and physics; and, pending the completion of the new laboratories, accommodation has been placed at their disposal by the Manchester University and the College of Technology. The information and records bureau will have for its main object the acquiring of all information regarding cotton, which will be available for the members of the association. In addition, current literature will be abstracted and indexed, and reports on previous work on cotton will be prepared. This naturally means the gradual acquisition of an extensive library, and it is hoped that, in accordance with the suggestion contained in the Report on Libraries and Museums of the Adult Education Committee of the Ministry of Reconstruction (Cmd. 9237), this will become a central library organisation for the cotton industry.

The council has taken a very broad view regarding the nature of the research work to be undertaken, which is necessitated by the almost complete interdependence of the various sections of the industry. Work which will benefit one section must of necessity exert an influence on the whole industry. Hence, as shown by a programme of research drawn up by the research committee for the general guidance of the director and research staff, the work will be mainly of a fundamental nature. For the future development of the industry it must be left to science to find out more of the life-history and properties of the cotton fibre, and to carry out fundamental research into the chemical and physical changes introduced during manufacture, before the users of the fibre, in conjunction with the research staff, can make suggestions for the improvement of existing processes and machinery. For example, the study of the properties (botanical, chemical, and physical) of the single cotton fibre is fundamental to the whole industry. The fibre is of a complicated nature, consisting of differing chemical products enclosed in an outer skin or cuticle, and it is not known certainly whether some bleaching processes remove the cuticle, or how its presence or absence affects the feel, lustre, dyeing, and wearing properties of fabrics. The botanical side will also be concerned with the conditions of growth and breeding of the cotton plant, in so far as these affect the quality of the raw material, and it is hoped that this work will be carried out in the closest conjunction with the research department of the Empire Cotton Growing Committee.

The general purpose of research in cotton spinning will be to connect the properties of the raw cotton with those of the yarn it produces. Evenness of yarn is of importance to both the spinner and the weaver, but methods for improving this and other qualities demand in the first place accurate methods of testing them. During the exploration of this field precise information should be obtained as to the manner in which each existing machine carries out its various functions, and as to the effect of different properties of the raw cotton and of mixings thereof on these functions. Such measurements and information require the invention of special scientific instruments and methods for measuring the properties of raw cotton—*e.g.* length of staple, the diameter, strength, and elasticity of yarns and fabrics, and the effect of temperature and humidity on the spinning properties of the fibre.

The sizing problem is also one of great importance. It is not known, for example, why sizes prepared apparently in the same way should produce in some cases hard, and in others soft, warps, or what is the effect on the size of adding waxes, fats, and other substances, or how these affect the penetration of the threads, strength, and resistance to rubbing; nor is it possible in many cases to trace the cause of defective sizing to its ultimate chemical or physical source, or to predict from an analysis the exact sizing qualities of a given sample of material.

Many other problems could be alluded to—*e.g.* the effect of water and of steam at high and low pressures on the fibre, and the tendering of fibres and fabrics by acids, light, and heat—but sufficient have been mentioned to show that the whole industry bristles with scientific problems awaiting solution.

In attacking these problems it is certain that a vast amount of purely scientific work will have to be undertaken. The association is fully alive to the fact that pure research has in the past, in this country at all events, been almost the monopoly of the universities; but the scientific workers of our universities have not, generally speaking, been sufficiently in communion with industry fully to appreciate the nature of the problems in pure science which any particular industry required to be solved. The association hopes to keep in close touch with the universities, and that by so doing the ties between the scientific workers and industry may become closer in future. Certainly the association looks to the universities for much help as regards both the pure research work which will emanate from them, and the skilled research workers trained by them.

There is a further way in which relations with the universities may become more intimate, for, owing to the generosity of some of its members, the association possesses a number of scholarships tenable at any university, two of which have just been awarded; it also has the power to endow scholarships and bursaries for the training of persons engaged in studying the principles involved in any of the industries using cotton, or connected therewith, and four such scholarships are now held at universities, two being provided jointly with the Empire Cotton Growing Committee.

The relationship with pure science cannot, however, be strengthened by a policy of the purely "take and be thankful" type; something must be given in return; and it is hoped that science will be enriched by the publication of the pure scientific research carried out in the Shirley Institute. More particularly may this be the case in connection with the development of the department of colloid chemistry and physics, representing as it does a branch of science which has received comparatively little attention in this country.

Obituary.

LORD GLENCONNER.

BY the death, on Sunday, November 21, of Edward Priaulx Tennant, Baron Glenconner of Glen, the country has lost an appreciative friend of all good work, whether in the direction of art or of science, as well as a man of simple, lovable disposition and sterling character.

From his father, Sir Charles Tennant, the first baronet, Lord Glenconner inherited chemical works at Glasgow, to the business of which he attended; but his own tastes lay chiefly in the direction of forestry, natural history, and antiquarian pursuits. To study methods of forestry he had travelled in Germany and in many parts of the world, and his estates bear witness to the care bestowed on tree cultivation. It is well known that he purchased and gave Dryburgh Abbey to the nation a few years ago; and it is more than suspected that he had intended to do the same with Stonehenge had not another benefactor forestalled him. His house, which was characterised by admirable simplicity, was the resort of many distinguished persons, and his picture gallery was often thronged to hear about some discovery of scientific interest.

The loss of his exceptionally promising eldest son in the war was a profound grief to Lord Glenconner, from which perhaps he only half recovered; but he became convinced, and allowed himself to express publicly his conviction, of a reality underlying the old idea of human survival after bodily death.

REGINALD J. FARRER.

MR. REGINALD FARRER, whose death was reported in the *Times* of November 19, was an extraordinarily enthusiastic horticulturist, possessing, in a high degree, a poetic and artistic temperament, an experienced and intrepid traveller, and an accomplished and versatile writer. In horticultural circles he will be remembered as an ardent collector and cultivator of alpine plants, which he knew as few know them. He had studied them on many occasions in their native haunts, and had cultivated them under ideal conditions in his garden at Ingleborough. Many new plants, some of them of great interest and beauty, have been discovered and introduced by him into our gardens, enriching them, and at the same time making a valuable contribution to our knowledge of the flora of China and Tibet. As a geographer also Farrer will be known to many. The award of the Gill memorial medal of the Royal Geographical Society early this year was a recognition of the useful work he had done for geography in his journeys on the Chinese border of Tibet. His lectures before the society on these journeys were published in the *Geographical Journal*, vol. xlix., pp. 106–24, and vol. li., pp. 341–59.

Reginald John Farrer was a Yorkshireman, born forty years ago. At his home, near the beautiful Ingleborough Mountain, he had for many years made gardening, and especially rock gardening, a dominating interest. His natural rock garden is probably a unique example of such a garden in this country. In 1894, when a mere boy, he contributed to the *Journal of Botany* a note on the rare *Arenaria gothica*, which he had discovered in another station at Ingleborough some miles distant from that where alone it had previously been known in Britain. In 1898 he entered Balliol College, Oxford, as a commoner. Later he made several explorations in the European Alps with the special object of studying their vegetation. These explorations were described in several articles published in the *Gardeners' Chronicle* and in his book "Among the Hills," which appeared in 1911.

In 1903 Farrer undertook a journey round the world, visiting among other places Canada, China, and Japan. He visited Ceylon in 1907, and the years 1914 and 1915 were spent, in company with Mr. William Purdom, formerly of Kew, in exploring the Kansu region of Western China. "On the Eaves of the World," published in 1917, is a narrative of his wanderings and experiences during 1914, which were also the subject of a series of articles in the *Gardeners' Chronicle*. Last year another journey to Eastern Asia was undertaken with Mr. E. H. M. Cox. When about to return home, while travelling on the frontier range between Burma and China, Farrer fell a victim to diphtheria, and died on October 16.

Among the plants Farrer discovered were many new to botany as well as to horticulture. Several new species bear his name; he is also commemorated in Farreria, a new genus of Thymelæaceæ. In addition to works of fiction and those already specified, he wrote "My Rock Garden" (1907), "Alpines and Bog Plants" (1908), "In a Yorkshire Garden" (1909), "The Rock Garden" (Present-day Gardening Series), and "The English Rock Garden"; the last, containing more than 1000 pages and 102 plates, was published in 1919, and was reviewed, perhaps somewhat adversely, in NATURE for February 19 last, p. 664.

In spite of the extravagant, sometimes absurd, language of many of Farrer's writings, he accomplished much work of great value, and his untimely death is a distinct loss, which many will profoundly regret.

Notes.

THE Ministry of Agriculture and Fisheries has issued a memorandum (General Service, November 13) on the mode of spread of foot-and-mouth disease. The outbreaks which have occurred since the beginning of 1919 have enabled a closer analysis to be undertaken of the circumstances favouring infection than has hitherto been possible, the work being carried out by the Chief Veterinary Officer, Sir S. Stockman. One fact emerges as established, viz. that Great Britain, freed from the disease as endemic among animals in a particular district, is invaded only when the disease is prevalent on the Continent, particularly in the North of France, Belgium, and Holland. Livestock being excluded as a factor of spread of the disease, suspicion falls on human beings, on imported feeding-stuffs, and on litter coming from infected Continental districts. Importation of hay and straw, except for exceptional purposes, has, however, been prohibited since 1908 without materially influencing the occurrence of outbreaks. Carriage of infection by human beings and other means, *e.g.* by bird migration, seems equally improbable. The conclusion is drawn that the virus may be air-borne. The sick animals slobber, and it seems reasonable to suppose that the particles of infected mucus may be carried for long distances in the air, just as volcanic dust is. The outbreaks in this country are more frequent in some districts than in others, and it is suggested that in the areas mostly invaded air-pockets of negative pressure may exist which would account for the suspended virus descending to earth or water.

IN a lecture on "Eugenics and Religion," delivered on November 16 under the auspices of the Eugenics Education Society, Dean Inge pointed out that antagonism to reasonable eugenics, *e.g* the prevention of deaf-mutes and epileptics from having children, comes not from religion, but from the anti-scientific temper. A general revolt against the dictatorship of science (surely not yet even on the horizon) had been the most remarkable tendency in modern thought. But it seems to us it would have been more accurate to say that the objections even to considering the scientific control of life have come from a widespread sluggishness of intellect, an instinctive dislike of upsetting innovations, and, not infrequently among the elect, an other-worldliness which regards mundane conditions as a swamp to be crossed as quickly as possible. According to Dean Inge, the prospect for the immediate future is as black as it could be, and partly because society has not the seriousness and courage to replace a relaxed natural selection by a thought-out rational selection. At present we are breeding from our worst stocks, and our best are being squeezed out of existence—an extreme statement, probably too epigrammatically reported. But it has enough of truth in it to make us uncomfortable. We note, however, to take a glimpse of the other side, that, apart from the professional classes, many members of which are now prompted by economic pressure to restrict their family or to have none at all —which, as Dean Inge says, means a diminution of the well-born—there is an abundant supply of strong, intellectually alert, and good-willed men and women among working people. It appears to us to be historically true that a large proportion of the men who count have emerged, not from select castes, but from the general body of the population. Dean Inge attaches great importance to the post-war strain on professional men, which makes for restriction of the family, but this has been going on for a long time. He looks forward to a keen struggle for subsistence, which will force man to become a eugenist or to go under. Towards extreme struggle the nation is at present hurrying blindly.

THE chairman of the Colour Users' Association, Mr. Vernon Clay, has issued an important memorandum on the present position of the dye industry in Great Britain from the users' point of view. It is stated that the necessity for the establishment of dye-making factories is particularly a question of national security, because they are capable of maintaining a larger number of trained scientific workers than any other industry. At present the chief drawback with which the dye manufacturer has to contend is lack of experience in factory production, and while he is obtaining this knowledge some sort of protection must be afforded him. Three methods of safeguarding the infancy of the industry have been suggested. The first, by tariffs, is regarded as useless on account of the fluctuating rates of exchange; the second, by subsidy, is also ruled out owing to the difficulty of allocating a grant in an industry which has numerous by-products; and the third, by prohibition and licensing, is regarded as the only practicable scheme. Only dyes the home manufacture of which was inadequate in quantity or quality would be admitted under licence as imports. Under the Peace Treaty Germany must sell a proportion of her dyestuffs to this country until 1925 at rates similar to those which she obtains from other customers, so that the consumer is protected until that date. The manufacturer receives no benefit, and probably will require financial assistance to enable him to establish his industry. Assuming that after January, 1925, a licensing body were set up, the State, the dye makers, and the dye consumers should be represented on it; the last should have the preponderating voice because they will bear the brunt of the expense and inconvenience caused, and are the persons who can best gauge the effects on export trade, but the Government would retain the right of veto. The Government urges that this would place the power to defeat legislation in the hands of the consumers, and therefore negotiations between the association and the Government have proved unsatisfactory.

A DECISION which will be of interest to all scientific workers was given by Mr. Justice Eve in the Chancery Division of the High Court on Wednesday, November 17, on the motion for an injunction to prevent Messrs. Brunner, Mond, and Co. from distributing 100,000*l*., as it was authorised to do by an extraordinary general meeting on August 5. It will be remembered that at this meeting the directors were empowered to distribute that sum to such universities or other scientific institutions in the United Kingdom as they might select for the furtherance of scientific education and research. The money was to be provided from the investment surplus reserve account. It was urged that in carrying out the resolution the directors would be acting in a way which was outside the scope of the stated objects of the company, but Mr. Justice Eve ruled that the resolution came within the bounds of what was likely to lead to the direct advantage of the company, and therefore refused to make an order on the motion.

FROM time to time scanty information has reached this side of the Atlantic of developments in the use of "colloidal fuel," and experts have looked forward to receiving fuller information by which they could judge the value of the many claims put forward. Mr. Lindon W. Bates, with whom has been associated Mr. Haylett O'Neill, has been the pioneer of colloidal fuel, and these gentlemen read papers before the Institution of Petroleum Technologists on November 16 in which they put forward all that could possibly be claimed for this particular type of fuel. It was described as a stable, mobile, atomisable fuel displaying colloidal characteristics, comprising particles of solids, droplets of liquids, or minute bubbles of gas suspended in one or more varieties of liquid hydrocarbons. For commercial purposes it contains 25 to 40 per cent. of pulverised coal, which is held in stable suspension in oil, so that the product can be handled and fired with the usual oil-burning apparatus. The solid components may be coal, coke, charcoal, hard pitch, or any grindable carbonaceous substance, for the best results ground so fine that 97 per cent. will pass through a 100-mesh screen and at least 85 per cent. through a 200-mesh screen, and but little is stated to settle out in reasonable periods. The colloidal fuel is often volumetrically richer in heat units than the straight oil, and a saving of cost as compared with straight oil is shown, but this is far from holding as compared with powdered coal. In general, the efficiencies of oil and colloidal fuel are claimed to be substantially the same, and it is stated that there is some evidence that a surface combustion effect on the myriads of fine particles of solid is favourable to efficiency.

SIR FREDERIC KENYON has been elected a foreign associate, and Sir George Grierson a foreign correspondant, of the Paris Academy of Inscriptions and Belles Lettres.

BY the will of Mr. E. W. Smithson, who died on August 11, leaving estate of the value of 40,010*l*., the ultimate residue, after the death of his wife, is bequeathed to the Royal Society "for the furtherance of research in natural science, with a view of new laws or principles rather than the exploitation of what is known."

THE Cavendish Society, Cambridge, has decided to reinstitute its annual dinner, and has fixed the date this year for December 10. This dinner, with its post-prandial proceedings of topical physics songs, is a well-known function to former physics research workers at Cambridge. Information may be had from the Secretary, Cavendish Laboratory.

THE KING has given orders for the following appointments to the rank of Commander of the British Empire (C.B.E.), to be dated June 5, 1920:—Dr. A. C. Jordan, for work in connection with radiology at Queen Alexandra's Hospital; Mr. H. A. Madge, principal technical adviser on the wireless telegraphy staff of H.M. Signal School; and Dr. F. Mollwo Perkin, for valuable services rendered to various Departments of State.

THE Secretary of State for the Colonies has appointed a Committee to consider and report what steps can be taken to secure the assistance of the universities of this country in carrying out the research work which is essential to the protection of the inhabitants of the Colonies and Protectorates from disease and to the successful development of their veterinary, agricultural, and mineral resources. The members of the Committee are:—The Right Hon. Lord Chalmers (chairman), Sir H. Birchenough, Sir J. Rose Bradford, Sir W. Fletcher, Prof. E. B. Poulton, Sir D. Prain, Sir H. Read, Sir S. Stockman, and Sir A. Strahan. Mr. A. B. Acheson, Colonial Office, is the secretary of the Committee.

THE following have been elected members of council of the Röntgen Society for the ensuing year:—*President:* Dr. R. Knox. *Vice-Presidents:* Prof. A. W. Porter, Prof. J. W. Nicholson, and Dr. G. H. Rodman. *Hon. Secretaries:* Dr. R. W. A. Salmond, 51 Welbeck Street, W.1, and Dr. E. A. Owen, National Physical Laboratory, Teddington, Middlesex. *Hon. Treasurer:* Mr. Geoffrey Pearce. *Hon. Editor:* Major G. W. C. Kaye. *Other Members of Council:* Dr. J. Metcalfe, Mr. E. P. Cumberbatch, Dr. A. E. Barclay, Mr. F. J. Harlow, Dr. W. Makower, Mr. J. Russell Reynolds, Prof. A. O. Rankine, Mr. Cuthbert Andrews, Major C. E. S. Phillips, Dr. R. Morton, Sir A. Reid, and Mr. A. E. Dean. The names in the above list are in order of seniority.

THE Forestry Commission, in consultation with the India and Colonial Offices, has appointed an Inter-Departmental Committee to prepare a scheme for giving effect to the resolutions of the British Empire Forestry Conference with regard to a central institution for training forest officers, including (1) its location; (2) its organisation, constitution, and control; (3) its cost and method of financing; (4) its relation to forest research; and (5) the qualifications, selection, and cost of maintenance of students. The Committee consists of the following members:—Right Hon. Lord Clinton, representing the Forestry Commission (chairman); Mr. P. H. Clutterbuck, representing the India Office; Major R. D. Furse, representing the Colonial Office; Sir Ronald Munro-Ferguson; and Prof. J. B. Farmer. Mr. W. H. Guillebaud, Forestry Commission, 22 Grosvenor Gardens, S.W.1, will act as secretary to the Committee.

MR. L. H. DUDLEY BUXTON, of the department of human anatomy, University Museum, Oxford, has been invited by Dr. Zammit, of the Malta University, to conduct an investigation of the physical characters of the ancient and modern inhabitants of Malta. A party, consisting of Mr. Buxton, Mr. A. V. D. Hort, of Brasenose College, Mrs. Jenkinson, of Somerville College, Miss Moss and Miss Mond, of Lady Margaret Hall, under the leadership of Mr. Buxton, will visit the island for this purpose during the coming Christmas vacation. Archæological investigations will also be undertaken, but only in so far as these may be necessary to throw light upon the physical anthropology. The expedition has received the approval of the Governor of Malta, and the expenses will be met by a grant from the Mary Ewart Trust and by a generous donation of 100*l.* from Sir Alfred Mond. A report on the results of the expedition is to be presented at a meeting of the Royal Anthropological Institute to be held early in the spring.

THE Institute of Industrial Administration is holding a meeting at the Central Hall, Westminster, on December 7, at 7 p.m., when Mr. Richard Twelvetrees will read a paper on "Road Transport as an Aid to Industrial Management." The chair will be taken by Mr. E. Shrapnell-Smith, chairman of the Commercial Motor Users' Association, and the subject will be discussed from various aspects, including the development of roads, traffic congestion, handling of goods, and the design and maintenance of road motor vehicles. The lecture will be illustrated by kinematograph pictures, and various interesting models will be on view. Up to the present time the development of road transport has been largely regarded as the province of the engineers responsible for the manufacture of the actual vehicles employed, but it is expected that a much wider field of discussion will be opened by the lecture, which should be of scientific interest, and readers of NATURE are invited to attend.

THE Institute of Physics has now been incorporated and has begun to carry out its work. The object of the institute is to secure the recognition of the professional status of the physicist and to co-ordinate the work of all the societies interested in physical science or its applications. Five societies have already participated in this co-ordination, namely, the Physical Society of London, the Optical Society, the Faraday Society, the Royal Microscopical Society, and the Röntgen Society. The first president is Sir Richard Glazebrook, who will preside at the opening statutory meeting of the institute, which will be held early in the new year. The list of members now includes the names of more than two hundred fellows. Sir J. J. Thomson, the retiring president of the Royal Society, has accepted the invitation of the board to become the first, and at present the only, honorary fellow. It is a tribute to the status already acquired by the newly formed institute that its diploma is now being required from applicants for Government and other important positions requiring a knowledge of physics. Particulars with regard to the qualifications required for the different grades of membership can be obtained on application to the secretary, Mr. F. S. Spiers, 10 Essex Street, London, W.C.2. Fellows elected before May 1, 1921, will have the privilege of being styled founder fellows.

THE new premises of the London School of Tropical Medicine and the Hospital for Tropical Diseases, Endsleigh Gardens, N.W.1, were opened by the Duke of York on November 11. Lord Milner in an introductory address sketched the history of the school, which owed its inception to Sir Patrick Manson during the Colonial Secretaryship of Mr. Joseph Chamberlain, who welcomed and helped the scheme. Opened in 1899, the work of the school was carried on for twenty years in buildings at the Branch Hospital of the Seamen's Hospital Society, Royal Albert Dock. During the war it was found desirable to remove the school to a more central position in London. Through the generosity of the Red Cross Society 100,000*l.* was received for the purchase of the new buildings, and it became necessary to raise an additional sum of 150,000*l.* for the endowment of the school, of which more than 100,000*l.* had been collected. The Duke of York, in declaring the buildings open, paid a tribute to the successive Colonial Secretaries who had furthered the progress of tropical medicine, and unveiled a tablet recording the munificent gift of the British Red Cross Society and the Order of St. John of Jerusalem. One of the wards in the hospital has been endowed by the Mesopotamia Comforts Committee in recognition of the services of Sir Stanley Maude, to whose memory a mural tablet was unveiled. It is a pleasure to record that Sir Patrick Manson, the "father" of the school, was able to be present at the ceremony.

SIR CHARLES LYELL in his "Antiquity of Man" remarked that "neither need we despair of one day meeting with signs of man's existence in the Cromer Forest bed, or in the overlying deposits, on the ground of any uncongeniality of the climate or incongruity in the state of the animate creation with the well-being of our species." Mr. J. R. Moir in a paper republished from the Proceedings of the Prehistoric Society of East Anglia for 1919–20 (vol. iii., part ii.) describes a series of humanly fashioned flakes found in the cliffs and on the shore at Mundesley, Norfolk. Discoveries of similar flakes were made by Mr. Lewis Abbott in 1897 and by Dr. W. L. H. Duckworth in 1911. So far no human bones have been found in these strata, but the author notes that the Mauer Sand in which the famous Heidelberg mandible was found corresponds in date of formation with the Cromer Forest bed.

THE definition of the term "species" in biology is a perennial source of discussion. Dr. J. Massart considers that the Linnean definition—"the smallest assemblage of organisms that resemble one another more than they resemble others, and that transmit their peculiarities to their descendants"—corresponds neither to the Linnean species nor to the Jordanian species, but to the pure line of Johannsen. This last, however, need not be propagated by self-fertilisation, nor need the parents be homozygotes, for self-sterile and heterozygote lines are known. Dr. Massart illustrates his remarks by observations on the ilex, in a single grove of which tree he claims to have detected thirty-two distinct lines. Clearly, as he says, the systematist and the geographer must content themselves for the present with Linnean, or at the most with Jordanian, species. Dr. Massart's paper is published by the Belgian Academy (*Bull. Classe des Sciences*, 1920, pp. 366–81).

THE *Review of Applied Entomology*, now approaching the completion of its eighth volume, is a monthly publication of widely recognised value. For the modest sum of 18*s*. per annum one is enabled to keep abreast of all published work in the agricultural, medical, and veterinary aspects of the subject. Since the review was commenced an increasing number of articles in out-of-the-way periodicals have been abstracted, particularly those in the Russian and Spanish languages. It may be said that it is largely due to these abstracts that the work of Russian economic entomologists is being more widely known in this country and America. "Economic" entomology is interpreted in a liberal sense, and no very hard-and-fast line of demarcation is drawn between it and "scientific" entomology. For this reason the professedly scientific student should not neglect to peruse the pages of this valuable journal, for only by its means are many unfamiliar papers likely to be brought to his notice.

THE *Volta Review*, the Washington monthly devoted to speech-reading, speech, and hearing, is printing and issuing in the form of reprints a series of profusely illustrated articles on the mechanism of speech by Dr. E. W. Scripture, the author of the Carnegie Institution publication on "The Study of Speech Curves," of "Elements of Experimental Phonetics," and other related works. The series promises to be of great interest to students of phonetics, to those with normal hearing no less than to those who are handicapped in this respect. The voiced *h* of the Sanscrit grammarians is not quite such a novelty in Europe as would appear from p. 5 of the first article (July, 1920). Its existence in English was recognised by David Lyle in his "Art of Shorthand Improved" (1762), and its claims, though denied by Whitney and others, were fully admitted by Sweet.

AN address by Mme. Curie on the radio-elements and their applications appears in the *Revue Scientifique* for October 23. After reviewing succinctly the marvellous progress in the subject during the past two decades, and the current views to which the study of radio-active substances has led, reference is made to their applications for the manufacture of luminous compounds and in medicine. The first, though largely developed during the war, are obviously of application in innumerable ways for peaceful purposes wherever the cost of the radio-active materials is not prohibitive. In addition to the medical applications, such as for the treatment of lupus and arthritis, radium-therapy was during the war applied to the treatment of unhealthy scars and wounds, healing in numerous cases being assisted by irradiation. In spite of the slowness of the progress so far made, radium is regarded as a very powerful means of combating cancer, the number of deep cancers successfully treated steadily increasing. It is important that in all countries full use should be made of all resources in radio-active materials. As possible new sources the more active springs are referred to, one in Italy being mentioned which gives about 30 millicuries of emanation in 250 cubic metres of water daily. If this could be separated it would prove of great service in medicine. The proper utilisation of these resources would be facilitated by the establishment of central national institutions for pure researches in radioactivity in connection with an industrial laboratory for the treatment of large quantities of materials, and a section devoted to radium-therapy and its teaching. In conclusion, a strong plea for such an institute is made for France which shall be worthy of the country and its capital. Hitherto the requirements of medical men and physicists have been too exclusively considered.

IN the May and November issues of the Journal of the Royal Photographic Society Dr. W. H. Mills and Sir W. J. Pope publish the results of their work during the last few years on photographic sensitisers. In the first communication they describe the preparation and sensitising effect of twenty different *iso*cyanine derivatives, one of which, trimethyl*iso*cyanine iodide, is now well known as pinaverdol or sensitol green. They find that the total induced sensitiveness diminishes steadily as the molecular weight of the dye is increased by the introduction of heavier radicals, and they are able to draw other inferences that may prove useful guides in seeking for new sensitisers. Of these twenty derivatives, which include ethyl red and pinachrome, it appears that none is so generally advantageous as sensitol green. The second communication treats of the "carbocyanines," and describes the preparation and action of eighteen different derivatives. One of the diethylcarbocyanine iodides is pinacyanol or sensitol red, and it is found that the sensitising power for gelatino-silver bromide is far less in the dimethyl derivative, and that it sinks gradually on passing to the dipropyl and dibutyl compounds. In the *iso*cyanines the two quinoline residues are linked by the group :CH·, while the joining group in the carbocyanines becomes :CH·CH:CH·. The lengthening of this linking chain is accompanied by an extension of the extra sensitisation far into the red region of the spectrum, and the authors suggest that if methods were available for still further lengthening this chain it would be possible to produce compounds that would sensitise still further into the infra-red. Inferences are also drawn with regard to the effects of the positions of the substituting radicals and other matters.

THE Research Defence Society has lately published four pamphlets of general interest, namely: (1) Vaccination, by Dr. Mary Scharlieb; (2) The Prevention of Tetanus during the Great War by the Use of Antitetanic Serum, by Sir David Bruce; (3) The Work of the Medical Research Committee, by Sir Walter Fletcher; and (4) The Value of Experiments on Animals: Notes of Personal Experience, by Sir Leonard Rogers. The set, price 2*s*., may be obtained from the society's Secretary, 11 Chandos Street, Cavendish Square, London, W.1.

IT is eight years since the first edition of Prof. F. Soddy's volume, "The Interpretation of Radium," was published, and during that momentous period the necessity for enlarging and revising the original version has been proved. Mr. Murray announces that the author has been at work, and, with due compressions and the right additions, particularly those that bear upon the problem of the constitution of the atom, has brought the volume as closely up to date as is possible with a large and rapidly extending subject.

Our Astronomical Column.

LONGITUDE BY WIRELESS.—The scheme for linking up the observatories of the world by utilising wireless time-signals was referred to in NATURE for May 20 last (vol. cv., p. 370). It must be understood that no appreciable increase of accuracy over the older method by cable signalling is claimed; indeed, where the observers are not interchanged the precision is less. But the gain in convenience, expense, and wide distribution of signals is considerable, and it is known that where the travelling-wire method of observing transits is adopted, personality is greatly reduced; what remains is of the same order as the small local deflections of gravity, which can be eliminated only by extensive geodetical operations.

Mr. Dodwell, the director of Adelaide Observatory, has communicated the longitude which he deduces by the reception of the Lyons and Annapolis signals at Adelaide and Greenwich. It is 9h. 14m. 19·95s. using Lyons signals, and 19·78s. using Annapolis ones. The Nautical Almanac value is 20·30s. Allowance has been made for time of transmission, assuming a speed equal to that of light.

Many of the Australian boundaries are defined as meridians east of Greenwich by a specified number of degrees. They were determined by lunar observations and are known to be in error by some miles. It is not, however, expected that any change will now be made in them.

AN APPARENT EARTH-EFFECT ON THE DISTRIBUTION OF SOLAR FACULÆ.—The Monthly Notices for June contains a paper on this subject by Mr. E. W. Maunder, who acknowledges important help from several others in discussing the material, which consists of the Greenwich photographs from 1878 to 1916. The research was undertaken to test the result announced by Mrs. Maunder in 1907 that there was a preponderance of spots on the eastern half of the visible disc. Suggestions were made that this might arise from the spots sloping backwards or from the surface being heaped up behind the spot, thus avoiding the necessity of invoking an "earth-effect." The faculæ, however, since they are evidently above the surrounding surface, could scarcely be affected in either of these ways, so that an eastern preponderance seems very hard to interpret otherwise than as an earth-effect. Such a preponderance is, in fact, shown for the greater part of the period under discussion. The average excess for thirty years is about 3 per cent.—a quantity of the same order as that found by Mrs. Maunder for spots, and later for prominences. The northern and southern hemispheres of the sun are plotted, and show a general accordance, with differences of detail. There is fairly clear evidence that the eastern excess varies with the progress of the sun-spot cycle, being least marked during the increase of solar activity and most marked during its decline. In other words, regarding the earth-effect as a damping influence on the spot activity, then the solar resistance to this damping is greatest at the time of increasing activity.

THE DENSITIES OF BINARY STARS.—In a paper in *Mem. della Soc. degli Spett. Ital.* (vol. viii., Ott., Nov., Dic., 1919) Dr. G. Abetti discusses the densities of several binaries of which the relative masses and parallaxes are known. The diameters are inferred from the absolute magnitude, and surface brightness is inferred from the spectrum. The extreme values of density are 0·002 for ϵ Hydræ A and 1·87 for ϵ Hydræ B. On plotting the mean densities as functions of spectral type, there is a slow but steady decline from 0·60 for A5 and 0·55 for F5 to 0·45 for G0 and 0·2 for K0. This agrees with Prof. H. N. Russell's hypothesis on the assumption that the stars in question are in the giant stage, passing from an early diffused condition (type K0) to one more condensed through the types G, F, and A. Plotting mass as a function of absolute magnitude, all masses above 1·5 have about the same absolute magnitude, while all the fainter absolute magnitudes have about the same mass, the mean for these being about 0·3. The number of stars discussed is too small to lay great stress on the results.

Science and Fisheries.[1]

By H. G. MAURICE, C.B.

I SHALL, without apology, introduce a controversial topic, and endeavour to maintain a view which I myself hold with conviction. That view, expressed in the simplest terms, is that scientific investigations of fisheries are primarily a matter for the State, and can, as a whole, be most successfully conducted by a Government Department charged with responsibility for fishery matters. I believe—and I may say that, in a general sense, it is the view of the Department of State I have the honour to represent—that a Department of Fisheries which does not conduct such investigations is, *ipso facto*, unfitted for the work it has to do and might as well cease to exist, and that in many respects the State is better placed for the purpose than a semi-private institution.

A Live Department of Fisheries Must do Scientific Work.

The function of a Fisheries Department is to promote progress in the industry. All development in the fisheries and in the trades allied to fisheries is dependent, in the long run, upon scientific investigations. A Department of Fisheries which is not adequately equipped for scientific research is, in my view, incapable of developmental work, and ought not to be kept in being at the public expense, because it certainly can do little good, and it may do a great deal of harm. If it is suggested that the Department can act on the reports of others, I say that that is not so. The Department must have a scientific intelligence of its own. In the ordinary course of events scarcely a day passes on which administrative officers have not occasion to seek information or advice of the scientific staff. Supposing that they could rely upon mere reference to scientific reports, the Department must have scientific officers to advise it on the bearings of those reports upon its work, and you can imagine what kind of a scientific staff it would be that existed merely for the perusal of reports and was cut off from every prospect of active scientific work and individual research.

There are many things which a properly equipped Department may do for the maintenance and development of the British fisheries, but there is practically nothing it can do effectively—and it is almost certain that it will do a great deal of mischief—if it has not a thoroughly competent, well-equipped, and earnest scientific staff actively engaged in scientific research. I say, therefore, that the Department of Fisheries *must* conduct scientific investigations.

Fishery Investigations can most Successfully be Conducted by the State.

(1) To begin with, for all practical investigations of the sea there must be a broad basis of statistics, and no person or institution can have the same facilities for the collection of statistics as a Government Department the authority of which is recognised in every fishing port. I have no doubt that if the Marine Biological Association sought statistics of the fish landed in the port of Plymouth, and, indeed, any neighbouring ports, it would get statistics of a sort gladly given in a friendly spirit. It would be difficult for it, however, to guarantee their accuracy, and if it asked for similar statistics at such distant ports as Grimsby, Hull, Fleetwood, etc., it would probably be refused, and the statistics would almost certainly not be accurate if given.

(2) The Department of Fisheries must be in close and constant touch with the fishing industry—that is to say, with the owners of fishing vessels, skippers, mates, and crews. It is, therefore, in a position to get assistance from them in various forms. One very valuable form of such assistance is the suggestions which fishermen themselves may offer, and which, even if wide of the mark, may, at any rate, be pregnant of ideas, as to what needs to be investigated, what lines investigations might usefully follow, or what is actually the cause of a hitherto unexplained phenomenon. Practical assistance can be given in the hospitality of their ships when engaged in commercial fishing. At the present time the Fisheries Department has fourteen fish measurers in its service, the majority of whom are working, by the courtesy of owners and skippers, on commercial fishing vessels. They take and measure all the fish in a definite number of hauls per day, with a view to the correlation of age, length, weight, and maturity, and with regard to the variations which occur corresponding to the differences in the nature of the bottom, position and season, and, to some extent, time. That work is particularly important now, because as regards at least three of the principal food-fishes we have the results of investigations which took place over a period of three years in the case of each fish before the war, and by the work which is being carried on we shall place ourselves in a position to compare the present condition of the stock of these fish in the sea with that of pre-war days, and thus be able to judge of the effect of the greatest measure of closure which has hitherto taken place. As one of the questions which we shall be bound to answer before long is whether in the interests of the conservation of that stock certain areas of the sea should be closed by international agreement to all fishing vessels, or to certain types of fishing vessel, permanently, or at certain times and seasons, it behoves us to make use of the great experiment which the war provided.

(3) Marine investigations on the scale which the preservation of our great fishing interests demands involve the use of deep-sea fishing vessels, which need to be kept in commission continuously throughout the year and from year to year, and they involve also the co-operation and assistance of other Government Departments concerned with shipping and with the sea, especially the Board of Trade and the Admiralty. The last-named Department in particular must of necessity carry out for its own purposes investigations which have a direct bearing upon our work, and, with certain necessary limitations, we can count upon its co-operation with us.

(4) The aim of our investigations, the only justification for them in the eyes of the State, which is calling upon the taxpayer to foot the bill, is the necessity of taking all practical steps to promote the development of the fishing industry, which, though the fact is not generally appreciated, undoubtedly saved this country from disaster in the late war. Moreover, the fishing industry brought into this country invaluable supplies of food; and even now we must, if we reflect, recognise the fact that fish is relatively cheap compared with other food, and, regarded as an import which does not involve any corresponding export, it is nationally by far the cheapest food the nation receives.

[1] Opening of a discussion on "The Need for the Scientific Investigation of Fisheries" in Section D (Zoology) of the British Association at Cardiff on August 26.

It behoves the State, therefore, to look well into the conservation of the stock upon which the prosperity of the industry depends; but it must be remembered that the bulk of the fish landed by our fishing vessels is taken in extra-territorial waters which are accessible to all nationalities alike. If, therefore, scientific investigations point to the necessity or desirability of regulations for the closure of certain areas of the sea or of such measures for the increase of the stock of fish or of the general bulk of the fisheries as transplantation or artificial propagation, it is essential that those measures should be adopted internationally in order that the good which one nation is endeavouring to do may not be undone by another nation which refuses to co-operate. If we are to have international regulations based upon the findings of science, those findings must be internationally accepted, and the simplest road to such general acceptance is co-operation in the work. Moreover, the area to be covered is so vast, the medium in which we are compelled to work is so obscure, the facts in the propagation and lives of fish which we are called upon to correlate are so many, and the study of most of them at the present time is so little advanced, that no one country working alone can hope to cover the whole field except at a prohibitive cost or at a rate which will leave the solution of the main problems to future generations. Therefore, combined international investigations are essential, and to none are they more important than to the greatest sea-fishing nation in the world. If we are to have such international co-operation, I maintain it must be co-operation between Governments.

The Scientific Aims of the Fisheries Department.

Whatever opinion may be held as to the capacity of a Department of the Government to conduct scientific research, at any rate it is something that a Government Department should be so firmly convinced of the importance of such research that it insists on carrying it out. The Ministry of Agriculture and Fisheries had before the war advocated and partly embarked upon a wide programme of investigation framed in consultation with an Advisory Committee of persons eminent in science. That programme was interrupted by the war. It included wholehearted co-operation with the International Council for the Exploration of the Sea in its general programme, and in the particular parts of it in which this country was more especially interested, and so much importance did the Ministry attach to these investigations and to the co-operation of our foreign colleagues that, alone of all the belligerent nations, Great Britain continued throughout the war to subscribe to the funds of the Council in order that the organisation which it represented might be kept in being to facilitate the revival of its work when conditions permitted. There is little doubt that, but for the financial and moral assistance of Great Britain, the International Council would have come to an end. I am convinced that the International Council will justify its existence; and it is interesting to observe that two new Powers, Spain and Portugal, have recently announced their intention of joining the organisation.

I have urged as a general thesis that the Department must carry out scientific investigations or run the risk of stultifying itself. I do not propose to discuss individual researches, but only to state the broad questions to which the Department seeks an answer. They are these:

(1) How can the stock of fish be maintained at its present level so that the prosperity of the fishermen may be preserved and the supply of food for the people not be diminished?

(2) Can the stock be increased by human endeavour while the fisheries continue to yield their present toll—or even an increased toll—to human necessity?

(3) Can we learn to foretell good and bad seasons for this or that fishery?

Having answered all or any of these questions, we must be prepared to answer as regards each one of them the further question:

(4) In what measure is the application of the findings of science practicable in existing circumstances?

I think those questions present with fair accuracy the positive aims of our investigations. I do not refer here to that other aspect of our work which concerns the utilisation of the fish when caught or to investigations affecting only inland and fresh-water fisheries; for the moment I am thinking only of what may properly be described as marine investigations. But these investigations, or rather the motive behind them, have also a negative aspect. The Department must always be prepared to resist what I may describe as panic proposals for legislation or proposals advanced by interested persons who use alleged facts of natural history as a stalking-horse. I need not particularise too closely. Most of you are aware of the outcry raised against the trawl on the ground that it damaged the eggs of fishes on so-called spawning-grounds, and how this allegation was disposed of by the discovery of science that the eggs of all the principal food-fishes of the sea, except the herring, were pelagic, and could not, therefore, be damaged by the trawl. That instance alone is sufficient to prove the importance to the Department, which may be called upon to introduce or to criticise legislative proposals for the regulation of fisheries, of having an adequate scientific intelligence.

The Relation of the Department to the Independent Scientific Worker.

These being the aims, broadly stated, of the Department, does it claim for itself the whole field of fisheries research, and does it seek to suppress independent effort? By no means. To me such a policy is inconceivable. Provided that the Department is itself supplied with funds for an adequate equipment in both apparatus and *personnel*, it must welcome the assistance of the independent worker, for the work to be done is so great and the field of research to be covered so vast that there cannot be too many workers in it.

Moreover, there is, I think, a perfectly clear and obvious distinction to be drawn between investigations proper to the State and those which are more properly confided to independent institutions. The State's business is to conduct investigations which are more or less expressly directed to the solution of clearly defined problems affecting the fishing industry, the demand for the solution of which either has arisen or can be foreseen. The function of the independent worker is to add to the sum of our knowledge without regard to the solution of any particular problem. The line must not be drawn too fine. On one hand, the Departmental staff must seek in the course of its inquiries all the knowledge it can get; and I, for one, hold that the Departmental scientific worker should, so far as is practicable, be given opportunities from time to time to take up and follow up a line of research of his own choosing in order that his vigour and freshness of mind may remain unimpaired. On the other hand, the independent institution or individual worker may properly be invited to take up a line of investigation which the Department foresees may be of importance, but has not the means or the time to prosecute itself. In short, the Department may see that such and such an institution or individual is admirably qualified for a particular piece of work, and may invite it or him to take it up at the Department's cost.

And so, while the Department maintains—and, in my view, must maintain—that fishery investigations are primarily its concern, and that it must have, so to speak, a first call upon State funds available for such research, its policy is to encourage every competent worker in the field; to procure adequate financial support for every institution which is giving its attention seriously to such researches and is so placed as to be in a position to prosecute them successfully; and to work in the closest and most cordial co-operation with them without seeking in any degree to limit their independence.

We are proud to represent the greatest fishing industry that the world has ever seen, and we are determined, if possible—and the possibility depends largely upon the measure of support we can secure from a nation amazingly ignorant of, and indifferent to, this all-important industry—to make Great Britain lead the world, not only in the practice of fishing, but also in the scientific studies upon which the future prosperity of the industry must depend. We have established close co-operation with our colleagues in Scotland and Ireland, and, I hope and believe, friendly relations with the scientific workers of those institutions which have established a reputation in this field of research and the continued prosperity and efficiency of which it is our hope to secure. And while we seek to lead the world, we seek also to secure the co-operation of the Governments of those other nations which exploit the harvest of the sea; for we have no monopoly of the fishing-grounds, though our position is most favourable for their exploitation, and whatever measures may be devised by science for the maintenance or increase of the harvest can be effective only if they are carried out by international consent, and wisely directed to the attainment of the object which forms the motto of the International Council: "The rational exploitation of the sea."

Scholarships and Free Places in Secondary Schools.[1]

AN interesting and important Departmental Report upon the above subject was published on October 25 by the Board of Education. The inquiry was begun a year ago at the instance of Mr. H. A. L. Fisher, President of the Board, and the Committee appointed was comprised of representatives of the Board, of the local education authorities, of persons engaged in elementary and secondary schools, and of others interested in the question. Some sixty-six individual witnesses were examined, including officers of the Board of Education and of local authorities, as well as teachers and others, representing in all thirty organisations wholly or partly concerned with education. The Committee was directed to inquire into the existing arrangements for the award by local authorities of scholarships tenable at secondary schools or institutions of higher education other than universities or institutions for the training of teachers, and into the provision of free places under the regulations of the Board of Education, and to make recommendations thereon with respect to the improvement of such arrangements so as to bring the facilities of higher education within the reach of all classes of the population and with special regard to the migration of pupils from one school area to another.

The report deals concisely with the history of scholarship provision at the instance of local authorities, and shows that the scholarships awarded by them tenable at secondary schools had risen from 2500 in 1895 to more than 12,000 in 1906, and if there be included those awarded to intending teachers, to more than 23,500. The next important step with the object of facilitating the transfer of suitable pupils from elementary to secondary schools was taken by the Board of Education in 1907, whereby, as a condition of qualifying for the higher rate of grant, secondary schools were required to admit a certain percentage of pupils (ordinarily 25 per cent. of the previous year's admissions) from public elementary schools, subject to an entrance test of proficiency. These were styled "free-place scholars."

The immediate effect of these regulations was to increase the number of pupils receiving free tuition in secondary schools, including those arranged for by local authorities, from 24 to 27 per cent. In 1911–12 the total number of pupils receiving free tuition in such schools had risen to 32 per cent., the actual figures being 52,583, of whom 49,130 had been in public elementary schools, and of this number 38,009 owed their exemption from fees to the scholarship and free-place arrangements of the local authorities. At the present time in 961 grant-aided secondary schools in England with some 246,000 pupils enrolled, the number of "free places" held amounts to 72,386, or about 30 per cent., made up of 53,460 awarded by local authorities, 16,548 by school governors, and 2378 by other endowments.

It is now the duty of the local authorities, made statutory by the Education Act of 1918, to make provision for the means of higher education for all children capable of profiting thereby. It is estimated on the basis of 20 per 1000 of the total population of England and Wales that there should be at least 720,000 duly qualified children in the secondary schools, or more than double the present number. The grave defect of the present system is, the report states, that exemption from fees alone does not, by reason of the poverty of many parents, enable their children to take advantage of the benefits of higher education, or if they do they are quite unable to keep them at school beyond fourteen years of age for the full period of secondary education. It is therefore recommended that maintenance allowances, including all incidental school charges, should be made available for all free-place pupils who are in need of them. Whilst favourable to the abolition of all fees in grant-aided secondary schools, the Committee scarcely considers the time ripe for so drastic a change, and therefore suggests as a tentative measure the raising of the percentage of free places from 25 to 40 per cent. of the admissions. The age of admission of free-place pupils should be between eleven and twelve, determined upon by an examination in English and arithmetic, followed by an oral examination. Free places should be awarded for the full school course, secured by agreement with the parents, and where a pupil migrates to another area he should be entitled to continue his education upon the same terms. It is recommended that children who have not been previously educated in public elementary schools shall be eligible as free-place pupils provided that the parents show inability to pay fees for higher education.

The report is signed by all the members of the Committee, subject to certain reservations on the part of a few members. It concludes with a valuable summary of statistics bearing upon various aspects of higher and specialised education.

Developments of Wireless Communication.

IN the course of his address to the Royal Society of Arts on November 17, Mr. A. A. Campbell Swinton, chairman of the council of the society, gave a remarkable experimental demonstration of some of the most recent developments in wireless telegraphy. Utilising only a small aerial on the roof, where the conditions were far from favourable, he commenced by picking up some messages of a general news nature which were being sent out by the 7000-metre continuous-wave station of the Admiralty at Horsea, near Portsmouth, about sixty miles from London. These messages were first received by means of a group of thermionic valves, and the clear-cut, distinct Morse signals were rendered audible to the large audience by a telephone receiver with a trumpet attachment.

A printing equipment of the pattern originally developed by Mr. F. G. Creed for line telegraphy, but now most successfully adapted to wireless working, was then put into action under the supervision of Mr. Creed himself, and the receiver was soon seen to be punching a paper strip in accordance with the Morse signals received. The strip was then put into the printer, and appeared on another strip automatically translated into ordinary type. A portion of the printed strip was projected upon the screen, and was seen to contain an extract from a speech by Mr. Bonar Law, with but few errors due to jamming or atmospherics. Between the experiments Mr. Campbell Swinton found time to explain briefly the way in which groups of thermionic valves connected in a particular way can be employed to detect and to amplify the received oscillations, and, by the addition of an auxiliary oscillation, to produce signals at a frequency audible in a telephone, by the method of beats. He also recapitulated the leading principles of the extraordinarily ingenious Creed receiving and printing instruments by which the signals are recorded in the Morse code and afterwards translated into ordinary type by means which we hope to deal with a little more fully later. The most impressive demonstration was the reception and printing of a special message sent from the Eiffel Tower by the kindness of Gen. Ferrié on the same apparatus, but with even more success than in the case of the Horsea messages.

Passing to wireless telephony, Mr. Campbell Swinton attributed the earliest accomplishment of real wireless telephonic communication to Prof. Poulsen, of Copenhagen, and showed diagrams of the latest arrangement used by the Royal Air Force. In conclusion, a special five-valve receiver, made for the purpose by Mr. H. W. Sullivan, was put into action, and the audience was entertained with some spoken remarks, whistling, and gramophone music from a short-wave installation in another part of London. Mr. Campbell Swinton predicts great developments in the field of wireless telephony, and looks forward to the time when a speaker at a political meeting will be able to make himself heard all over the world, or it will be possible for the King to address his subjects throughout his Empire simultaneously.

Engineering at the British Association.

SIXTEEN papers were read before Section G; these covered a wide field, but, with the exception of Prof. Howe's paper on radio-telegraphy, electrical engineering was entirely unrepresented. Several of the papers were of great importance in that they dealt with fundamental properties of materials and of internal-combustion phenomena. Prof. F. C. Lea read a paper on the effect of temperature on some of the properties of materials. Many materials, such as aluminium alloys, have highly desirable properties when cold, but undergo such changes at the temperatures met with in engine cylinders as to make them quite unsuitable. Fireproof buildings must be designed to have the requisite strength at temperatures likely to be experienced during a fire. The tensile strength and hardness of a large number of materials have been determined at various temperatures obtained by means of electric furnaces, details of which were given. In all the alloys tested the tensile strength and the hardness decrease as the temperature is raised, the decrease being very rapid between 200° and 400° C., which is a range likely to cover both the examples mentioned above. Concrete was among the materials tested on account of its importance in view of the behaviour of ferro-concrete buildings in case of fire.

Col. Crompton discussed the nature of the action leading to the blunting of the edges of cutting-tools. Without accurate knowledge of the nature of this phenomenon one cannot scientifically re-design cutting-tools when making them of the recently developed high-speed steels containing, in addition to carbon, such metals as tungsten, cobalt, molybdenum, nickel, and vanadium. These steels can be hardened like carbon steel, but, unlike it, they retain their hardness at the high temperatures caused by taking heavy cuts at high speed. They are also stronger to resist fracture, and can thus be made with a more acute angle. This angle varies from 90° in shears and punches down to 15° in the blades of safety razors. The smaller the angle the less is the force required to drive the edge into the material, but the weaker is the edge to resist breakage. If examined under a microscope the edge is seen to be blunted by the crumbling away of the material of which the tool is made. This crumbling is hastened by the shaving wearing a groove in the upper face of the tool, thus reducing the angle of the edge. The author was of opinion that all the ordinary tool angles could be reduced 25 per cent. when using high-speed steels.

It is not often that a paper is read before Section G by an author who speaks, not as an engineer, but as a critical user of the engineer's products. Mr. S. F. Edge's paper on farm tractors made one realise the importance of such communications. Mr. Edge evidently spoke from a wide experience of tractors of many types, and discussed them not only from the engineering and agricultural points of view, but also from that of their psychological effect on the labour question. He warned makers against sacrificing quality to cheapness, and expressed his belief in the future of the tractor industry if makers will give the farmers the best machines alike in design, material, and workmanship.

Mr. H. R. Ricardo's paper on a high-speed internal-combustion engine for research dealt with experiments carried out with an engine specially designed for fuel research at the request of the Asiatic Petroleum Co. Nothing had been spared to make the experiments trustworthy and exhaustive and of both scientific and commercial value. The author described the design and construction of the engine in detail, together with the arrangements for measuring the fuel supply, etc. With this engine one will be able to determine the efficiency of various fuels and the best conditions for the use of any fuel, and also to compare the performance with the calculated figures based on thermodynamic theory.

Prof. W. H. Watkinson described a dynamical method for raising gases to a high temperature without the use of high pressures, which consists in drawing the gas into a cylinder through a partly opened valve, so that the pressure in the cylinder is only a quarter, say, of that outside, and then compressing the gas up to the external pressure with consequent rise in temperature. By a cascade arrangement of several such pumps the temperature could be raised sufficiently high to ignite the gas in an internal-combustion engine.

Dr. C. Batho read a paper on the partition of the load in riveted joints, in which he explained that he treated the riveted joint as a statically indeterminate structure, and applied the principle of least work in order to determine the distribution of the load between the rivets. The details of the method have already been published in the Journal of the Franklin Institute (U.S.A.) for November, 1916. The author quoted some experimental results obtained with an extensometer which supported his theoretical treatment.

Prof. J. T. MacGregor-Morris described and demonstrated his portable direct-reading anemometer for the measurement of ventilation in coal-mines. This instrument, which is made by the Cambridge and Paul Instrument Co., consists of an ebonite handle carrying a cage containing four fine nickel wires, two of which are exposed and two shielded from the air. These wires form the four arms of a Wheatstone bridge, and the galvanometer is connected by means of a flexible wire passing through the ebonite handle. The galvanometer is first used as a voltmeter to adjust the applied voltage to the correct value for the observed temperature of the air. It is then used to indicate the out-of-balance bridge current, which depends upon, and is used as an indicator of, the velocity of the air-stream.

Messrs. H. T. Tizard and D. R. Pye read a paper on specific heat and dissociation in internal-combustion engines. Although very little advance has been made in recent years in the thermodynamical theory of internal-combustion engines, there have been great practical advances, and the actual efficiency of a modern high-speed engine is higher than the theoretical efficiency calculated on the old specific heat figures of Clerk and Lange. The temperature reached is about 2500° C., but the specific heats of the gases concerned were not known accurately above 1500° C., and the extent to which dissociation of CO_2 and H_2O takes place was also unknown. Data on these subjects are now available, having been obtained in Nernst's laboratory in Berlin. The authors apply these data to the engine and obtain results which are confirmed by experiment as regards variation of power and efficiency with strength of mixture, with compression ratio, and with different types of fuel. Closely allied with the foregoing was the paper by Sir J. B. Henderson and Prof. Hassé with the attractive title "The Indicator Diagram of a Gun." The diagram is not obtained experimentally, but by calculating the pressure from the temperature, which can be determined only when the specific heat and dissociation are known. The temperature of the explosion is of the order of 3140° C. absolute, and it is calculated that of the energy liberated from 92 to 95 per cent. is converted into kinetic energy in the projectile. A gun is a type of internal-combustion engine, and very similar difficulties arise in investigating the two problems.

A very important but difficult subject is the action in steam-nozzles, and a paper by Prof. A. L. Mellanby and Mr. W. Kerr recorded a great amount of careful experimental work carried out at the Glasgow Technical College, the data from which were analysed and discussed in the paper. Pneumatic elevators for the unloading of grain were invented in England, but, as in many other things, it was in Germany that later study and development took place. Prof. Cramp, who had studied Continental practice before the war and commenced a research on the factors determining the efficiency of such apparatus, was afterwards given a grant by the Department of Scientific and Industrial Research to enable him to continue the work. His paper gave an account of the experiments made by him at Manchester University. To design apparatus intelligently one must be able to calculate the weight of grain which can be lifted a given height through nozzles and pipes of a given shape and size by a given vacuum and a given power. Whereas mechanical elevators can be made to work with 75 per cent. efficiency, the pneumatic type cannot reach a higher theoretical value than 40 per cent., and in practice falls far short of this. In spite of this pneumatic elevators are used because of their labour-saving qualities and freedom from dust.

The most striking and imaginative paper read before the Section was that of Wing-Comdr. Cave-Brown-Cave on airships for slow-speed heavy transport and their application to civil engineering. The author discussed the use of airships with one or more trailing air-barges for the transport of men and material over virgin country through which a railway was being constructed or in which it was necessary to carry on prospecting. In his opinion the present stage of development of airships and of the methods of handling them is such that their use for such purposes is quite practicable and offers great advantages.

Prof. G. W. O. Howe discussed the efficiency of aerials and the power required for long-distance radiotelegraphy. Of the power supplied to an aerial, the fraction which is radiated decreases with increase of wave-length, but, on the other hand, the longer waves are transmitted around the earth with less attenuation than shorter ones. On the latter point, however, there are but scant empirical data; on the usually accepted assumptions the author calculated the power required to produce a given strength of electric field at various distances with different wave-lengths. Using the optimum wave-length in each case, the power required for a range of three or four thousand miles varies as the sixth to the eighth power of the distance. Prof. Howe mentioned that recent experiments between America and Italy indicated the necessity of much smaller powers than those given in the paper. In conclusion, the author pointed out the need for extended research on this subject to enable a network of stations to be designed intelligently.

In the concluding paper Dr. J. S. Owens gave a very interesting description of the removal by drilling and blasting of 11,000 tons of rock-reefs from the bed of a river. No divers were employed, but holes were drilled from a floating barge, using a 5-in. steam drill. "Sausages" of dynamite were fed into the holes through a pipe and fired electrically in groups of about eight holes. The cost was a mere fraction of what it would have been if divers had been employed.

University and Educational Intelligence.

BIRMINGHAM.—The first list of donations in response to the appeal of the University for 500,000*l.* has been published, showing gifts or promises to the amount of more than 250,000*l.* Nearly half of this amount, however, is given to the Petroleum Mining Endowment Fund, and, whilst making the University unique as a centre of instruction and research in this particular branch of engineering, it will not be directly available for relieving the general indebtedness. The largest single gift is an anonymous one of 50,000*l.* for the general fund. A sum of 5000*l.* is earmarked for a chair of Italian, and an equal amount is given by the James Watt Memorial Fund for a James Watt research chair in engineering. The Birmingham Small Arms Co. gives 6500*l.*, and the Daimler Co. 3500*l.* A gratifying feature of the list is the number of names of old students who have contributed. The Birmingham Chamber of Commerce has given 3200*l.*, and the Worcestershire Education Committee has made an additional grant of 200*l.* per annum. It is announced that a second list will be issued shortly, and it is to be hoped that more of the large firms in the city and neighbourhood will appear therein.

CAMBRIDGE.—Mr. A. F. R. Wollaston has been elected a fellow of King's College for his explorations in the Sudan, Ruwenzori, Pacific, and Dutch New Guinea.

DR. W. T. DAVID has been appointed professor of engineering at the University College of South Wales and Monmouthshire, Cardiff.

IT is announced that Prof. H. MacLean, professor of chemical pathology in the University of London, has been appointed director of the clinical medical unit at St. Thomas's Hospital. The appointment of a physiologist and biochemist to be director of a clinical medical unit is significant as indicating the modern tendency of medicine towards recognition of the value of the work of the scientific investigator for purely medical fields.

THE University of Manchester has recently received a bequest of 30,000*l.*, free of duty, under the will of the late Mr. Jesse Haworth. The amount is to be used for the purpose of enlarging the present Jesse Haworth Building for Egyptology. Mr. Haworth, to whose generosity the University owes the greater part of its valuable Egyptological collection, was always a most generous benefactor to the museum, and shortly before his death subscribed 10,000*l.* to the University Appeal Fund, this amount being earmarked for museum purposes. The University Appeal Fund now stands at about 217,000*l.*

THE Toronto correspondent of the *Times* reports that complete success is anticipated in the centennial endowment campaign to raise 1,000,000*l.* for McGill University, Montreal. Up to November 16 ten individual subscriptions of 20,000*l.* each, one of 10,000*l.*, and nine of 5000*l.* had been received. Among the chief contributors are Lord Atholstan, Mr. R. B. Angus, Col. Molson, Mr. J. W. McConnell, Sir Herbert Holt, and the Dominion Textile Co. On November 20 it was reported that the endowment fund exceeded 800,000*l.* Among the later heavy subscriptions are 50,000*l.* each by the Canadian Pacific Railway, the Bank of Montreal, and the Royal Bank, and 25,000*l.* by the Merchants' Bank.

THE annual general meeting of the Science Masters' Association will be held at Oxford from the evening of Tuesday, January 4, 1921, to the morning of the following Friday. Lodging accommodation for members of the association will be provided in the rooms of Balliol and Trinity Colleges. Meals will be served in Balliol College hall. Lectures, discussions, and demonstrations will take place in the lecture-rooms and laboratories of the University. The provisional programme includes the following addresses and lectures:—President's address: Some Aspects of Science and Education, A. Vassall; Indicators and the Law of Mass Action, Brig.-Gen. H. Hartley; The Study of Crystals, T. V. Barker; Glass Blowing, B. Lambert; Recent Advances in Genetics, J. S. Huxley; Spectroscopy, Prof. T. R. Merton; and The Hedjaz, Dr. D. G. Hogarth.

THE Hudson Bay Company, as one means of celebrating the 250th anniversary of its foundation and its long connection with Western Canada and with Winnipeg, recently offered the University of Manitoba a fellowship of the annual value of fifteen hundred dollars for the years 1920–29 inclusive. This fellowship, which the University has gratefully accepted, will be called the Hudson Bay Company Research Fellowship, and is open to graduates of any Canadian university. It is tenable at the University of Manitoba, and each fellow must devote his entire time to original research in some branch of pure or applied science (*i.e.* the natural and physical sciences, the medical sciences, engineering, and agriculture). Each fellow will be appointed for one year, and the first appointment will be made at an early date. The company and the University of Manitoba are to be congratulated upon the creation of this important research benefaction.

THE mayoral statement for 1920 of the Huddersfield Technical College has been issued. During the session there were 658 day and 2590 part-time students; the latter figure included some 300 apprentices who attended special afternoon classes. The total number of students enrolled showed an increase of 876 above the number for the previous year. Ex-Service students accounted in part for the large increase in numbers: those under the Board of Education scheme for the higher education of ex-Service students received training in industrial and general science; the remainder, under the Ministry of Labour industrial training scheme, had a more direct and practical training in numerous crafts and trades. The textile and the dye departments have been enlarged and a new research laboratory has been added to the chemical section, though the demand made by the increase in the numbers of students on the staff of the college has left little opportunity for the pursuit of such studies. External classes in non-vocational subjects have also been established. Two gifts have been received for the endowment of scholarships: one, to be known as the Joseph Blamires scholarship for chemical research, made by Mrs. Blamire, and another, a textile scholarship, made by Sir Charles Sykes.

Societies and Academies.

LONDON.

Zoological Society, November 2.—Sir Sidney F. Harmer, vice-president, in the chair.—Dr. A. **Willey**: A note on the respiratory movements of Necturus and Cryptobranchus.—J. H. **Lloyd**: Some observations on the structure and life-history of the common nematode of the dogfish, *Scyllium canicula*.—Mrs. O. A. Merritt **Hawkes**: Observations on the life-history, biology, and genetics of the lady-bird beetle, *Adalia bipunctata*, Mulsant.—Prof. H. R. **Mehra**: The sexual phase in certain Indian Naididæ (Oligochæta).

Linnean Society, November 4.—Dr. A. Smith Woodward, president, in the chair.—J. H. **Owen**: Further researches into the life and habits of the sparrow-hawk, *Accipiter nisus* (Linn.), Pall. After some preliminary remarks on some of the less known habits of the sparrow-hawk, the author showed a series of nearly eighty lantern-slides depicting various incidents of the incubation and nestling periods. The slides were from photographs of six different nests. Of special interest were series showing (1) the efforts of the hen to protect the nestlings from the effects of the sun, and (2) the behaviour of the hen during incubation as affected by climatic conditions.—H. N. **Dixon**: The mosses of the Wollaston Expedition to Dutch New Guinea. The mosses were, unfortunately, not described with the higher plants, but have since been worked out by the author, and have proved of great interest. Although consisting of only some sixty gatherings, the collection contained types of at least two new genera, Hymenodontopsis and Callistomium, and more than a dozen new species, including two new species of Dawsonia, a genus which is more highly represented in New Guinea than in any other part of its rather limited distribution. A further collection by the Rev. J. B. Clark, of the London Missionary Society, in the neighbourhood of Boku, British New Guinea, is also included, and contains ten new species, comprising a very beautiful Pterobryella, and other interesting things. A small species, probably of Rhizogonium, named provisionally *R. orbiculare*, may possibly represent the ancestral form of the Rhizogoniaceæ.

Mineralogical Society, November 9 (Anniversary Meeting).—Sir William P. Beale, Bart., president, in the chair.—Dr. E. S. **Simpson**: A graphic method for the comparison of minerals with four variable components forming two isomorphous pairs. In the spinel-chromite series the two pairs are MgO,FeO and Al_2O_3,Cr_2O_3, and the general formula is (Mg,Fe)O.$(Al,Cr)_2O_3$. The relative molecular preponderances of the components of each pair stated as a percentage of the maximum are given by the formulæ $x=100(m-f)/(m+f)$ and $y=100(a-c)/(a+c)$, where m, f, a, c represent the number of molecules of MgO, FeO, Al_2O_3, and Cr_2O_3 respectively. The values of x and y, calculated from a number of published analyses, and from new analyses of ceylonite from Camban, Western Australia, are plotted on rectangular co-ordinates. The four corners of the main square are occupied by the pure compounds MgO.Al_2O_3 (spinel), FeO.Al_2O_3 (hercynite), FeO.Cr_2O_3 (chromite), and MgO.Cr_2O_3 (here named picrochromite). Sub-species and varieties of intermediate composition are divided off in symmetrical areas within the square.—L. J. **Spencer**: Fibrolite (=sillimanite) as a gem-stone from Burma and Ceylon. Water-worn, prismatic crystals from the ruby mines in Upper Burma measure up to 1½ cm. in length, and are clear and transparent, with a pale sapphire-blue colour and marked pleochroism. A fine faceted gem cut from this material is shown in the British Museum collection of minerals. Determinations were given of the optical constants; the birefringence shows a wide range, $\gamma-\alpha$ being seventeen times $\beta-\alpha$. On a somewhat similar, but etched, crystal from Ceylon the axial ratios were determined. Other crystals from Ceylon are pale greyish-green with a marked chatoyancy.—Dr. J. W. **Evans**: The origin of the alkali rocks. The alkali-igneous rocks form an exceptional series varying in composition from acid to basic, characterised by a high percentage of alkalis, especially soda, and a deficiency in alumina and the oxides of the divalent elements. They appear to occur mainly in areas where the earth's crust has, as the result of ancient folding or the accumulation of granitic rocks, consolidated to a considerable depth, and where the temperature gradient is normally low. Such areas are rarely subject to new folding, but are frequently folded, and with these faults the alkali rocks appear to have a genetic relation. In such areas crystallisation must proceed in the sub-crustal magmas, which are believed to be basic in composition under exceptional pressure, with the result that minerals with low specific volumes, having regard to the materials of which they are composed, will preferentially crystallise out. Garnet, zoisite, fibrolite, and kyanite are examples the materials of which crystallise out under less pressure with greater specific volumes. As these minerals are mainly silicates of aluminium and the divalent elements, the uncrystallised residue will be poor in these constituents and rich in the alkalis, especially soda, which was present in the original magma in greater proportion than the potash. It will also contain the volatile fluxes in large amount. As a result of the faulting of the crust this residue may be pressed out, find its way upwards, and give rise by further differentiation to the alkali rocks.—A. F. **Hallimond**: Monticellite from a mixer slag. The crystals, which are essentially monticellite containing about 20 per cent. of olivine in solid solution, have the following physical characters: Orthorhombic, $a:b:c=0.4382:1:0.5779$; forms 010, 110, 021; refractive indices, 1·663, 1·674, 1·680; 2V, 73¼°; specific gravity, 3·20.—Dr. H. H. **Thomas** and A. F. **Hallimond**: A refractometer for the determination of liquid mixtures. A telescope and collimator with Websky signal are fixed in alignment; between them is inserted a parallel-sided trough containing the liquid to be determined, in which is immersed a right-angled prism of known index near that of the liquid. Two images of the signal are formed, and the angular distance between them is read on the eye-piece scale; this reading is proportional to the difference of index between the liquid and the prism. The scale division has the same value whatever the index of the prism used.

Royal Meteorological Society, November 17.—Mr. R. H. Hooker, president, in the chair.—C. E. P. **Brooks** and H. W. **Braby**: The clash of the trades in the Pacific. The mechanism of rainfall in the equatorial Pacific. Considering the months January to June, and first the area east of 180° long., the trades meet at a low angle. The south-east wind is the warmer, and therefore the less dense, and rises above the north-east wind on a long slant, beneath which eddies are formed, giving occasional west winds. From the rising south-east trade wind rain is condensed, and falls through the north-east or west winds. East of 180° long. the trade winds meet almost at right angles, and, as their densities are the same, they mingle and produce a great volume of rising air, forming a low-pressure area, into which air is drawn from all sides. This low-pressure area is a mobile "action centre," the position of which determines the character of the season: if it lies far to the west the season is dry; if it takes an easterly position the season is wet.—Dr. W. H. **Steavenson**: The mirage. The visibility of the mirage was found to be dependent solely on the distribution of temperature near the ground, so determined by the altitude of the sun. The appearance was, therefore, not necessarily associated with hot weather, and had been well seen when the shade temperature was below 50°. Investigations had shown that the old reflection theory was untenable, and that the phenomenon was purely a refraction effect. The appearance of the mirage was subject to variations which were dependent upon such factors as the contour of the ground, the height of the observer, and the altitude of the sun.

PARIS.

Academy of Sciences, November 2.—M. Henri Deslandres in the chair.—M. **de Sparre**: The ram-stroke in pipes feeding turbines with strong reaction. The ordinary formula giving the pressure in a water-main set up by a sudden stoppage of the motion of the water cannot be applied without serious error to mains supplying turbines with a strong reaction. The necessary modifications of the formula are given.—G. **Ciamician** and C. **Ravenna**: The biological signification of alkaloids in plants. Alkaloids have been regarded as refuse products which the plant is unable to eliminate. From an experimental study of the action of various alkaloids and substances related to them on young bean plants it is shown that this view cannot be sustained.—M. **Gevrey**: The resolution of problems at the limits relating to equations of the second order of elliptical and parabolic types.—B. **Gambier**: Couples of two minimum surfaces corresponding as focals of a rectilinear congruence, with conservation of the asymptotic lines and the lines of zero length.—M. **Risser**: An application of Volterra's equation to the problem of distribution by age.—MM. **Claude** and **Driencourt**: A new type of prism astrolabe. A description and photograph of the new instrument are given. Compared with the older type, it is less than half the weight and easier to set up and adjust.—M. **Holweck**: Experimental researches on X-rays of great wave-length. In the apparatus described ionising rays were produced for a difference of 70 volts between the anode and cathode; this would correspond to a wave-length of about one-sixth of Schumann's ultra-violet. Determinations were made of the coefficient of absorption of the soft X-rays in different gases.—J. **Cabannes**: Measurement of the luminous intensity diffused by argon. New determination of Avogadro's constant. The value found by this method is $6{\cdot}9\times10^{23}$, in good agreement with the well-known values of Millikan ($6{\cdot}07\times10^{23}$) and Jean Perrin ($6{\cdot}85\times10^{23}$).—MM. **Chauvenet**, **P. Job**, and **G. Urbain**: The thermochemical analysis of solutions. Equimolecular solutions of various salts are mixed in varying proportions, the volume being kept constant. The heat evolved on mixing is measured, taking account of the specific heats of the solutions. Curves are given illustrating the application of this method to the systems potassium iodide–cadmium iodide, copper chloride–aluminium chloride, and copper chloride–magnesium chloride. The formation of the complex salts, K_2CdI_4, $(2CuCl_2,3MgCl_2)$, $(3CuCl_2,2MgCl_2)$, $(CuCl_2,2AlCl_3)$, and $(2CuCl_2,AlCl_3)$, was clearly indicated by this method.—P. **Loisel**: The variations of the radio-activity of the springs of Bagnoles-de-l'Orne and their relation to the rainfall.—M. **Chopin**: An automatic indicator of the amount of moisture in cereals.—J. **de Lapparent**: Crystals of felspar and quartz in the limestones of the Middle Trias of Alsace and Lorraine.—G. **Depape**: The presence of *Juglans cinerea fossilis* in the Plaisancian flora of Saint-Marcel-d'Ardeche.—J. **Touch**: The diurnal variation of temperature in the Antarctic.—A. **Lumière**: The awakening of the soil. The activity in the soil, with rapid germination of seeds, which takes place in the spring, was at one time supposed to be caused by rise of temperature; this, however, was disproved by Müntz and Gaudechon, who showed that a maximum of microbial activity was produced independent of the temperature. Their suggestion that this recurrence of activity was to be ascribed to a predilection of the micro-organisms for a given period of the year, atavism, the author regards as unsatisfactory, and he now suggests another possible cause, the existence in the soil of toxic products secreted by the roots of plants or resulting from the transformation of vegetable débris after the fall of leaves and the death of annual plants. Experiments in support of this view are described. Soil collected in November was thoroughly washed to remove soluble toxic products, and at the temperature of the laboratory this soil produced vegetation with great rapidity. The same soil unwashed was sterile as regards growth. The washings, concentrated, were proved to prevent growth.—F. **Vincens**: Abnormal ligneous formations in the bark of *Hevea brasiliensis*.—J. **Dufrenoy**: The experimental bacterial tumours of Epicea.—J. **Delphy**: The reproduction of mudworms: fecundation, segmentation, and morphogenesis.—M. **Nicolle** and E. **Césari**: The effects and constitution of the antibodies.

NAPLES.

R. Accademia delle Scienze fisiche e matematiche, May 3.—Prof. Monticelli, president, in the chair.—F. **Tricomi**: Series of functions of lines.

May 8.—Prof. Montesano, vice-president, in the chair.—F. **Amodeo**: Researches of a Neapolitan eighteenth-century mathematician on certain theorems of Archimedes. Nicolò de Martino (born at Faicchio in 1701, died at Naples in 1769) rediscovered and proved by new and original methods several theorems in mensuration contained in the lost manuscripts of Archimedes. These, which were published in 1768 in a text-book on solid geometry and conic sections intended for Army cadets, show De Martino to have been a mathematician of great power.

June 7.—Prof. Monticelli, president, in the chair.—C. **Colamonico**: A zone of carso known as "vurgo" in the Bari territory. This forms part of a series of researches by the author on the carso of southern Italy. The present zone occurs in a little-known district of Apulia.—M. **Pascal**: N'ple integrals in the complex field.

June 12.—M. **Pascal**: Multiple integral of a differential form.

June 19.—F. **Tricomi**: Series of powers in the field of functions of lines, ii.

CAPE TOWN.

Royal Society of South Africa, September 29.—Dr. J. D. F. Gilchrist, president, in the chair.—J. R. **Sutton**: A possible lunar influence upon the velocity of the wind at Kimberley. IV. The object of this part of the discussion is to determine whether there are any points of agreement between the air tides and the lunar wind period sufficiently definite to form the nucleus of a theory which could be used to explain the comparatively great air speeds found in previous papers and attributable to the moon. For this purpose the air tides at perigee and at apogee have been determined (by Sabine's method) for the ten years 1897–1906 and compared with the wind movements. A diagram is given showing how the air pressures and wind movements compare one with the other. Both agree in the main, though with certain important exceptions confirming previous conclusions that the lunar influence upon the velocity of the wind cannot be exerted in a very simple way through the medium of the air tides.—J. P. **Dalton**: The integrated velocity equations of chemical reactions. The object of the note is to show how the integrals of many velocity equations which occur in practice may be written down in terms of a certain function of the relative initial concentrations of the reactants and of its derivatives.—C. **Pijper**: Medical folk-lore of the Abantu in the Lijdenburg district.

The paper contains contributions to our knowledge of the methods of treatment used by witch-doctors. —J. W. C. **Gunn**: The action of *Urginea Burkei*. Experiments were performed on frogs, rabbits, cats, rats, and guinea-pigs with extracts of *Urginea Burkei*, Baker, commonly known as the Transvaal slang-kop. It has an action on the alimentary system, producing vomiting and diarrhœa, and on the nervous system, resulting in loss of power in the limbs, diminution of reflexes, and final paralysis. Its main action is on the circulatory system.—G. A. **Boulenger** and J. H. **Power**: A revision of the South African Agamas allied to *Agama hispida*, *A. atra* and *A. anchietae*. The paper contains a revision of the group of South African reptiles which has stood most in need of revision. The account in the British Museum Catalogue of Lizards has long ceased to fulfil its purpose, and the attempt is now made, with the help of a very large amount of material, to arrive at conclusions which will stand the test of time.—S. H. **Skaife**: A species of Microdon (Diptera) from Natal. The paper gives a description of the larva, puparium, and adult female of *Microdon illucens*, Bezzi, the growth being under the author's observation.—J. D. F. **Gilchrist**: Note on living fish brought by H.M.S. *Challenger*.

SYDNEY.

Linnean Society of New South Wales, September 29.—Mr. J. J. Fletcher, president, in the chair.—Dr. J. M. **Petrie**: The chemical examination of *Macrozamia spiralis*. A complete summary of its poisonous record is given. In the leaves the following constituents were identified: Formic, acetic, valerianic, and lauric acids; oleic, stearic, and higher fatty acids; a volatile essential oil; a phytosterol; a paraffin with the properties of triacontane, and an olefine having the properties of octodecylene. The nuts contained 39 per cent. of starch and much mucilage. In feeding experiments white rats were given with their ordinary food (1) crushed fresh leaves, (2) grated seeds, (3) the rich, fatty, and resinous components extracted from the leaves by ether, and (4) aqueous extracts of the leaves and the seeds. The animals showed no signs of being affected after feeding for three weeks.—A. P. **Dodd**: Two new Hymenoptera of the superfamily Proctotrypidæ from Australia. A new genus is proposed in the family Diapriidæ, and a new species of Prosoxylabis (Belytidæ), the former being a primary parasite of the sheep-maggot flies.—Prof. W. N. **Benson**, W. S. **Dun**, and W. R. **Browne**: The geology and petrology of the Great Serpentine Belt of New South Wales. Part ix.: The geology, palæontology, and petrography of the Currabubula district, with notes on adjacent regions. The extrusive rocks comprise keratophyric tuffs of the Burindi and Kuttung series, with which are interbedded soda rhyolite flows and tuffs and basalt. The Werrie series consists of decomposed basalts, occasionally slaggy. Invading these, and also the underlying Kuttung and Burindi beds, is an immense series of sills and dykes comprising quartz keratophyre, quartz trachyte, quartz latite, andesite, lamprophyre, normal and albite dolerite, teschenite, and basalt. Attention is directed to the peculiar association of calcic and alkaline rock-types linked by intermediate types, and evidently derived from a common stock magma. Though the dominant rocks in this area are intrusive, and those in the Paterson, Seaham, and Pokolbin districts are effusive, the petrographical similarity of the Carboniferous igneous rocks in the two districts is most marked.—A. M. **Lea**: Descriptions of new species of Australian Coleoptera. Part xvi. Nineteen species and one variety of Ditropidus, three species of Elaphodes, and three species of Cœnobius are described as new. In addition, notes on synonymy, etc., partly the result of examination of some of Macleay's and Olliff's types from the Australian Museum, are given for seventy-one species belonging to twenty-two genera.

Diary of Societies.

THURSDAY, NOVEMBER 25.

ROYAL SOCIETY, at 4.—Special General Meeting to consider the Annual Report of Council.—At 4.30.—Prof. L. Hill: The Growth of Seedlings in Wind.—Prof. P. T. Herring: The Effect of Thyroid-feeding and of Thyro-parathyroidectomy upon the Pituitrin Content of the Posterior Lobe of the Pituitary, the Cerebro-spinal Fluid, and Blood.—W. A. Jolly: Reflex Times in the South African Clawed Frog.—Prof. J. A. Gunn and R. St. A. Heathcote: Cellular Immunity. Observations on Natural and Acquired Immunity to Cobra Venom.—L. T. Hogben: Studies on Synapsis. III. The Nuclear Organisation of the Germ Cells in *Libellula depressa*.

CHADWICK PUBLIC LECTURES (at the Medical Society of London), at 5.15.—Prof. J. B. Farmer: Some Biological Aspects of Disease.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—W. B. Woodhouse: The Distribution of Electricity.—R. O. Kapp: Some Economic Aspects of E.H.T. Distribution by Underground Cables.

CONCRETE INSTITUTE, at 7.30.—E. F. Etchells: Presidential Address.

EGYPT EXPLORATION SOCIETY (at Royal Society), at 8.30.—Prof. G. Elliot Smith: The Royal Mummies.

ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.

FRIDAY, NOVEMBER 26.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 5.—Dr. D. Drury: Malformation of the Face, Ear, Eye, and Hand occurring in an Infant.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Section) (at the City and Guilds Technical College, Leonard Street, E.C.), at 6.30.—A. J. C. Watts: Electricity and the Paper-making Industry.

OPTICAL SOCIETY AND PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 7.—The Making of Reflecting Surfaces. (*a*) Technical Methods of Production.—R. Kanthack: Description of the General Features of Published Processes.—H. N. Irving: Methods of Silvering.—J. W. French: Workshop Notes on Silvering.—F. Ellerman and H. D. Babcock: The Silvering of Glass Reflectors.—J. Rheinberg: Platinum Reflecting Surfaces on Glass by the Burning-in Process.—R. S. Whipple: The Silvering of Glass and Quartz Fibres.—H. A. Hughes: Demonstration of a Silvering Process.—C. W. Davidson: The Silvering of a Large Reflector. (*b*) Reflecting Powers of Surfaces, etc.—J. W. T. Walsh: The Photometric Measurement of the Reflecting Powers of Mirrors.—Prof. Féry: A Note on some Permanent Mirrors for Reflecting Heat Radiations.—W. G. Collins: Rustless Steel Mirrors.—R. W. Cheshire or Dennis Taylor: Note on Increasing the Transmitting Powers of Surfaces.—F. Simeon: Demonstration of Apparatus used for Producing Mirrors by Cathodic Bombardment.

JUNIOR INSTITUTION OF ENGINEERS (at Caxton Hall), at 8.—C. O. Mourant: Reinforced Concrete Coal Bunkers and Silos.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at 11 Chandos Street, W.), at 8.—Resumed Discussion on Paper by Prof. W. Yorke: The Present Position of Trypanosomiasis Research.—G. Dudgeon: Some Important Tropical Fruit Foods.

ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.30.—Dr. A. Chaplin: Measures for Preserving the Health of Seamen on Board Ship.

MONDAY, NOVEMBER 29.

THE INSTITUTE OF ACTUARIES (in Staple Inn Hall), at 5.—Sir Alfred Watson: Address.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.—A. F. Harmer and Others: Discussion on Electrical Transmission on Petrol Vehicles.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—Professional Questions.

ROYAL SOCIETY OF ARTS, at 8.—A. Chaston Chapman: Micro-organisms and some of their Industrial Uses (Cantor Lecture).

TUESDAY, NOVEMBER 30.

ROYAL HORTICULTURAL SOCIETY, at 3.

ROYAL SOCIETY, at 4.—Anniversary Meeting.

ROYAL SOCIETY OF MEDICINE (Tropical Medicine Section), at 5.—Dr. F. G. Rose: The Incidence of Filariasis in British Guiana.

INSTITUTION OF CIVIL ENGINEERS, at 5.30.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Technical Meeting), at 7.—G. C. Weston: Dark Room Dodges.

WEDNESDAY, DECEMBER 1.

GEOLOGICAL SOCIETY OF LONDON, at 5.15.—Special General Meeting.—At 5.30.—Ordinary Meeting.—Dr. E. Greenly: An Æolian Pleistocene Deposit at Clevedon, Somerset.

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—R. V. Wadsworth: Estimation of Theobromine.—B. S. Evans: A New Process for the Estimation of Small Quantities of Chromium in Steels.—P. V. and F. H. Dupré: Some Notes on the Reactions between Fulminate of Mercury and Sodium Hyposulphite.

ROYAL SOCIETY OF ARTS, at 8.—Miss L. F. Pesel: Embroidery: National Taste in relation to Trade.

THURSDAY, DECEMBER 2.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.—Major G. H. Scott: Airship Piloting.—Flight-Lieutenant F. L. C. Butcher: Airship Mooring.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. W. Brown: The Value of Suggestion in Education.

CHEMICAL SOCIETY, at 8.—Sir Prafulla C. Rây: Varying Valency of Platinum with Respect to Mercaptanic Radicles.—H. E. Cox: The Influence of the Solvent on the Velocity of certain Reactions. Part II. Temperature Coefficients. A Test of the Radiation Hypothesis.—K. J. P. Orton and P. V. McKie: Preparation of Chloropicrin from Picric Acid and Trinitrotoluenes.

FRIDAY, DECEMBER 3.

ROYAL ASTRONOMICAL SOCIETY (Geophysical Committee), at 5.—Discussion: The Cause of Magnetic Storms.—In Chair: J. H. Jeans. Opener: Prof. F. A. Lindemann.—Other Speakers: Prof. S. Chapman, Dr. C. Chree, Rev. A. L. Cortie, E. W. Maunder, C. S. Wright, and Others.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Further Discussion on The Human Factor in Industry, by A. Ramsay.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Section) (at King's College), at 6.30.—A. Serner and Others: Discussion on The Modern Tendency to Trusts. Is it Beneficial?

SATURDAY, DECEMBER 4.

GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.1), at 3.—H. J. Elwes: The Primitive Races of Sheep in Great Britain.

The Application of Science to Agriculture.

THE circumstances of the time call for the fullest possible utilisation of the national resources of both men and material, and never has there been more urgent need for the high training and intellectual interests that science can give to mankind, or for the properly directed application of science to national problems. When rapid changes are coming about before our eyes, and the community is being shaken to its foundations, it is essential to inquire whether the guardians of scientific studies in this country are still able to maintain the work at a proper level of efficiency. What, for example, is the position of the application of science to agriculture—the greatest of our industries? There have been some recent developments, though on a relatively small scale. If, however, a satisfactory organisation is possible in this case, there will be much ground for hope that the more general problem of the application of science to industry as a whole can be solved.

Prior to the war the application of science to agriculture was brought about in the main by the enterprise of a few individuals such as Lawes and Gilbert, of Rothamsted; Spencer Pickering, at the Woburn Fruit Farm; the Voelckers, father and son; and a few others. The landowner, as a rule, looked on in a not unfriendly way, but, his education never having been good, he was unable to understand what the man of science was trying to do. Character was his strong point; he administered justice in the village, while his wife dispensed charity; both were, as a rule, conscientious, hard workers, strong in the faith that they were doing the right thing, and true to the ideals that had been handed down to them by a long line of ancestors like themselves. It was not until 1894 that any sort of beginning was made in the country, when the so-called "whisky money" was available for technical education, and the county authorities had the option of developing agricultural education.

A few did so: Kent and Surrey combined to open the Wye Agricultural College; Norfolk and the eastern counties supported a school at Cambridge. The county bodies, however, did little for science. A distinction was made between "education" and "research"; if a teacher were repeating something already known, he was eligible for a Government grant, and was, therefore, a person who could be encouraged; but if he were seeking to discover something unknown, he was not eligible for grants, and was rather a problem for the authorities. Fortunately, however, institutions in the country cannot be completely governed from Whitehall, and common sense has a way of prevailing; much scientific work was, in point of fact, carried out by keen men working on their own account, and often in part at their own expense.

It was not until the passing of the Development Act in 1911 that Government support was forthcoming for scientific investigations in agriculture. The Act set up a Development Fund which subsidised certain institutions and allowed of much needed expansion. Considerable experience has been gained during the past ten years of the best method of utilising the available resources. The broad result is a threefold scheme, including: (1) Research institutions where agricultural science is developed; (2) colleges and farm institutes where instruction of various types is given to students wishing to become experts, farmers, etc.; (3) county advisers attached to some of the foregoing institutions, whose function it is to advise farmers on the various problems or difficulties with which they may be confronted.

At the beginning a rather large number of research institutes was set up, mainly at the universities. Of recent years there has been a tendency towards centralisation, four of the new institutes being afterwards transferred to other institutes already in existence. This was not originally intended, and, so far as is known, formed no part of a deliberate policy; it was the inevitable result of workers in different lines finding so much common ground that close association became essential. An institute such as Rothamsted, with excellent laboratories and library, standing in its own grounds of 300 acres, right out in the country, with well-kept historic field plots and a staff of assistants highly trained in field work, has obvious advantages over a university department situate in a town remote from agricultural practice and interests, and one is not surprised to find that it has grown and is still growing. The larger institutes now are: Rothamsted, for soil, plant nutrition, plant pathology (including entomology, helminthology, and mycology); the Imperial College, South Kensington, for plant physiology; Cambridge, for plant breeding and animal nutrition; Long Ashton and East Malling, for fruit; Reading, for dairy; Aberdeen, for animal nutrition; and Oxford, for agricultural economics.

Success or failure, however, depends on the men working the scheme, and shortly after the Armistice the Ministry of Agriculture put into operation a research service scheme, which has been found satisfactory in its essential features, and has enabled the leading research institutions to attract a body of highly competent workers and to retain those who wish to stay. Automatic increments of salary are made annually, subject to proved service, up to a certain maximum, and there is the possibility of promotion to a higher grade. As the scheme stands at present, a young man or woman taken on the staff begins with a salary which, including bonus, amounts to 450*l.* per annum, and he or she can rise continuously to a salary which, with bonus, amounts to 1010*l.* per annum. It does not follow that all will rise to this level; there are stopping places at 510*l.* and 780*l.* respectively, beyond which further progress may be impossible for a given individual. In addition, there is a superannuation scheme, to which the institute makes an annual contribution equal to 10 per cent. of the salary There are also still higher posts as directors, etc.

In the commencing or third grade the substantive salary is 300*l.* per annum, with bonus of 150*l.*, total 450*l.*, rising by annual increments of 20*l.* to 360*l.* *plus* 150*l.*—*i.e.* 510*l.* per annum. Should it appear that the holder is unsuited for the higher posts, the institute may terminate the appointment after three years. On the other hand, if paucity of posts or other reasons render promotion improbable, the institute may make the appointment permanent, provided sufficiently good work has been done to justify this course. Probably, in most institutes—certainly in the larger ones—there are excellent workers in the third grade for whom promotion into the second grade is only a remote contingency.

The middle- or second-grade appointments are limited in number—usually to half of those in the commencing grade—and the possibility of promotion thereto depends on the accident whether or not a post happens to fall vacant. Such cases inevitably arise under any scheme. The salary with bonus begins at 550*l.*, and rises by increments of 23*l.* to 780*l.* The highest or first-grade posts are also limited in number, being generally the same as the second grade; the commencing salary with bonus is 780*l.*, rising by eight annual increments to 1010*l.* The terms of appointment to these two grades are the same as those of a permanent reader at a university, so there is ample security of tenure. Above these come the directors, posts which, however, vary according to the institute.

Although the scheme is put forward, financed, and imposed on the research institutes by the Ministry of Agriculture, the holders of the posts are neither Civil Servants nor officers of the Ministry. The appointments to all these posts are made by the governing bodies of the institutes, which retain all rights of such bodies. In case of a grievance, any holder of a post has, however, the right of appeal through the governing body to the Ministry.

Promotion to a vacancy in a higher grade is possible only on the recommendation of the governing body and with the approval of the Ministry. There is a provision that all vacancies in higher grades must be notified to all likely candidates in the lower grades at all research institutes, but the appointment rests with the governing bodies, which, in the interest of their institutes, will presumably select the best candidate, whether in the service or out of it. As the scheme was originally put forward, there was a seniority clause giving preference to men or women already in the service; but this met with so much opposition from those responsible for the efficient conduct of the institutes that it was abandoned. A research institute is no place for promotion by seniority. Such promotions would stultify the whole purpose of research; they would stifle initiative, blot out all possibility of bringing in new ideas, lead to stereotyped dogmas, and do infinite harm to the cause of progress. At all costs, a research institute must choose the best possible man or woman, regardless of other considerations. Only in this way is it possible to bring in the new ideas and the new light which alone make research successful.

The reception of the scheme by the younger scientific workers has been very satisfactory, and the responsible authorities of the institutes have been in the gratifying position of finding excellent candidates for their posts. At no time in the last twenty years have the research institutes been better staffed than now.

Provision has also been made for the creation of a link between the university and the research service. The Ministry of Agriculture awards scholarships of the value of 200*l.* per annum to men and women, possessing an honours degree or equivalent qualification, who are desirous of entering the service. The successful candidates are attached to whichever institutes they may prefer, and have their opportunity in the event of a vacancy occurring. They will, however, usually find other scholarship holders at the institutes—1851 Exhibitioners, various university scholars, and other post-graduate workers also waiting for posts—and they can hope for appointments only if they happen to be the best of the available candidates.

Thus the scheme provides for selection from the universities of the most promising young men and women for research work; it allows of a probationary period in which each candidate can show his or her fitness for the work; it affords permanent posts for those finally chosen; it gives increments of salary commensurate with the value imparted by experience; and for the highly gifted worker it affords prospects of promotion to posts which, considering their freedom from routine duties and from worries, must be regarded as distinctly good. The scheme is economical and effective; it works with the minimum of friction and without interference with the individual research worker; and it may confidently be recommended as a model to other Government Departments which are concerned with the promotion of scientific research.

Philosophy of Relativity.

The General Principle of Relativity: In its Philosophical and Historical Aspect. By Prof. H. Wildon Carr. Pp. x+165. (London: Macmillan and Co., Ltd., 1920.) Price 7s. 6d. net.

PROF. WILDON CARR has produced in this little volume a really valuable book. There was an hiatus in the current expositions of the principle of relativity. Its significance and importance had been clearly set forth in their bearing on mathematical physics. But the doctrine had not been connected with its position in the history of general philosophical thought. This Prof. Carr has now done, and with great knowledge of philosophy.

After explaining the old difficulties, he shows how Descartes and Leibniz had partially recognised their origin. The exposition of the discussions by each of these thinkers is lucid and informing. In particular, there is an admirable explanation of the Leibnizian theory of monads, and of how Leibniz was driven to its adoption. Both philosophers were mathematicians of great eminence. They saw that the explanation of matter must come after that of movement, and could not precede it. Extension was not "stuff." The explanation of gravitation given by Newton follows. The book goes on to deal with the difficulties that led to Einstein's revision of the whole of the Newtonian hypothesis of space and time as absolutely existing frameworks. The special principle of relativity is then explained, and it is shown that the general, or later, Einstein principle is simply a full statement of what is implied in its earlier form. The first dealt with a definite phenomenon—the velocity of light. The second extends the explanation to the laws of Nature generally. There is no longer a particular finite velocity taken to be a constant and limiting one. As soon as we extend the special case of relativity to non-uniform and rotational systems of motion, the doctrine of equivalence between the experience of the observer taken to be at rest, and the experience of the observer in another system relatively to which the observer taken to be at rest is regarded as being in motion, becomes apparent. The explanation of the possibly non-Euclidean character of space systems, and of the necessity of correlating observations by adequate formulæ of transformation, becomes clear. The idea of pure objectivity disappears. Mind appears as relating the centre of a universe which is no longer infinite in the sense given to the word as applied to Newtonian space. For the observer is not a fixed point existing at a fixed instant. "Space and time are not containers, nor are they contents; they are variants. They change as my system of reference changes."

One of the difficulties experienced in reading even Einstein himself is the lack of a thoroughgoing connection of his principle with the new character really given by it to space and time. They are discussed as though they remained changed, not in kind, but in degree only, and based on what is original and still present, transformed in shape and measurement only. But more than this is implied in Minskowski's famous discourse at Cologne in 1908, which Einstein seems to adopt. The former deposed the intuitional space and time of our supposed direct experience to the status of mere shadows. The reality was to be sought in "the world-line," in a *continuum* the factors in which were not space and time, but deeper lying and inseparable phases of reality, to which space and time present only imperfect analogies. Some of the language of modern mathematical writers is obscured by the employment of words suggesting that we have only to correct imperfections in the description of our space and time as actual facts. Minskowski, on the other hand, seems to point to the reality being something radically different from the space and time of our discourse in science even of the most modern type. "Die dreidimensionale Geometrie wird ein Kapitel der vierdimensionalen Physik. Sie erkennen, weshalb ich am Eingange saghte, Raum und Zeit sollen zu Schatten herabsinken und nur eine Welt an sich bestehen." There is one English mathematical writer who has seized on the full meaning of this interpretation and carried it out to its logical conclusions in his "Concept of Nature." I refer to Prof. Whitehead.

The metaphysical foundations of this further view of Einstein's doctrine are made apparent in Prof. Carr's book. That is what makes it important for scientific readers, as well as for the general public, who will gather from it what the principle of relativity means. Like all books on this subject, it requires careful reading and unbroken attention, but the time these necessitate, even for this short book, will, I think, be found to have been thoroughly well spent.

HALDANE.

The Human Hand.

The Principles of Anatomy as Seen in the Hand. By Prof. Frederic Wood Jones. Pp. viii + 325 + 2 plates. (London: J. and A. Churchill, 1920.) Price 15*s*.

IN this work Prof. Wood Jones has made a notable contribution not only to the literature of human anatomy, but also to that of philosophical biology. The book is the result of an intensive study of a single part of our anatomy undertaken in the belief that if we understand it thoroughly and correctly we shall understand much more—shall, in fact, know the principles upon which the whole of our anatomy is formed. In selecting the hand for his purpose the author has chosen wisely, for it is, we think, without doubt the part which is most characteristic of us—that which has played the chief *rôle* in our development. Prof. Wood Jones's method is to take the various tissues forming the hand—viz. the skin, nails, fasciæ, bones, muscles, vessels, and nerves—separately, describing them in considerable detail from both the morphological and the practical points of view. As we can readily imagine, he is not able to confine himself strictly to the hand, any more than was Sir Charles Bell in his century-old book on the same subject. (We might say in passing that the comparison between the two books, which are further alike in that they are largely illustrated by the authors themselves, is extremely interesting and illuminating, as showing the great advance in our knowledge and the great change which has come over our conception of man's place in Nature during the last hundred years.)

From internal evidence alone the book appears to have been begun as a morphological study, and to have been given its practical bias in consequence of experience with patients suffering from nerve lesions acquired in the war. The fact—if fact it be that this was the order of its evolution—will go far, we think, to explain the peculiar value and interest of the book. It is seldom that anatomy is treated from both the morphological and the practical points of view; here, however, we have a book in which this is not merely observed, but impartially observed, with a result which, we believe, completely justifies those who look upon morphology as the guiding spirit of anatomical research, and upon anatomy itself as the only solid basis on which scientific medicine and surgery can be founded. An admirable example of the close connection which exists between morphology, anatomy, medicine, and surgery is, we think, to be found in the chapter on the skin creases or flexure lines, subjects which, we agree with the author, have not been given the consideration they deserve by either the physician or the surgeon.

In the chapter on the osteology of the hand the form of the primitive vertebrate hand is discussed at some length, and the conclusion reached that the primitive hand was not only pentadactylous, but also characterised by a smaller number of phalanges in the preaxial digit. The discrepancy in the number of phalanges in this digit compared with those in the other digits may, of course, be due to a decrease in the preaxial or to an increase in the other digits. Despite the fact that, as is pointed out and emphasised, no animal living or extinct has more than two phalanges in the preaxial digit, whereas the number of phalanges in the other digits is frequently subject to increase, Prof. Wood Jones accepts the former of the two alternative explanations, and hazards the opinion that the reduction has been brought about by the fusion of the two terminal phalanges. If on this matter he is not so logical as we could wish, we are more content with him in certain of his other explanations, and think the reasons he gives for the fusion of the fourth and fifth carpalia and tarsalia to form the unciform and cuboid, and for the shifting of the axis of the foot from the line of the third toe to that of the second, both adequate and ingenious. We are inclined also to accept his view of the fate of the os centrale, although here, as in other parts of the book, we think it would have been well if the evidence from morphology had been supplemented with that obtainable from embryology. The curious order in which the bones of the hand ossify is a matter upon which we should like to have had some light, but, unfortunately, none is forthcoming.

In the chapter on the extrinsic muscles of the hand reference is made to the muscles of the foot, and the extensor brevis digitorum and the peroneus tertius are spoken of as derivable from a deep extensor sheet, the slips to the four inner toes passing down into the foot, while the slip to the little toe remained in the leg as the peroneus tertius. This is a view of the origin of these muscles which is in direct opposition to those of Ruge, Bryce, and Keith, for they have shown that the extensor brevis digitorum, despite its innervation, has entered the foot, not from above, but from behind, passing under the external malleolus, while the peroneus tertius has originated in quite a different fashion—by segmentation of the extensor longus digitorum. The matter is, of course, of almost purely morphological interest, but we have ventured to refer to it because of the interesting problem presented by the nerve-fibres for the extensor brevis digitorum changing from the musculo-cutaneous branch to the anterior tibial branch of the external popliteal nerve.

Perhaps the most original and valuable part of the book is that dealing with muscles and their action. Here we have the results of a singularly close study of the various muscles of the hand, both in health and in disease, both after organic lesions and after functional disturbances, results which enable the author to furnish us with the very useful classification of muscles into prime movers, antagonistic, synergic, and fixation muscles, according to the particular part they play in different movements. We are also given the exact meaning of the phrase "at rest" as applied to a limb or a muscle, and supplied with a physiological explanation as to when and why the position of rest is attained. The distinction between a limb which is immobilised or mechanically at rest and one naturally at rest is clearly drawn. In the chapters dealing with the nerves an interesting summary is given of the most recent work of Head, Elliot Smith, Kinnier Wilson, and other neurologists—a summary supplemented by many original observations and speculations, as, for example, the particular association of trophic effects with injury to the median nerve, and the possibility that the Pacinian corpuscles are part of the sympathetic sensory system the fibres of which in the hand run mainly in the median nerve.

Altogether, the book is one which, in our opinion, places its author in the front rank of anatomists, and does more, we think, than any book published in recent years to rehabilitate the subject of anatomy, and restore it to its rightful place as the most fundamental and pervasive subject in the medical curriculum. W. W.

Identification of Monosaccharides.

Anleitung zum Nachweis, zur Trennung und Bestimmung der reinen und aus Glukosiden usw. erhaltenen Monosaccharide und Aldehydsäuren. By Dr. A. W. van der Haar. Pp. xvi + 345. (Berlin: Gebrüder Borntraeger, 1920.) Price 64 marks.

THROUGHOUT the development of organic chemistry the glucosides have maintained, amongst phytochemical products, a position of interest primarily due to their connection with sugars. Their attraction as materials for chemical study is intrinsic also, because they present alluring structural problems, and reveal the power of sugar molecules to combine with a great variety of other types—for example, in amygdalin, myronic acid, indican, and salicin. Furthermore, it is largely upon the production and examination of artificial glucosides that our present conception of glucose itself is based.

The diagnosis of a natural glucoside is complete only when the carbohydrate component has been identified, and chemists have long been conscious of the difficulties inherent to such an operation, especially when only small quantities of material are available. The purpose of the work under review is to facilitate this procedure, and the author has assembled in concise form the vast collection of experimental observations which have been accumulated in this field. Thus the volume offers ample and valuable information to those concerned in the identification of monosaccharides.

It is axiomatic that in such a treatise much attention should be devoted to the formation and properties of the large class comprising condensation products derived from substituted hydrazines, and the latter half is allotted almost entirely to this voluminous branch. The service thus rendered is conspicuous, for, in addition to arranging in logical sequence the numerous and scattered records of previous investigators, the author has elaborated methods based on his own research for dealing with mixtures containing two, three, and four monosaccharides. Due notice is given also to the recognition and estimation of glycuronic acid, the importance of which in glucoside chemistry is well known. The two concluding chapters provide detailed examples of the application to typical cases of the analytical processes under discussion.

The appearance of such a book emphasises in a very remarkable manner the facilities for monograph production offered by German publishers, and concurrently illustrates the difference in treatment adopted by Continental and by Anglo-Saxon authors. Van der Haar's treatise must be accepted as faithful and complete when viewed as a record of facts, yet it is useful only to a small number of specialists, whilst E. F. Armstrong's "Simple Carbohydrates and the Glucosides," dealing with identical materials, appeals alike to students, specialists, and general practitioners of organic chemistry. One presents the bones for sixty-four marks, the other makes a personal introduction to a living body for twelve shillings.

The present work is admirably produced, and remarkably free from errors, most of which are conveniently overtaken in a list of corrections on the concluding page; but the absence of a subject-index is to be regretted. M. O. F.

Our Bookshelf.

Solubilities of Inorganic and Organic Substances. By Dr. Atherton Seidell. Second edition, enlarged and thoroughly revised. Pp. xxii+845. (London: Crosby Lockwood and Son; New York: D. Van Nostrand Co., 1920.) Price 45*s*. net.

SOLUBILITY determinations are often incidental to other investigations, and are, consequently, not indicated in the title of the original paper, or included in the index of the journal in which they appear. For this reason such data are often difficult to locate, and Dr. Seidell's well-known compilation is a valuable contribution to chemical literature.

Originally published in 1907, the work was the first successful attempt to present a critical survey of available quantitative solubility data and to select from the discordant results of different observers the most trustworthy values for any given substance. An enormous mass of solubility data has since accumulated, and the present much enlarged edition, which brings the subject-matter up to 1918, is certain of a warm welcome. The nomenclature, especially of organic substances, has been revised, and the scope of the work extended to include freezing- or melting-point data for binary and ternary systems.

The author has endeavoured to maintain "unremitting vigilance" to avoid errors, but attention may be directed to an unfortunate lapse in the second table on p. 518, where an error has been made in converting milligram-molecules into grams, and where KOH ought to be K_2O. All the values in the fourth and fifth columns are wrong. In some cases the author has detected errors in calculation of original results, and indicates the necessary corrections—*e.g.* under strontium formate (p. 681) and ammonium perchlorate (p. 43).

New features in the present edition include a detailed explanation of the tables for the guidance of those more or less unfamiliar with the usual tabular methods of expressing such data; a chapter describing some of the methods used for the accurate determination of solubilities, with excellent diagrams; and an author index, with references to all the original papers consulted.

S. A. K.

Small Holding and Irrigation: The New Form of Settlement in Palestine. By Dr. S. E. Soskin. Pp. 63. (London: George Allen and Unwin, Ltd., 1920.) Price 2*s*. net.

THIS small publication has been issued by the Zionist Organisation in the interests of agricultural and horticultural settlements in Palestine. Intensive gardening is the main theme, and the application of the water resources of the country to the development of vegeculture, as a primary industry, is strongly urged. "The intensive utilisation of the irrigable areas for vegetable and fruit plantations should not come at the end of a period of development of years and decades, but at the beginning of our work of reconstruction in Palestine." After the preface and introduction, the subject is elaborated in four chapters. The first chapter deals with the general principles of irrigation in Palestine, as also does the introduction, contrasting the climatic conditions with those which obtain elsewhere in tropical and subtropical regions. It is claimed that artificial irrigation will work wonders, rendering two, three, and even four crops a season a possibility. The second chapter discusses the features of intensive gardening and the utilisation of manures and other adjuncts to cultivation. Tomato growing is represented as a promising venture, as also is the cultivation of the banana. The next chapter, headed "A Garden City," indicates the opportunities for, and the value of, co-operative effort. The last chapter is a brief, final word on the essential preparations for the first settlements under the scheme.

Every Boy's Book of Geology: An Introductory Guide to the Study of the Rocks, Minerals, and Fossils of the British Isles. By Dr. Arthur E. Trueman and W. Percival Westell. Pp. 315. (London: R.T.S., n.d.) Price 6*s.* net.

THIS is a good introduction to geology, lucidly written and thoroughly up-to-date. The illustrations are simple, and are line-sketches only, but they convey their meaning. The authors rightly presume that those who read their chapters are prepared to be interested in the subject. There is no talking round about, in the hope of disguising what is going to be a lesson rather than a mere encouragement to learn. There is not much room for originality in the selection of the facts put forward; but the merit of this book lies in its accuracy and simplicity of statement. The old discussions that were at one time held to be necessary in every text-book, such as the evidence of earth-movement afforded by coral-reefs, are wisely left to larger treatises. The suggestions we have to make are merely trivial. It seems cumbrous nowadays to write the names of chemical elements and compounds with capital letters. On pp. 32 and 131 felspars and beryl are respectively described as of "very complex" composition; but, when the reader has learnt the use of chemical symbols, he will not find matters so alarming. On p. 33 "twinning" should be omitted or more exactly defined. Potash is as important in biotite as in muscovite (p. 35). It is not at all necessary for a limestone to be melted before passing into crystalline marble (p. 73). We are glad to note the recommendation of a bicycle to the young explorer in our islands. Fossils do not necessarily lie on the tracks of chars-à-bancs.

G. A. J. C.

Education for Self-realisation and Social Service. By Frank Watts. (The New Humanist Series.) Pp. xii+275. (London: University of London Press, Ltd., 1920.) Price 7*s.* 6*d.* net.

UNDER the title of "The New Humanist Series," with Mr. Benchara Branford as editor, the University of London Press is projecting a series of volumes in which "the most modern advances of knowledge will be sought in order to fructify the many and varied fields of education. The subjects of the curriculum will be discussed by experts not too far removed by time from their own school years." These will be preceded by general volumes, of which the present book is the first. The treatment is adequate, and may be profitably compared with that of Prof. Nunn in the opening volume of another educational series. Without neglecting the rather intellectualistic psychology on which teachers of an earlier generation were brought up, it seeks the foundations of character and conduct in the innate tendencies to which the child is heir from an evolutionary past. The work of psycho-analysts is laid under contribution, and some of their terms, such as "sublimation," are adopted or adapted. In a diagrammatic "Tree of Human Development," from roots in *l'élan vital*, two main stems, the nutritive *hormic* and the distributive *libido*, arise, and from the latter are derived the flower and fruitage of the sublimated will or *eros*. There are many practical suggestions which will be found of value by teachers.

Utilisation des Algues Marines. By Prof. Camille Sauvageau. (Encyclopédie Scientifique: Bibliothèque de Botanique Appliquée.) Pp. vi+394. (Paris: Octave Doin, 1920.) Price 7.50 francs.

MANY possible uses of seaweeds are described in Prof. Sauvageau's excellent treatise—agricultural, industrial, alimentary, therapeutic. Their value as manure is great, but is limited by cost of carriage. Among industrial uses of brown algæ may be mentioned the kelp industries, formerly so profitable as the source of soda, and still yielding potash, iodine, and bromine. Algin, norgin, and tangin are patented products used as dressings for textiles, etc., as also are the mucilages extracted from red algæ. During the war acetone was produced on a large scale by fermentation of brown algæ in American munition factories, and used as a solvent for gun-cotton, etc. By a similar fermentation, alcohol can be manufactured in quantity for motor fuel. The Germans devised a "fuse" of Laminaria to explode shells falling into water. Algæ, though commonly eaten in Japan, China, and elsewhere, are really valueless as human food, but for domestic animals they have for ages been used as winter fodder. During the war French horses were successfully fed on a partial diet of algæ; the new food, though quite indigestible at first, gradually became assimilable, probably through the adjuvant action of bacteria or yeasts. Prof. Sauvageau's monograph is a welcome acquisition.

Letters of Travel. (1892–1913.) By Rudyard Kipling. Pp. vi+284. (London: Macmillan and Co., Ltd., 1920.) Price 7*s.* 6*d.* net.

WITH his faculty for noting the little significant things, as well as the big and striking things, Mr. Rudyard Kipling gives us wonderful pictures of life in America, Canada, and Egypt. Some of the letters are old—they are reprinted from periodical publications—but all are fresh in human interest, because they dwell on big, essential problems. The volume is Kipling at his best, without the "tobacco and blood" in which he often indulges, and with his wealth of illustration and telling incidents of travel. These short chapters give truer impressions of the lands they treat of than all the ponderous volumes of painstaking travellers, collecting facts and arranging statistics.

Slide Rules and How to Use Them. By T. Jackson. Pp. 30. (London: Chapman and Hall, Ltd.) Price 1*s.* 6*d.* net.

THE principles upon which the construction of slide rules depend are described in this pamphlet, and numerous examples are given of the methods of use of such mechanical aids to calculation.

Electric Switch and Controlling Gear: A Handbook on the Design, Manufacture, and Use of Switchgear and Switchboards in Central Stations, Factories, and Mines. By Dr. C. C. Garrard. Second edition, revised and enlarged. Pp. xxii+654. (London: Benn Brothers, Ltd., 1920.) Price 25s. net.

No considerable alterations have been made in this work since the first edition was reviewed in NATURE of March 1, 1917. Slight modifications have been effected, and recent data in connection with high-tension gear, lightning arresters, etc., added. Two new sections, one dealing with the standardisation of switchgear and the other with automatic contactor switches, have also been inserted.

Milk Testing: A Simple Practical Handbook for Dairy Farmers, Estate Agents, Creamery Managers, Milk Distributors, and Consumers. By C. W. Walker-Tisdale. Second revised edition. Pp. 90. (London: J. North, *Dairy World* Office, 1920.) Price 3s. 6d. net.

THE recognition of the value and importance of "milk recording" is making it increasingly necessary that simple but trustworthy methods of testing milk should be published for the use of practical farmers. This need is well met by the present edition of Mr. Walker-Tisdale's little book, which has been enlarged and revised since the second edition was noticed in NATURE of August 10, 1911.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Energy of Cyclones.

THERE can be no doubt, I suppose, that solar and terrestrial radiation are ultimately responsible for the kinetic energy of the winds. The doubts expressed by Mr. R. M. Deeley in NATURE of November 11 and by Mr. W. H. Dines in the issue of November 18 can refer only to the details of the phenomena consequent on the process of transformation of the energy. The first stage is obviously the storage of energy in the potential form of air charged with heat and moisture at the surface or lower levels and cooled by radiation at high levels, especially in the polar regions, as on the plateau of Greenland or on that of the Antarctic continent, or on the sunless slopes of the Himalaya. Equally without doubt the next step is convection, the greater part of which is indicated here and there by falling rain or snow. Measurements of rainfall assure us that there is no lack of energy available for violent winds if the heat-engine is at all efficient.

The general effect of the process of convection is the development of a vast circulation in the upper regions of the atmosphere from west to east round the poles, which has its counterpart in the normal distribution of pressure at corresponding levels. That is probably most pronounced at a level of 8 km., because at that level density is equal all over the globe at all seasons of the year. Above that level, up to the level of equal pressure at 20 km. of which Mr. Dines writes, there is, on the average, a gradient of density from the equator to the pole, and below the level of 8 km. a gradient of density in the opposite direction. The layer of maximum average velocity is above the layer of maximum pressure-gradient on account of the diminution of density with height.

Below the level of 8 km. the distribution of pressure is affected by the gradient of density in a very irregular manner, because the distribution of land and water is irregular. The net result at the surface is the complicated distribution of average pressure which we find in the maps of normals for sea-level.

The maintenance of the average general circulation from west to east in the higher levels is due to the gradual convergence towards the polar areas from which the cooled air flows. That must obviously be balanced by a corresponding flow towards the equator, and as poleward flowing entails a westerly circulation, so flowing towards the equator entails an easterly one. We must, therefore, find room in the system for a body of air flowing from the east comparable at least with the circulation from the west. We find such a body of air in the great easterly circulation of the intertropical regions, which is naturally stowed away over the equator as far as possible from the centres of the two polar demi-hemispheres of influence of pressure-gradient.

These great circulations, easterly and westerly, form a normal "groundwork" of all atmospheric motion; and when Mr. Deeley and Mr. Dines write of the energy of cyclones, they are not concerned, I think, with the energy of the general circulation of the upper levels which I have described, but with the minor circulations which represent the perturbations of the major circulation.

I think myself that the convection of warm, moist air, combined with the vagaries of temperature in the lower layers, will, in the end, prove to be sufficient to explain the energy of cyclonic air-currents—whether directly or as the secondary effect of current-differences, I cannot say. Probably, in order to get a correct view of the perturbations, we ought to subtract vectorially from the observed winds the local motion of the normal circulation, or else accustom ourselves more than we do to the theoretical combination of local circulation with a general circulation.

There are four other aspects of the problem upon which we are at present almost uninformed. The first is the locality where the cyclone, which is the subject of study, was generated; just as the cyclone itself is a perturbation of the general circulation, so what we see going on over our heads is the perturbation of a cyclone which may have originated in the general circulation thousands of miles away. A cyclone is a more or less stable dynamical system which certainly travels, but changes as it travels. The second aspect is the variation of velocity of the wind with height in the general circulation and in the cyclonic area itself. The third, which is closely connected with the second, is the trajectory of convected air. This could be calculated if we knew the point from which it started and the variation with height of the current which carried it. One often reads of convected air rising *vertically*, but we know that the actual trajectories of a pilot-balloon are of very various shapes, seldom vertical, and the balloon may part company from the air which supported it at the start by a distance measured in tens of kilometres. Air in convection rises very slowly. If we set its vertical velocity at one-hundredth of that of a pilot-balloon, the convected air may be thousands of kilometres from the starting point before its upward journey is finished, and its path may be very complicated. It is possible that this conception of the slow, gradual ascent of air may have a bearing upon the cloud-formation associated with a coming cyclone, but the subject is too long for a letter.

The fourth aspect is the behaviour of the convected air with regard to its environment. The slowness of its rate of ascent is dependent largely upon the development of eddies and consequent dilution of its mass with the cooler environment. This cannot of itself arrest the upward motion, though it delays it, and, consequently, when the convected air has arrived at its ultimate level it will have carried with it some of the air which formed its environment on the way. Hence the rising air will have "evicted" a certain amount of air by its passage.

The importance of combining these aspects is at once apparent if we consider that convection in still air would simply mean a readjustment of the mass in the vertical. The potentially warm air would be at the top instead of at the bottom, and the effect of a completed process of convection would be that pressure would rise within the area of operations. But if the risen air were delivered into a rapidly moving current at the top, the air which it had "evicted" from the environment on its way would be lost to the column, and when the process was completed the air would close in from the top, the bottom, and the sides. If there were any relative motion to begin with—and there is always some—closing in from the sides must develop cyclonic circulation with a cold core. Closing in from the bottom with air colder and drier than that which began the convection would stop on account of dynamical cooling, and closing in from the top means the settling down of the air of the stratosphere and a consequent low tropopause with a column of air above it warmer than its environment.

These conditions describe what the late Lord Rayleigh postulated for superposing a vortex on a current with relative velocity of its parts. They also agree with what Mr. Dines describes as the results of his examination of actual cyclonic conditions in England. And this view of the procedure is borne out by the examination of tropical cyclones. We can form legitimate inferences from the pressure records of these visitations because the normal conditions of the localities where they occur are extremely regular. We can see by an inspection of the graph of pressure that the region covered by a cyclone has simply lost a certain part of the air which it normally possesses. In one example I estimated the loss as equivalent to 40,000 cubic km. at sea-level. Beyond all doubt or question air had gone; it was not piled up in anticyclones fore and aft, as we used to think the convected air of our cyclones must be; it was gone clean away. I suspect that it travelled away in some upper current until slowed down over the tropical anticyclone of some ocean. The story will not be complete until that surmise is verified or the correct account substituted. Hence, for the time being, I am as curious about the life-history of convective air-currents as I was twenty years ago about that of surface air-currents.

In any case, it seems to me certain that, because it carries away part of the air which it meets on its path, convection, wherever it occurs, must entail convergence, and therefore, except at the equator, it must give rise to a cyclonic circulation which may be transient or, if circumstances are favourable, permanent. The function of the stratosphere seems to be not constructive, but conservative and registrative. It protects the energy from being dissipated by "filling up," because the descent of its isothermal air is arrested by the adiabatic rise of temperature. That is, indeed, the common function of all "decks" or lids in the atmosphere, of which the stratosphere is the chief. At the same time, for an observer the stratosphere registers the locality of low pressure by the lowness of the tropopause and the relative warmth of the air column above it. It seems to be a law for the general circulation and for local circulations that as pressure diminishes in the troposphere the tropopause is lowered and the temperature of the columns above it rises.

Consequently, my view at the present time is that the energy of a cyclone is due originally to convection in a region with a suitable law of variation of velocity with height; it is guarded at the top by the isothermal condition of the stratosphere, and on the sides by the balance of pressure and rotation. It is open to slow attack at the bottom on account of the friction of its winds with the surface, and unless its energy can be maintained by additional convection it must perish. I do not think that a travelling cyclone carries its supply of rain for long distances; it probably manufactures it out of the material in the lowest levels which it has to pass over. But it uses the energy so supplied first to form a secondary, and afterwards to absorb it or to be absorbed by it.

NAPIER SHAW.

Imperial College of Science and Technology, S.W.7.

It is a well-known hydrodynamical result that, in the absence of any external stabilising influence, any surface of discontinuity of velocity in a fluid must be unstable. The effect of this instability is seen in the eddies produced in a millpond, at the margin of the entering stream. A sufficiently rapid shearing, without actual discontinuity, will produce the same effect. Most atmospheric eddies are developed in this way. In the case of differences of velocity between different masses of air at the same level, gravity is not directly available to damp any eddies that may be produced, and hence it does not seem likely to be difficult to account for eddies with their axes vertical.

Thus the origin of cyclones may well be explained on the lines suggested in Mr. W. H. Dines's letter in NATURE of November 18. It is rather more difficult to see what determines the size and intensity to which they grow. Ground friction must play its part; also, where the warm stream on the south side bulges northward, it must do so to some extent over the top of the cold air already there, and this arrangement makes for stability, and when sufficiently developed must prevent the further growth of the disturbance.

The speed of translation of the cyclone on this theory should be the mean of the velocities of the two currents, which is usually about correct. The geostrophic condition must also hold approximately, otherwise the disturbance would spread out with nearly the velocity of sound and disappear. What is not easy to see, however, is why the isobars tend to become more or less circular instead of wavy.

HAROLD JEFFREYS.

Meteorological Office, South Kensington.

I SHOULD like to express my agreement with Mr. W. H. Dines's view (NATURE, November 18, p. 375) regarding the origin of the *initial* difference of pressure which leads to the development, under the influence of the earth's rotation, of cyclonic circulation, and to state that I have often suggested that this initial disturbance may have a mechanical origin (see Quart. Journ. Roy. Meteor. Soc., vol. xliii., 1917, p. 27). At the same time it seems that one cannot, on many grounds, ignore the effect of temperature contrasts as a contributing factor in the further development and maintenance of storm energy.

To take the very fact which Mr. Dines cites, namely, the exceptional storminess of the Atlantic to the north-west of Scotland. This region is, in a most conspicuous degree, stormier in the winter months than in the summer, and it is almost one of the canons of physical geography that the excessive development of storm-energy during the cold season is favoured by the great contrast in temperature between the frostbound continents and the warm Atlantic, the individual cyclonic systems breeding not so actively over the land areas, where the general pressure is high, as over the oceanic areas, where the general pressure is low. On the other hand, during the warm season—when the temperature gradient between the oceans and the continents is reversed, but is much less steep than the winter gradient—cyclonic energy in the North Atlantic is far less powerful, whilst over the sun-heated continents storm-energy takes the form, not of extensive wind-systems, but of localised convectional thunder-systems. Furthermore, in the southern ocean, between 40° and 60° S., where there are no disturbing land masses, there does not appear, judging from the reports of navigators, to be such conspicuous seasonal difference in storminess, and this is borne out by statistics available for the Falkland Islands (Meteor. Office Geophys. Mem., No. 15). L. C. W. BONACINA.

November 19.

SIR OLIVER LODGE's suggestion and mine in NATURE of November 25 are not contradictory, but rather complementary. Work done by the alternate evaporation and condensation of moisture implies a thermodynamic cycle. Both air and aqueous vapour must, I think, play the part of working substance.

J. R. COTTER.

Trinity College, Dublin, November 26.

Luminosity by Attrition.

ALLOW me to add to the list of minerals showing this phenomenon one which I have already given in my book "Diversions of a Naturalist." It is that of corundum. I found that water-worn pebbles of corundum (so identified in the department of minerals of the Natural History Museum) gave flashes of light when rubbed together, but required for this result a heavier pressure than do pebbles of silica. The same odour as that observed when silica is used was produced.

I may also repeat here what I have stated in my book, that a spectroscopic examination of the luminous flashes of quartz pebbles gave a continuous spectrum and no detached bright lines.

E. RAY LANKESTER.

November 28.

SOME ten years ago when grinding down a thin slice of limestone under water I was surprised to find that the operation was accompanied by faint flashes of light which seemed to issue from certain spots of superior hardness; on examining the slice under the microscope it was found that these spots consisted of quartz. This led me to devise an apparatus by which the luminescence could be continuously produced and so rendered a subject for precise observation. The substance to be examined was attached to the free end of a hinged bar and adjusted so that it rested against the edge of an emery, or, still better, a carborundum wheel which was rotated by an electric motor. Of some forty minerals experimented upon no fewer than eighteen emitted light while being ground. Those that did not included all the sulphides which were examined, viz. zinc blende, cinnabar, antimonite, galena, copper pyrites, and arsenical pyrites. Iron pyrites, of course, yielded sparks, but these were not accompanied by tribo-luminescence. Almost all the silicates emitted light, *e.g.* orthoclase, labradorite, idocrase, garnet, tourmaline (one variety, another did not), epidote, zircon, topaz, and glass; several oxides, *e.g.* corundum, magnetite, hæmatite, cassiterite, quartz, and flint; light was also obtained from wavellite, apatite, celestine, and barytes. But the most remarkable results were obtained from fluorspar; all the varieties of this mineral which were examined gave light, but one in particular, distinguished by its green colour, emitted blue light, not only in great quantity, but also of such persistency that the whole periphery of the wheel was alive with it.

Curiously enough, no electrical phenomena were observed in any case; an electroscope, possibly not a very sensitive one, gave no signs even when fully exposed to the current of dust driven off during grinding.

The light emitted was in most cases white, but often coloured reddish or yellowish, and in a few instances bluish. It would be quite possible to examine (as I did) the light with a spectroscope, and after some preliminary trials I planned apparatus for photographing the spectrum. The outbreak of the war, however, put a stop to my experiments, and I have not yet had time to resume them.

November 25. W. J. SOLLAS.

Stellar "Magnitudes."

MAY I ask whether it is not time to overhaul and improve the conventional specification of stellar magnitudes?

When first introduced, on the basis of ordinal numbers, the plan was natural enough; a third magnitude was naturally inferior to a first, and a group of some twenty stars could be considered as of the first magnitude.

But when it was found possible to measure and specify magnitudes with numerical accuracy—by instrumental means not, I confess, fully known to me—so that a Variable could be said to decrease from 2·14 to 2·56, the cardinal number specification looked inverted. Moreover, magnitudes less than unity became necessary for the brighter stars, and a sufficiently bright star would presumably have the magnitude 0; a nova, for instance, might blaze up from magnitude 12 to magnitude zero, or even become of negative brightness at the height of its career. Indeed, I gather that a more recent system, of what are called "absolute magnitudes," really does involve negative numbers.

Would it not be well to reconsider the convention and devise something more convenient?

OLIVER LODGE.

Higher Forestry Education for the Empire.

THE question has been recently raised by the Government of India as to the advisability of either training the probationers for the Indian Forest Service entirely in India or confining the training to one centre in this country. The question has come to the front owing to the changes to be introduced in the administration of India, under which a larger proportion of Indians will enter the Indian Forest Service in the future, it being therefore considered desirable to train the European and Indian probationers all together. The professional forestry opinion of Indian officials, with which Prof. Troup and I agree, would appear to be unanimous in condemning the possibility of training the forest probationers in India owing to the fact that the Indian forests are, as yet, very far from having reached the standard necessary to provide students with the full practical object-lessons which are to be seen only in forest areas which have been under scientific management through one or two rotations of the crops.

The alternative suggestion is to revert to the one centre at home, which was given up when the forestry branch at Coopers Hill was closed down in 1905. This question of one centre was considered at the Empire Forestry Conference held in July last in London. The Forestry Commissioners suggested that a new centre should be created apart from the universities, and that both Indian forest probationers and the Colonial and Dominion probationers required for the Empire should be trained at the centre. It was suggested that the probationers should be selected from graduates in natural or pure science at the universities, and that these probationers should then be sent to the centre to undertake a two years' course in forestry and the applied science subjects. The conference voted in favour of this proposal. The situation of the centre, whether at one university or apart from the universities, was left in abeyance. The Indian Government representatives wished the centre to be at one university at which a forestry college should be erected for the probationers, the latter otherwise taking advantage of the university courses, laboratories, and so forth.

At the present moment the three Universities of Oxford, Cambridge, and Edinburgh are recognised by the India and Colonial Offices as qualified to train their forest probationers. The suggestion to confine the training in the future to one university would be, therefore, subsidising one university as against the other two, thus involving the waste of the capital sunk by these universities in placing their forestry schools in an efficient position. To carry out the one university centre idea it would be necessary to obtain considerable grants of money from the Indian and Colonial Governments, and it is doubtful whether one university could be thus subsidised by the Government at the expense of the others. The suggested alternative is the one centre apart from the universities.

At the end of September last the Forestry Commissioners called a meeting of the heads of the schools giving forestry training in this country.

In the discussion on the one centre proposal the heads of the forestry schools of Oxford, Cambridge, and Edinburgh were unanimous in condemning the one centre away from the university, considering that it would introduce a rigid type of teaching which would give rise to a forest officer with a narrow outlook. It would also be difficult to get first-class teachers to take up appointments in an isolated centre. The cost of the new buildings and their equipment and the outlay on salaries would also be a very heavy charge. The period of three years for the science degree and two years for the later training in forestry was also deemed too long, involving the probationers joining the Services at an unnecessarily advanced age. They were also of opinion that the complaints of the Indian Government as to the inadequacy of the training of some of their forest officers were due to the present method of selection, many probationers being selected before they had any training in forestry or knew anything of the life of a forester. It is common knowledge at the university centres training for forestry that men, finding they have no taste for the forestry subjects, change over to another side of the university at the end of their first year and while there is still time to do so. The selected forest probationer with a Government training grant is not often in a financial position to enable him to throw up his grant. Yet the proposal for the single centre away from the university is based on the continuance of this selection system. The heads of the university departments were also strongly in favour of the higher forestry education being given at the university, as the men, European and Indian alike, profited greatly by mixing with others training in other branches.

It became apparent at the Empire Forestry Conference that many of the delegates had only a superficial acquaintance with the latter-day developments in forestry education at the three Universities, which, to a great extent, have been the result of the work of the last decade.

With the view of providing for the India Office requirements that *esprit de corps* should be engendered amongst its probationers by living together, and also the practical needs of the future forest officer, which are now greater than they were, I made the following suggestion:—That the forestry probationers for India and the Home and Colonial Services should be selected from the men who had obtained a degree or diploma in forestry at the universities, and that these selected probationers should then be sent for a period of six months or a year to the new Empire Research Institute, which the Empire Forestry Conference delegates suggested should be inaugurated in this country. The probationers could be given such specialised courses as were required at this centre with a very small extra expense. The Indian probationers would thus live together during part of their training, and that *esprit de corps* required by the Indian Government would be engendered.

In the Memorandum of the Education Committee of the Conference (White Paper, Cmd. 865, p. 15) it was stated that my proposal *in re* extra specialised courses was "a tacit admission that existing courses were capable of extension with advantage." I have shown that time will not permit of an extension of the curriculum during the three years required for the forestry degree. The question of extending the degree course to four years has been under consideration at Edinburgh. The Indian Government delegates have stated that the forest officers of the future would be the *corps d'élite* of the Indian Forest Service. I fully agree with this view. To train the men to this standard will require extra specialised or advanced courses, and these can be given either at the universities or, as in my suggestion to meet the views of the Indian Government, at the Empire Research Institute.

Apart from India, the suggestion of the one centre is made on the ground that it will prove cheaper owing to the large demand for grants in aid of forestry education which have been made to the Forestry Commissioners; but in this matter of the higher training for the forest officer only three universities in this country are at present in question.

It should be possible to find out what additional funds the three universities require to maintain their schools in the highest possible efficiency, and this amount, combined with the additional sum required for the extra training of the probationers at the Empire Research Institute, would be likely to be far below the amount, to which India and the Colonial Office would have largely to contribute, which would be required to create a new isolated centre apart from the universities.

The decision on this point of the future of the higher forestry training is a momentous one, since it involves no less than the future correct management of the majority of the forests of the Empire.

British Laboratory and Scientific Glassware.

I HAVE read with much interest the letters in NATURE of November 4 from Prof. Bayliss and Mr. Frank Wood on the subject of British glassware, and I think the whole truth lies, perhaps, between the two opinions put forward. As a manufacturer of scientific apparatus, and primarily of X-ray tubes, I have had probably as trying an experience of glass as any manufacturer since 1914.

It is well known, I presume, that prior to the war the whole of the glass bulbs and tubing used in the manufacture of X-ray tubes came from Germany, and the quality was undoubtedly very fine indeed. Since 1914 we have been obliged to depend upon glass of French, American, and English manufacture. Although by no means without merit, the products of the two first-named countries were discarded directly the English makers were in a position to give us anything at all adequate to work with, and since 1916 I think we have not used any glass whatever other than that made in this country.

At the present time the position is that a glass reasonably good for our purpose is made by at least two British firms. It works well in the flame and preserves a good appearance, but it is impossible to say that it has reached the high standard set by the German product. So far as the purchasers of the finished instrument are concerned they are not affected, because the imperfections of the British glass, where they exist, manifest themselves during the manufacture of the complete X-ray tube, and the difficulties, therefore, are entirely connected with manufacture, and not with the efficiency of the working of the apparatus which is being constructed.

It has seemed to me for a long time past to be a matter for regret that the British manufacturers could not make those small final improvements which would give us exactly the material we require instead of, as at present, stopping a little short of the ideal.

I believe there is no particular difficulty at the moment in obtaining supplies of glass from Germany, but up to now I have resisted every temptation to do this, partly on general sentimental grounds, but largely because of the enormous amount of trouble which has been taken by the two firms of which I spoke in order to produce a glass suitable for X-ray purposes. I am sure that from start to finish the profit on this undertaking must have been negligible, and there have been endless experiments and a very large amount of waste, the cost of which has fallen chiefly on the glass manufacturers themselves.

For this reason I feel that every endeavour should be made to place the British glassmakers in a position whereby they could continue to produce these special glasses, the demand for which is comparatively small, but which are, nevertheless, of the very greatest importance to scientific workers in this country. Those firms engaged in my particular branch of the electro-medical industry are always only too ready to co-operate in every possible way with the glass houses in order to secure in this country absolute independence in the matter of the supply of material.

Heredity.

IN his letter to NATURE of November 25 Sir Archdall Reid has ably stated some fundamental biological truths concerning heredity, and with many of his statements I believe all biologists would agree. From the developmental point of view there is certainly a sense in which all characters are alike, arising as the result of the interplay of the germ and its environment, nature and nurture. In this limited sense it is doubtless beside the mark to inquire whether nature or nurture is more important, seeing that both are essential elements in any development at all. From this point of view it may be true, to cite Sir Archdall Reid's example, that there is no fundamental difference between the head and the scar; both may be in one sense germinal, and in another acquired.

But this does not go to the root of the matter, as may be most readily pointed out by referring to the latter part of the letter in NATURE. Sir Archdall Reid says: "The sole antecedent of non-inheritance is variation." The statement is true, of course, but he goes on to assume tacitly that all variations are in one category. Sir Archdall Reid recognises the fact, which Weismann emphasised, that "heritage travels down the germ-tract," and draws the "*necessary* [his italics] inference from this" that all characters of the individual are "innate, acquired, and inheritable in exactly the same sense and degree." But this is surely a *petitio principii*, for while all inherited characters may come to travel down the germ-tract, it does not follow that they all originated as variations in the germ-tract. It is surely legitimate to assume, until the contrary is proved, that new characters may arise (to use ordinary biological terms) as germinal variations or as impressed modifications of the soma which are not represented in the germ-tract. Indeed, this is the current distinction drawn between mutations and fluctuations. In the latter case the question will arise whether the modified soma may ultimately affect the germ-plasm; in other words, whether a modification or an acquired character may come to be inherited by bringing about an alteration in the germ-plasm. This is surely a legitimate inquiry. If so, it implies the possibility that the "scar" might ultimately, having become germinal, appear without the specific stimulus that is now necessary to call it forth.

The Mechanics of Solidity.

UNDER this title Mr. J. Innes (NATURE, November 18) suggests, for the benefit of engineers, that coefficients of thermal expansion are fairly closely related to hardness. His list of thirty-eight materials ranging from diamond to indiarubber is given in order of thermal expansion. No definition of hardness is suggested, and the figures, taken from three tables of "hardness," are admittedly somewhat conflicting.

Hardness, I take it, is due in part to closeness of atomic packing. Diamond, the hardest substance known, possesses also the lowest known atomic volume, while potassium, the softest element on Mr. Innes's list, has by far the highest atomic volume, *i.e.* has the loosest atomic packing.

Diversities in hardness depend also on how far each substance tested is removed from its melting point. Taking fourteen elements from the list, and assuming tests for hardness were made at uniform temperature, the order of degree-distance below melting point comes out:—Diamond, iridium, platinum, iron, gold, copper, silver, aluminium, arsenic, antimony, lead, tin, bismuth, and sulphur.

The order of hardness is: Diamond, iridium, platinum, iron, arsenic, antimony, gold-copper-silver, aluminium, tin, bismuth, and lead-sulphur. (It is probable that arsenic and antimony were tested in a crystalline state, in that respect differing from the three metals above and the four below them.)

The order of ascending coefficients of expansion is:—Diamond, arsenic, iridium, platinum, antimony, iron, bismuth, gold, copper, silver, tin, aluminium, lead, and sulphur. Here the agreement is not so close as before.

Doubtless coefficients of expansion themselves depend partly on how far the mean range of temperature from which they are calculated is removed from the melting point. For strict comparison, what are known as "corresponding temperatures" should be taken. If this is done for coefficients of expansion of gases, then the values become identical; with solids (or liquids) the coefficients would approach, but never reach, uniformity.

In practice engineers are bound to consider arbitrary temperatures which will affect their mixed materials, but a knowledge derived from comparison of physical properties at corresponding temperatures would enable them to predict special changes among the mixed material which would occur when temperatures rise or fall.

University College, Reading.

The Hardening of Metals under Mechanical Treatment.

IT appears from an article by Mr. Ernest A. Smith in NATURE of November 18, p. 381, that the cause of the hardening of metals under mechanical treatment is still regarded as obscure.

May I suggest, for the consideration of research associations and others concerned, that all the phenomena of plastic deformation, including hardening by distortion, are aspects of what Osborne Reynolds has called "dilatancy," and that this twentieth century is no time for random empirical experiments conducted without either guiding principles or clearly defined objectives?

Reynolds has shown that the density of a granular solid must change when the solid is distorted. There is ample evidence that distortion alters the density of metals, and no very valid reason for assigning the accompanying alteration of "hardness" (and other properties) to anything but a change in the pattern of the grains, *i.e.* to dilatancy.

Systematic experimental investigation can scarcely fail to have far-reaching results, and may even bridge the gulf between mechanics and the more exact sciences.

Tube-dwelling Phase in the Development of the Lobster.

WHILST the development of the lobster from the Schizopod stage onward to an inch or a little more is fairly well known, the great rarity of the stages between that and 3 in. or 4 in. (second year) has often puzzled marine zoologists. For instance, only once in many years has a small lobster of about 4 in. been seen at St. Andrews, and this example was tossed amidst a vast quantity of débris on shore after a violent storm. Prof. Prince, Dominion Commissioner of Fisheries for Canada, and president-elect of the American Fisheries Society, who has inaugurated many important advances in scientific fisheries work, tells me that Prof. Knight, who has been investigating the subject, finds that "after the pelagic stage the young lobster appears to frequent shallow bays and make a definite burrow with two entrances, and it sits on guard at one, but if in danger escapes by the other. It is very quick in emerging, but Prof. Knight and his assistant got 200 to 300 in a bay in Prince Edward Island. Now we know the reason of our failing to capture these very small lobsters from 1½ in. to 3 in. long. The dredge cannot secure them, yet they must occur in countless millions in our Canadian bays, since many more than 100,000,000 adults are taken in our waters for canning and the live-lobster trade in good years." Thus the rarity of the little lobsters of the stage indicated is explained.

It is interesting that the adult, as shown by Dr. H. C. Williamson, of the Scottish Fishery Board's staff, has a similar fondness for cavities, which it searches for with its antennæ, and will even turn out a weaker neighbour and seize its shelter.

W. C. McINTOSH.

Contractile Vacuoles.

I HAVE just read W. Stempel's paper, "Ueber die Funktion der pulsierenden Vacuole," to which Prof. Bayliss kindly directed my attention in NATURE of November 18, p. 376. Stempel's idea as to how the contractile vacuole works appears to differ fundamentally from my conception of its mechanism. He regards it as a preformed organ of the cell, developed to eliminate the waste products of metabolism, these products being introduced into the vacuole by the radiating canals which he endows with peristaltic action. He further postulates the existence of non-return valves between these radiating canals and the vacuole, and also of one at the point of exit of the fluid to the exterior. He considers that the evacuation of the contents is effected by the osmotic pressure in the vacuole, opening the valve and thrusting out the fluid, by the surface tension of the extruded drop, and by the pressure of the protoplasm. He does not indicate that the elasticity of the protoplasm or its tenacity enters into the mechanism. My suggestion may be summed up in the much simpler statement that the contractile vacuole is a necessary development in the protoplasmic semi-permeable gel wherever sufficient soluble material accumulates, the radiating canals being formed by the elastic recovery of the gel after rupture.

Leptocephalus of Conger in the Firth of Clyde.

IN a recent issue (vol. xii., No. 2, July, 1920) of the Journ. Mar. Biol. Assoc. Mr. E. Ford, in a "Note on a Leptocephalus Stage of the Conger," gives a "summary of captures around the British Isles." To the records there given, may I add two from the Firth of Clyde?

(1) July, 1907: off Keppel Pier; 3 fms.; length, 120 mm.; depth, excluding fins, 8 mm.; a distinct row of black spots along the lateral line. Taken from the stomach of a saithe (*Gadus virens*).

(2) March, 1908; Ardneil Bay, 10 fms.; taken from the stomach of a cod (*G. callarius*); too much digested to give any details.

RICHARD ELMHIRST.

Marine Biological Station, Keppel, Millport.

Spiranthes autumnalis.

SIR HERBERT MAXWELL will, I am sure, allow me to make a little correction in his statement on p. 409 of NATURE of November 25; it was not Sir Joseph Hooker, but Sir William who in 1843 doubtfully described a solitary specimen of *Veronica tetragona* as a species of the coniferous genus Podocarpus. Oddly enough, the plant was correctly described from a flowering specimen in the same volume of Hooker's "Icones" on a later plate.

Prof. Sherrington's Work on the Nervous System.

By Dr. E. D. Adrian.

PROF. C. S. SHERRINGTON, who was elected president of the Royal Society at the anniversary meeting on November 30, is well known as the leading authority on the physiology of the central nervous system. The guiding principles of his researches are to be found in his book on "The Integrative Action of the Nervous System," based on the text of the Silliman lectures which he delivered in Yale University in 1906. This book gathers up the arguments of the most important of his papers on the physiology of the nervous system, and it is safe to say that no other book in any language has had such an immediate and profound effect on our conceptions of neurology.

Prof. Charles Scott Sherrington, President of the Royal Society.

The integrative function of the nervous system has long been recognised. An animal which has attained some degree of complexity is made up of different groups of cells forming the muscles, glands, supporting framework, etc., and each group is specially adapted to carry out certain functions. If these different cell groups are to work harmoniously together, their activities must be co-ordinated with one another and with the environment of the organism, so that a change in environment will cause a response in the animal as a whole, and not merely a series of disconnected responses in the different active tissues. This integration is carried out by the nervous system, which forms a complex network of nerve-cells and nerve-fibres connected, on one hand with the sense-organs, and on the other with the different muscles and glands. A disturbance of equilibrium initiated in the sense-organs travels rapidly along the sensory nerves to the central mass of nervous tissue in the spinal cord and brain. Every moment an immense number of impulses are entering the central nervous system from the million or more sensory fibres connected to the receptive organs, and other impulses are continually passing out down the motor nerves to the muscles. Any change in the environment will modify the inflow of sensory impulses and call for some change in the activity of the animal, and the whole function of the central nervous system consists in adjusting the passage of impulses through it so that the total effect produced by the outgoing impulses to the active tissues bears an appropriate relation to the total effect of the ingoing sensory impulses. The aim of the neurologist is, therefore, to discover the means by which this adjustment of the flow of impulses is carried out. There are, roughly, three main lines of research by which the problem has been approached. The first method consists in tracing the connections of the different fibres and cell groups in the nervous system, so as to map out the path by which the impulses must travel. The second attempts to find out the contribution made by different parts of the nervous system (*e.g.* the cerebellum or the cortex) to the working of the system as a whole. Both methods have yielded information of great importance, but neither of them gives much prospect of explaining the intimate nature of the processes involved in nervous co-ordination. The third, a field relatively barren until Prof. Sherrington's work, consists in analysing the simplest activities of the nervous system by a detailed study of the reflexes.

A "simple reflex"—*i.e.* the performance of an isolated movement as the direct consequence of sensory stimulation—is generally regarded as the unit reaction of the nervous system, the behaviour of the animal being compounded out of a series of simple reflexes. But as this compounding of reflexes is the chief work of the nervous system it is naturally a difficult matter to isolate a single reaction out of the whole behaviour of the organism; indeed, in an animal which is intact we find that the response to a given stimulus may depend not only on that stimulus, but also on the total effect of all the sensory impulses which are entering the central nervous system or have entered it previously. Prof. Sherrington overcame this difficulty by isolating a part of the central nervous system, so that relatively few sensory impulses can reach it, and the reflex response to a given stimulus can be studied under approximately constant conditions. His method takes advantage of the fact that in the higher animals the great majority of sensory impulses are those which enter the brain from the special sense-organs in the head. These organs—the eye, ear, and nose—supply information about events happening at a distance, and it is on such information that the behaviour of the higher animals is largely based. For this reason the brain has come to be the most important part of the nervous system, and is in complete control of the more primitive spinal cord, which receives impulses only from sense-organs in the skin and in the interior of the body.

If the brain is cut off from the spinal cord, the latter is at first completely disorganised, but in a short time it recovers from the initial shock, and carries out simple movements of the limbs in response to stimulation of the skin or of the sensory nerve-fibres. These simple reflexes will now occur with almost mechanical regularity, because the spinal cord is isolated from the great mass of continually changing impulses which would otherwise reach it from the brain. In practice the animal is anæsthetised and the brain destroyed, usually by cutting off the entire head; as the breathing will cease, some form of artificial respiration must be employed, but with this the decapitated carcase will continue to show reflex movements for many hours. Prof. Sherrington has carried out a detailed analysis of certain of these spinal reflexes, in particular the scratching movements of the hind leg in response to irritation of the shoulder area, the withdrawal of the foot on the application of a painful stimulus, and various movements which form a part of the act of walking. He has studied also the "tonic" reflexes whereby the animal maintains a continued posture by the steady contraction of certain groups of muscles.

As a result of this method of research, he has been able to show the chief differences between conduction in the simple nerve-fibre and in the more complicated pathway through the central nervous system. He has shown how reflexes are compounded together so that two antagonistic muscles (*e.g.* the flexors and extensors of a limb) can never be called into play at the same moment, and how one reflex becomes fatigued and gives place to another so that the pattern of nervous conduction is continually changing and the behaviour of the animal varies even though the environment remains unaltered. The general principles of reflex action which Prof. Sherrington has formulated have had an immediate practical application to the problems of nervous disease and experimental psychology, and it is no exaggeration to say that his researches have opened up an entirely new chapter in the physiology of the central nervous system.

Industrial Research Associations.

IV.—The British Research Association for the Woollen and Worsted Industries.

By Arnold Frobisher.

The main object of the British Research Association for the Woollen and Worsted Industries is to promote co-operation amongst wool-using firms with the view of establishing a national scheme of research into the problems presented by the woollen and worsted industries. In the formation of the association, and in the matter of providing facilities for some work that has already been done, much assistance has been given by educational bodies, particularly by Leeds University and by the Bradford Technical College.

The scope of the work of the association includes the investigation of problems arising in all branches of the woollen and worsted industries—that is to say, the growth of wool, scouring, carbonising, carding, combing, spinning, weaving, hosiery manufacture, dyeing, bleaching, printing, finishing, and other auxiliary or related processes. As certain classes of "woollen" goods also contain substitute fibres, the investigation of these is also necessary.

One of the first duties of the council of the association has been to make a survey of the field of research which is likely to be beneficial to the industry. In this connection members of the association can be of great assistance in the framing of a thoroughly comprehensive scheme by making suggestions relating to that part of the industry with which they are intimately acquainted.

In addition to conducting the ordinary laboratory research work, provision has been made for entering into agreements with mills and works for carrying out any experiments on the manufacturing scale which have, or may, become necessary.

Considerable progress has been made towards the establishment by the association of a wool textile library, where literature relating to the industries is being indexed, abstracted, and arranged. In this connection it is hoped to work in close co-operation with the university and commercial libraries already in existence, so that there shall be a minimum of overlapping.

There is also being established a bureau of information, to which any member of the association can apply for assistance in the technical and other difficulties which he may encounter in his business. If the information necessary for the solution of his difficulty is available, it will be supplied to him; if this information is not available, the member will be able to rely on attempts being made to procure it.

Besides the scheme of co-operative research for the common good of members of the association, it is proposed to make provision for carrying on investigations at the request of individual members, at their own cost and for their own benefit. In such cases the work will be done under the supervision and control of the Director of Research, and fees will be charged to cover the cost of the investigation.

The association has purchased a large mansion in about four acres of ground, which is at present being converted into physical, chemical, and mechanical laboratories, with rooms specially adapted for photographic and photomicrographic work. A feature is being made of the possibility of modifying and improving testing machines and devices for fibres, yarns, fabrics, etc.

In the basement of the premises a room is being fitted up, the atmosphere of which can be automatically controlled as to temperature and humidity. The chamber is of sufficient size to enable experiments to be conducted within it under known and controllable conditions. At least two such rooms exist in the U.S.A. for use in testing paper and textiles, but, so far as is known, there are none in this country, apart from arrangements for *increasing* humidity. A small experimental plant is also being installed for the investigation of problems of scouring, milling, and finishing, and, as necessity arises, small-scale plants will be installed for other experiments.

As regards the programme of research, a number of "practical" problems have been formulated, among which may be mentioned the effect of "condition" (*i.e.* percentage of moisture), strength, finish, handle, waterproofing, efficiency and suitability of machinery, etc. For the solution of these problems a large amount of work is required on the ultimate properties, physical, mechanical, chemical, etc., of the fibre. Even for the commoner processes and reactions the information available is by no means complete or convenient. The early work of the association is bound, therefore, to include a great deal of former work by way of review and amplification. There are very many branches of the subject that have been worked at many times, but not completed. This particularly applies to the absence of micrographic and often of physical tests.

For example, some information is available on the swelling and elongation of fibres with water and reagents, on the manner in which the strength and elasticity of fibres are affected, and how they stiffen, soften, etc. The information at present available on those points is, however, neither sufficiently authoritative nor complete. Again, similar investigations will require to be extended to yarns, etc. Then there is the whole question of the effect of tension on the measuring and winding of yarn. Also, there is no accurate method of standardisation of qualities or descriptions in the trade, and the possibility of establishing accurate standards is to be investigated. Experiments have been going on for some time into the matter of the electrification of fibres during certain processes, and the better control of this factor would be of great commercial importance.

It is on the basis of such information as is indicated above that manufacturing processes ultimately depend. Whenever a problem in manufacturing arises, it is nearly always found that the investigation leads back to questions of a fundamental character.

Appointments of staff have already been made to cover the sections relating to physical, chemical, and mechanical problems. On the physics side an analysis will be undertaken of the ultimate physical conditions which distinguish wool from other fibres. This will lead up to a definition of the properties of any substitute. Many experiments will be made in the special humidity-controlled room, and tests carried out during and after the various processes through which the fibre passes before becoming finished fabric.

A wide field is opened up on questions of the effect on strength, elasticity, etc., of numerous reagents, and in this connection very many notes have been made of the action of various reagents, which require further investigation. It is intended to examine the many proposals for the preparation of wool substitutes, and to compare the actual properties of the resulting products.

Attention will also have to be paid to the elimination of waste in the various processes and to the recovery of grease, soaps, etc. This might be done more by way of demonstration than by investigation, as many processes are known but are not in regular use. Comparisons will be made of the detergent power of soaps and other detergents, and also of the soaps of various fats as between themselves.

On the biological side it is emphasised that there is much scope for improving the quality of British wools, and several conferences have been held at which all interested bodies and classes, including the Boards of Agriculture, sheep-breeders' associations, flock-owners, university professors, and manufacturers, were represented. It was generally agreed that by the method of selective breeding and the establishment of new crosses, etc., an improvement in wool, without loss of mutton characters, is feasible. Experiments directed to this end are already in hand in several quarters, and it is hoped that with the co-operation of the Boards and breeders substantial advances will be made.

The management of shows and individual prize-givers can also do an enormous amount to further the objects in view. It is suggested that the services of a wool expert should be retained for the more important shows, and that, in all classes where such is possible, points should be given for the wool. This expert should direct attention to its merits and defects for manufacturing.

Much work might be done in the microscopic examination of fibres and in the actual carrying-out of small- and large-scale breeding experiments, with the object of improving the wool, particularly of British breeds.

The question of large-scale experiments is not being neglected, and a site has already been purchased upon which it is proposed to build an experimental factory for investigating under actual commercial conditions, on a manufacturing scale, the many problems connected with woollen carding and spinning. This factory will be equipped with the most up-to-date machinery and staffed with the most expert labour available, with the view of conducting experiments and investigating variations of present-day methods. A well-qualified man of science will be engaged in the factory to observe conditions and keep records, and any variations in method or investigations with a view to improvements will be under his supervision. Individuals will be allowed to use the machinery for private investigations at a fee to cover the working costs. Members have also been of great assistance in allowing experiments to be made in their factories. On these questions, and, in fact, on all other topics upon which it is considered expedient, publications will be prepared, and several have already been issued.

It is clear that the work of this association overlaps or dovetails with that of other bodies in many directions. Co-operation is a welcome necessity, and has been given or offered by several Government Departments, universities, technical schools, the Industrial Fatigue Research Board, the other research associations, etc., as has already been mentioned in one or two connections.

The Education Committee of the association has submitted, after some months of very careful and detailed deliberations, a series of revised syllabuses for textile courses in technical colleges, etc., and much outside support has been given to the recommendations it puts forward. These new syllabuses are the outcome of the joint discussion of existing syllabuses and standards by heads of textile departments in the universities and colleges and by the manufacturers themselves, and they have laid the foundations of a system whereby the actual needs of industry can be put plainly before those responsible for the training of the manufacturers of the future. The committee also hopes to aid the colleges in placing students in the industries both during and after their usual technical training.

It is intended not only to award prizes to inventors, research workers, and others for work of benefit to the industries or to the association, but also to establish scholarships and to subsidise research workers and educational institutions which devote themselves primarily to the objects which are before the association.

All questions relating to these matters should be addressed to the Secretary, Torridon, Headingley, Leeds.

Obituary.

Prof. Eric Doolittle.

PROF. ERIC DOOLITTLE, director of the Flower Observatory at the University of Pennsylvania, died on September 21 at the early age of fifty years. His father, C. L. Doolittle, was professor of mathematics and astronomy at Lehigh University, and the author of a well-known treatise on practical astronomy. In 1896 the father was appointed professor of astronomy at Pennsylvania University, and the son was placed in charge of the 18-in. refractor in the Flower Observatory, which was established that year in connection with the university. The latter remained there for the rest of his life, at first in the capacity of observer and instructor, and later as professor. The refractor had been specially designed for work on double stars, and the young astronomer adopted this line of study with great energy and enthusiasm. His published work embraces some 4600 pairs, and further observations are ready for issue. In 1913 Prof. S. W. Burnham, finding himself unable to continue the work of observing double stars and discussing their orbits, paid Prof. E. Doolittle the compliment of handing over his books and manuscripts to him. The latter proved himself worthy of the trust, continuing the classification and discussion of the observations of an immense number of pairs. This work is already available in card-catalogue form, and will be published later.

Another subject in which Prof. E. Doolittle took a great interest was the computation of the secular perturbations of the planets, in which he followed a method developed by Dr. G. W. Hill. His results were published by the American Philosophical Society in 1912.

In 1917 he was called on to organise and conduct a Navigational School at Philadelphia. The work, in addition to his university duties, proved beyond his strength, and brought about the breakdown which led to his early death, cutting short a career of great usefulness and promise. We are indebted for the details given above to an article in *Science* for October 22.

NATURALISTS interested in the marine and freshwater fisheries will regret to hear of the sudden death of SIR CHARLES E. FRYER at the age of seventy. Sir Charles Fryer was born in 1850, and entered the Civil Service, at the age of twenty, as Clerk to the Inspectors of Fisheries. In 1870 he became associated with Frank Buckland and Sir Spencer Walpole, and acted as secretary during the well-known inquiry into the natural history of the marine fisheries held during that and succeeding years. He had a unique knowledge of the history of the fishing industry and of the many inquiries that have been held with regard to its administration, and, though in no sense a man of science, he was keenly interested in all fishery biological questions—particularly with regard to the river fisheries. Sir Charles was due to retire at the beginning of the war, but continued to act at the Board of Agriculture and Fisheries during 1915 and 1916. Many fishery naturalists will regret his death.

THE death, on August 20, at Mussoorie, India, of MR. FRANK MILBURN HOWLETT, at the early age of forty-three, is greatly to be regretted. Mr. Howlett represented a type of entomologist comparatively rare in this country, being particularly interested in the physiological aspects of his subject. Educated at Wymondham Grammar School and at Christ's College, Cambridge, he went out to India in 1905, and in 1907 joined the staff of the Pusa Research Institute, where he afterwards became pathological entomologist to the Government of India. Although his published papers are relatively few, they exhibit marked originality of ideas. His studies of the chemotropic responses of various Diptera attracted very wide attention, and subsequent research has demonstrated that they were the forerunners of a line of investigation which has a promising future. Mr. Howlett was also a capable athlete and a clever artist, but his activities suffered severely from ill-health during his Indian service.

THE brief announcement of the death of DANIEL PAULINE OEHLERT made to the Paris Academy of Sciences on October 11 will arouse in many British geologists a host of delightful memories, for he guided an excursion of the Geologists' Association through the beautiful country of Mayenne, as well as an excursion of the International Geological Congress. Than Oehlert and his accomplished wife, who shared his labours, no better guides could be found, for they had surveyed the district for the Carte détaillée Géologique de France. Together also they published some sound palæontological papers, chiefly on Devonian fossils. Since the death of Mme. Oehlert some years ago, Oehlert had withdrawn from active geological work, and devoted himself to the museum of his native city, Laval. He was a fine man in body and in spirit.

THE death, on November 7, is reported, in his seventieth year, of DR. SAMUEL JAMES MELTZER, head of the department of physiology and pharmacology in the Rockefeller Institute of Medical Research. Dr. Meltzer is best known for his discovery, in 1912, of an improved method of artificial respiration by which he was able to resuscitate persons whose hearts had stopped beating. Three years later he announced a successful treatment for tetanus, which consisted in the injection of a prophylactic dose of serum into the wounded patient, combined with the injection of a solution of Epsom salts into the spinal membrane, which produced complete relaxation of the muscles long enough for the serum to take effect. Dr. Meltzer was a native of Russia, was educated at Königsberg and Berlin, and went to America in 1883. At the time of his death he was president of the American Association for Thoracic Surgery and of the Medical Brotherhood.

Science of November 5 announces that PROF. ARTHUR SEARLE, Phillips professor emeritus of astronomy at Harvard University, died at his home in Cambridge, Massachusetts, on October 23. Prof. Searle, who was born in England in 1837, and graduated from Harvard in 1856, became assistant in the Harvard College Observatory in 1869. He was appointed assistant professor of astronomy in 1883, and full professor in 1887, retiring in 1912 with the rank of professor emeritus. He contributed largely to scientific magazines, and in 1874 published a text-book of astronomy.

THE death is announced of DR. H. N. MORSE, professor of chemistry and director of the chemical laboratory at the Johns Hopkins University. Dr. Morse was born in 1848, and became associate at the Johns Hopkins University in 1876. He was the author of a number of scientific papers, among which may be mentioned communications on the atomic weights of cadmium and zinc, the preparation of osmotic membranes by electrolysis, and cells for the measurements of high osmotic pressures.

THE death of MR. CHARLES MCNEIL is recorded in *Engineering* for November 26. Mr. McNeil was born in Glasgow in 1847, and was the founder of the Kinning Park Hydraulic Forge, Glasgow. He was the inventor of the well-known manhole door which bears his name, and was elected a member of the Iron and Steel Institute in 1891.

Notes.

A pleasant surprise was experienced by those who attended the meeting of the Wireless Section of the Institution of Electrical Engineers on November 24 in meeting Dr. Alexander Graham Bell, the veteran inventor of the telephone, who had been on a visit to England and to his old home in Scotland, but is now on the way to his adopted home in the United States. Dr. Bell, who stated that his connection with telephone matters had ceased some thirty years ago, expressed his pleasure at meeting that section of the electrical world which represented the future perhaps more than any other, and referred to the remarkable developments that were being made in wireless telephony, in which the telephone had gone far beyond his most sanguine conceptions of its possibilities. The *Times* reports an interesting account given at a later interview by Dr. Bell of his researches which led up to the invention of the telephone forty-five years ago. Dr. Bell had long been interested in the mechanism of speech, and in reading of the researches of Helmholtz on the nature of vowel sounds, in a language with which he was unfamiliar, he had at first wrongly concluded that Helmholtz had transmitted such sounds by electrical means. Although he soon discovered his mistake, the idea that a transmission of this kind should be possible remained in his mind, and came to fruition later when he combined two separate lines of research which he had been prosecuting on multiple telegraphy by currents of different frequencies and on recording sound-waves for the benefit of the deaf, and thus arrived at the production and application of an undulating current representing the sound-waves of speech. The freedom of his native city of Edinburgh was conferred upon Dr. Bell on Tuesday, November 30.

Prof. W. H. Eccles, chairman of the Wireless Section of the Institution of Electrical Engineers, in his inaugural address at the meeting referred to above, gave a masterly review of the progress of research during and since the war on the thermionic-valve tube, which originated out of the Fleming oscillation valve, and had become, in its three-electrode or "triode" form, the basis of all modern wireless telegraphy. He reviewed some of the interesting papers which had already described the intensive development of the subject under the stimulus of war, but not the least interesting part of his address was his account of some of his own extensive researches in the investigation of the interdependence of the currents and voltages in the various circuits connected to the grid, anode, and filament of the tube, with a view to greater certainty in the design of such tubes to fill the conditions required with a maximum of efficiency. Owing to the number of variables involved, he had extended his treatment from the ordinary plotting of curves in two dimensions to the manufacture of a series of clay models of surfaces in three dimensions, which should be of very great value in elucidating the properties of these tubes. Other scientific questions raised by phenomena met with in wireless telegraphy which Prof. Eccles dealt with included the diurnal variations in the ionisation of the upper layers of the atmosphere, which he suggested might possibly account for certain remarkable discrepancies in the results of wireless direction-finding apparatus at particular times in the day by causing a rotation of the plane of polarisation of the received waves.

At the opening meeting of the Röntgen Society, held on November 18 at University College, it was announced that the first award of the Mackenzie Davidson medal had been made to Dr. F. W. Aston. The award, which was instituted to perpetuate the memory of the late Sir J. Mackenzie Davidson, is made by the council of the society for the most noteworthy contribution to its meetings during the session on some subject bearing upon radiology. Dr. Aston's paper was read on June 1, and appears in the current issue of the Journal of the society under the title "Positive Rays." It deals with the remarkable series of isotopes among non-radio-active substances, which Dr. Aston has been investigating for several years.

The twenty-sixth annual congress of the Royal Institute of Public Health, which will be of an international character, will be held next year in Geneva, on the invitation of the University, from Tuesday, May 10, to Monday, May 16, inclusive. Further particulars can be obtained from the Secretary, 37 Russell Square, W.C.1.

The British Silk Research Association has been approved by the Department of Scientific and Industrial Research as complying with the conditions laid down in the Government scheme for the encouragement of industrial research. The secretary of this association is Mr. A. B. Ball, Silk Association of Great Britain and Ireland, Inc., Kingsway House, Kingsway, W.C.2.

The Government of the Czecho-Slovak Republic has established, under the Ministry of Education, a Weather Bureau in Prague, to do for that country the work formerly done at the meteorological central stations of Vienna and Budapest. The new bureau will extend the meteorological service formerly conducted in connection with the K. k. Sternwarte, Prag-Klementinum (Astronomical Observatory). The director, Dr. Rudolf Schneider, is anxious to receive for the library of the bureau all the reports of observations and meteorological publications formerly sent to the Sternwarte, and he will be glad to send to other meteorological stations and offices publications of his bureau in exchange.

For some time past the National Union of Scientific Workers, the Institute of Chemistry, and the British Association of Chemists have had under consideration the matter of income-tax assessment of scientific workers. After several discussions it was agreed unanimously to prepare a memorial to the Lords of the Treasury setting out under six distinct headings a claim for abatements. The memorial was forwarded to scientific societies and to research and technical staffs of various institutions and science faculties of the universities of the United Kingdom, many of which associated themselves with the memorial. It was then sent to the proper authorities. The secretary of the joint committee has now been informed that the Chancellor of the Exchequer has arranged for the Commissioners of Inland Revenue to meet a deputation of scientific workers on Friday, December 10, to afford them the opportunity of supporting their claims.

THAT excellent institution the Children's Museum of Brooklyn has sent us an issue of its *News*, which is devoted to an account of the museum's efforts to Americanise the children drawn to New York from all the countries of Europe. The museum, it is claimed, can supply that which the teacher cannot provide, namely, an American background for the intellectual life of the child. This is effected by helping the pupils to visualise incidents in the lives of past Americans through the numerous models and objects of historic interest in the museum. By contact with these concrete exhibits the abstract knowledge provided in school becomes more real to them, and a personal link with the country's past is forged in the mind of each child. The influence of the museum is even wider than mere Americanisation, for "the person whose intellect is overtrained to the neglect of the senses is perhaps a greater menace to the community than the illiterate."

THE fourth annual Report of the National Research Council of the United States of America consists of 68 pages, and shows that a large proportion of the programme of the Council is now in operation. The funds are provided mainly by the Carnegie Corporation of New York, the Rockefeller Foundation, the General Education Board, and the Commonwealth Fund. Its purpose is to promote research in the mathematical, physical, and biological sciences with the object of increasing knowledge and contributing to the public welfare. One of its thirteen divisions deals with foreign relations, and represents the Council at the meetings of the International Research Council. Another deals with the physical sciences, and already has research committees on atomic structure, celestial mechanics, X-ray spectra, electrodynamics, photo-electricity, etc. The engineering division has committees on fatigue in metals, heat treatment of steel, pyrometers, highways, etc. The chemistry division has committees on synthetic drugs, colloids, ceramics, etc. The Council is to be congratulated on the speed with which it has got to work.

WE have received a copy of the appeal issued by the University of Birmingham for 500,000*l*. The present financial position, as set forth in the circular, is indeed critical. The increase in cost of administration and maintenance, coinciding with an increased demand on the capacity of the University—each additional student costs about three times as much as he contributes—has made bankruptcy the only alternative to a large addition to its resources. Among the objects of the appeal the first place is rightly given to the improvement of the salaries of the teaching staff, especially of the non-professorial section. Provision has also to be made for the enlargement of existing departments to cope with the demands made upon them. It is further pointed out that additional chairs are required in many subjects (*e.g.* mathematics, physics, chemistry, engineering, and biology) and that increased facilities for research are urgently needed. There is, moreover, an insistent and growing demand on the part of industrial workers for extra-mural work, and classes have been created for trade unionists, in which special instruction is given in English literature, economics, and modern history, in co-operation with the Workers' Educational Association. The provision of hostels for men students is also very desirable. Finally, it is urged that grants or gifts to the University will in all probability secure an equivalent from the Government. A first list of contributions shows promises amounting to more than 250,000*l*., of which nearly one-half is given by representatives of the petroleum mining industry for a petroleum mining endowment fund. We sincerely hope that further lists may show that the Birmingham and Midland district is alive to its responsibilities in the matter and that the desired sum may be raised.

IN the Museum Journal of the University of Pennsylvania (vol. xi., No. 1, March, 1920) a valuable article, with excellent illustrations, is published describing a collection of "fetish" figures from equatorial Africa. The word "fetish" is now suspect among anthropologists, as its meaning has been unreasonably extended. At the same time, the great majority of these wood carvings have undoubtedly some connection with the religious magic of the negro, and among the special group of the Bakuba-Baluba peoples in the South-Western Congo region the best and least contaminated negro art is found among a race which possesses a more highly developed system of cults, religions, or magico-religions than any other Congo people possessing such a high degree of culture.

THE *Archives of Radiology and Electrotherapy* for October (No. 243) contains the continuation of a sketch of the history of electrotherapy by Mr. H. A. Colwell. The period dealt with is from 1800 to 1879, and the apparatus of various inventors is described and figured, such as Golding-Bird's contact-breaker (1838), Neef and Wagner's and Benedict's induction coils, Piscii's magneto-electric shocking machine (1832), and various portable batteries. Contact-breakers worked by an assistant were in use as late as 1849. The account, which is a very interesting one, is to be continued.

Medical Science: Abstracts and Reviews for November (vol. iii., No. 2) contains a critical review of the cancer problem, particularly of work done during the last twenty years. In England and Wales one woman in eight and one man in eleven above the age of thirty-five years dies of cancer. Acquired immunity to transplanted cancer in the mouse and rat can be produced by means of *living* cancer-cells. Altmann's granules are absent from the cells of malignant growths. The blood and tissues of cancerous persons contain more potassium than normal, and human cancerous material contains more radium than normal. Considerable space is devoted to the various methods of treatment of cancer, which it is concluded must proceed along the lines of a judicious combination of surgery and irradiation.

IN the Museum Journal of the University of Pennsylvania (vol. x., No. 4, December, 1919) we have an account of head-hunting among the Jivaro tribe, occupying a large territory on the eastern slope of the Andes in the Republic of Ecuador. They have been called cannibals, but they never eat any part of the human body. The mummified heads of their enemies are the most esteemed war trophy, because the head must be present at the victory feast which the hero is expected to give. The head must be preserved, because it requires many months to clear a field and grow yucca and bananas to provide food for the numbers attending the feast. The head is fixed on a staff and paraded, with a tribute to the valour of the slayer, before the assembled tribesmen. After this an orgy of eating and drinking continues for days until all the supplies are exhausted.

THE way in which one part of an organism regulates the activity of another is a problem of supreme interest in biology. In unicellular organisms the transmission is local, but in multicellular organisms conduction may be by the circulating fluid or by nerves. Conduction by nerves is the main theme discussed by Prof. R. S. Lillie in an address on "The Nature of Protoplasmic and Nervous Transmission" (*Journ. Physical Chemistry*, vol. xxiv., 1920, p. 165). The propagated disturbance in nerves cannot be a chemical transport because of its rapidity. A nerve-impulse is always accompanied by an electrical change of potential of sufficient voltage to stimulate another nerve. The hypothesis is advanced that the current of action stimulates a contiguous portion of nerve, thus accounting for the transmission of the impulse. The negative electrical potential at an active part of the nerve is short-circuited through the surrounding electrolyte solution, so that the current passes in at the active portion of the nerve and out at an inactive part. The inactive portion of nerve is thus stimulated as if by the cathode of an external stimulating circuit. The time required for the potential to reach its maximum is 0·001 of a second, and, assuming that the current is effective over a length of 3 cm., the rate of conduction would be 30 metres per second; this is the value obtained for a frog's nerve at temperatures of about 15° C. The propagation of the nerve-impulse is compared to "passive" iron and its activation, the two processes having much in common.

THE newly established French Office Scientifique et Technique des Pêches maritimes is issuing a series of Notes et Mémoires, and No. 2, "Le Merlu," by Dr. Ed. le Danois, has just been published. It is a summary of our knowledge of the life-history of the hake. Of late years this has become one of the most important of marine food-fishes because of its wide distribution. Compared with our knowledge of other fishes, very little is known as yet of the general biology of the hake, and it has been proposed (by the International Council for the Exploration of the Sea) to institute investigations (to be carried out by France, England, and Ireland) on this and other fishes inhabiting the south-western European area. The paper under notice is therefore opportune. It is almost entirely a *résumé* of the research which has been carried out on the hake by the various fishery authorities, and it is accompanied by a series of sketch-charts representing the seasonal distribution of the fish, the localities of fishing, the spawning places and periods, and the migrations. A summary of the European commercial hake fisheries is also given. The author discusses the causes of migration, and suggests a factor which seems to be new (though this is difficult to say, for no references to published work are given). Food is not a factor, for that taken by the hake is variable, and during its spawning periods (when its migrations are most noticeable) it does not eat at all. Its migrations cannot be correlated with any seasonal changes in the plankton. On the other hand, changes of temperature throughout the year either enlarge or restrict its range of distribution, and variations of salinity are also factors. The body of the young hake is relatively dense, but as the genital organs mature the density diminishes. This leads to a greater energy requirement in relation to the locomotion of the fish, and it seeks water of lower salinity or higher temperature, or both. Thus, by reason of "the principle of least effort," the hake migrates into shallower, warmer, and less saline waters as its breeding season approaches.

A CHADWICK public lecture was delivered by Prof. J. B. Farmer in the lecture hall of the Medical Society of London on November 5, the subject being "Some Biological Aspects of Disease." The lecturer pointed out that it was now a recognised fact that co-ordinated growth in an organism leading to the development of a particular form depended on the serial or sequential nature of the reactions which went on in its cells and tissues. Recognition of this was essential to a proper appreciation of the larger problems of health and disease. By the consideration of examples, taken chiefly from the plant-world, it was shown how differences in chemical or physical environments produced definite changes in the organism, though close analysis of the facts emphasised the essential point that it is only when environment was able to interfere, as it were, with the protoplasm itself that response of this kind was obtained. The effects of the temporary isolation of parts of the body from the material influences exerted by adjacent parts might result in a permanent loosening of the ties which previously had knit the constituent cells into a coherent organism, while the union of parts hitherto separate sometimes led to the formation of a synthetic new organism; lichens are striking examples of this. The consequences of the mutual relations established between parasite and host were dealt with, particularly with reference to the abnormal growths which can be traced to substances injected by parasitic animals. Prof. Farmer then passed on to discuss briefly the abnormal growths or neoplasms which originate as the result of obscure changes taking place within the cells themselves. The essential features of malignant growths were described and the outline of a plan of research for the advancement of our knowledge of the causes of cancer was suggested.

THE proceedings of the sixth annual Indian Science Congress, which was held in Bombay on January 13–18, 1919, have been published in the Journal and Proceedings of the Asiatic Society of Bengal, vol. xv., No. 4. The volume contains full reports of the presidential address delivered by Sir Leonard Rogers, an abridged version of which appeared in NATURE of May 29, 1919, and of the presidential addresses delivered to the various sections. The latter are followed by brief abstracts of the other papers read at the meeting.

A GAZETTEER of streams of Texas has been compiled by the United States Geological Survey and published as Water Supply Paper No. 448. Source, length, and topographical details are given in all cases, while in that of the more important streams other information, such as season of greatest flow, gradient, and precipitation in the basin, is added. The work is based on the best maps available, supplemented by personal reconnaissance. References are given to sheets of the topographic survey. The addition of a map to the volume would have rendered it more useful for reference.

WE learn from the *Geographical Journal* for November that Col. P. H. Fawcett is planning to return to his work of exploration in Western Brazil east of the Bolivian frontier. The expedition, which has the active support of the Brazilian Government, will include, besides Col. Fawcett, two Brazilian officers and Major Lewis Brown, of the Australian infantry. The investigation of the Indian tribes is one of the chief objects of the expedition. Cartographical work will be governed by astronomical observations and based for its longitudes upon the courses of the main rivers as determined by the work of the Rondon Commission.

THE potentiality of Australia for white settlers is discussed by Dr. Griffith Taylor in an article entitled "Nature *versus* the Australian" in *Science and Industry* for August. After a discussion of the amount and variability of rainfall in Australia, Dr. Taylor divides the country into seven regions based on rainfall, in terms of which agricultural and pastoral production can be classified. Farming and close white settlement generally are, and, he contends, will be, confined to three of these regions, which embrace the Riverina, Victoria, Tasmania, eastern Queensland, the north-east of New South Wales, and "Swanland" in Western Australia. The distribution of minerals, especially coal, will in time result in dense population irrespective of agricultural potentiality, but in Australia the coalfields occur in the regions favoured by climate, and so tend to more centralisation of population. Dr. Taylor is not hopeful of white settlement in tropical Australia, and gives adequate climatic reasons for his opinions. The paper concludes with a tentative map showing the habitability of the globe. In the southern hemisphere south-eastern Australia and New Zealand alone are indicated as areas with a potentiality in white settlement of more than 125 per square mile.

THE Department of Agriculture of the Union of South Africa has recently issued a report (Bulletin No. 4, 1920) on investigations in the wool industries of Great Britain and the United States of America with a view to the betterment of the industry in South Africa. An interesting survey is made of the kinds and qualities of wool and its substitutes, and a useful comparative statement gives the countries to which South African wool was exported from 1913 to 1919. Next to Great Britain, Germany was the largest purchaser of South African wool previous to the war, and since then her place has been taken by America and Japan. Very informative tables are appended showing the world's wool production and the estimated world's wool stocks in the 1919–20 season. While the usual annual supply of the world is estimated at 2,700,000,000 lb., there was available in 1919–20 for consumption by manufacturing countries as much as 4,200,000,000 lb. The defects of South African wool are gone into in detail, and useful suggestions are made with a view to their elimination. Great care appears to have been taken in estimating the capital expenditure required to build and equip factories for specialisation in the various branches of manufacture of woollens and worsteds, the expected output from certain machines is properly tabulated, and the cost of labour is shown for England, France, the United States, Germany, and Austria, while the cost of running and maintenance of plant is dealt with systematically.

UNTIL recently the process of the melting and casting of metal in a brass mill was very similar to that practised 240 years ago. As a rule, small crucibles having a maximum holding capacity of about 300 lb. were used. The advent of the electric furnace, however, is now rapidly revolutionising the industry. In one type the heat of the electric arc is used, and in the other—the induction type—the metal is melted by the electric currents induced in it. An interesting account of the latter kind of furnace is given by Mr. G. H. Clamer in the Journal of the Franklin Institute for October. Official tests show that about 10 lb. of two-to-one yellow brass are brought to the casting temperature (2000° F.) per electric unit expended in the Ajax-Wyatt furnace. The metal is melted directly by the Joule effect, the electromagnetic forces keeping it circulating. A very interesting induction furnace has been invented by Dr. Northrup. Instead of using alternating current of the ordinary commercial frequencies, he uses currents having frequencies of 10,000, similar to those sometimes used in long-distance radio-telegraphy. In this case no resistance column of molten metal is necessary. The metal contained in a plain cylindrical crucible is brought to any required temperature by the induced eddy currents. These furnaces are suitable for very high temperature melting, such as is required, for instance, by alloy steels and precious metals.

Under the comprehensive title of "Sterilisation of Water by Chlorine Gas" a paper by Capt. J. Stanley Arthur was read before the Institution of Mechanical Engineers on November 19. The part of the paper dealing with the general aspect of the subject adds little or nothing to our knowledge, and contains statements which, to say the least, are still debatable. For example, the author states that water treated with chlorine gas is less liable to an objectionable taste than when treated with bleaching-powder, and, further, that any taste so imparted can readily be removed by the addition of sulphur dioxide. Other experimenters have found that there is little or no difference between bleaching-powder and chlorine gas as regards taste, and also that some tastes produced by chlorination are absolutely unaffected by the further addition of sulphur dioxide. Also, no mention is made of the pioneer work on chlorination of Houston and McGowan at Lincoln in 1905 or of any of Houston's later work on the subject. The greater part of the paper consists of the detailed description of an American device for accurately administering the dose of chlorine and its adaptation for the purpose of sterilising the water-supply to the troops during the war. These descriptions are very clearly stated and well illustrated with careful drawings. No other types of chlorinators are described, although there are others equally efficient now on the market. The paper concludes with a warm tribute to Sir William Horrocks for his work on water purification for the Army, and is further evidence of the great part played by the sanitary section of the R.A.M.C. in winning the war; it is probable, however, that Sir William and his colleagues would be the first to acknowledge their indebtedness to others not mentioned in Capt. Arthur's paper.

The latest catalogue (No. 407) of second-hand books offered for sale by Mr. F. Edwards, 83 High Street, Marylebone, W.1, is devoted to botany, ranging over the subjects of agriculture, gardens, orchids, trees, fruits, fungi, lilies, and roses. It should be of interest to many readers of Nature. Many choice and rare works are listed, among them several herbals, a complete set of the *Annals of Botany*, *Curtis' Botanical Magazine*, 1787–1915, and Sir J. D. Hooker's "Botany of the Antarctic," 6 vols.

We are informed that the office of the Assistant Commissioner of Forestry for England and Wales (Mr. Hugh Murray) is now situated at 30 Belgrave Square, London, S.W.1. The headquarters of the Commission remains at 22 Grosvenor Gardens, London, S.W.1.

Our Astronomical Column.

The Leonid Meteoric Shower.—Mr. Denning writes that on November 15 and 16 the Leonids returned in moderate numbers. Mr. C. P. Adamson, observing at Wimborne, Dorset, watched the sky during a period of ten hours, and saw thirty-three Leonids out of a total of ninety-eight meteors recorded. The radiant point was placed at $150°+22°$, and the display furnished objects of the usual swift and streak-leaving character.

Miss A. Grace Cook, at Stowmarket, also witnessed the return of the meteors on the same nights and determined the radiant in precisely the same position as Mr. Adamson. Mr. A. King made observations from Lincolnshire, and on November 15, during a watch of three hours between 11h. 18m. and 14h. 37m., saw thirty meteors, of which nine were Leonids directed from a radiant at $152°+23°$. Other showers were seen from $63°+22°$ (five meteors), $107°+35°$ (seven meteors), and $116°+49°$ (five meteors) at the middle of November.

The reappearance of the Leonids adds another link to the chain of past observations, which prove that this stream of meteors is visibly continuous throughout the entire orbit, and that it may be viewed every mid-November when the prevailing atmospheric conditions are favourable.

Radiation Pressure on Electrons and Atoms.—Mr. Leigh Page discusses this subject in *Astrophys. Journ.* for September. It was formerly concluded that radiation pressure reached a maximum for particles of diameters comparable with a wave-length, and fell off rapidly for smaller particles. The present paper shows that this result neglects resonance, and that the radiation pressure on an atom "depends on the intensity of that portion of the incident radiation which has a frequency equal to the natural frequency of the oscillator." It is deduced that the pressure of solar radiation is greatest on an atom which has a resonant frequency in the infra-red near to wave-length 9000 Å., being within one-third of this maximum value for the range 4000 Å. to 28,000 Å. The pressure may be further increased if the atom has more than one resonant frequency.

It is shown that in certain circumstances the repulsive force may be thirty times that due to gravitation. It thus seems sufficient to explain most of the phenomena of comets' tails, and removes the difficulty formerly felt, namely, that the spectroscope shows the presence of certain gases in the tail, for the molecules of which the pressure was thought to be negligible. The author states that since writing the paper he has found that some of his conclusions were published by M. Gouy in 1913 (*Comptes rendus*, vol. clvii., p. 186).

Perturbations in a Stellar Orbit.—There are not many cases where perturbations in stellar orbits can be observed with any degree of accuracy. Mr. J. S. Paraskevopoulos examines the case of 13 Ceti in *Astrophys. Journ.* for September. This is a visual binary with a period of 6·88 years, while the brighter star is a spectroscopic binary with a period of 2·0818 days. The eccentricity of the orbit of the visual pair is 0·725. The author has remeasured a number of spectrograms taken at the Yerkes Observatory between 1906 and 1913, deducing separate orbits at three different epochs. These show that the period is shorter by 1/200 day at apastron of the visual companion than at periastron, this being analogous to the period of the moon at aphelion and perihelion. Motion of the line of apsides is well established. It is concluded that the mass of the visual companion does not fall far short of, and may exceed, that of the spectroscopic pair. Taking the parallax as 0·050″ (J. A. Miller), m/M becomes 1·32.

The system 85 Pegasi is referred to, in which Prof. G. Van Biesbroeck deduced that the mass of the brighter component was only 0·36 of that of the whole system.

Anniversary Meeting of the Royal Society.

AT the anniversary meeting of the Royal Society, held on Tuesday, November 30, the report of the council was presented, and the president, Sir Joseph Thomson, delivered his valedictory address. Sir Joseph succeeded Sir William Crookes in the presidential chair in 1915, and has therefore served through as difficult a period as any in the history of the society. What the society and the nation owe to his activity and genius can be understood only by those who have been associated with him on some of the many committees or other bodies constituted during these troublous years to maintain national life and security. All the resources of British science have been organised and rendered available for public service with these ends in view; and a record of the aid thus afforded to the country by the society during Sir Joseph Thomson's presidency would afford convincing evidence of the value of science to the nation and of the patriotic spirit of scientific workers. Sir Joseph is succeeded as president by Prof. C. S. Sherrington, Waynflete professor of physiology in the University of Oxford, a short account of whose notable work on the central nervous system appears elsewhere in this issue.

State Aid to Science.

Several important matters are referred to in the report of the council of the society. In March of last year a memorandum on State aid to science through grants to universities and to the Royal Society was submitted to the Lords Commissioners of H.M. Treasury. The memorandum contained the following statement of the relation of purely scientific work to human progress:

"The promotion of research in pure science without regard to its industrial applications is important:

"(1) Because science is not merely the handmaid of arts, but depends on study which elevates a nation, and wherein the natural curiosity of the mind finds exercise and satisfaction.

"(2) Because the history of science shows that many of the discoveries which have revolutionised old industries, and established new ones, have been made by those whose aim was simply to extend our knowledge without any reference to practical applications.

"The encouragement by the nation of research of this kind must, in our opinion, follow different lines from those which may be adopted with advantage for promoting research in applied science. Any direct endowment of research, to safeguard it from abuse, involves something in the nature of a report at regular intervals which should be submitted to experts for their approval. Research in pure science is inevitably intermittent, and may be gravely injured if required to show results at any particular date. Its ideas are often novel, and so far opposed to existing views that they may not obtain the approval of men with long-established reputations, such as those to whom the reports would naturally be submitted.

"A large part of this pioneer work in science has in the past been done in the universities, and this is likely to be true to a still greater extent in the future. We consider, therefore, that the best way of promoting research in pure science would be to put the universities in such a position that they can provide for their teachers adequate salaries, appliances, and time for research. This will involve increased grants to the universities. These will be necessary even if the universities are merely to maintain their output of research at the present level, owing to the greatly increased expense of the upkeep of a laboratory due to the higher wages and cost of material. But in our opinion research in our universities ought to be greatly extended and not merely prevented from decreasing. A substantial increase in the grants to universities and university colleges is therefore required.

"For these reasons we are agreed that for the advancement of science the first need is to make adequate provision for the promotion of science at the universities."

The purpose to which the Government grant to the Royal Society is applied includes: (1) Grants for providing apparatus and materials for researches approved by the Government Grant Committee. (2) Grants in aid of scientific expeditions, such as those for observing eclipses or for the exploration of the polar regions. Grants have also been made separately by the Treasury to international undertakings, such as those to the International Geodetic Association (300*l.*), the Seismological Association (160*l.*), and the Metric Convention (200*l.*–300*l.*), which in future will be organised by an International Research Council formed under the authority of the principal academies of the countries concerned.

In response to the council's memorandum the Lords Commissioners increased the annual grant for research from 4000*l.* to 6000*l.*, and, although they were not prepared to make a separate annual grant for scientific expeditions and stations, a non-recurrent grant of 5000*l.* was included in the Parliamentary estimate for the year. With regard to international research, they proposed the provision of an annual grant of 2000*l.*, provided the society would "assume responsibility for the payment of subscriptions for all classes of international research." After correspondence this responsibility was somewhat qualified, and the provision proposed accepted.

Rudolf Messel Bequest.

By the terms of the will of the late Dr. Rudolf Messel the Royal Society becomes entitled to four-fifths of the residuary estate. It is estimated that the value of the bequest will be, in the first instance, not less than 70,000*l.*, ultimately increasing to about 90,000*l.* The clause of the will governing the disposal of the residuary estate is as follows:—"I give four of such parts to the Royal Society, Burlington House, and the remaining part to the Society of Chemical Industry, Broadway Chambers, Westminster, and, without imposing any trust or obligation, I think fit to set forth my desires with regard to the fund given to each of these societies as follows: (i) The fund should be kept separate from the other funds of the society and be known under my name or otherwise as the society may think fit. (ii) The capital of the fund should be kept intact. (iii) The society should apply the whole of the income of the fund in such manner as it may think most conducive to the furtherance of scientific research and such other scientific objects as the council of the society may determine, and should not apply any part of the income for such charitable objects as the granting of pensions and the like. . . ."

It must not be supposed, however, that the society is relieved of financial anxiety by this generous bequest or by the State grants referred to above. The bequest has to be kept separate from the general funds, and the society acts solely as administrator of the Government grants. On account of increased expenses, a heavy deficit on the year's working had to be faced; and the council points out that even if the whole income from the Messel bequest were used to defray the cost of publications, there would still be a deficit. The annual subscription of fellows has been raised and steps have been taken to reduce expenditure wherever possible, yet the situation is still serious, and further financial provision must be secured if the society is to maintain its activities.

Presidential Address.

In his presidential address Sir Joseph Thomson referred to distinguished achievements of fellows of the society lost by death during the year, and to the admission of the Prince of Wales as fellow on January 22 last. He directed attention to the large increase in the cost of publishing the Proceedings and Transactions, and suggested that something might be done to make the papers published by a society as accessible to the scientific public as those published in other ways. "I think," he added, "some improvement in our sales might possibly be effected and science benefited if there were some organisation, private or otherwise, for the sale of separate papers. The formation of a library, to include all papers on one of the great branches of science, such as physics, requires a longer purse and more bookshelves than most are able to afford. But there are many, I think, who would like, and could afford, to form a fairly complete collection of the literature of one or more of the subdivisions of the subject in which they are especially interested—say, for example, electrical waves or low-temperature research. As lists of the papers in these subdivisions are published at regular intervals by various agencies, it ought not to be difficult to arrange for the distribution of the separate papers if these could be obtained from the societies."

The Medallists.

The Copley medal is awarded to DR. HORACE T. BROWN in recognition of his work on the chemistry of carbohydrates, on the assimilation of atmospheric carbon dioxide by leaves, and on gaseous diffusion through small apertures. As was the case with Pasteur, so with Horace Brown, problems and difficulties arising out of a branch of the fermentation industry supplied the incentive to investigations which are of fundamental importance in chemistry and botany. His work began in 1871 with the investigation of one of the diseases of beer, and includes an exhaustive study of the chemistry of starch, the germination of the barley grain, and the changes occurring in the green leaf during photosynthesis.

The Rumford medal is awarded to LORD RAYLEIGH, who is distinguished for his researches into the properties of gases at high vacua, and whose work has opened the way to many valuable investigations. Some years ago Lord Rayleigh made a number of interesting observations on the afterglow in various gases noticeable after the cessation of an electric discharge, and these led in 1911 to his Bakerian lecture on "The Afterglow of Nitrogen." The investigation thus started has proved the subject of much of his recent work, and in a series of most valuable papers he has studied the properties of the gas in which this afterglow is visible.

A Royal medal is awarded to PROF. GODFREY HAROLD HARDY, who is well known both in this country and on the Continent for his researches in pure mathematics, particularly in the analytic theory of numbers and allied subjects. Immediately after taking his degree at Cambridge Prof. Hardy engaged in a series of researches on the theory of functions of a real variable, from which results of the greatest importance and generality were obtained, at first by himself alone and later in collaboration with Mr. J. E. Littlewood. Among the more important researches of which Prof. Hardy is sole author may be mentioned papers on Dirichlet's divisor problem, on the representation of numbers as the sum of n squares, on the roots of the Riemann ζ-function, and on non-differentiable functions.

A Royal medal is awarded to DR. WILLIAM BATESON, who is universally recognised as a leading authority on genetics, and has done more than anyone else to put that branch of inquiry on a scientific basis. The work that stands to his name is, however, but a fraction of that which he has inspired wherever biological research is prosecuted. In conjunction with Prof. Punnett he worked out in detail one of the earliest cases of sex-linked inheritance. Peculiar association of genetic factors in gametogenesis had previously been discovered by the same authors and described under the terms "coupling" and "repulsion." In 1911 they published two papers which proved that these phenomena are part of a more general phenomenon of linkage, the orderly nature of which was pointed out. Since these papers appeared the phenomenon has been shown by various workers to be widespread in both animals and plants. Three papers by Bateson and C. Pellew record a discovery of high interest and importance, viz. that the germ-cells of the same plant may vary in their genetic properties. It is further pointed out that the variation proceeds in an orderly way from the base of the plant to the apex. The conception is a novel one, and is bound to have great influence on the development of genetical theory.

The Davy medal is awarded to MR. CHARLES THOMAS HEYCOCK, who, in collaboration with the late Mr. F. H. Neville, published a remarkable series of papers, all characterised alike by great experimental skill and originality, as well as by precise, yet simple, mathematical treatment. The molecular complexity of metals when dissolved in other metals, the composition and constitution of binary and ternary alloys, and the part which the eutectics play during the cooling of a complex alloy were clearly revealed, not only by freezing-point methods, but also by a most ingenious method of chilling, as well as by etching by means of many new reagents. These researches have not only added very greatly to our theoretical knowledge and conceptions, but have also been of the greatest importance to industrial metallurgy in many directions.

The Darwin medal is awarded to PROF. ROLAND HARRY BIFFEN, who has worked out the inheritance of practically all the obvious characters of wheat and barley. Perhaps his best-known work is that on the inheritance of strength in wheat and on the inheritance of susceptibility and resistance to yellow rust in wheat. Biffen's activity is not by any means to be measured by his published work. Two of his new wheats—Little Joss, which owes its value to its immunity from rust, and Yeoman, which combines high yield with first-class baking quality—are among the most popular wheats in the country, and together account for something like a third, or even a half, of the wheat crop of England.

The Hughes medal is awarded to PROF. OWEN WILLIAMS RICHARDSON for his researches on the passage of electricity through gases, and especially for those relating to the emission of electrons from hot bodies, a subject which Prof. Richardson has made his own and christened "thermionics." The subject is of great industrial as well as of scientific importance.

The anniversary dinner of the society was held on Tuesday at the Royal Palace Hotel, Kensington.

The Mackie Ethnological Expedition to Central Africa.

THE REV. J. ROSCOE, the leader of the Mackie Ethnological Expedition to Central Africa, has recently returned to this country after an absence of more than eighteen months. The expedition, which was made possible by a generous donation from Sir Peter Mackie, placed at the disposal of the Royal Society, had for its object the investigation of the laws, customs, and beliefs of the native tribes under British rule in Central Africa, particularly in the Uganda Protectorate, in accordance with a scheme which had been planned and urgently advocated for many years by Sir James Frazer, but for which funds had hitherto been wanting. The tribes which the expedition proposed to investigate had been very little modified by contact with civilisation, and it was felt that a detailed examination of their institutions and beliefs would not only add very materially to our scientific knowledge, but would also conduce to the good government and economic development of the country in the future.

The expedition left this country in the spring of 1919. The first part of its labours was devoted to the study of the Bahima of Ankole, an important pastoral tribe, in the western part of the Uganda Protectorate. During a stay of three months Mr. Roscoe gathered an immense amount of detailed information relating to the clan and totem organisation and tabus, the system of government, and the beliefs and rituals connected with the care of cattle and the milk, which play an important part in regulating the life of the community.

From Ankole the expedition moved to Kigezi, where a short stay was made for the purpose of studying the Bakyiga, a large and fierce mountain tribe of many clans, partly pastoral, partly agricultural. The tribe is believed to be the original stock, which the Bahima were never able to conquer. This is borne out by the fact that they are of the same type as the slaves in Ankole and the lower order of people in Bunyoro.

On leaving Kigezi the expedition set out for Bunyoro, proceeding westward to the arm connecting the two lakes Edward and George, and then northward along the line of these lakes and Lake Albert—a country very little known, which was found to be of extraordinary beauty.

In the course of a short rest of a week a superficial examination of the Bamba and Bakonja of Mount Luenzori was made. The expedition then proceeded from Port Ntoroko by steamer to Butiaba, the port for Masindi, the capital of Bunyoro, where it entered upon the second and, as it proved, the most fruitful part of its labours.

The King of Bunyoro gave every assistance to the expedition. He is now a Christian, but as the repository of the tradition and practice of the religion of the people his knowledge, which was placed freely at Mr. Roscoe's disposal, proved of inestimable value.

The Bunyoro tribe, or rather nation, consists of two distinct races, the Bahuma and the Bairu—the latter a subject people of agricultural peasants belonging to Bantu stock and descended from the original inhabitants of the country; the former a purely pastoral people akin to the Gallas, who form a ruling aristocracy, descended from a people which invaded and conquered the country from the north. Intermarriage between the two races is rare, though not absolutely forbidden. The greater part of the life of the king is, or rather used to be, devoted to ceremonial observances connected with his cattle in order to increase the progeny of man and beast and the supply of food. So much was this the case that the whole of his day was mapped out for him, and he rarely, if ever, quitted his kraal. One peculiar feature of the ritual was a daily meal at which he partook of sacred beef. The royal cook knelt before the king and placed four pieces of meat in the king's mouth with a special fork, taking care not to let the fork touch the royal teeth under penalty of death.

From Masindi the expedition proceeded to Mount Elgon, where it made some further inquiries among the cannibal Bagesu, whom Mr. Roscoe had already visited and described. It had been intended originally to pass northward into Karamojo in order to investigate the Turkana, an interesting people, remarkable for their great stature, of whom very little in detail is known. Unfortunately, military operations which were being carried on in that region made that impossible. The expedition therefore turned to Busoga, and after a short stay there returned to Bunyoro, whence it started on its homeward journey down the Nile.

E. N. F.

The Indian School of Mining and Geology.

THE recent decision of the Government of India to establish a School of Mining and Geology at Dhanbaid follows the recommendations of Sir Duncan McPherson's Committee of 1913–14 on mining education, of the expert Committee which examined the system of mining education in England in 1914–15, and of the Indian Industrial Commission of 1916–18. The site of the proposed school has caused some difference of opinion in the past. Thus the Calcutta University Commission enumerated the many advantages which Calcutta was believed to possess, but in finally deciding on Dhanbaid the Government of India has followed the recommendations of the three Committees, and come to a conclusion with which those who know local conditions best will cordially agree. Dhanbaid enjoys an excellent situation, and return visits to the coal-mines will occupy only a few hours; from Calcutta they would take at least thirty-six hours.

The provision at present made for mining education in India comprises (1) courses at the Sibpur Engineering College, near Calcutta, and (2) evening classes on the coalfield. The existing provision for higher training in geology is even less satisfactory. The proposal is that the new school will be an institution of collegiate type, in which the highest form of teaching in the art of mining and its accessory sciences is to be undertaken, so that in time it will rank with similar institutions in this country, and give equal opportunities for the study of geology and mining in all their branches. Thus natives of India will eventually be able to obtain in their own country that specialised training which to-day is an essential qualification for the more responsible posts in the mining and geological professions.

With the school on the coalfield both students and staff will be in close contact with a well-developed mining industry, and the great desirability of having intimate relationship between the industry and mining education will be realised. Further, the teachers of the evening classes, who undertake part of the work of imparting elementary mining education at present, will be enabled to keep themselves *au courant* with the latest developments and to obtain advice and assistance from the school.

The Central Government will assume responsibility for its maintenance and administration, as the development of India's mineral industry is an Imperial undertaking which affects vitally the general advancement of the country as a whole. Under the Reforms Scheme only central agencies and institutions for research and for professional or technical training or for the promotion of special studies will be under the Government of India, as it is only for such that funds can be allotted from the Imperial revenues.

The fact that both coal and metalliferous mines are now being developed in other Provinces is not lost sight of. The school will be open to students from all parts of British India, and facilities are to be provided for others from the Indian States. Although the school will supply trained officials for the coal-mining industry, it has been definitely laid down that instruction in metalliferous mining shall receive due attention. It is hoped that provincial Governments, mining associations, and the great mining companies of India will give liberal support to the school by the institution of scholarships, travelling fellowships, and lectureships.

Elementary instruction in coal and metalliferous mining is not one of the objects of the school; this will receive due care from the provincial Governments concerned. A final decision has not yet been reached with regard to the higher training of mine surveyors, which is left for the future consideration of the governing body. Should a metallurgical institute be established in the future at Jamshedpur, full arrangements are to be made for the interchange of facilities in research and advanced training between it and the new School of Mines and Geology.

The school will not be affiliated to any university, at least in its initial stages, though it must, of course, maintain touch with the highest form of educational thought, methods, and standards. Both the Universities of Calcutta and Patna will be represented on the governing body. The latter consists of fourteen members, presided over by the Director of the Geological Survey of India. Other official members are the Chief Inspector of Mines, the principal of the college, and the representatives of the Governments of Bengal and of Bihar and Orissa. The rest are non-officials, appointed by the mining associations, etc., of various parts of India, and the two university members already mentioned.

Steps have already been taken to acquire a suitable site at Dhanbaid, and the governing body is to formulate proposals at once for buildings and equipment, staff, courses of study and examinations, rules of admission and an estimate of the initial and recurring costs of the school.

J. C. B.

University and Educational Intelligence.

CAMBRIDGE.—Mr. A. B. Appleton (Downing College), Mr. D. G. Reid (Trinity College), and Mr. A. Hopkinson (Emmanuel College) have been appointed demonstrators in anatomy, and Mr. A. Hutchinson (Pembroke College) has been re-appointed demonstrator in mineralogy and assistant curator of the museum of mineralogy. It is proposed that Dr. Myers should be appointed reader in experimental psychology, and that the University lectureship which he now holds should cease.

A LECTURE on "Recent Developments in Astronomy," in connection with the London County Council's lectures for teachers, will be given by Prof. A. Fowler at the Regent Street Polytechnic, W.1, on Saturday morning, December 4, at 10.30 o'clock. The chair will be taken by Mr. E. Walter Maunder.

THE Toronto correspondent of the *Times* stated on November 25 that, including the grant of 1,000,000 dollars from the Government of the Province of Quebec and 1,000,000 dollars from the Rockefeller Foundation, the McGill University centennial endowment fund has reached the total of 6,321,000 dollars (approximately 1,580,000*l*.), which exceeds the amount the recent campaign was started to raise.

AN exchange of university students between Belgium and the United States has recently been made; twenty-four Belgian students have been admitted to American universities and twenty-two Americans have entered Belgian universities. The exchange has been arranged and endowed by the Education Foundation of the Belgian Relief Commission from funds which remained after the Commission had completed its work in 1919. All travelling expenses of the selected students will be met from this fund, and fees will be remitted by the Belgian and some of the American universities for exchange students. In addition, Belgians entering American universities will each receive a maintenance grant of 1000 dollars per annum, while American students in Belgian universities will each be allowed a sum of 10,000 francs per annum for living expenses.

IN his presidential address to the members of the British Academy, now reprinted, Sir F. E. Kenyon discussed the subject of international scholarship. Like other societies, the Academy suffers from lack of funds, and the appeal now made for a Treasury grant will meet with the support of all who are interested in learning. The question of the resumption of relations with German scholars was considered, and while Sir F. Kenyon sees the difficulties which impede any *rapprochement*, he "looks forward to the revival of normal relations between English and German scholars, and I desire that it may come without delay." Meanwhile, international organisation of scholarship need not be suspended, and we can work in full accord with our Allies. As a result of a meeting held in Paris in 1919 a series of proposals for future work was submitted by the representatives of the nations present. Sir F. Kenyon's review of these proposals deserves careful consideration.

THE calendar of the West of Scotland Agricultural College for the session 1920–21 has just been received. The college undertakes to give instruction in general agriculture, dairying, forestry, horticulture, and poultry keeping to farmers, teachers, and grocers as well as to students studying for the regular diplomas, certificates, and degrees. The course provided for farmers is held during the winter months and completed in one session; it is intended for the sons of farmers who are unable to take full-time courses. At the grocers' class, held in conjunction with the Glasgow Grocers' and Provision Merchants' Association, the lectures deal principally with milk, butter and butter-making, cheese and cheese-making, bacon, and eggs. For full-time students courses are provided which lead to college certificates and diplomas in agriculture, dairying, forestry, and horticulture and to the various national diplomas which are granted, while lectures in preparation for the degree of B.Sc. (Glasgow) are also given. The year is divided into two terms, a winter session which is held in Glasgow, and a summer session spent at the experimental schools at Kilmarnock. Evening lectures are available, and a certain amount of extension work in the form of lecturing at local institutes, conducting experiments, giving expert advice to farmers, etc., is also done.

A LARGE and impurtant part of the extension work of most of the universities, colleges, and departments of education in the United States of America is done by correspondence methods (Bureau of Education, Bulletin No. 10, 1920). A list of the institutions developing this means of satisfying the desire for knowledge contains no fewer than thirty-eight universities. Seventy-three institutions are given in all, of which sixty-one are supported by public funds, and they are conducting correspondence courses for nearly one hundred thousand students. The Massachusetts Board of Education has provided some figures which show the motives actuating the pupils who enrolled for their correspondence courses, and also their previous educational history. More than 50 per cent. undertook courses in the hooe of immediate practical gain, while only 22 per cent. began the work from motives of culture or enjoyment; the educational history of the pupils showed that 49 per cent. came from secondary schools, and 35 per cent. had received elementary education only. At the same institution 76 per cent. of those who enrolled for correspondence classes were above school-age; the average age was 26·3 years. The results obtained from studies of the ages of correspondence students in the University of Wisconsin, Indiana University, and other institutions differ little from those obtained in Massachusetts.

THE University Colleges of Newcastle-upon-Tyne—the College of Medicine and Armstrong College, both of which are units of the University of Durham—have launched an appeal to the district they serve for 500,000*l.* A large committee representing the four northern counties has been set up, under the presidency of Viscount Grey of Fallodon, and at a recent meeting, at which the Duke of Northumberland acted as chairman, this committee pledged itself to do all in its power to relieve the colleges from their present embarrassment. The financial position of Armstrong College is little short of desperate. In July, 1921, the college will be faced with an annual recurring deficit of more than 19,000*l.*; the salaries of the staff, though they have already been augmented, are still far too low; it has been found impossible to keep equipment up to date; and students have had to be refused admittance in large numbers. This college, the only university college between Leeds and Edinburgh which teaches science, is faced with bankruptcy. The situation of the College of Medicine, though less serious financially, is also unsatisfactory. It is badly hampered by lack of accommodation, and unable to develop its teaching to the full along modern lines. Believing that their needs have only to be made widely known to their district to be relieved, the two colleges have thrown themselves upon the generosity of Tyneside and the surrounding counties.

A PUBLIC meeting was held on Thursday, November 25, at the Leeds Town Hall, under the presidency of the Lord Mayor, to inaugurate an appeal for funds for the University of Leeds. The University is asking the public of Yorkshire, and others interested in the progress of higher education in the county, for 500,000*l.*, and the Vice-Chancellor (Sir Michael Sadler) was able to announce to the meeting that towards this fund gifts amounting to 112,800*l.* had already been received or promised. Amongst those who spoke in support of the appeal were representatives of local authorities, who contribute largely to the revenue of the University, and a number of prominent professional and business men. The needs of the University for additional funds were explained at the beginning of the meeting by the chairman of the council (Mr. Arthur G. Lupton), the treasurer (the Hon. Rupert Beckett), the Vice-Chancellor, and Prof. Smithells. The number of students in the University is now nearly three times as large as before the war. Most of the departments are overcrowded, and the annual expenditure of the University has enormously increased as a necessary consequence of the new conditions created by the war. New laboratories are required in nearly all the University's departments of pure and applied science and for the school of medicine, and new buildings are needed for the department of agriculture, the school of dentistry, the University library, the Students' Union and gymnasium, and as halls of residence for men and for women students. A large addition to the general endowment fund of the University is also desired.

Societies and Academies.

LONDON.

Royal Society, November 18.—Sir J. J. Thomson, president, in the chair.—Sir A. **Schuster**: The absorption and scattering of light. The paper is based on the generally accepted theory that refraction and dispersion are caused by the oscillations of electric resonators embedded in the medium through which the light passes. With homogeneous light each resonator responds with a forced oscillation, together with a motion following the laws of free oscillations, and gradually dying out. If white light falls on the medium the forced oscillation has to be replaced by an integral and other terms have to be added that are due to disturbances caused by neighbouring molecules. The equation for the displacement of an oscillator then takes the form:

$$z=\int_0^\infty \mathrm{E}f(n,w)\cos(wt-\epsilon)\,dw+\Sigma \mathrm{C}_s e^{-\kappa(t-t_s)}\sin\sqrt{n^2-\kappa^2}(t-t_s).$$

The principal result of the paper is that all the terms of this equation are spectroscopically identical. If the proper value for $f(n, w)$ be introduced, and if E be regarded as constant, then the integral in the first term of the right-hand side is merely the analytical representation by Fourier's integral of any of the terms of the summation, with a proper adjustment of ϵ and t_s. As it stands, it represents a motion beginning at time $t=0$ and continuing according to the laws of a damped oscillator. The mechanism of scattering and absorption is discussed, and Lord Rayleigh's equation for the coefficient of extinction in a scattering medium is obtained in a more vigorous manner, so as to include cases where $\mu-1$ is not necessarily small.—Prof. O. W. **Richardson**: The emission of electrons under the influence of chemical action. The electron currents to a surrounding metal electrode from spherical drops of the liquid alloy of sodium and potassium under the influence of chemical action with a number of gases have been investigated and measured under various conditions. The gas which has been studied most is phosgene ($COCl_2$), then, in decreasing order, Cl_2, H_2O, and HCl. In all cases the relation between the current and the applied potential difference is of the same general character. When proper allowance is made for the contact potential difference between the two metal surfaces it is found that the electron currents are nearly constant for small accelerating electric fields. Thus, as in the case of photo-electric emission, the saturation value of the current is reached with a potential difference very close to zero. With retarding fields the currents fall off rapidly as the applied potential difference increases. Like similar thermionic electron currents, they approach the voltage axis gradually and not sharply, as in the photo-electric case. The true zero on the voltage scale is difficult to determine on account of fluctuations in the contact potential difference. In the case of $COCl_2$ it has been possible to locate the zero to within 0·10 volt by a photo-electric method. The proportion of the chemically emitted electrons the kinetic energy of which lies between u and $u+du$ is very closely represented by

$$\frac{udu}{k^2T^2}e^{-u/kT}$$

where k is Boltzmann's constant and T is a certain temperature. For the case of $COCl_2$, T is near 3300° K, and for the case of Cl_2, T is about 4900° K. The formula above represents a Maxwell distribution for the temperature T. Thus the distribution of kinetic energy among the chemically emitted electrons is the same as that among the molecules of a gas at the uniform temperature T.—Dr. A. E. **Oxley**: Magnetism and atomic structure. This communication is an extension of former papers on "The Influence of Molecular Constitution and Temperature on Magnetic Susceptibility" (Phil. Trans. Roy. Soc., vol. ccxiv., A, 1914; vol. ccxv., A, 1915; and vol. ccxx., A, 1920). From Tyndall's work and recent experiments of the author on the characteristic deportment of diamagnetic and paramagnetic crystals in the magnetic field, it appears that in non-ionised crystal structures the fundamental unit of the space lattice is the molecule. It is shown that the electron orbits in atoms must be distributed in space round the nucleus, each electron describing a small orbit, or alternatively the electron itself may be a complex unit endowed with magnetic properties. In either case the distribution must be such that the aggregate projected area of the electron orbits on a plane perpendicular to the principal cleavage is a maximum in both diamagnetic and paramagnetic crystals. This result is consistent with a closer packing of the molecules in a direction parallel to the principal cleavage. In crystals of the simple cubic form X-ray analysis has indicated that the structure is an ionised-atomic one, and the cleavages are all of equal value. Such crystals show no appreciable structural deportment in the magnetic field. The above views relating to electron distribution are consistent with the cubical atom theory of Lewis and Langmuir, but not with Bohr's theory. The coupling forces between atoms and molecules in non-ionised crystals are due to the mutual magnetic induction between pairs of electron orbits. A model of the hydrogen molecule is given, in which the arrangement of the coupling units determines a diamagnetic molecule as required by experiment. It is considered that the above views and those of Bohr may eventually be brought into line by a fuller recognition of the possible differences between radiating and non-radiating matter.—Prof. A. O. **Rankine**: The proximity of atoms in gaseous molecules. In this investigation a close examination is made of the relations between the estimates of atomic diameters obtained by Prof. W. L. Bragg from X-ray crystal measurements and those deduced from the kinetic theory of gases. The examination is carried out from the point of view of the Lewis-Langmuir molecular theory. It is shown that if, for example, a hypothetical molecule be constructed of two argon atoms with their centres separated by the distance demanded by Prof. W. L. Bragg's figures, the behaviour of such molecules in thermal agitation would be almost identical with the actual behaviour of chlorine molecules. Similar relations are shown to exist for the pairs of gases neon-oxygen, krypton-bromine, and xenon-iodine. The following conclusions are regarded as justified: (*a*) There is substantial *quantitative* agreement between the estimates of atomic dimensions deduced from X-ray crystal measurements and from the kinetic theory of gases. (*b*) In size and shape the atoms of the monatomic inert elements are nearly indistinguishable from the atoms respectively of the neighbouring diatomic elements in the periodic table. (*c*) The Lewis-Langmuir molecular theory accounts satisfactorily for the kinetic behaviour of the molecules of oxygen, chlorine, bromine, and iodine in relation to the behaviour of the corresponding inert atoms neon, argon, krypton, and xenon.—Prof. A. O. **Rankine**: The similarity between carbon dioxide and nitrous oxide. The two gases in question have been shown by Langmuir to have almost identical physical properties. In particular, they have the same viscosity, and the application of modern kinetic theory indicates that their molecules have the same size and shape. In the present paper it is shown, by the extension of methods already described by the author, that the kinetic behaviour of the molecules of both CO_2 and N_2O is consistent with their being identical in size and shape with three neon atoms in line and contiguous, *i.e.* with outer electron shells touching. This is in accordance with Langmuir's view of the constitution of these molecules.—Dr. A. M. **Williams**: Forces in surface films. I.: Theoretical considerations. II.: Experimental observations and calculations. III.: The charge on colloids. I. and II.: Attention is directed to the effects of (i) accessibility of surface and (ii) adsorption on the apparent specific volume of finely divided solids. A simple theory of these effects is developed, with which observations are in agreement. The true specific volume of a specimen of charcoal, which appeared to be 0·51 in water and 0·46 in chloroform, was evaluated as 0·67 c.c. per gm. The attractive pressure on the surface film on the charcoal was calculated and found to be of the order of 10,000 atmospheres, while the internal pressure of the charcoal itself was evaluated as of the order of 50,000 atmospheres. III.: It is shown that compressive forces of the order previously determined may give rise in the adsorption layer to a diffusion potential difference of the magnitude observed in the case of suspensoids. The influence of the diffusion of hydrogen- and hydroxyl-ions on the potential difference is emphasised, and the neutralisation of the charge on suspensoids and their consequent precipitation explained in terms of diffusion potential.

Physical Society, November 12.—Sir W. H. Bragg, president, in the chair.—Dr. F. H. **Goucher**: Ionisation and excitation of radiation by electron impact in helium. Measurements have been made of the critical potentials for helium by the method used in the experiments of Davis and Goucher, these being compared with the ionising potential of mercury vapour taken as a standard. Assuming the ionising potential of mercury to be 10·4 volts, two critical potentials occur in helium, one at about 20 volts and the other at about 26 volts. These critical values agree well with those obtained by Horton and Davies. The effect of radiation alone on the metal parts of the apparatus was studied under conditions which would yield evidence of use in the interpretation of the results obtained when the production of both ionisation and radiation was taking place simultaneously. The conclusion was drawn that the lower critical potential was a radiation potential, though some ionisation was produced also at this potential. This, however, was attributed to the presence of impurity, probably hydrogen. The higher critical potential was that at which ionisation took place.—J. **Guild**: The location of interference fringes. The conditions under which interference fringes, produced by reflection of light from the two surfaces of a "thick plate," are visible to an observer. The treatment lays stress on the physical significance of the term "location" as applied to interference fringes and on the dependence of the observed phenomena on the conditions of observation. For a broad source of light a formula is obtained which is equivalent to that derived by Michelson. For a joint source of light at infinity it is shown that the fringes obtainable are equally visible at all distances from the plate.—J. **Guild**: Fringe systems in uncompensated interferometers. An investigation of the form of the fringe system observable at infinity, or in the focal plane of a telescope, when a broad source is employed with a Michelson interferometer in which the glass paths of the two interfering beams are not equal. The fringes may be elliptical or hyperbolic, with circles and straight lines as special cases. In the recently developed method of using the instrument for optical testing, the fringes due to a joint source at infinity are employed. It is shown that the form of the fringes in this case are unaffected by lack of compensation, but that the visibility of the fringes is conditioned by the nature of the fringe system due to a broad source.—Dr. G. **Barr**: A new relay for heavy currents. The action of the relay depends on the fact that no arc can be maintained between mercury electrodes in hydrogen. One lead is brought to mercury contained in a vertical tube within a solenoid. An iron rod, at the upper end of which is a glass cup floats in the mercury. The cup also contains mercury, and the other lead is connected to an iron rod which dips into this. When no current flows in the solenoid the rim of the cup is about 1 cm. above the level of the main body of mercury. When the relay current (about 0·03 ampere) is running the iron rod is sucked down until the rim of the cup is submerged by about 0·5 cm. The space above the mercury contains hydrogen. The relay can be used to break quite large currents (20 amperes) without much spark.

EDINBURGH.

Royal Society, November 1.—Prof. F. O. Bower, president, in the chair.—Three connected papers by Dr. J. **Rennie**, Miss Elsie **Harvey**, and B. **White**: The Isle of Wight bee disease. The results of these investigations, which were being carried out in the Parasitical Laboratory at Aberdeen, showed that the so-called Isle of Wight disease was due to a small mite living in the respiratory system of the bee. This was contrary to the views advanced some eight years ago by workers in England, who claimed that the causal organism was a protozoon named *Nosema apis*. Mr. Anderson, of Aberdeen, was the first to call in question this hypothesis, and the series of papers now presented established the existence of a new type of parasitism in bees of a remarkable kind. The small mite which was the cause of the disease belonged to the genus Tarsenemus. It was highly specialised in structure, was bred within the bee, and was confined to an extremely limited, but very important, region of its breathing system. Within the space of a few cubic millimetres scores of these creatures might be seen in all stages of development, sometimes packed in dense columns so as to cut off effectually the air-supply from the surrounding organs. The detailed pathology described in Mr. White's paper proved the destructive character of the parasites' habits. Thousands of bees had been examined from large numbers of stocks throughout the country, and it had been found that every stock reported by trustworthy beekepers or certified by the investigators as suffering from the disease harboured this parasite. Similarly, every individual bee known from its stock-history and individual symptoms to be suffering from the disease was likewise found to contain these parasites and to exhibit the internal disorders which caused the disabling symptoms. The investigators stated that they were now able to diagnose the disease in its earliest stages while the bees were capable of flying and foraging. Miss Harvey's researches showed that infection appeared to occur mainly in the hive, the conditions of the cluster making this comparatively easy. Mites had been obtained from the outside of the bee apparently on their migratory passage. Tarsenemus included several species destructive to plants, and there were some which have been found in malignant growths in man and other animals. The bee parasite was more closely allied to the latter group. Many bees from different countries outside Great Britain have been examined, and so far Tarsenemus has not been found in these. All the evidence hitherto obtained points to the parasite being peculiar to this country, coinciding with the general testimony regarding the insular character of the Isle of Wight disease. This name had long been regarded as unsatisfactory, and "acarine disease" was proposed as more appropriate. In view of the great practical interest taken by Mr. A. H. E. Wood, of Glassel, in the work of the research. Dr. Rennie proposed to designate the new species *Tarsenemus Woodi*. To Mr. Wood and to the Development Commissioners special recognition was due for having provided in equal measure funds necessary to finance the investigation, and the authors also record their high appreciation of the support of beekeepers throughout the country in supplying bees and other assistance so essential for the successful conduct of the research.—Prof. J. H. M. **Wedderburn**: The equations of motion of a single particle.

PARIS.

Academy of Sciences, November 8.—M. Henri Deslandres in the chair.—L. **Lecornu**: The permanent movements of liquids.—P. **Termier** and W. **Kilian**: The western edge of the glittering schists in the Franco-Italian Alps between Haute-Maurienne and Haut-Queyras. A discussion of the question as to whether the contact between these schists and the Briançon series is normal or abnormal. A careful study of more than 100 km. shows that the contact of these two strata has none of the characters of a normal contact, and the idea of a stratigraphical continuity is highly improbable.—L. **Lumière**: The photographic representation of a solid in space. Photostereo-synthesis.—H. **Parenty** and G. **Vandamme**: Utilisation of the energy of tides and waves. A description of an arrangement of cells made of reinforced concrete, by means of which air is compressed or rarefied by the shock of the waves. The apparatus has been constructed and gives pressures of 2–3 kg.—J. **de Lassus**: A transmission of mechanical energy utilising an invariable mass of gas in closed circuit.—A. **Danjon**: A new variable star of short period. The star *d* Cygnus varies in magnitude from 5·16 to 5·36, and the passage from maximum to minimum may be observed during one evening.—L. **Dunoyer**: Remarks on an article by Irving Langmuir and on another by R. W. Wood. A question of priority.—E. **Jouguet**: Application of the Carnot-Clausius principle to waves of shock in elastic bodies.—R. **Biquard**: Abnormal indications furnished by radiochromometers with very penetrating X-rays. The principle upon which Benoît's radio-chromometer depends is not valid for the X-rays from a Coolidge tube under a potential of 60,000 volts or higher, and the use of this instrument should be confined to the measurement of X-rays of medium or low penetration such as those utilised in medical radiography or superficial radio-therapy.—L. and E. **Bloch**: The spark spectra of mercury, copper, zinc, and thallium in the extreme ultra-violet. The measurements were made with a prism spectrograph, and the wave-lengths given are based on Lyman's data obtained with a grating. New lines are given for all four metals.—C. **Raveau**: The determination of the number of independent components. The rule of M. Dubreuil; the action of water on a mixture of salts.—J. B. **Senderens**: The catalytic dehydration of fermentation amyl alcohol. Catalysis by aluminium silicate at 340° to 350° C. gives a mixture of three amylenes, and the proportion in which these are present depends on the length of time the catalyst has been in use. The first litre of amylenes collected contained 93 per cent. of amylene soluble in diluted sulphuric acid, the third litre only 75 per cent.—R. **Cornubert**: The spectrochemical study of the α-allyl- and α-allylmethyl-*cyclo*hexanones.—L. **Duparc** and G. **Favre**: The deposit of oolitic iron ore at Ain-Babouche (Algeria).—H. **Jumelle**: The katoka, a Madagascan tree with edible seeds. The tree is a new species of the genus Treculia, and is named *Treculia Perrieri*. It is abundant in the west of Madagascar and produces a good wood and edible seeds. The latter are consumed by the natives as food, and have been imported into France for the extraction of their oil.—H. **Bouygues**: The terminal meristem of the stem and its division into regions.—P. **Lesage**: Evaporometers and the motion of fluids through membranes.—A. **Damiens**: The bromine and chlorine existing normally in animal tissues. Bromine was found in all the organs examined, except in two or three cases where the quantities of material available were too small. The ratio of bromine to chlorine in the organs of any given animal is sensibly constant, and is of the order 0·001 to 0·002.—L. **Mercier**: Variation in the number of the fibres of the longitudinal vibrator muscles in *Chersodromia hirta*. Loss of the power of flight.—C. **Julin** and A. **Robert**: Organogenesis in the blastozoites of Perophora.—T. **Tommasina**: Remarks on the note by M. Louis Besson on the relation between the meteorological elements and the number of deaths by inflammatory diseases of the respiratory organs at Paris.

Diary of Societies.

THURSDAY, DECEMBER 2.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.—Major G. H. Scott: Airship Piloting.—Flight-Lieutenant F. L. C. Butcher: Airship Mooring.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. W. Brown: The Value of Suggestion in Education.

CHEMICAL SOCIETY, at 8.—Sir Prafulla C. Rây: Varying Valency of Platinum with Respect to Mercaptanic Radicles.—H. E. Cox: The Influence of the Solvent on the Velocity of certain Reactions. Part II. Temperature Coefficients. A Test of the Radiation Hypothesis.—K. J. P. Orton and P. V. McKie: Preparation of Chloropicrin from Picric Acid and Trinitrotoluenes.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—C. White: Sodium Bicarbonate Tolerance in the Toxæmias of Pregnancy.—Major C. A. F. Hingston: The Necessity for the Reduction of Blood Pressure in Eclampsia.—Dr. R. W. Johnstone and Dr. J. Young: Case of Accidental Hæmorrhage associated with Eclampsia.—Dr. J. Young and Dr. D. Miller: Further Observations on the Etiology of Eclampsia and the Pre-eclamptic State.

FRIDAY, DECEMBER 3.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.45.
ROYAL ASTRONOMICAL SOCIETY (Geophysical Discussion), at 5.—The Cause of Magnetic Storms.—In Chair: J. H. Jeans. Opener: Prof. F. A. Lindemann.—Other Speakers: Prof. S. Chapman, Dr. C. Chree, Rev. A. L. Cortie, Major G. M. Dobson, E. W. Maunder, C. S. Wright, and Others.
INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Further Discussion on The Human Factor in Industry, by A. Ramsay.
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Section) (at King's College), at 6.30.—A. Serner and Others: Discussion on The Modern Tendency to Trusts. Is it Beneficial?
JUNIOR INSTITUTION OF ENGINEERS (at Caxton Hall), at 8.—G. F. Shotter: Electrolysis as applied to the Measurement of Water.
ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—Informal Meeting.

SATURDAY, DECEMBER 4.

GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.1), at 3.—H. J. Elwes: The Primitive Races of Sheep in Great Britain.

MONDAY, DECEMBER 6.

VICTORIA INSTITUTE, at 4.30.—Dr. D. Anderson-Berry: The Psychology of Man, Experimentally Considered.
ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Berkeley Moynihan: The Surgery of the Diseases of the Spleen (Bradshaw Lecture).
ROYAL INSTITUTION OF GREAT BRITAIN, at 5.
SOCIETY OF ENGINEERS (Inc.) (at Geological Society), at 5.30.—H. Banks: Blackpool Sea Coast Defence Works.
ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street), at 8.—Prof. W. P. Montague: Variation, Heredity, and Consciousness.
SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.—Dr. H. Levinstein: The Dyestuff Industry.
ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Major-Gen. L. C. Dunsterville: From Baghdad to the Caspian in 1918.
MEDICAL SOCIETY OF LONDON (at 11 Chandos Street, W.1), at 8.30.—The Surgical Treatment of Malignant Disease of the Colon, introduced by Sir Berkeley Moynihan, to be followed by Sir W. Arbuthnot Lane, Bt., G. Wright, L. Mummery, G. G. Turner, and H. W. Carson.

TUESDAY, DECEMBER 7.

ROYAL SOCIETY OF ARTS, at 4.30.—A. H. Ashbolt: The Trade of Australia During and After the War.
INSTITUTE OF INDUSTRIAL ADMINISTRATION (at Central Hall, Westminster), at 7.—R. Twelvetrees: Road Transport as an Aid to Industrial Management.
ROYAL SOCIETY OF MEDICINE (Surgery: Sub-section of Orthopædics), at 5.30.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—F. Martin-Duncan: Photomicrography from the Ordinary Photographer's Point of View: Exhibition of Various Forms of Photomicrographic Apparatus and Demonstration of Use.
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—L. S. Palmer: Some Late Keltic Remains from a Mendip Cave.
SOCIOLOGICAL SOCIETY (at 65 Belgrave Road), at 8.15.—Major Douglas: The Mechanism of Consumer-Control.
ROYAL SOCIETY OF MEDICINE (Pathology Section) (at Laboratories of Medical Research Council, Mount Vernon, Hampstead), at 8.30.—Prof. L. Hill: The Measurement of the Capillary Blood Pressure.—Capt. S. R. Douglas: The Serological Races of the Cholera Vibrio.—Dr. W. Mair: Dohler's Bodies in Scarlet Fever and Pneumonia.—J. E. Barnard: The Use of Ultra-Violet Light in the Differentiation of Animal Tissues.—Dr. L. Colebrook: Actinomyces.—Major H. W. Acton: The Formation of the Gametocyte of Benign Tertian Malaria.—Dr. Lovatt Evans: A Method for the Determination of the Reaction of Blood.

WEDNESDAY, DECEMBER 8.

ROYAL SOCIETY OF ARTS, at 4.30.—E. A. Brayley Hodgetts: A Retrospect of the Personal Influence of Britons in Russia.
INSTITUTION OF AUTOMOBILE ENGINEERS (at Institution of Mechanical Engineers), at 8.

THURSDAY, DECEMBER 9.

ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Lord Rayleigh: Doubly Refracting Structure of Silica Glass.—Prof. J. W. Nicholson and Prof. T. R. Merton: The Effect of Asymmetry on Wave-Length Determinations.—Prof. T. R. Merton: The Effect of Concentration on the Spectra of Luminous Gases.—Prof. E. Wilson: The Measurement of Low Magnetic Susceptibility by an Instrument of New Type.—Prof. W. T. David: The Internal Energy of Inflammable Mixtures of Coal-Gas and Air after Explosion.—Prof. A. McAulay: Multenions and Differential Invariants.
LINNEAN SOCIETY, at 5.—Prof. R. Newstead: Uganda Biology (Lantern Lecture).
LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—S. Beatty: The Algebraic Theory of Algebraic Functions of One Variable.—F. Debono: The Construction of Magic Squares.—Prof. A. S. Eddington: An Application of the Calculus of Tensors to the Theory of Finite Differences.—Prof. A. R. Forsyth: Developable Surfaces through Two Curves in Different Planes.—J. E. Jones: The Distribution of Energy in the Neighbourhood of a Vibrating Sphere.—L. J. Mordell: (1) The Reciprocity Formula for the Gauss's Sums in a Quadratic Field. (2) A New Class of Definite Integrals.—Prof. G. N. Watson: The Product of Two Hypergeometric Functions.—Prof. W. H. Young: (1) Integration over the Area of a Surface and Transformation of the Variables in a Multiple Integral. (2) A New Set of Conditions for a Formula for an Area.
ROYAL SOCIETY OF MEDICINE (Balneology and Climatology Section), at 5.15.—Dr. Max Porges: Mud Baths and Nephritis.—Dr. F. Hernaman-Johnson: The Importance of Combined Methods in Diagnosis and Treatment.—Dr. S. Burridge: Some Possible Ill-effects of Barium Waters.
INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Adjourned Discussion on Papers by W. B. Woodhouse and R. O. Kapp on The Distribution of Electricity and Some Economic Aspects of E.H.T. Distribution by Underground Cables.
ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Dr. F. Buzzard: Tabes, its Early Recognition and Treatment.

FRIDAY, DECEMBER 10.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in the Botanical Theatre, Imperial College of Science), at 2.30.—Exhibition of Specimens and Short Communications.—W. J. Dowson: Problems of Economic Biology in British East Africa.—Dr. M. C. Rayner: Nitrogen Fixation in the Ericaceæ.
ROYAL ASTRONOMICAL SOCIETY, at 5.
PHYSICAL SOCIETY OF LONDON, at 5.—J. St. V. Pletts: Some Slide Rule Improvements.—F. H. Newman: The Absorption of Gases in the Electric Discharge Tube.—F. H. Newman: A Sodium Vapour Electric Discharge Tube (with Demonstration).—N. A. Allen: The Current-Density in the Crater of the Carbon Arc.
ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.
INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.
TECHNICAL INSPECTION ASSOCIATION (at Royal Society of Arts), at 7.30.—Dr. G. H. Gulliver: Some Features of Tensile Fractures.
ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30.

The Dye Industry.

FOLLOWING on the agreement which has at last come about between the dye-makers and the dye-users, the Cabinet decided, on December 1, to introduce a Bill for the protection of British dyestuffs. This was promptly presented to the House of Commons on December 2 by Sir Robert Horne, President of the Board of Trade, read a second time this week on Tuesday, and is expected to be passed into law before Christmas.

The Bill is quite short, and prohibits the importation into the United Kingdom of all synthetic dyestuffs, colours, and colouring matters, and all organic intermediate products used in their manufacture, for a period of ten years and no longer. The Board of Trade will, however, have power by licence to authorise the importation of any of these products, and for the purpose of advising it with respect to the granting of licences a Committee will be constituted, consisting of five persons concerned in the trades in which the above goods are used, three persons concerned in the manufacture of such goods, and three other persons not directly concerned in the production or use of dyes. One of the latter three persons will be chairman of the Committee. The Board may charge in respect of a licence a fee not exceeding 5*l*. The Act will not apply to goods imported for exportation after transit through the United Kingdom or by way of transhipment.

If, as is expected, this Bill is passed into law the British dye manufacturer will be relieved that the promises of the Government have been redeemed, and he may now set himself with redoubled energy to secure that his products are beyond reproach, and to erect plant for the manufacture of dyes not yet produced here, which are urgently wanted by the dye-users. Such will, no doubt, be imported under licence for a time, but a period of ten years should be ample for establishing in this country a great industry which will provide every possible requirement of the dye-user, and a combination of chemical manufacturers, if it can be brought about, ought to place the economic position of this industry beyond fear of attack.

The great advantages to be derived from co-operation in the dye industry, so well indicated by the great German combination, the "Interessengemeinschaft," have evidently been realised in America, for, according to the *Times* of December 1, five of the largest chemical works in the United States—namely, the General Chemical Co., the Semet Solvay Co., the Solvay Process Co., the Barrett Co., and the National Aniline and Chemical Co.—are to merge their interests, and the combination is to possess a capital of about 60,000,000*l*. This sum is about as large as that of the German Trust, but the scope of the American company will be rather wider, including, as it will, the distillation of coal-tar, the fixation of atmospheric nitrogen, and the manufacture of heavy chemicals.

This is an important step in the direction of the consolidation of interests in America, and, in view of the protective legislation which is now being considered by Congress, everything points to the firm establishment of the dye industry in that country. The output of dyes is already high, being about 30,000 tons per annum, and the wide interest that is being taken in the field of industrial organic chemistry is further shown by the fact that there are nearly 200 firms engaged in the manufacture of crude products, intermediates, dyes, lakes, medicinal preparations, flavouring media, photographic chemicals, synthetic phenolic resins, synthetic tanning materials, and explosives.

It is much more important to give attention to developments of this kind than to over-emphasise the relation of the dye industry to war products in order to enlist the sympathy of the public for its protection. In an article in the *Observer* of December 5 Prof. H. E. Armstrong expresses the opinion that, had the dye-users taken active and financial interest in the British Dyes Corporation during the war period, the present situation would probably not have arisen.

Evolution of Water Plants.

Water Plants: A Study of Aquatic Angiosperms. By Dr. Agnes Arber. Pp. xvi+436. (Cambridge: At the University Press, 1920.) Price 31*s.* 6*d.* net.

WE have here a comprehensive work embodying the results of a ten years' study of water plants, and dealing in a very practical fashion with the mass of literature that has grown up around the subject. As a book of authority on aquatic plants, it will be ranked with Schenck's work of a generation ago, and it would not receive its due if we did not add that it worthily holds the place. But we must not forget that other industrious investigators have in the meantime filled the gap. Prominent among them are Gluck, Goebel, Henslow, Pond, Sargant, Sauvageau, Willis, and many others. Since Schenck's time, however, new points of view have arisen, and new methods have been in use by numerous inquirers of both sexes, all keen in their desire to take a part in the new era of research.

Yet we find ourselves in an age of unrest and uncertainty in the botanical world. There is a note of discord in the rivalry of the two schools of thought that are divided between the respective claims of the present and the past, or, rather, of the last and first stages of the evolution of the higher plants, to occupy the attention of the investigator. Dr. Agnes Arber speaks of "the deep obscurity involving all evolutionary thought" in our own day, and demurs to the objection that when we cannot even be sure as to the origins of the numerous varieties springing up under our eyes it is not a time for discussing the origins of Dicotyledons or Monocotyledons. In this she is impugning the policy of restricting our efforts to the study of the last stage in the unfolding of the story of plant life. So we get the keynote to her book, the first six-sevenths of which are regarded by her as "a clearing of the ground for the more theoretic considerations concerning the evolutionary history of water plants." But inquiries into their origin must necessarily raise great issues affecting also their relatives on the land; and thus we find in our hands a book that in its general bearings will give birth to much serious thought.

Yet, apart from theory, we have here a very extensive record of observation, experiment, and research on aquatic plants and their ways. The practical side, as we have seen, occupies by far the greater part of the work, and there is a wealth of illustration, mostly original. Quite a third of the space is devoted to the life-histories of the various groups of aquatic flowering plants, and these are followed by discussions on heterophylly, the morphology and anatomy of stems and leaves, the relation of the flowers to their environment, the wintering of water plants, the physical factors in their conditions of existence, and several other matters.

Taking our cue from the author, we will pass on to notice the more speculative portion of her book. There is first the question which might be placed among the "posers" little children are supposed to put. A primitive question about a primitive issue is concerned with the priority of the land- and the water-plant. As usually happens, the problem needs a good deal of straightening out before a reply can be made. Whilst it is generally recognised that the primeval forms were lowly aquatic plants, and that it is only in the higher plants that the terrestrial habit has become firmly established, we are far from being in a position to connect the one with the other.

Botanists are agreed that the aquatic Angiosperms are derived from terrestrial ancestors, but a cleavage in opinion began when they differentiated between Monocotyledons and Dicotyledons. Nature seemed to differentiate between them, and, being impressed by the preponderance of aquatic families among the Monocotyledons, botanists accredited the class with special aquatic proclivities. After considering the matter more closely, the author forms the opinion that these tendencies are hard to maintain.

Continuing to treat aquatic Angiosperms in the mass, and heeding only the systematic distribution of aquatics, the author lays down the principle that when a single genus or a species in an otherwise terrestrial family has taken to aquatic life, the habit may be a recent one; but when a whole family holding several genera is aquatic, we are dealing with a very ancient group of water plants where "the differentiation of the genera has occurred since the adoption of the aquatic habit." There are, in fact, "aquatics, new and old"; and they tend to choose their places in the systematic scale according to their age, the more ancient among the more primitive of the Angiosperms, and the more recent among those more advanced.

To the query as to which are the most primitive of the Angiosperms, the answer is: The families that are held within the Ranalean plexus. Those numerous families that go largely to form the Incompletæ of Bentham and Hooker, and which Engler places at the beginning of the Archichlamydeæ in the scale of development, are regarded as the more advanced and reduced forms of that series. Dr. Newell Arber, who supplied the original impulse for this work, laid the foundation for the author's position in this respect, and Miss Sargant's derivation of the Monocotyledons from the primitive Ranalean plexus is here accepted.

An explanation of the great structural reductions involved in the transition from terrestrial to aquatic life, and in the transference by hypothesis of so many families from the beginning to the end of the series of the Archichlamydeæ, became a necessity; so the author proposed her "Law of Loss," which has proved to be related closely to Dollo's "Law of Irreversibility" for animals. This rests on the principle that what is lost in the course of plant evolution can never be regained, and, if required again, "must be constructed afresh in some different mode." From this point of view the leaf-blades of several aquatic plants would be regarded as expansions of the petioles, and much light would be thrown on the many difficult questions involved in the interpretation of the flowers.

The author's position regarding natural selection is discussed, so far as it is determined by aquatic plants. The principle is almost protean in its appearances. When we think we have disposed of it in one shape, it arises in another. If, like Dr. Willis, we exclude it in the case of the genera and species of the Podostemaceæ, it turns up again as the principal factor in the adaptation of the group for life in rapid waters. Dr. Agnes Arber shares with many others her difficulties in accepting whole-heartedly the principle May it not be possible to assume that these difficulties would disappear if we broadened the basis of the theory? Whilst supporting Darwin through so many years, Hooker was holding a view of divergence, under the name of "centrifugal variation" (really a conception of differentiation), that was directly opposed to important points of the theory. Yet he considered that the greatest hope of the investigator lay in the *general* lines marked out by Darwin.

However that may be, we are reminded by the author of this book of an evolutionary idea, both old and new, that is capable of great development. The principle that what organisms gain in specialisation they lose in plasticity presents us with quite another way of viewing evolution—a view in which progression offers itself as a succession of lost opportunities. Progress in one direction involves the closing of the gates in "countless other directions," the possibilities of choice ever narrowing as we go up the scale. It is suggested that this would be impossible but for the inheritance of acquired characters, bound up, probably, with the inheritance of unconscious memory. At all events, it presupposes a primeval era of plasticity in which heredity had but little power. The line of thought is similar to that followed by Beccari in his theory of plasmation. Here a long vista opens up, and at its distant end lie the problems connected with the origin of the great groups of the plant world.

H. B. GUPPY.

The Behaviour of Beetles.

The Glow-worm and other Beetles. By J. Henri Fabre. Translated by Alexander Teixeira de Mattos. Pp. viii+488. (London: Hodder and Stoughton, Ltd., 1919.) Price 8*s*. 6*d*. net.

THIS is the second volume on beetles in the complete English edition of Henri Fabre's entomological works. The first essay, "The Glow-worm," which gives its name to the book, did not form part of the "Souvenirs Entomologiques," but was written for translation into English towards the close of the veteran naturalist's life. Several chapters, like this first one, have already seen the light in English, but most of the book is fresh, and it is very convenient to have the studies on beetles brought together. Eventually there will be four volumes on beetles. The experienced translator, Mr. Alexander Teixeira de Mattos, has done his work with great skill.

These are wonderful stories. The glow-worm tweaks a snail with its sharp mandibles, and administers an anæsthetic; a number of other glow-worms hasten to the repast and fall to; the flesh is converted by exuded ferment into a sort of gruel, and the fluid is sucked up by the hollow jaws. We suspect that there is some inaccuracy in Fabre's account; it seems clear, for instance, that the fluid food enters the gullet by the mouth, and not *via* the mandibles. In any case, Fabre's observations must be compared with those of Bugnion and Miss Kathleen Haddon. In regard to the luminescence Fabre was cautious:—

"From start to finish, the glow-worm's life is one great orgy of light. The eggs are luminous; the grubs likewise. The full-grown females are magnificent light-houses, the adult males retain the glimmer which the grubs already possessed. We can understand the object of the feminine beacon; but of what use is all the rest of the pyrotechnic display? To my great regret, I cannot tell. It is and will be, for many a day to come, perhaps for all time, the secret of animal physics, which is deeper than the physics of the books."

The close of this frank admission of ignorance has the characteristic Fabre touch, the precise point of which is not very obvious. Bio-chemistry and bio-physics are both very young, but they have already had their triumphs, which pass automatically into the contemned books. What is wrong with the physics of the books except that naturalists do not read it?

The succeeding five chapters deal with the remarkable life-histories of sitares, oil-beetles, and the like, and they certainly demand the reader's close attention. It is easier to follow the fine study of the capricorn (the grub of the Cerambyx beetle), which burrows in the stem of the oak.

"This grub, so poor in sensory organs, gives us with its prescience no little food for reflection. It knows that the coming beetle will not be able to cut himself a road through the oak, and it bethinks itself of opening one for him at its own risk and peril. It knows that the Cerambyx, in his stiff armour, will never be able to turn and make for the orifice of the cell; and it takes care to fall into its nymphal sleep with its head to the door. It knows how soft the pupa's flesh will be and upholsters the bedroom with velvet."

Here we have an instance of Fabre's strength and weakness; the facts are so interesting; the discovery of them was a triumph; the exposition of them is extraordinarily vivid; but the interpretation seems wildly anthropomorphic. We do not, we confess, understand instinctive behaviour; but we feel sure that the "inimitable observer," as Darwin called him, was off the scent. We get tired of this "knowing" and "bethinking," all the more because we doubt whether Fabre believed in it himself. "It knows the future with a clear vision," he says, "or, to be accurate, behaves as though it knew the future." But even this wobbling between inaccurate and accurate expression might have been accepted with good humour—a little fly in the fine ointment of fact for which every naturalist is grateful—had not Fabre made us wince by such *obiter dicta* as "now that the evolutionists' interpretations of instinct have been recognised as worthless."

One of the fine qualities of Fabre's essays is the way in which they raise questions which we cannot answer. How is it that the sawfly Sirex, which undergoes metamorphosis not far from the centre of the trunk of the tree, makes its way out to the light by the shortest route? Over and over again we find these puzzling problems stated; one attempt at solution is tested and then another, only to be rejected; and then the author gives it up for the time being: "I leave the matter to the conscientious masters, to the experts who are able to say: I do not know." This is much more educative than a prejudiced dismissal of evolutionism.

Biologically of great interest is the essay on insect colouring, in which Fabre expounds and illustrates the theory that various bright colours are due to a utilisation of ammonium urate or some related nitrogenous waste-product.

"While the larvæ of the Hunting Wasps, unable to do better, stipple themselves with uric acid, there are plenty of industrious creatures that are able to make themselves a superb dress by preserving their excretions in spite of their own open sewers. With a view to self-embellishment [again the anthropomorphic taint], they collect and treasure up the dross which others hasten to expel. They turn filth into finery."

When he got hold of an attractive idea, Fabre often let himself go, and we like him none the less for that.

"Nature, that sublime economist, delights in these vast antitheses which upset all our conceptions of the values of things. Of a pinch of common charcoal she makes a diamond; . . . of the filthy waste products of the organism she makes the splendours of the insect and the bird. The metallic marvels of the Buprestis and the Ground-Beetle; the amethyst, ruby, sapphire, emerald and topaz of the Humming-Bird; glories which would exhaust the language of the lapidary jeweller: what are they in reality? Answer: A drop of urine."

It seems almost profane to ask how many of the pigments of birds are known to be chemically related to urates; it seems niggling to ask whether the picturesque reference to sapphire and emerald is relevant at all, since these particular colours in the humming-bird are surely due to physical sculpturing rather than to any number of drops of urine.

The Fabre we like best is the patient and ingenious and sympathetic observer who tells us, in other chapters, of the accomplishments of the burying-beetles and their not less marvellous limitations, of "death-feigning" in Scarites and Buprestis, of animal hypnosis at higher levels, of the supposed suicide of scorpions, and of the *vie intime* of half a hundred beetles. Was there ever such an observer? We suppose Réaumur and two or three others might be mentioned. But was there ever any other observer of this rank who could tell his story so that we fancy ourselves seeing what he saw? We know of none. And so we come back to our homage to Fabre.

Kinetic Theory.

A Kinetic Theory of Gases and Liquids. By Prof. R. D. Kleeman. Pp. xvi + 272. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) Price 16*s.* 6*d.* net.

THIS book deals mainly with the "free path phenomena" in the kinetic theory of gases, but this department of the subject is comprehensively treated. Whether the chief object of such a work—namely, to gain some information about the intermolecular forces—can ever be attained without taking account of the other parts of the subject seems somewhat doubtful.

The body of the book is concerned with the various forms of transfer which occur in gases and liquids—transfer of energy or heat conductivity, transfer of momentum measured by the viscosity, and transfer of matter as evidenced in diffusion. Some ten years ago it might have seemed that it was in these properties, which are a measure of the free path, that the key to the riddle of molecular interaction was to be found. To-day, one is inclined to feel, they have been overemphasised when such a subject as the law of equipartition of energy is given only a couple of pages, and the fundamental problem of the reason why it breaks down is not considered at all. In particular, a statement (pp. 32-33) that "it is unnecessary and futile to endeavour to establish the law of equipartition of energy on assumptions relating to the interaction of molecules, when the law follows directly from the fact that a molecule is continually radiating heat energy," should really not occur in a modern book intended for university readers. The statement entirely begs the question of defining the temperature. The "fact," if such it be, should be established by more adequate proof than by a reference to the hot air rising from a surface, and the main point—namely, that the law which is represented as so obvious, in reality does not hold—should be mentioned. Far from being "unnecessary and futile," it is one of the most urgent problems in physics to examine why a law which can be proved to be a necessary consequence of the most general assumptions in dynamics should not hold in actual practice.

Apart from these and allied problems—*e.g.* the chemical constants of substances and the change in the ratio of the specific heats of hydrogen at low temperatures—the kinetic theory is admirably treated. Even the kinetic theory of electrons in metals is developed, though it is to be regretted that the essential fallacy of treating these as a perfect gas is not emphasised, and the uninitiated reader is left to believe that there are $2\cdot10^{24}$ free electrons per unit volume, when such a number would involve a specific heat about fifteen times as great as is actually observed.

In spite of these omissions, however, the book is certainly to be recommended, especially to those who are interested in free path phenomena, although these alone are scarcely able to throw light on the process of molecular interaction until the quantum problem has been solved.

A Monograph on Margarine.

Margarine. By W. Clayton. (Monographs on Industrial Chemistry.) Pp. xi + 187. (London: Longmans, Green, and Co., 1920.) Price 14*s.* net.

CURIOUSLY enough, the introduction of artificial butter dates from the early days of the Franco-Prussian War, and, while the butter and lard substitute industry has been carried on on a small scale since then, margarine, as an industry, became of prime importance to the nation only during the Great War. Many important improvements have been made, and these are set forth in the book under review.

In the first part a brief account of the oils employed in the manufacture of margarine is given, and some less known oils, such as Cohune oil, tea-seed oil, and Babassu kernel oil, are mentioned. Later chapters deal with hydrogenised oils, and for the present writer's views on this subject reference may be made to the notice of Dr. G. Martin's book on "Animal and Vegetable Oils, Fats, and Waxes" in NATURE of September 9 last.

Interesting chapters treating bacteriologically of the pasteurisation of milk and of the production of "starters" for the ripening of the milk follow. A brief description of the actual manufacturing operations of forming an emulsion between the mixed oils and the milk is then given. The theory of emulsification is, of course, very well stated, as Mr. Clayton is an authority on colloid chemistry. His opinions are therefore of great interest, and when they have been digested by technical chemists, very valuable results should arise in their industrial application.

In regard to the causes of rancidity in fats, Mr. Clayton seems inclined to accept the view that they result from bacterial actions on the glycerides. We believe that rancidity is due, in the first instance, to the formation of super-oxides of the unsaturated glycerides and their subsequent decomposition with the production of aldehydes and aldo-acids by the action of moisture, aided, perhaps, by the growth of micro-organisms. It would be out of place, however, to develop these views here.

The chapters on the analysis of margarine, etc., contain little to comment upon, except that enough stress is not laid on the iodine value and the hexabromide tests. In the portions dealing with nutritional chemistry the author gives a welcome review of the work done and of the opinions held by medico-chemists on the so-called "vitamines," "food hormones," "accessory food factors," "sitacoids," and "advitants." These are "substances" which are supposed to be present in, and give digestibility to, natural fats, and to be absent in prepared or artificial fats. The medico-chemist has thus named them. As Goethe says:—

> Denn eben, wo Begriffe fehlen
> Da stellt ein Wort zur rechten Zeit sich ein.

Blessed words! Not one of these so-called substances has been isolated, and no one knows their chemical formulæ or characters. Why a "substance" and not a "condition" of a known substance—say, a peroxidised form of some fat? Mr. Clayton seems to see this, and that the whole matter needs consideration from the chemical rather than from the medical point of view, for he states that the term "vitamine" is wrong, as no nitrogen has ever been detected in any of these alleged substances.

The book contains thirty-five pages of bibliography, and a patents index, and should prove of great assistance to food and emulsion chemists.

HARRY INGLE.

Our Bookshelf.

Le Parc National Suisse. Par S. Brunies. Traduit par Samuel Aubert. Pp. 274. (Bâle: Benno Schwabe et Cie, 1920.) Price 12 francs.

THE map of the Swiss Topographic Survey, on the scale of 1 : 50,000, forms part of this attractive publication. The reserve, established by the Federal Government in 1913, occupies a mountainous district trenched by two tributaries of the Inn. The best approach is by Zernez in the Lower Engadine, and the carriage-road to the Münstertal passes across the park. The author's description, translated from the original German, is picturesque and vivid; but the features that appeal to the visitor trained in scientific pursuits are always kept in view. Special chapters deal with geology and natural history, and the studious revival of the local Latin dialect is recognised by the stress laid on "romand" names. Pronunciations and a list are considerately furnished, and the careful translator informs us that the pronunciations given are those used in at least one village—that of Sinuos-chel. Great praise must be given to the illustrations. Apart from the four exquisite photogravures of the scenery of the park, Mr. H. Pfendsack of Pontarlier has supplied vigorous line-drawings of animals and plants, in every case connecting the subject with its stern environment. Compare, for instance, his *Pinus montana* (p. 149), recumbent but undefeated, clutching at the rock, with the climbing birds enjoying themselves as *alpinistes* on p. 217. He represents with equal insight the family life of the ibex, which it is proposed to restore to its former haunts, and the prolific poppy growing from a heap of stones. The author has well represented the history of the Alpine overfolds by successive sections. It is a pleasure to possess his book.

G. A. J. C.

(1) *Easy Lessons in Einstein: A Discussion of the More Intelligible Features of the Theory of Relativity.* By Dr. Edwin E. Slosson. With an article by Albert Einstein and a bibliography. Pp. vii + 128. (London: George Routledge and Sons, Ltd.; New York: Harcourt, Brace, and Howe, 1920.) Price 5s. net.
(2) *From Newton to Einstein: Changing Conceptions of the Universe.* By Dr. Benjamin Harrow. Pp. 95. (London: Constable and Co., Ltd., 1920.) Price 2s. 6d.
(3) *Die Einsteinsche Relativitätstheorie.* By Prof. U. Kopff. Pp. 24. (Leipzig: Greszner und Schramm, 1920.) Price 1.50 marks.

(1) DR. SLOSSON gives us in his book a breezy account of what he calls the more intelligible features of the theory of relativity with popular illustrations of distorting mirrors, references to Mr. H. G. Wells's "Time Machine" and other scientific romances, diagrams purporting to portray a four-dimensional cube, and general good-humour—a book with which the absolute layman may amuse himself for a few hours.

(2) Dr. Barrow gives a more serious, but equally readable, summary of the development of physical science from the mechanical period of the eighteenth century through the electrical theories of the nineteenth to the present day. Here also the layman will find profitable reading.

(3) The little pamphlet by Prof. Kopff is a reprint of a lecture on the relativity theory to the Natur-historisch-Medizinischen Verein at Heidelberg in June, 1920.

Technical Handbook of Oils, Fats, and Waxes. By P. J. Fryer and F. E. Weston. Vol. i., *Chemical and General.* Third edition. (The Cambridge Technical Series.) Pp. xii + 280 + xxxvi plates. (Cambridge: At the University Press, 1920.) Price 15s. net.

THE changes occurring in the industrial situation have caused the authors to add a certain amount of matter, and to make a number of alterations in the text of the first edition, which was reviewed in NATURE of January 17, 1918. Another addition has been made in the form of analytical data inserted in the text, and a number of footnotes, chiefly giving references to original papers, are now included.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Name for the Positive Nucleus.

A NAME is wanted for the fundamental unit of matter, which is also the unit of positive electricity as at present known. The name "electron" is best limited to the unit of negative electricity, about which a good deal is by this time known. Less is known about the positive unit, but it appears to be the brick of which all atoms are built up, electrons acting as cement. Nearly all the mass belongs to the positive unit, and the simplest atom—namely, hydrogen—appears to consist of one positive and one negative unit electric charge. The heaviest atom known has ninety-two such charges, and among the chemical elements are all intermediate grades. Prout's famous hypothesis that every element was a multiple of hydrogen is thus, with some modification, being confirmed, though the unnamed unit is not exactly an atom of hydrogen, but the nucleus, the main substance, of that atom.

At the Cardiff meeting of the British Association Sir Ernest Rutherford suggested, or tentatively approved the suggestion, that the name "proton" should be applied to this hydrogen nucleus or unit of positive charge. To call it a positive electron is undesirable—that name might be assuming too much—for it is just conceivable that the progress of discovery may detach from the proton a positive charge more closely akin to the negative electron—in fact an image of it. (It is not clear why a positive unit should differ so markedly, as at present it does, from the negative unit.) But, whatever the proton's relation to positive electricity, and whatever its constitution may be, it seems undeniable that it is the most essential and massive ingredient in every atom of matter.

From the scientific point of view the name "proton" is therefore good, for it signifies a fundamental substance and conveys a suggestion of Prout. But from the literary point of view there may be some objection, and a name for the foundation-stone of the material universe ought to be capable of being used in poetry, as the word "atom" has been used. It would seem well, therefore, to ask for suggestions before any name is adopted and allowed to get into general use.

Added Later.—Before sending in the above explanatory note I consulted some men of letters, who will, I hope, allow their names to be mentioned, and who have made some excellent suggestions:

AMBRON, as an English version of *electron*, suited to the unit of positive electricity.

MERRON, a conventional modification of *μέρος*.

UR-ON, or something based on the root Ur-; or even UR itself.

PRIME, as a primordial substance irresolvable into factors.

CENTRON, as a nucleus round which things revolve.

HYLON, as the fundamental unit of matter.

Of these I personally prefer *Hylon*; it serves to convey a fact with a minimum of hypothesis; it is itself a convenient word, and it surely need not be regarded as too metaphysical. If its first syllable suggests a real, but painfully illegitimate, relationship to hydrogen, that may be for it or against it, according to taste. I find the word "proton" is not liked; it has been described as "used up and very dull." Wrong pronunciation may be hostile to "Ur," and, besides, it might be confused with the other end of the series (uranium), though otherwise it shares some of the advantages of the happily invented word "gas."

OLIVER LODGE.

The British Association.

THE correspondence in NATURE under this heading has been most instructive. The widely spread feeling that the Association fails as an organisation to promote the growth of the scientific spirit could not well be more definitely brought to light, particularly as many who are known to hold strong views have refrained from expressing them; unfortunately, moral indecision is fast becoming a characteristic of our class. It is all very well for the late secretary and the present holders of the office to hint that the recommendations cancel out; maybe they are different; nevertheless, excepting our dear old member, Father Cortie, who has the sense of humour on all occasions, everyone agrees that the Association does not touch the public.

The most serious contribution to the discussion, that of greatest import, is the frank statement by the secretary of the Press and Publicity Sub-Committee at Cardiff—for once a man who dares to give open expression to the views he has formed—that we were in no way worth what we cost the locality; he has voiced a whisper, not seldom heard at previous meetings, which has long weighed on the conscience of some members of the Association.

The least satisfactory letter is that of the two secretaries, who are merely apologetic, in no way constructive. The manner in which, in their opening paragraph, they quietly imply that they are "It" would be amusing were the issue not so serious. Majestically they tell us to send *them* our views and that *they* will consider them. No doubt—and consign them to the waste-paper basket, as of yore.

Even outsiders see that science is losing its influence. Dean Inge, in one of his recent outspoken addresses, pointed out that "a general revolt against the dictatorship of science had been the most remarkable tendency in modern thought. In politics the anti-scientific temper was rampant. The revolution which more than a hundred years ago guillotined Lavoisier, 'having no need of chemists,' was now proclaiming that it had no need of intellectuals of any kind. In Russia they had been tortured and massacred; in our own country they were ignored and despised."

Ephemeral writers such as Mr. G. K. Chesterton openly scoff at us and lead the public to believe that evolution is a theory of the past and eugenic doctrine moonshine. Their word is accepted, ours is not; the clown is ever popular, the comic actor always preferred to the tragic; if we will assume only the prophet's mantle we must expect to be stoned.

It is useless for Sir Ray Lankester to take such men across his knee and thwack them in his best grandfatherly style. The literary braggadocio is only to be silenced by showing him up as ridiculous; he is but playing a part—writing nonsense because it pays; it is his trade and we must not blame him but blame the school in which the class is bred and has its being. We are too conceitedly serious, hopelessly narrow in our outlook, too self-centred to be alive to public needs—so individualised and so hopelessly jealous among ourselves that we will not co-operate and organise our forces. Nothing could show this more clearly than the way in which the Royal Society has sacrificed its opportunities during the war period by failing to bring all its fellows together and thus make our corporate influence felt. Little wonder that science is being more and more excluded. We are talking of government by public opinion but real opinion cannot be made public. The columns of the Press are not open to any serious discussion from our side; the books we write are not understood even by ourselves. Owing to excessive specialisation we are becoming less and less able to express and protect ourselves, less interested in stating our case in any broad way; what is worse, too selfishly immersed each in his own narrow occupation to consider the general interest: an we bé not careful the position won for us by the protagonists of the past will soon be lost to us.

Our failure is as window-dressers; we have not displayed our goods in the right manner. When a business is a failure, the only way to re-establish it is to reconstruct the management. That we have yet to learn this elementary truth is clear, however, from the recent appointment to the treasurership. A young man should have been found for the office, gifted not only with scientific experience but also with some breadth of outlook, some understanding of men and affairs; instead, a senior member of the Association has been chosen.

If a senior were desirable, no better choice could have been made; but I believe my old friend Principal Griffiths will not mind my saying that he is saved from inclusion in my class of elderly amiables only by the fact that throughout the war he was conspicuously active in his efforts to bring the value of scientific method before the public; he is far too soft-hearted to face the exigencies of the present situation.

The council must cease to be all but entirely an old or even an elderly man's show; responsibility must be forced upon the younger generation of active workers.

The secretaries obviously have no policy; new men must be chosen at the earliest possible date—I trust on the three years' hire system advocated in my former letter, so that the different subjects may be cared for at shorter intervals.

The real question at issue is: "How are we to get at the public?" To do this we must look beyond the meetings and in some way arrange for the preparation and issue each year of a few authoritative tracts dealing with bedrock problems in language that can be understood by all. Subjects can easily be found; under E alone enough are to hand—*Economics*, *Education*, *Energy*, *Entomology*, *Eugenics*, *Evolution*. Nobody believes in these, few know what the terms comprise, yet the future of our race depends on an intimate understanding and application of the doctrines they cover. A great work would be done by the Association if only, by real discussion not the dreamy, introspective twaddle of Section L, the nonsense now spoken of as education were reduced to terms of wisdom.

HENRY E. ARMSTRONG.

The Constitution of the Elements.

SINCE my last letter under the above title in NATURE of July 1, experiments have been made with a few more elements. The work has been progressively more and more difficult, for it has not been easy to find volatile compounds suitable for use, and when found the very objectionable chemical properties of some of them have led to experimental trouble and disappointing results. Thus selenium, tin, antimony, and tellurium have so far yielded no result of any value.

Fortunately, iodine (atomic weight 126·92) gave definite and unmistakable effects. It proves to be a simple element of mass 127—a result satisfactorily confirmed by a single line at 142 corresponding to CH_3I, the vapour used in the experiments. This result has particular interest in view of the recent work of Kohlweiler (*Zeit. Phys. Chem.*, vol. xcv., 1920, p. 95), who deduces five isotopes of iodine, all of even integral atomic weights, and claims to have effected a considerable separation of these by diffusion.

Owing to the kindness of Prof. Collie and Dr. Masson in providing me with a sample of gas rich in xenon, I have been able to identify two more probable isotopes of that element and obtain trustworthy values for the atomic weights of the five already found. The provisional figures given for these turn out to be too low. The values quoted below were obtained from the position of the second-order line 64·5. They should be trustworthy to about one-fifth of a unit.

Additional evidence on argon leads to the conclusion that its isotope 36 need no longer be regarded as doubtful.

The following table gives the results to date:

Table of Elements and Isotopes.

Element	Atomic number	Atomic weight	Minimum number of isotopes	Masses of isotopes in order of their intensity
H	1	1·008	1	1·008
He	2	3·99	1	4
B	5	10·90	2	11, 10
C	6	12·00	1	12

F. W. ASTON.

Cavendish Laboratory, November 30.

Solar Variation and the Weather.

IN NATURE of July 29 last (p. 678) appears an article by Dr. C. G. Abbot on solar variation and the weather, in which reference is made to the use of solar data by the Argentine Weather Service. Drs. Nansen and Helland-Hansen have also found some interesting correlations between the variations of solar radiation as measured by Dr. Abbot and variations of temperature and pressure in Norway.

As other investigators will no doubt be tempted into this field, I feel that it may be of interest to give briefly a summary of our latest results and conclusions. These conclusions are based on the study of an immense amount of data from various parts of the world, the results of which will be published in due time.

The first and most striking result is that the solar radiation exerts a cumulative effect on the atmosphere so that prolonged periods of high or low solar radiation have a much greater response in atmospheric action than shorter periods of greater intensity. Thus a deviation of 5 per cent. from the average radiation of short duration might not produce so great an effect as a long period, with a mean deviation of 2 per cent.

The second result is that as the sun changes from one hemisphere to another the effect on the weather changes, so that in the hemisphere where the sun is nearly vertical the pressure falls over the land surface and rises over the water surface, while the opposite effect is found in the other hemisphere. This effect I take to be a proof that a considerable part of the increased solar radiation reaches the earth's surface and intensifies the normal effect of absorption of solar radiation by the land. There are, however, clear indications that a considerable part of the increased solar radiation is absorbed by the upper air and gives origin to atmospheric waves which, if they are not the determining cause, at least are very influential in determining the discontinuities referred to recently in NATURE by Prof. Bjerknes.

These atmospheric waves are of a complex nature, and for this reason the correlations with solar changes are best seen by separating the solar and weather changes into shorter and longer (or slower) waves.

By taking averages of ten days we found for 1916 correlations as high as 84 per cent. with certain Argentine stations, and correlations exceeding 80 per cent. in later years. The shorter waves do not give such high correlations, apparently for several reasons, the most important, perhaps, being that there are still some errors in the solar values due to the difficulties of eliminating the effect of changing transparency of the air while the solar observations are being made.

This difficulty has undoubtedly been greatly diminished during recent months by the use of the pyranometer, which enables the observers to get measurements of the solar heat from a single bolograph. Certainly since this method was begun the correlations of the solar variations with atmospheric waves have increased. Another difficulty appears to be that while the waves start from definite centres of action, these centres shift position to some extent, so that the time interval of the effects following solar changes is variable, and this variability is of greater importance in the shorter waves.

The prolonged effects following unusually high or low values of radiation shown by Dr. Abbot's curves, reproduced in NATURE, I believe to result from the normal sequence of events on the surface of the sun. After a marked excess or defect of radiation there is likely to follow a similar deviation from the normal after an interval of ten to thirteen days.

This result I believe to arise from the fact that when there is a marked outbreak of heated solar gases on the edge of the sun, where absorption is normally great, the total radiation is more intensified than when the outbreak is near the centre. If the outbreak is near the edge it will be carried by rotation to the opposite edge in from about eleven to nineteen days, according as to whether the position is on the east or west edge.

In the same way cooled gases produce their greatest absorbing effects when near the edge of the sun, and there is the same tendency to repeat. These effects also tend to repeat themselves after a solar rotation, but in that case the interval is so long that marked changes have usually occurred. However, these repetitions are sufficiently numerous to make it practically certain from the length of the rotation that the conditions causing the marked deviation from normal are in the region of the prominences, and not in that of the sun-spots, which have a period of about twenty-seven days.

These studies of the relations between solar changes and the weather have been in progress in the Argentine Meteorological Office for several years, so that when a station of the Solar Physics Observatory of the Smithsonian Institution was opened in Chile, arrangements were made between Prof. G. O. Wiggin, director of the Argentine Weather Service, and Dr. Walcott, director of the Smithsonian Institution, for the transmission of the solar radiation measurements by cable to Buenos Aires and for their use so far as possible in weather forecasting. To this work Prof. Wiggin and the assistant chief have given enthusiastic support, and through their efforts, and as a result of a growing interest in the subject in Argentina, the Legislature has recently appropriated some 25,000 pesos for the installation of a solar observatory in Argentina.

The forecasts are made for a week in advance by publishing estimated temperatures for each day, and also forecasts of expected rains. With increased experience there have been steady improvements and an increasing demand for the forecasts by commercial interests.

There are many complexities which remain to be solved, and perhaps some which can never be solved, but I believe that a distinct advance has been made in forecasting, and the progress is too far advanced to be turned backward. One of the greatest difficulties is the inversion of the solar relation with the season, and occasional inversions for other reasons not yet clearly understood.

Heretofore, most of the studies by others in regard to the relation of solar changes and atmospheric phenomena have been in reference to the sun-spots. Dr. Abbot's observations indicate clearly that there is a change of solar radiation corresponding to the eleven-year sun-spot period. The radiation increases with the increase in spottedness, but this change is of relatively small importance compared with shorter changes of greater intensity.

Sir Norman Lockyer suggested some years ago that there were weather changes due to solar changes other than the eleven-year period, and brought evidence to show that a period of about four years in the outbreak of prominences caused atmospheric changes having the same period. But solar radiation shows a variability far greater than is indicated by the observations of prominences, and the high value of the correlation between these and the weather which we have found for the Argentine and for other regions of the world leads me to believe that these changes are the chief, if not the only, cause of weather changes as distinct from the well-known diurnal and annual periods.

Oficina Meteorológica Argentina.

The Physical Meaning of Spherical Aberration.

THE nature of the distribution of light round the axial focus of a lens is a problem which has frequently been attacked mathematically. It has been quite successfully solved for points in the principal focal plane of an "aplanatic" lens when the intensity is found to depend on functions of the form (assuming Huygens's principle)

$$\text{Intensity} = \text{const} \times J_1^2\left(\frac{2\pi k}{\lambda} \cdot \frac{a}{R}\right),$$

where J_1 is the Bessel function of the first order, R the radius of the wave-surface at the lens, a the semi-aperture, and k the distance of the point from the axis. At present it has not been found possible to give an expression for the light distribution in the presence of spherical aberration, or away from the focus, which can be physically interpreted in such a simple way. Prof. Conrady has been able, however, to determine the distribution numerically (Monthly Notices, R.A.S., vol. lxxix., No. 8) in a series of simple cases by mechanical quadratures which give the value of the integral

$$I = \text{const} \times \int_{a=0}^{a=a_1} \{J_0^2(\alpha a)\cos^2\eta_a + J_0^2(\alpha a)\sin^2\eta_a\} d(a^2),$$

where

$$\alpha = \frac{2\pi k}{\lambda R},$$

η representing the phase which is supposed to vary in a spherical reference-surface by an amount depending on the spherical aberration. Prof. Conrady assumes a series of likely cases for phase distribution. No analytical expression for η can be obtained for any but the simplest optical systems, but empirical expressions can easily be derived from the result of trigonometrical ray tracing or Hartmann tests in the most complex systems, thus enabling the truth of the numerical results for light distribution to be checked experimentally. The value of

$$\eta_a = \frac{2\pi}{\lambda} \int_0^a \theta da \text{ (very nearly)},$$

where θ is the angular aberration derived from the calculated or observed lateral aberration or lateral intercept due to displacement from the centre of the spherical reference surface.

It is not too much to say that the thorough solution of the problem is of the greatest importance in the study of the performance of optical instruments. In order to search for the actual phenomena predicted by Prof. Conrady in theoretical cases, and further to explore the subject, I have recently carried out a critical examination of the image of a very small source of light (a fine "pinhole" in a silver film) produced by a microscope objective having excellent spherical correction, and for which the curves, glasses, etc., were known. The spherical aberration introduced by varying the tube-length can thus be calculated for any conditions. A nearly linear relation was found between the phase difference of the paraxial and marginal rays at the marginal focus and the reciprocal of the tube-length.

As a check on the calculation, I was able to devise a method of performing a test on the microscope objective very similar to the well-known Hartmann test employed for telescope object-glasses. By this means the properties of the objective became well known.

The changes in the distribution of light at the best focus in the presence of varying amounts of spherical aberration have been examined quantitatively, both visually and photographically. A perceptible loss of light from the central disc, estimated at 20 per cent., occurs when the residual aberration at the best visual focus amounts to 0·25λ. Such light is scattered into the surrounding field; it does not appear in the first bright ring at this focus. The sizes of the rings in the diffraction pattern at the best visual focus do not depart measurably from the theoretical values in the presence of residual aberration amounting to 0·6λ at the focus where there is least confusion of phase.

The "out of focus" appearances present many points of great interest. It appears that the successive bright rings retain a marked individuality, but suffer periodic variations in brightness and "thickness." This causes the dark rings between them to suffer corresponding variations in "darkness" and in radius. Under a high magnification the familiar broad, dark diffraction rings which appear to grow in the expanding "out of focus" disc are found to grow as the result of this periodic motion of the smaller dark interference rings, the whole action resembling that of a model to illustrate the propagation of the compression waves of sound.

If, when the aberration is a minimum, we go sufficiently far out of focus to introduce a path-difference between marginal and paraxial rays, $dp = 0{\cdot}5\lambda$, on either side of the focus, we find that the first dark ring has nearly filled with light. At about $dp = 1\lambda$ the central disc has lost all its light, and the first bright ring is at a maximum. At about $dp = 1{\cdot}5\lambda$ the central disc has again reached a maximum, the first ring is at its minimum, the second at a maximum, and the third nearly equal to the second. We thus see the first broad, dark diffraction ring between the central disc and the annulus of light formed by the second and third bright rings. So the various changes progress, the location of the successive bright rings being given fairly nearly by the ordinary theory. When, however, a definite amount of *aberration* is introduced, sufficient to cause a residual variation of phase of 0·5λ at the best focus, the changes are violently dissimilar on the two sides of the focus—a fact which is fairly well known. On one side there is a quick dissolution of the central concentration into a mere haze, while on the other a bright and well-formed ring system is found in which the broad diffraction rings spread out with much the same action as before, except that the periods of the variations are altered from those in the "no aberration" adjustment. Further, on this side of the focus, as was suggested by Prof. Conrady's numerical results, a central concentration persists which diminishes considerably in size as compared with the "best focus" disc, but remains brighter than the rest of the ring system up to a path-difference $dp = 3\lambda$—a displacement in the actual focussing point of 7 mm. in a total tube-length of 23 cm. It can easily be seen that this effect is quite capable of rendering possible instrumental performances, so far as resolving power alone is concerned, far in excess of any value possible in the absence of spherical aberration, although this would be a perfectly legitimate conclusion only for such cases as that of a double-star resolution by a telescope objective. A fairly complete set of photographs to illustrate the various appearances has been made. These have been measured and examined for the purpose of intensity determinations.

The importance of these matters lies in the determination of the effects of aberration, expressed in ray intercepts, on the distribution of light in the image, as the distribution suggested by ray concentration is often nothing approaching the truth. The "out of focus" appearances, too, are of great importance in dealing with "roundness of field." It is possible, in the light of such results, to form ideas as to legitimate tolerances in design and manufacture.

The investigation, to become complete, must be extended to other types of aberration, but it is hoped shortly to publish a complete account of the experimental work, of which the foregoing *résumé* may give an idea of the scope. The photograph herewith shows the ring system when a residual aberration, in the sense of "over-correction," of 0·5λ is present at the best focus, and when the reference plane is taken sufficiently far outside the focus to make the path-difference $dp = 1{\cdot}8\lambda$. The small central concentration and the persistent individuality of the interference rings are shown. The first "broad" diffraction ring is now formed through the low intensity of the first bright interference ring. The whole of the above work relates to nearly monochromatic light only.

A good many of the broad features of these aberration and "out of focus" effects can be explained without difficulty on the basis of the Fresnel zone theory, and it is hoped to include a short discussion of this kind in the paper. No more need be said at present except to direct the attention of the readers of Nature to the importance of the paper on "Star Discs" to which the reference is given.

L. C. Martin.

Imperial College of Science and Technology,
November 25.

"Phenomena of Materialisation."

In Nature of November 18 I find what purports to be a review of Dr. von Schrenck-Notzing's work translated by me under the above title. I have always supposed that a reviewer should tell the reader what the book is about. The review in question is headed "The Newer Spiritualism," and begins: "'Of making many books' on spiritualism 'there is no end.'" It states that the phenomena are alleged to have "a spiritistic interpretation," and refers to "the numerous photographs of her [the medium] sandwiched between faked spirit photographs." All this is thoroughly misleading. The book is not about spiritualism. Both the author (p. 30) and the translator (p. x) discard the "spirit hypothesis" as unnecessary. The author says that "it impedes and hinders in every way serious scientific investigation." The book contains no portrait of the medium, and not a single "spirit photograph," faked or otherwise. The photographs reproduced have not been manipulated in any way except Nos. 127, 128, 134, 136, 138, and 140, in which, for purposes of publication, the sex characteristics have been obliterated. These six photographs are marked "retouched," and the reason for retouching is stated in the text.

The review abounds with other inaccuracies. A red light was not always employed (see p. 306). Mme. Bisson did not "hop in and out" of the cabinet. The rare occasions on which she entered it are stated, as are all the other conditions, with what the reviewer calls "dreary uniformity," but with what the ordinary scientific reader would call conscientious accuracy.

The reviewer's challenge to "exhibit" the phenomena in London before well-known hostile critics is about as reasonable as to ask a performing mouse to exhibit its tricks before an audience of hungry cats. The psychological element would probably produce similar inhibitions in both cases. The phenomena are nearly as rare as the fall of a meteorite from the sky, and nearly as spontaneous as the production of biological "sports." They cannot, therefore, be produced before a massed audience. It is useless to think that any living individual is eminent enough to carry a general conviction of the reality of the phenomena, even though he be personally convinced. The only resource is to take the phenomena as and when they come, to record them carefully, if possible by photography and other instrumental means, and to make the experimental conditions gradually more rigid until we can only conclude that we are face to face with a new set of biological phenomena exhibiting the known powers of the human organism in an intensified and much accelerated form. And this is precisely what Dr. von Schrenck-Notzing has done.

E. E. Fournier d'Albe.

It will be well to deal with Dr. Fournier d'Albe's charges against my accuracy *seriatim*:

(1) "Both the author (p. 30) and the translator (p. x) discard the 'spirit hypothesis' as unnecessary." I might have made this clearer, but the repudiation is not easy to reconcile with the contents of a book crammed with references to occult phenomena, as, *e.g.*, mediumistic, psychic, and telekinetic.

(2) "The book contains no portraits of the medium, and not a single 'spirit photograph.'" This is an amazing statement. There are 225 illustrations. Of these there are 13 "drawings," so-called; all the rest are flashlight photographs of the medium (if not, then of whom?) in various attitudes, a large number showing the teleplasma issuing from her mouth, etc. There are 20 flashlight photographs—"phantasms" they are called—of dead and living people. Among the former Mme. Bisson recognised the features of a deceased nephew, Georges Thurner, and also of her husband, who died in 1912.

(3) "A red light was not always employed (see p. 306)." "All the sittings took place in a red light, so that during the four years there was not a single dark séance" (p. 21). The translator may be left to reconcile this statement with the exception to which he gives the reference.

(4) "Mme. Bisson did not 'hop in and out' of the cabinet." Probably she neither hopped nor skipped, but her visits to the cabinet were frequent enough to arouse suspicion as to collusion with a medium over whom she had "absolute control" (p. 59). Dr. Fournier d'Albe does not appear to have been present at the sittings.

(5) "The reviewer's challenge" cannot be accepted because the phenomena cannot "be produced before a mixed audience. . . ." "We are face to face with a new set of biological phenomena." So long as those who assert their belief in teleplastic exudations from the body and in the genuineness of photographs of the dead refuse to submit these "new biological" phenomena to the conjoint judgment of men of science and conjurers, they must not be surprised that their so-called "evidence" carries no weight save among the credulous.

The Reviewer.

Higher Forestry Education for the Empire.

A correspondent has sent us some remarks upon Prof. Stebbing's letter dealing with forestry education in Nature of December 2, but he has omitted to give his full name and address. No use can, therefore, be made of his communication.—Editor, Nature.

Automatic Printing of Wireless Messages.

ONE of the recent developments in wireless telegraphy, which, as we have already announced briefly, was demonstrated by Mr. A. A. Campbell Swinton during his address on November 17 to the Royal Society of Arts, is the automatic printing of wireless messages in roman type. Several systems of printing telegraphy are in use on ordinary lines, but the ingenious method designed by Mr. F. G. Creed is, we believe, the only one that has been adapted to the printing of wireless messages. High-speed wireless reception in various forms is being used to an increasing extent, and Morse code messages are recorded by optical and mechanical methods, as well as by an instrument analogous to a phonograph; but the actual printing of the words in ordinary type on a paper strip presents obvious and very great advantages.

That this result has been rendered possible of achievement is mainly due to the greatly improved methods of amplification of the signals received now available, which have enabled current impulses of sufficient strength for the actuation of the necessary relays to be obtained from the minute oscillations in the receiving aerial. Briefly, the system consists in a combination of the existing printing telegraph apparatus designed by Mr. Creed with the latest arrangements of groups of thermionic valves such as those devised by Capt. L. B. Turner and other workers, who carried on important researches in this direction during the war.

In the Creed system, whether for wireless or line transmission, the message is first translated into the Morse code by punching a perforated strip of paper in an apparatus, with a typewriter keyboard, so contrived that each key perforates the strip, by a solenoid operated mechanism, with the Morse equivalent of the letter in question. This strip, exactly as in the case of automatic Wheatstone working, is passed through the transmitting instrument, which sends out current impulses in the ordinary way in the dots and dashes of the Morse code. These, in ordinary telegraphy, go direct into the line, but in wireless working they are used to actuate a special transmitting contact maker, forming the equivalent of a high-speed relay-operated Morse key. Messrs. Creed and Co. have developed several sizes of transmitters for this purpose, including one suitable for very powerful installations, worked by an electro-pneumatic relay arrangement, and capable of dealing with as much as 300 kw. This has eight sets of contacts in parallel, each breaking under a powerful air-blast.

The waves at the receiving station are picked up by a thermionic-valve receiver, and considerably amplified by a number of valves in cascade in the manner employed in connection with other methods of recording. Current impulses are thus supplied to the relay magnet, forming part of the apparatus known as the Creed receiving perforator. This is of the same form as that used in line telegraphy, and, as employed hitherto for wireless reception, is worked by compressed air, although the company is now developing an electrically driven pattern on a mechanical principle, which is simpler and more compact, and dispenses entirely with compressed air. The Creed air-engine relay used in the instrument is a very interesting piece of apparatus. The tongue of the electrical part of the relay, instead of operating electrical contacts, actuates a very small slide valve controlling a little auxiliary piston, which moves the slide valve of the larger main piston. This, by moving in one direction or the other, drives forward one or other of the perforating punches, through a system of levers.

A very ingenious device arrests the motion of the strip while the holes are being punched. The strip from the receiving perforator, which is still in the Morse code, is the exact counterpart of that used at the transmitting station, with holes side by side to indicate dots and staggered to represent dashes, and a continuous row of holes down the centre for feeding purposes. The arresting action is effected by a plunger being thrust forward between the teeth of a spur-wheel on the shaft of the feed-sprocket. The holes are punched opposite each other if the second punch moves forward soon enough after the first for this wheel not to have advanced a whole tooth pitch, so that the arresting plunger, in reaching the bottom of the space between the teeth, really brings the paper back a little way. On the other hand, if the wheel has advanced by a whole tooth pitch or more, the plunger engages in the next space, and the second perforation is advanced beyond the first. A Creed receiving perforator is seen in the centre of Fig. 1.

The perforated strip is then passed on to the Creed printer. The great feature of this remarkable piece of apparatus is that it forms an automatic typewriter controlled entirely by the position of the holes in the perforated strip, and translates Morse code into printed characters. It is impossible here to do more than to indicate the general principle on which the instrument works, although it is on the perfection of the design of details that much of its success depends. In Fig. 1 the strip from the perforator is seen passing direct to the printer, and a printer by itself is shown in Fig. 2.

The perforated paper strip is fed past a group of spring selecting needles, ten on each side, and when it is momentarily at rest with the portion corresponding to a letter opposite the needles, a certain number, forming a pattern corresponding to the letter, protrude through the holes in the strip. Each needle which has thus advanced causes, in a way indicated later, a change in the position of one of a pack of thin steel strips or sliding valve plates. These valve plates lie between two fixed perforated plates, and are themselves perforated in such a way that the position assumed for each combination of the selector

FIG. 1.—Complete receiving-printing apparatus, including receiving perforator with relay and printer.

needles corresponding to a letter in Morse on the strip causes coincidence of the perforations at one point only, so that there is a clear aperture through the whole pack in a position corresponding to a letter. The bottom plate is supplied with compressed air at the moment in the cycle of operations corresponding to the printing of a letter, and each aperture in the fixed top plate communicates with a small cylinder, in which moves a piston actuating one of the type bars, through levers like those of an ordinary typewriter. Thus a letter is printed corresponding to the position of the coincidence of the valve-plate apertures.

The arrangement whereby a variable feed is given to the strip, according to the length of the letter, is combined with that for actuating the valve plates in accordance with the selection made by the needles. A reciprocating feed-rack is provided, which, when required, can gear into a spur-wheel on the same shaft as the feed-sprocket. The length of its downward travel while out of gear depends upon the point where it is arrested by the projection of one of a group of spacing levers. Normally, these levers are pushed out of the way by the selecting needles, but where neither of a pair of selecting needles advances—*i.e.* where there is a space signal—a space lever continues to stand out, thus limiting the movement of the rack to the length of the letter. A sideways movement is then given to the rack, putting it into gear and causing the perforated strip to feed forward, by exactly the length of the letter just dealt with, during its return journey. Each selecting needle, as it advances, causes a hinged piece on the corresponding valve-plate extension to move forward and to form a shoulder by the side of the feed-rack, so that the sideways movement of the feed-rack is also the actual cause of the shifting of the selected valve plates. It was mentioned above that there are only ten valve plates, whereas twenty selecting needles are provided. It is only the lower group of ten needles that controls valve plates, but the remainder are required to actuate spacing levers. Although more selecting needles may pass through the strip than those corresponding to the letter in question, only the proper number of slide valves are acted upon by the rack, on account of the limitation of its travel by the spacing levers. There are several other features, including the method of withdrawal of the selecting needles and the timing of all the various operations by means of cams, which we cannot dwell upon. The whole apparatus, including a small attached air-compressor, is driven by an electro-motor, so that no external source of compressed air is required.

FIG. 2.—Creed type printer translating from perforated Morse strip.

Messrs. Creed and Co. have also developed an improved form of printer, in which compressed air is dispensed with, and the type characters are mounted on a circular disc and hit from behind by a little selecting hammer which is caused to stop at the part of the revolution corresponding to a letter by a circular group of selecting levers. This form of the apparatus is much more compact than the original instrument, and has a much higher printing speed; but we understand that it has not yet been adapted to wireless reception.

The Creed system with compressed-air working, as adapted to wireless reception, is capable of a speed of transmission of about 180 words a minute, which is in excess of the speed of the printer; so that, in order to obtain the full capacity, two printers would have to be installed for one receiving perforator. The improved printer, however, will be capable of keeping up with the receiver, even in its improved form, and will be able to deal with something like an increase of 50 per cent. in the speed of transmission. Apart from considerations of traffic, high transmission speeds present advantages in that there is more chance of the message being completed without interruption by atmospherics or other extraneous effects. Very successful experimental working has been carried out between Cologne and the War Office station at Aldershot, and a wireless printing equipment of this kind is to be adopted between Brussels and a large station in the Congo district.

The New Oilfield of Northern Canada.

By W. Jones.

CONFIRMATION has now been received from Canada of the news that an important oil-well has been obtained in the North-West Territory of Canada. The full significance of this event is only gradually being realised by the public. It is probable that this is the commencement of the development of the largest oilfield in the British Empire—possibly one of the largest in the world.

For several years it has been known that geologists had found a land of much promise in the north, but until now, owing to the difficulties of transportation, no drilling operations had been attempted. The well, which is situated on the banks of the Mackenzie River, 48 miles beyond Fort Norman, within a few miles of the Arctic Circle, is about 1000 miles N.N.W. from Edmonton. It is 1300 miles journey by water beyond the northern limit of the railroads. This is the "farthest north" oil-well in the world, and is some 500 miles distant from any previous drilling. (The nearest producing oil-wells are those in Alaska.)

Little detailed geological information about this part of the North-West Territory is available, but it will be remembered that a geological exploration of the Mackenzie River basin was conducted by a party of English geologists, led by Dr. T. O. Bosworth during the year 1914, on behalf of a Canadian syndicate. On the return of the expedition it was reported that a great oilfield region had been determined. At that time much interest was aroused by the discovery, but, owing to the war, less attention was paid to the prospects than they would otherwise have received. The present development is the long-delayed sequel, for, according to the particulars now received from Canada, the well is located on the oil-claims which were "staked" by the Bosworth expedition. These claims have since been acquired by the Imperial Oil Co., the geological department of which has been headed by Dr. Bosworth for a number of years.

The drilling machinery was sent north in 1919, and the well has been drilled on the site which was chosen in 1914 for the crucial test. The drillers stayed at their post throughout last winter, and the actual drilling commenced in the spring of this year. In the first 200 ft., useful quantities of a very high grade oil were struck, and at 800 ft., according to the report of the drilling party, the oil gushed up from the 6-in. casing in a column which rose 15 ft. above the top of the derrick. After half an hour the drillers capped the well, so that the oil may be preserved until storage tanks can be constructed. Until that time the well's exact yield will not be measured, but it is probable that it will produce a thousand, and possibly several thousand, barrels of oil a day.

According to the brief statement made in 1915 by Dr. Bosworth to the Institution of Petroleum Technologists (Journ. Inst. Pet. Tech., March, 1915), and also in the *Petroleum World* (February, 1915), abundant seepages of oil were found throughout a very large region occupied by the Devonian rocks, and "in that region all the geological evidences of oil conspicuously occurred." The source of the oil was a thick deposit of "black bituminous shales and limestones, which cover an area of enormous extent." "In some places the black shales were actually undergoing combustion at the present time, and in several places oil was seeping out into the water for distances of several miles." The structure also was favourable, for the region is traversed by a system of mountain building anticlines. In Dr. Bosworth's opinion "the discoveries which had been made were of the greatest importance," and "fields of the utmost promise had been marked out, bearing all the indications and evidences that an unexploited field could be expected to show."

The foregoing remarks, together with the splendid result of the first test well, are significant. On studying a geological map of North America it will be seen that the Devonian formation of the Mackenzie River covers a very large area, extending for hundreds of miles along the direction of the river. In the reported words of a geologist who accompanied the drilling party this year, "the biggest oilfield in the world is what has now been opened in the north."

Before this great oilfield can be made commercially profitable there are, of course, many difficulties to contend with, especially the long distance from civilisation, the severity of the Arctic climate, and the lack of adequate transportation. But as these obstacles did not prevent the exploitation of the gold in Klondike, we need have little fear but that this precious fluid in the Mackenzie valley will be won.

Several of the Canadian Geological Survey Memoirs describe the Mackenzie River district, though they do not enlighten us much on the subject of petroleum, which was the special object of the Bosworth expedition. The most interesting of these is the report by Mr. R. G. McConnell, published in 1891, which mentions the bituminous rocks and pools of tar and oil, which he observed in many places. Memoir 108, on "The Mackenzie River Basin," by Messrs. Charles Camsell and Wyatt Malcolm, which appeared in 1919, also cites particularly the oil indications which Mr. McConnell had found, some of which had been noticed also by Sir John Franklin a century ago. This official memoir is very guarded on the subject of petroleum, and does not afford great encouragement to oil prospecting on the Mackenzie; but it is a comprehensive summary of the previously established facts, together with many valuable observations, old and new.

During the next few months there can be little or no progress made with the development in this frozen land, but doubtless many preparations are afoot, and next spring will see an unprecedented migration of oilmen to this northern clime.

Industrial Research Associations.

V.—The British Portland Cement Research Association.

By S. G. S. Panisset.

ALTHOUGH the Portland cement industry had its origin in this country, the chief developments have occurred elsewhere, and the greater part of the manufacturing plant now in use is either of foreign production or a close copy thereof.

It may be disputed that this position has arisen from the absence of organised research in this country, but it is certainly true that the amount of scientific investigation in the British Portland cement industry has been insignificant compared with the work done in the United States and on the Continent.

With these circumstances existing, it is clear that the British Portland Cement Research Association is a needed institution, and it is some comfort to know that its arrival is not too late to be effective. The extent of the field of research still awaiting exploration is such that no agreed answer can be given to the fundamental questions, "What is Portland cement?" and "What happens when cement sets?"

In spite of the extensive research that has been conducted in the United States by Government institutions and by universities, the real nature of cement, and the chemistry and mechanism of its setting, are still matters of controversy, owing to the lack of concrete evidence.

The manufacture, in fact, is still in the empirical stage, based solely upon the knowledge that a mixture of calcareous and argillaceous materials containing about 76 per cent. of carbonate of lime will, when heated to incipient vitrefaction, yield a product which on grinding has pronounced hydraulic properties. Whether the hydraulic effect is due to the presence of simple silicates and aluminates of lime, whether complex ternary compounds exist, or whether a part of the lime is uncombined and in the state of solid solution, are all problems which must be solved before it can be claimed that the best possible constructional material is being produced.

In connection with the setting of cement, it is still undecided whether this is due to colloidal or to crystalline action, and the manufacturer is accordingly in the dark as to whether he ought to be aiming at the production of colloids or of crystalline bodies to produce the best results.

The composure of manufacturers has now and again been disturbed by predictions that cement can be made from a mixture containing only two-thirds the conventional proportion of lime, and again that the stage of incipient vitrefaction now produced in rotary kilns can be improved upon by adopting blast-furnace methods and carrying the temperature to melting point. From the point of view of scientific knowledge the manufacturer is unable to deny that such statements are within the range of possibility, and hence there is always the fear that more than half the present cement-making plant may be rendered obsolete by new discoveries.

This is not a happy position for an industry, especially when such a discovery is likely to be the property of those who have hitherto been foremost in research—namely, the foreign competitor—and in this connection the advent of the British Portland Cement Research Association is not a day too soon.

Again, if it be supposed that the present methods of manufacture are permanent, the fact has to be faced that the thermal efficiency of the kilns in use is seldom more than 50 per cent., and here is a field for research that may lead, upon cultivation, to a reduction in the cost of production. The importance of the matter to an industry consuming $1\frac{1}{2}$ million tons of fuel in a year can be readily appreciated.

It is obvious, therefore, that a very wide field lies before the British Portland Cement Research Association, and the scope both for scientific and for industrial research is ample warrant for the existence of the association for some years to come.

The British Portland Cement Research Association was incorporated in November, 1918, and had the advantage of being founded upon the research department of the two largest cement manufacturers in the country. This research department had been in existence for five years, and had gathered together an experienced staff and a valuable equipment of scientific apparatus, while the large amount of spade-work that had been done has proved of great value to the association. Both staff and equipment were taken over entire, so that no time had to be spent in organisation, and research was in progress from the first day of the association's existence.

The council of the association has addressed itself in the first instance mainly to the industrial side of research, and the chief activity has been the investigation of the thermal efficiency of rotary kilns. The basis of this investigation has been the fact that the consumption of fuel in an ideal kiln for cement calcination would be no more than 15 per cent., compared with the 30 to 40 per cent. consumptions which are prevalent in actual practice to-day.

Another prominent subject of investigation has been the mechanics of pulverising and grinding, and the importance of this will be realised when it is stated that, as a rule, the production of Portland cement involves reducing to powder three materials with a total weight three times that of the final product, the power so absorbed ranging from 60 to 150 h.p.-hours per ton of cement.

A feature of investigations of this nature has been the commercial scale upon which they have been undertaken, involving the presence of the research staff of engineers and chemists upon the factories of one or other of the members of the association, and this intimate connection with the practical side of the industry has been of value in preventing research becoming too academic and too far removed from practical issues.

The purely scientific side, however, has not been neglected, and in the laboratories of the association at Greenhithe researches upon the setting of cement, the influence of raw materials upon cement, and other chemical subjects are in progress, while an experimental grinding mill has also been set up in the laboratory.

The aim of the association may be briefly summarised as an attempt to cheapen the production and to improve the quality of cement, and the achievement of this aim cannot fail to benefit the consumer while tending to stabilise the British industry.

The hearty co-operation of British manufacturers in this enterprise is shown by the fact that more than 90 per cent. of their number are members of the association.

Obituary.

SIR WILLIAM ABNEY, K.C.B., F.R.S.

ANOTHER of the conspicuous leaders of British science who rendered the latter part of the nineteenth century and the commencement of the twentieth so famous as a time of remarkable progress, and whose name was almost a household word throughout the land, passed away on December 2 in the charming and unique personality of Sir William de Wiveleslie Abney. Sir William Crookes, Sir Norman Lockyer, and now Sir William Abney—the recent months have indeed been heavy with fate for that glorious band of scientific workers, and the only consolation that these severe losses in the front rank leave with us is the knowledge that their great work was done, that their last paper was written with all their full mental powers, and that they passed away, at a ripe age truly, but before any failure of their great master minds became evident to the world at large.

Sir William Abney will ever be remembered, especially under his better-known earlier designation as Capt. Abney, for four things in particular: for his great services to the nation and to the cause of science in the Department of Science and Art at South Kensington; for his researches on the infra-red of the spectrum, leading on to his masterly use of the spectrum in regard to colour vision and colour measurement; for his development of photography into an exact science; and for his studies of the forms of ice and snow in the high Alps. Those of us who had the great privilege of attending his lectures on colour and its measurement at the Royal College of Science, where for many years he was occasional lecturer in physics, will ever regard those hours as among the most delightful and thoroughly enjoyable ever spent in a lecture-room. They were brilliant, not for what was said so much as for what was done, for the experiments were ever most elegant, beautiful, and even exquisite as regards the phenomena exhibited, and marked by an originality which was the direct outcome of a most original mind. It was a still greater privilege to be able to follow him into his research laboratory, and to see something of the most fascinating experimental work going on there, with the aid of his devoted assistant, Mr. Walter Bradfield, and which at frequent intervals resulted in a paper to the Royal Society, of which Sir William was elected a fellow so early as the year 1876.

Yet perhaps the most charming side of Sir

William Abney's personality was brought out during his annual summer visits to his beloved mountains. There, among the monarch peaks, glaciers, and snowfields of the Swiss, French, and Italian Alps, he was at his best, a most delightful companion, from whom one learnt something of value almost every moment, and by association with whom one learnt to appreciate the beauty and the "call" of that magnificent world, high up above the vain ambitions and struggles of the world below, in a manner which became one of the highest experiences of one's life. For Sir William was not merely a man of science; he was also both a philosopher and an artist.

He saw and realised the beauty of the natural world as few perceive it, and he had quite a gift of expressing it in water-colours, yet was never satisfied, because he alone understood in so unique a manner how utterly inadequately the pure colours of sky and sea, landscape, and the eternal snows of the Alps can ever be imitated in pigments. And the luncheons on the ice, high up above the Alpine valleys, or the after-dinner talks when the expeditions were over, with the congenial company of distinguished climbers, such as his old friends, Mr. Horace Walker and his sister, Miss Lucy Walker, Mr. Matthews, Mrs. Jackson, Mr. Eccles, Miss Venables, and M Loppé—these are all memories of Sir William in his happiest moments, when, with Lady Abney and Miss Janet Abney, and often other members of his family, the most delightful anecdotes and stories from his immense répertoire used to delight all within earshot.

Sir William was the eldest son of Canon Abney, of Measham Hall, Leicestershire, and was born on July 24, 1843. He was educated at Rossall, and became Lieut. R.E. in 1861, and Capt. in 1873. He was president of the Royal Astronomical Society from 1893 to 1895, and of the Physical Society from 1895 to 1897. He was also chairman of the Royal Society of Arts in 1904. He was created K.C.B. in 1900, and was Hon. D.Sc. and D.C.L. of several universities. He was Principal Assistant Secretary, Board of Education, from 1899 to 1903. Besides his very numerous scientific memoirs to the Royal Society and other learned societies, he is perhaps best known for his published books, the chief of which are: "Instruction in Photography" (1870), "Treatise on Photography" (1875), "Colour Vision," "Colour Measurement and Mixture" (1893), "Thebes and its Five Great Temples" (1876), "The Pioneers of the Alps" (with C. D. Cunningham, 1888), and "Trichromatic Theory of Colour" (1914).

The moment, however, is not one for the appraisement of so full a life of scientific work, for the loss of his many-sided delightful personality is too fresh upon us. It is rather of the kindly, genial, and altogether lovable man himself that we think, and deplore the fact that nevermore shall we see his burly form and jovial face, and hear his cheery words, ever full of inspiration to all that was highest and best.

A. E. H. TUTTON.

MR. WILSON HARTNELL, who died on November 10 in his eighty-second year, was well known in connection with his work on steam-engine governors. He was elected a member of the Institution of Mechanical Engineers in 1872, and his paper on automatic expansion gears, read in 1882, has been a mine from which hosts of engineers interested in governors have extracted theorems and data of great practical value.

SIR FREDERICK TAYLOR, BT., who died on Thursday, December 2, was born in 1847, and received his medical training at Guy's Hospital. He proceeded to the degree of M.D. at London University in 1870, and was university scholar in obstetric and forensic medicine; later he represented the university on the General Medical Council. Sir Frederick was appointed consulting physician to Guy's Hospital, and remained in close touch with that institution throughout his life; he was also physician to the Seamen's Hospital, Greenwich. In 1907 he delivered the Harveian Oration. His career reached its culminating point when he was elected president of the Royal College of Physicians, and had illness not intervened he would probably have been re-elected for a second term of office. Sir Frederick was the author of numerous contributions to medical societies and journals, although he is probably best known for his "Practice of Medicine," a standard work which has reached its eleventh edition.

Notes.

IT has been generally understood that the Water Power Resources Committee of the Board of Trade has for some time been considering the possibility of tidal-power development, with special reference to the Severn estuary. In view of this it would be of interest to know to what extent the scheme formulated by the Ministry of Transport has been influenced by the conclusions of that Committee. As outlined and illustrated in the *Times* of November 26, the scheme would appear to be open to certain weighty objections, and, in view of the large number of technical problems, alike in mechanical, electrical, and hydraulic engineering, which require to be co-ordinated and solved before any such scheme can be embarked upon with any certainty of ultimate success, there would not appear to be any likelihood of its materialising immediately. At the same time the prospects of the scheme, should it prove commercially and mechanically feasible, are so great that every endeavour should be made to have the matter investigated in the fullest detail by a strong technical and scientific Commission. As pointed out in NATURE of June 3 last, much still requires to be known on such questions as those regarding the effect of the proposed barrage on the silting of the estuary and on the general *régime* of the river, the best size and form of turbine and generator, the use of alternating- or direct-current generators and of geared or ungeared turbines, the maximum economic capacity of the installation, and the volume of water actually available in the case of such an estuary as that of the Severn under operating conditions. All these are problems to which existing data are inadequate to enable a complete answer to be supplied, but to which such experience as is available, augmented by some special experimental investigations, should be adequate to give a definite answer. Tempting as the scheme may appear, it would be wise to suspend judgment as to its possibilities until the report of some such Commission as is suggested is available.

In continuation of the article in Nature of April 1 last, p. 153, on the Tropical Agricultural College in the West Indies, it may be noted that a circular letter dated January 27, 1920, was sent out by the Colonial Office to Governors of West Indian Colonies directing their attention to the report of the Committee upon the proposed agricultural college, and to the advantages that would be likely to accrue to the Colonies from its establishment. It was pointed out that the West Indies had now the chance of creating an epoch in their economic history, especially as they are at present so prosperous that they might well hope to equal or surpass any similar institution on foreign soil. Much hard work and skilled direction will, however, be necessary if Buitenzorg is to be surpassed. The letter ends by demurring to the proposal that the Imperial Government should contribute half the cost, pointing out that the Colonies do not contribute to the cost of institutions in this country that are of value to them. Later telegrams announce that the vexed question of the site has been settled in favour of Trinidad, which Colony has now a great opportunity before it. The site has been selected on the Government farm at St. Augustine, about six miles from Port of Spain. The Governments of Trinidad, Barbados, Grenada, St. Lucia, St. Vincent, the Leeward Islands, as well as Bermuda, have offered financial support.

A considerable impetus should be given to electrical research by the incorporation under the Department of Scientific and Industrial Research of the British Electrical and Allied Industries Research Association, which is the outcome of the joint activities of the Institution of Electrical Engineers and the British Electrical and Allied Manufacturers' Association. Half of a guaranteed minimum income of 16,000*l.* per annum is to be contributed by the Department of Scientific and Industrial Research, which has also undertaken to contribute pound for pound against further manufacturers' subscriptions up to twice that figure. The association is in close touch with the British Engineering Standards Association and the National Physical Laboratory, and the council, which is under the chairmanship of Mr. C. H. Wordingham, includes seven representatives each of the Institution of Electrical Engineers and of the British Electrical and Allied Manufacturers' Association, with Prof. W. H. Eccles and Sir J. E. Petavel as representing the Department of Scientific and Industrial Research. The character of the work already undertaken gives some indication of the wide field which may be covered. This includes a comprehensive investigation into composite and fibrous insulating materials, porcelain, and mica, and inquiries into particular classes of apparatus such as mining switchgear. The present programme also includes investigations on sludging in insulating oils, the preparation of data for standard specifications for these and other insulating materials, and a research on the heating of buried cables. Arrangements are in hand for rapidly extending the programme of research, and all communications regarding the association should be addressed to Mr. E. B. Wedmore, secretary and director of research, at 19 Tothill Street, Westminster, S.W.1.

The British Music Industries Research Association has been approved by the Department of Scientific and Industrial Research as complying with the conditions laid down in the Government scheme for the encouragement of industrial research. The association may be approached through Dr. R. S. Clay, Northern Polytechnic Institute, Holloway, London, N.7.

The next meeting of the Chemical Society will be held on Thursday, December 16, at 8 p.m., in the lecture hall of the Institution of Mechanical Engineers, Storey's Gate, Westminster, S.W.1, when Sir Robert Robertson will deliver a lecture entitled "Some Properties of Explosives."

Sir J. F. C. Snell, member of council of the Institution of Civil Engineers and past-president of the Institution of Electrical Engineers, has been appointed by an Order of Council to be a member of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research.

Prof. J. Perrin (Paris) and Prof. C. Fabry (Marseilles) have been elected honorary members of the Royal Institution, and Prof. Arthur Keith has been re-elected Fullerian professor of physiology for a further term of three years. The Christmas course of juvenile lectures this year will be delivered by Prof. J. Arthur Thomson on "The Haunts of Life," commencing on Thursday, December 30, with The School of the Open Shore as the subject, and followed by The Open Sea, The Great Deeps, The Fresh-waters, The Conquest of the Land, and The Mastery of the Air.

On December 1 the Natural History Museum Staff Association held, by permission of the Trustees, the last of its scientific reunions for the current year. Many interesting exhibits of new acquisitions to the museum collections and other specimens of exceptional interest were shown in the board room, and in a darkened room close by Dr. E. A. Cockayne gave a demonstration of the remarkable fluorescent properties of certain moths and butterflies in ultra-violet light, the specimens used being drawn from the museum collection. Among the visitors present were Lord Rothschild, Lord Sudeley, Lt.-Col. A. W. Alcock, Prof. E. B. Poulton, Prof. J. H. Ashworth, Prof. A. W. Hill, Prof. A. Dendy, Prof. J. P. Hill, Prof. E. W. MacBride, Dr. J. W. Evans, Dr. W. D. Matthew (of the American Museum of Natural History), and M. F. Le Cerf (of the Muséum de l'Histoire Naturelle, Paris).

The weather for the autumn season in the several districts of the United Kingdom is shown in the Weekly Weather Report of the Meteorological Office for the week ending November 27. The period comprises the thirteen weeks from August 29 to November 27. Temperature attained its highest reading, 76° F., in the south-east of England, and the lowest shade temperature in England was 18° F. in the south-west. The mean temperature for the period was above the normal except in the eastern districts of England and in the Midland Counties; the greatest excess was 2° in Ireland. For the whole of the British Isles the mean was 51·1°. Rainy days were fewer than the average except in the south of Ireland. The amount of rain varied from 11·34 in. for the north of Scotland to 3·77 in. for the north-east of England. The fall was less than the average except in Ireland; the greatest deficiency was 4·17 in. for the north-west of England. Bright sunshine was deficient except in England east and north-west. At Greenwich the mean temperature for the autumn was 51·2°, which is 0·5° above the mean. The mean of the day or maximum readings was 1·5° in excess of the normal; the mean of the lowest or night readings was 0·7° in defect. September had a normal temperature, October an excess of 2°, and November a deficiency of 0·5°. The rainfall for the autumn was 1·23 in. deficient. September had an excess of 1·70 in., October a deficiency of 1·54 in., and November a deficiency of 1·39 in. Remarkable as the October deficiency of rain is in 1920, the amount measured in 1919 was even less at Greenwich.

Johnson Cañon, probably the largest of the eastern tributaries of the Mancos Cañon, lies on the divide between La Plata and Montezuma Counties in Colorado. Here some important ruins are described by Mr. E. H. Morris in the thirty-third annual Report of the American Bureau of Ethnology. Large collections of interesting pottery, consisting of coil-ware ollas and some beautifully ornamented black-and-white and black-and-red bowls, have been discovered. The culture, as a whole, was a rather restricted characteristic of the Mesa Verde region, the materials for weaving, building, and pottery being procured in the immediate neighbourhood, while the fruits of wild trees and plants, as well as the cultivated crops, came, with few exceptions, from the neighbouring cañons and mesas.

The Bulletin of the New York Zoological Society (vol. xxiii., No. 4) is devoted to a survey of the history of the white rhinoceros of the Belgian Congo. The habits and external characters of this vanishing species are tersely reviewed and comparisons made with its near ally, the black rhinoceros. The traffic in the horns of this animal, it is contended, must be completely restricted if it is to be saved from speedy extinction. A number of remarkably fine illustrations add much to the value of this publication.

The Field Naturalists' Club of Victoria was founded in May forty years ago. In 1906 Mr. F. G. A. Barnard published in its organ, the *Victorian Naturalist*, a history of its first quarter of a century. In the October issue of that magazine he gives a retrospect of the last fifteen years. This vigorous society does excellent work in promoting a love of Nature and the study of natural history in the neighbourhood of Melbourne. That it succeeds in arousing the interest of the general public is shown by the fact that five exhibitions of wild flowers held during the war period for special objects brought in more than 622*l*.

Among the more important papers published in the thirty-third annual Report of the American Bureau of Ethnology is that by Mr. M. R. Gilmore on "The Uses of Plants by the Indians of the Missouri River Region." The writer remarks: "We shall make the best and most economical use of all our land when our population shall have become adjusted in habit to the natural conditions. The country cannot be wholly made over and adjusted to a people of foreign habits and tastes. There are large tracts of land in America whose bounty is wasted because the plants which grow on them are not acceptable to our people. This is not because these plants are not in themselves useful and desirable, but because their qualities are unknown. So long as the people of the country do not demand articles of food other than those to which our European ancestors were accustomed, these articles will be subject to demand in excess of production, with consequent enhancement of cost, while at the same time we have large land areas practically unproductive, because the plants they are best fitted to produce are not utilised."

The report of the council presented to the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne at the end of October records an increase of membership and a resumption of activity after the war. The museum building, of which a large part had been occupied by Armstrong College, has been overhauled, lectures and talks have been well attended, an entomological section has been established, and field excursions have been organised. Though there is nothing of particular interest to report, it is pleasing to note that the exceedingly valuable collections of the Hancock Museum have received skilled curatorial attention.

The United States Department of Agriculture has just issued Bulletin No. 794 on the waterfowl and their food-plants in the sandhill region of Nebraska, which is valuable and instructive because the resorts of these economically important birds are becoming more and more restricted owing to the draining of lakes and marshes. Hence, before it is too late, the Department has decided to take steps to conserve the remaining supply of waterfowl inhabiting these areas. This inquiry, it urges, is very necessary "if we are to take intelligently directed steps towards passing on what remains of our heritage of natural wealth." In this far-seeing policy the United

States sets an example which might well be followed by our own Ministry of Agriculture, which has frequently been urged to establish a Bureau of Ornithology for similar functions.

THE results of the inquiries made by the Special Committee on Food-grains with regard to the Indian rice industry are embodied in a report on the trade in Indian rice, to which are appended two further reports on the production and uses of rice and on the utilisation of Burmese rice and its by-products respectively ("Indian Trade Enquiry: Reports on Rice," published by John Murray). In the main report reference is made to the two branches of the world's rice trade, viz. the Far Eastern branch, requiring a cheap rice for feeding the native population, and the Western branch, requiring large quantities of a medium quality rice and smaller quantities of a high quality product. The sources of supply of these markets are referred to, and sections are devoted to the following subjects: The world's trade in rice; the rice trade of India with the British Empire and with the Continent; imports, exports, and home consumption of rice in European countries and the United States; and the comparative cost of handling, milling, and transporting rice in the United Kingdom and on the Continent. The industrial uses of rice are also dealt with, and a series of statistical tables forms an appendix to the report. In 1913 India (chiefly Burma), Siam, and Indo-China together contributed 94 per cent. of the world's exported surplus of rice (including paddy, *i.e.* unhusked rice), the amount of the Indian exports roughly equalling those from Indo-China and Siam combined. The total Indian export (2,450,000 tons) is approximately equivalent to the total requirements of the British Empire from the three chief exporting countries.

THE Cardiff Naturalists' Society has instituted a faunistic survey of Glamorgan, and as a preliminary has issued a useful pamphlet of instructions to collectors. Regional and faunistic surveys form part of the activities of many societies in Great Britain, but the work is hampered, as a rule, by the lack of concise instructions for collecting. This is a difficulty which the Cardiff Naturalists' Society has wisely foreseen and endeavoured to overcome. The pamphlet is concerned only with the terrestrial and fresh-water fauna, and each group of animals is dealt with separately and in detail. The collector is furnished with valuable hints on the habitats in which to search for special animals, and with instructions for their capture, preservation, and packing. We are glad to note the stress which is laid on the necessity for adequate data to accompany each specimen. It is a point which cannot be too often or too strongly insisted upon. The attention of workers is further directed to the advisability of collecting both the external and internal parasites of the vertebrate groups and of an examination of the stomach contents. Due regard is paid to the value of field observation in a survey such as this society contemplates, and useful advice on special points requiring further elucidation is given under each group of animals. The section devoted to insects is particularly good and full, and the collector will be specially grateful for the many hints on the manipulation of the more delicate and smaller forms. His work will be made easier for him, and the results will be more gratifying to the referees and to those who will ultimately have charge of the specimens. Altogether this is an admirable pamphlet which should be of the greatest service to those who are undertaking the field-work in connection with the survey, and should go far to ensure the success of the scheme. Other organisations contemplating similar work will find it invaluable. We understand that copies of the pamphlet may be obtained from the secretary of the Cardiff Naturalists' Society, Dr. J. J. Simpson, 35 Park Place, Cardiff, at a nominal charge of 6*d*. each, or in larger quantities at special rates if desired.

THE latest part of the Annals of the Transvaal Museum (vol. vii., part 2, 1920) contains two valuable papers by Dr. E. C. N. van Hoepen on remains of carnivorous dinosaurs from the Karroo formation of South Africa. The fossils are described in great detail, with adequate illustrations, and include all important parts of the skeleton except the skull. They seem to represent some genera allied to the European Triassic Plateosaurus, others to the North American Triassic Anchisaurus. One femur is exceptional in not being hollow. The author is to be congratulated on his painstaking work, which makes possible a more exact comparison of the South African Triassic carnivorous dinosaurs with those from other parts of the world.

DISEASES of bees known as foulbrood are dealt with by Mr. G. F. White, of the United States Department of Agriculture. In Bulletin No. 810 European foulbrood is discussed. It is an infectious disease of the brood of bees, characterised by death of the brood during its uncapped stage and by absence of odour. The stock may be weakened, or even exterminated, by the disease. In 1885 Cheshire and Cheyne ascribed the disease to a sporing bacillus, *B. alvei*. According to Mr. White, however, this organism is only a secondary invader of the dead larvæ, and not the cause. The causative organism is *B. pluton*, an ovoid and sometimes yeast-like form, which cannot be cultivated, and gains entrance to the larvæ by the mouth. American foulbrood (Bulletin No. 809) is characterised by a decided ropiness of the decaying brood and a peculiar foul odour. It is of almost world-wide distribution, and occurs in this country. The causative organism is a sporing bacillus, *B. larvae*, which can be cultivated on an agar made from bee larvæ and on an unheated egg-yolk agar. Full details respecting these diseases are given in these two bulletins.

THE latest volume (vol. xvi.) of the Special Reports on the Mineral Resources of Great Britain, issued by the Geological Survey, contains an account of the petrography and chemistry of the refractory materials, ganister, silica-rock, sand and dolomite, by Messrs. H. H. Thomas, A. F. Hallimond, and E. G. Radley. It may be looked upon as a continuation of vol. vi.

of the same series, which dealt with the geology and mode of occurrence of these materials, and thus completes the information on these important substances already published. The chemistry of the raw materials and the chemical changes which they undergo in order to fit them for use in the furnace are discussed in some detail, and a number of complete analyses, most of which have been made in the Survey laboratory, are included. Much attention has also been devoted to the microscopic examination of the materials in their native state, as prepared for use in the furnace and after such use. The volume is, therefore, likely to be found extremely valuable to all users of refractory materials, more particularly to steel-makers, whose requirements have evidently received special attention.

THE process of cold vulcanisation of rubber invented by Mr. S. J. Peachey, to which reference was made in NATURE of July 15, p. 625, consists in treating the rubber alternately with sulphur dioxide and hydrogen sulphide. The gases are separately absorbed by the rubber, and by interaction produce a highly active form of sulphur which brings about vulcanisation. The process obviates the use of sulphur chloride, and, since it takes place in the cold, renders possible the use of organic filling and colouring agents which are not affected by the two gases, but would be decomposed in the ordinary process.

AN excellent feature of a new catalogue received from Mr. Cuthbert Andrews (47 Red Lion Street, W.C.1) is a series of six coloured plates illustrating X-ray tubes in action. These illustrations, besides being extremely good technical productions, should be very instructive to those who desire to familiarise themselves with the various appearances of X-ray tubes. There is, of course, still a wide field of utility in the gas-tube, and the various devices designed to overcome some of their vagaries are dealt with in detail in this catalogue. Protective measures in X-ray work are not lost sight of; the appliances manufactured by Mr. Andrews are given the rather happy name of "Protex."

THE difficulty experienced by workers in damp climates in maintaining the insulation of electrostatic measuring instruments has, according to the July issue of the Journal of the Asiatic Society of Bengal, led Prof. Jackson and Mr. A. T. Mukerjee to enclose their Dolezalek electrometers in hermetically sealed cases and to test the efficiencies of the desiccators in common use. They find that for reducing the rate of leak from such an electrometer calcium chloride, sodium, quicklime, and phosphorus pentoxide are valueless, owing possibly to the chemical action between them and the moisture they take up producing ions which render the air conducting. Sulphuric acid boiled with a small quantity of ammonium sulphate, as recommended for Kelvin electrometers, and having a density of 1·84, corresponding to 95 per cent. of pure acid, is the only desiccant they have found to be entirely suitable. If occasionally stirred it retains its efficiency for several weeks.

THE October issue of the Journal of the Franklin Institute contains the address on optical glass given by Dr. A. L. Day, the director of the geophysical laboratory of the Carnegie Institution, and during the war in charge of optical glass production, to the physics and chemistry section of the institute in March last. In the course of the address Dr. Day described the steps taken by the United States Government to help the manufacturers to overcome the difficulties of the manufacture of optical glass in sufficient quantities to meet the demand produced by the war. It was found that the manufacture was not beset with mysteries as it had been represented to be, but that it was a straightforward scientific problem solvable by the methods commonly used in attacking problems of high precision. The results of the experience are all published, and are available for those who wish to make the manufacture of optical glass a permanent industry of the country. It is, however, recognised that the demand will be small, and that the industry may have to be subsidised by the Government, or, if not, to depend on other lines for its profits.

MESSRS. PASTORELLI AND RAPKIN, LTD., of 46 Hatton Garden, London, E.C.1, have forwarded to us their list of self-recording meteorological instruments. The various forms of barographs afford ample choice to satisfy the different uses for which these instruments are required. The "dial barograph," which gives the face of the ordinary aneroid as well as the charted record, adds much to the interest of the reading of atmospheric pressure. With the new units of measurement which are now becoming of such general use it seems desirable that the scale should be given in millibars as well as in inches. Barothermographs showing the records of pressure and temperature on the same drum will be welcomed by many. The Edney hygrograph seems an improvement on the ordinary arrangement for securing an accurate temperature and for reducing the sluggishness introduced into some other forms of thermographs. Prices are necessarily high in comparison with pre-war rates, but the advance is not excessive. The firm has a long record, since 1750, which is essentially an advantage to a maker of all kinds of scientific instruments, as many improvements are the more easily recognised.

THE presidential address of Mr. Ll. B. Atkinson to the Institution of Electrical Engineers, delivered on November 18, marked the commencement of the jubilee year of the institution, which was founded in 1871 as the Society of Telegraph Engineers, although a previous society, called the Electrical Society of London, had existed from 1837 to 1845. In reviewing the progress achieved during the last half-century the president traced the changes in our conceptions of electrical and other physical phenomena from Maxwell's original ideas to the modern electron theory and the newer outlook revealed by the researches of Einstein and others. The development of methods of generation of electrical currents by mechanical means was followed from the discovery of the self-exciting dynamo in 1867 to the large turbo-alternators of to-day. Mr. Atkinson looked forward to further progress in the gas turbine, and hinted that some process of current production avoiding the limits imposed by the second law of thermodynamics might be found, and that perhaps an electrical method of unlocking the stores of energy in the atom might ultimately be discovered. After a few words on the history of electric supply, transmission of power, and cable manufacture, Mr. Atkinson passed on to a review of telegraph and telephone progress. Both submarine and land line telegraphy had reached a high degree of advancement when the institution was founded, but the telephone did not exist, and such ideas as there were on the possibility of communication without wires were in the direction of earth conduction. Recent developments included applications of the wonderful thermionic amplifier to cable telegraphy as well as to line telegraphy and wireless. Among matters requiring further research were the development of more exact methods of estimating the quality of transmitted speech and multiplex and superposed telephony.

Messrs. W. Heffer and Sons, Ltd., Cambridge, have just issued a catalogue (No. 194) of publishers' remainders which should be seen by those on the look-out for standard books in a new condition as Christmas or New Year presents. Many of the volumes offered for sale deal with scientific subjects, but most are of general interest. All are listed at prices far below those at which they were published. The catalogue is obtainable upon application.

Our Astronomical Column.

The December Meteors.—These meteors are due to reappear on the nights of December 10–13, and with suitable weather ought to be well observed this year, as there will be no interference from moonlight. The maximum will probably occur on December 12, when the radiant will be at $112° + 33°$ near α Geminorum. The point of radiation apparently moves eastward at the rate of 1° daily. The meteors are moderately swift, sometimes slow, but their individual aspects depend in a measure upon their relative positions with respect to the observer and the radiant. In the early hours of the evening the flights are longer than in the later part of the night, the radiant being higher in the sky in the small hours of the morning.

Minor Planets.—Ceres will be in opposition on Christmas Day in high north declination, its magnitude being 7·2. The following approximate ephemeris for Greenwich midnight is from Marseilles Circular No. 412:

	R.A. h. m. s.	N. Decl. ° ′		R.A. h. m. s.	N. Decl. ° ′
Dec. 3	6 37 48	25 27	Dec. 18	6 24 30	26 41
8	6 33 54	25 52	23	6 19 24	27 5
13	6 29 24	26 17	28	6 14 6	27 27

Log r, log Δ December 3, 0·424, 0·240; December 23, 0·421, 0·219.

The planet is close to ε Geminorum at the beginning of December.

Astr. Nach. Circular No. 46 reports the discovery of a very interesting planet which has been provisionally named HZ. It was found photographically by Dr. W. Baade at Bergedorf on October 31, and observed again on November 2 and 12, its magnitude being about 13. Dr. G. Stracke has computed the following elements:

Epoch 1920 *October* 31·5 *G.M.T.*

M = 348° 33′ 35·4″	μ = 320·085″
ω = 57 38 40·2	log a = 0·696494
☊ = 21 22 26·8	log q = 0·2887
i = 41 28 58·6	T = 1921 March 9·2
φ = 37 31 0·8	Equinox 1920·0

It will be observed that the value of the mean motion would make it a member of the Trojan group, but the very large inclination and eccentricity (which are cometary rather than planetary) would prevent any close adherence to the equilateral configuration with the sun and Jupiter, which is the characteristic of that group.

Ephemeris for Greenwich Midnight.

	R.A. h. m. s.	N. Decl. ° ′
December 6 ...	0 8 16	18 27
10 ...	0 7 24	19 18

The perihelion and aphelion distances are 1·944 and 7·998 respectively.

Photographic Parallax Determinations at Allegheny.—Vols. iv. and v. of the Publications of this observatory, of which Prof. F. Schlesinger is director, contain parallaxes of nearly three hundred stars, the average probable error being given as 0·008″. A few of the larger parallaxes are recorded below, with notes on previous determinations. An asterisk denotes a spectroscopic parallax:

Star	Parallax ″	Some previous determinations in ″
τ Cygni ...	0·058	0·125, 0·029, 0·006, 0·023
ι Pegasi ...	0·067	0·063, 0·120
μ „ ...	0·043	
β Virginis ...	0·096	0·110, 0·100*, 0·096
42 Coronæ ...	0·064	0·119, 0·058
ζ Herculis ...	0·114	0·172, 0·101, 0·146, 0·086, 0·066*
μ „ ...	0·104	0·122, 0·126, 0·093, 0·051, 0·096*
85 Pegasi ...	0·084	0·054, 0·096, 0·084, 0·101, 0·096*
{OΣ 547 (mean)	0·103	0·134, 0·095, 0·120*
{Furuhjelm star[1]	0·099	0·112
χ Orionis ...	0·096	
8 Canum Ven.	0·109	0·089, 0·084, 0·105*
ξ Boötis ...	0·147	0·225, 0·151*
η Cassiopeiæ...	0·173	0·188, 0·182, 0·178*, 0·180
61 Cygni (mean)	0·285	0·270, 0·272, 0·322, 0·301
Castor (mean)	0·070	0·053

[1] This star has the same P.M. as OΣ 547, being 5½′ distant.

The great advance in the accuracy of photographic parallaxes in recent years is very satisfactory. It may be ascribed to the many additional precautions now taken, notably the equalisation of magnitudes by rotating sector or otherwise, and confining the photographs to the neighbourhood of the meridian to minimise the effect of atmospheric dispersion.

Vol. vi., No. 2, of the Allegheny Publications contains a paper by Mr. C. J. Hudson on the amount of error arising from this dispersion. The effect on pairs of plates taken at considerable hour-angles east and west is 0·021″. It should be quite negligible on the parallax plates.

Migrations of Cultures in British New Guinea.

THE HUXLEY MEMORIAL LECTURE FOR 1920.

THE Huxley memorial lecture of the Royal Anthropological Institute was delivered by Dr. A. C. Haddon at the rooms of the Royal Society on November 23.

In opening his address Dr. Haddon suggested that the immediate cause of the interest taken by Huxley in anthropology may have been the memorable voyage which he made more than seventy years ago in the *Rattlesnake* when he was sent out to survey the marine zoology of the Torres Straits and various parts of the coast of New Guinea. He himself had been first attracted to anthropology when in 1888 he visited the Torres Straits, also with the object of studying marine zoology. It was therefore, in his opinion, not inappropriate that it had fallen to his lot to pay homage to the memory of a master of scientific method and of clear exposition, and that he should select the area of their respective first experiences in travel for the subject of his discourse.

On the coast of British New Guinea is found a series of cultures, some of which are evidently related, others as obviously unrelated. Their affinity suggests a common origin, but any idea of indigenous development or of cultural migration from Australia may at once be dismissed.

The cultural problems of the south-eastern peninsula and of the outlying islands of New Guinea are, in the main, quite distinct from those to the west, and the differences between the two groups of cultures indicate clearly that there cannot have been any extensive cultural movements from the Papuo-Melanesians of the east to the western Papuans. We are thus driven, on general grounds, to the supposition that the cultures of the southern coast of British New Guinea came down more or less from the north.

The Tugeri, who live just beyond the Netherlands border, are cannibals and inveterate head-hunters who chew kava, *vati*. The inhabitants of several villages assemble at initiation ceremonies, at which bullroarers are swung, but the bullroarer is not known elsewhere in Netherlands New Guinea. There are many dances at which masks are worn and animals represented. The bullroarer is anthropomorphised as Sosom, a mythical monster of the bush, who at the annual festival at the beginning of the south-east monsoon devours the novices, but brings them back to life. There is such a striking resemblance between this complex and that of various tribes in the area from Astrolabe Bay to Huon Gulf that a relationship cannot be denied.

The use of kava has such ethnological interest that it is worth while noting its distribution in New Guinea. Several of the bush tribes west of the Fly estuary chew kava. Effigies of crocodiles are presented with kava by the Masingara, and a legend suggests a former monster who ate novices at the initiation ceremony. Kava plays an important part in the several ceremonies of the Kiwai peoples, and only those who have passed through all the stages of initiation may drink it. The Gogodara, who live between the Fly estuary and the Bamu, have an initiation ceremony in which a boy is supposed to be eaten by a crocodile, and kava is drunk. The tribes to the north of Huon Gulf hold a periodic circumcision ceremony at which, to the humming of bullroarers, the initiates are dragged into a hut constructed like a monster, which thus symbolically swallows them. An important part of the initiation ceremonies consists in teaching the novices how to play the sacred flutes.

To return to the south coast. The Kerewa folk live in Goaribari Island and its neighbourhood. They have carved shrines to which skulls of people who have been eaten are attached. Further east are the Namau group. Here are enormous ceremonial houses with numerous shrines, associated with a *manes* cult, in front of which are heaps of animal, and formerly of human, skulls. In the dim recess of the building are basketwork monsters. The Elema or Gulf culture, further east, is essentially similar, except that the monsters are lacking and the people are not cannibals.

The Great Sepik River possesses several cultures along its course, one of which is characterised by so many general similarities with the cultures of the south coast that there must have been some connection between them; for example, there are numerous plaitwork masks which find an exact counterpart in the Middle Fly, on the Bamu, and in the Kerewa country. The great difficulty alike in the supposed spread of kava-drinking from the Huon Gulf-Astrolabe Bay area to the mouth of the Fly and beyond, and in the extension of the Sepik culture to the south coast, is the great mountain chain of New Guinea. It would be easier to suppose that these cultures, which, so far as is known at present, are discontinuous, were carried to their respective areas by seafaring people, but no traces of similar cultures are found in the intervening coastal areas; furthermore, the western canoes (except in the Torres Straits area) are a river type, and can be matched from the Sepik. An interesting problem is that of the woven rattan cuirasses; these occur on the north coast at the Netherlands boundary and some way to the east of it, also some distance inland south of this area, and again on the Palmer River and Upper Fly, and, finally, a feebler type is found in the mountains up the Utakwa River in Netherlands New Guinea. It is inconceivable that a migration could have carried this armour all round New Guinea and right up the Fly without leaving traces *en route*. The most rational view is that it has spread down from the north coast, in which case it would have crossed the mountain chain, as the Sepik cultures are assumed to have done.

The south-eastern peninsula of New Guinea is characterised by the absence of the features of the western cultures and the presence of a big feast, with which in the region round Milne Bay is associated the cult of the mango-tree. In the Mambare and Kumusi river-systems initiation ceremonies are again met with, the bullroarer is employed, and a pair of sacred flutes played. The use of the sacred flutes links up with the initiation ceremonies of the peoples to the north of Huon Gulf, and their use extends all along the coastal peoples well into Netherlands territory, as well as up the Sepik. It seems as if the use of the flutes tended to supplant that of the bullroarer. The distribution of the flutes further coincides fairly closely with the employment of slit gongs. Both these instruments appear to belong to a relatively recent cultural movement from northern Melanesia.

From this it will be evident that the ethnological history of New Guinea is extremely complex; movements have taken place within the island, and cultural influences have come in from without. The south-eastern peninsula has been the scene of two different migrations, resulting in the Motu and Massim cultures, and probably a third one influenced the Trobriands. These were perfectly distinct from the probable migrations from northern Melanesia which have modified the northern coastal cultures. These have come on the top of Papuan cultures, the more striking features of which have probably been due to earlier cultural drifts from Indonesia. At present it is only possible to state some of the problems and to hazard conjectures as to their solution. Very much work remains to be done before the history of this fascinating island can be unravelled.

At the conclusion of the address the Huxley memorial medal was presented to the lecturer by Sir Everard im Thurn, the president of the Royal Anthropological Institute.

International Weather Telegraphy.

THE International Commission for Weather Telegraphy, appointed at the general Meteorological Conference at Paris in October, 1919, met at the Air Ministry during the week November 22–27. The delegates were welcomed at the first meeting on Monday, November 22, by Major-Gen. Sir F. H. Sykes, Controller-General of Civil Aviation, who emphasised the special need for international agreement in meteorology because nations were more interdependent in respect of that science than of any other.

During the meeting the Commission came to an agreement upon the codes for the transmission of surface observations and upper-air observations in land messages and for a new figure code for the transmission of reports from ships at sea.

It also agreed upon a time-table for the issue by radio-telegraphy of data messages for the preparation of synoptic charts and upon the distribution of stations in Europe for the issue from the Eiffel Tower of collective data messages for the whole European *réseau*.

The principal changes in the new code are:

(*a*) The number of figures for reporting barometric tendency is reduced from two to one, and the unit for barometric tendency is standardised as the half-millibar per three hours, or, for countries using the millimetre scale, the half-millimetre per three hours.

(*b*) A two-figure code for reporting the weather takes the place of the old single-figure code, and permits the intensity and character of the precipitation to be reported.

(*c*) Provision is made for reporting visibility up to 30 km. according to a graduated scale.

(*d*) One figure is allotted to reports of humidity which will be given to the nearest 10 per cent.

Prior to 1911 the code for international messages provided for reports of the temperature of the wet bulb as well as of that of the dry bulb. The temperature of the wet bulb was omitted after the introduction of barometric tendency, and thereafter no information about humidity was included in the messages. The new conditions, which permit of the international exchange of the full report for 1 p.m. and 6 p.m., and for the inclusion of humidity in the upper air for reports of surface humidity, should prove of considerable value.

(*e*) One five-figure group is allotted to reports of the form, amount, and height above ground of the clouds. It may be noted that the height of the clouds above ground and the visibility are at present the two elements of the greatest importance to aviation.

(*f*) Provision is made for reporting twice a day the hour of commencement of rainfall. This has been proved to be of great value by actual trial in Scandinavia, and it is anticipated that it will ultimately be one of the most important data in the preparation of forecasts for agriculture.

(*g*) A special group of five figures is allotted to a selection of stations in each country for the purpose of reporting as exactly as possible the direction and relative speed obtained by nephoscopic observations of clouds.

(*h*) Three special groups are allotted to selected stations in each country for reporting the direction and speed of the upper wind as determined by observations with pilot-balloons, shell-bursts, kite-balloons, and other methods.

(*i*) Ten groups as a maximum have been allotted to one, two, or three stations in each country where facilities are available for obtaining the temperature and humidity of the upper air to great altitudes by means of aeroplanes or kite-balloons.

In connection with the observations of the upper air, the Commission was interested to learn from Prof. de Quervain of the proposal to establish a station in Switzerland at an altitude of 3500 metres, from which barometric observations would be of the highest value in the construction of charts for that level.

The code adopted for the reports by wireless telegraphy from ships at sea provides for the same information as that which is given in the messages on land with the omission of barometric tendency, relative humidity, and the height of clouds. A new feature is the introduction of the method of checking the reports already used in the Meteorological Service of India. The necessity for some system of this kind was emphasised at the Meteorological Conference at Innsbruck in 1905 during a discussion on the possibility of obtaining wireless messages from the Atlantic. The new code provides a simple and practical method for discovering any error which exists and for correcting it.

The Commission learned with much interest that meteorological observations were being made this winter on behalf of the Norwegian Institute in the Island of Jan Mayen, which is situated about 600 miles north-east of Iceland; and that there was a prospect in the not distant future of obtaining meteorological observations from Greenland by radio-telegraphy.

The hard work of the business meetings of the Commission was relieved by a number of social gatherings. On November 22 Sir Napier and Lady Shaw gave a reception to the delegates at 10 Moreton Gardens, S.W. On the afternoon of November 24 a visit was paid by the delegates to Croydon Aerodrome, and an opportunity afforded them of seeing the meteorological and wireless arrangements necessary at the terminus of air routes. On November 25 the delegates were entertained to luncheon at the Carlton Hotel by his Majesty's Government, when the Marquess of Londonderry, Under-Secretary of State for Air, referred in a characteristic speech to the achievements of the delegates, some of whom had come from countries so widely separated, both by distance and by climate, as Java and Iceland. On the evening of November 26 the Maharaj Rana of Jhalawar gave a dinner in honour of the delegates; they were one and all delighted with the informal hospitality of his Highness, who had assisted at the last meeting of the Commission in 1912 and had maintained his interest in meteorology, especially British meteorology, which had made notable advances under the direction of Sir Napier Shaw, the president of the International Meteorological Committee.

Zoology at the British Association.

THE meetings of Section D attracted a large gathering of zoologists from this country and a worthy representation from the Dominions and from the United States. Prof. Gilson, of Louvain, was the only Continental guest of the Section.

Discussions.

The discussion on the need for the scientific investigation of the ocean has already been reported in NATURE of September 2 (p. 30), and Mr. H. G. Maurice's address in which he urged that fisheries research is the business of the State was published in NATURE of November 25. The discussion on this address may now be briefly summarised.

Prof. James Johnstone entirely agreed with Mr. Maurice that a Government Department of Fisheries ought to be thoroughly staffed and equipped for the prosecution of scientific research. But this policy brought a serious responsibility, for sooner or later the fishing industries would ask for the results of the investigations, *e.g.* whether fish had become more abundant or whether investigation had suggested new and improved methods of utilising sea-fish and products at present useless. As a practical suggestion he thought that in all such economic scientific investigations a new kind of worker was now necessary—the man of the inventor type of mentality—whose task it would be to apply to industry the new discoveries of the laboratory, marine station, or exploring vessel. Pure scientific investigation for its own sake was the proper work of the universities and marine stations, and no development of economic research ought to curtail it.

Prof. Gilson (delegate of Belgium on the International Council) supported the view that a maritime country should have a Department of Fisheries Research, and stated that Belgium has adopted this system and, notwithstanding the profound disorganisation of her finances, granted the sum asked to enable her full share of oceanographical and fisheries research to be undertaken.

Prof. Garstang remarked that twenty years ago they were in the midst of acute controversies between rival groups of marine biologists and between all these and the Fisheries Department in regard to the initiation of the International North Sea Investigations. It was, therefore, particularly gratifying to him to note the unanimity which now prevailed as to the wisdom of the arguments which induced the Government to proceed with that enterprise and were now put forward by the Ministry of Fisheries as convincing reasons for its continuance. It must, however, be recognised that there is a danger to science of its best exponents in one subject being concentrated into one Government Department.

Prof. Meek said that all were of the same mind that a Government Department should be fully equipped for research so long as the independence of pure science was maintained and it was recognised that much of the work could be done in independent institutions. He then went on to refer to recent trawling results on the Northumberland coast, which showed that fishery conditions in those waters were the same to-day as in 1913. He referred to the areas of distribution of fish from the Canaries to Barents Sea, and pointed out that explanations must be sought in the study of movements of water and of the lives of diatoms and other microscopic organisms.

Mr. Neale (Cardiff) stated that neither the Government nor practical fishermen have given enough consideration to the future of fisheries. He found the catches to be no larger now than before the war, and in some cases they were smaller, and he was inclined to believe that natural causes were mainly contributory, and that knowledge of these was required. The amount of ocean fished is very small as compared with the total area of the ocean, and he asked for investigations which owners of commercial trawlers could not carry out.

Dr. E. J. Allen expressed satisfaction with the broad views on scientific research now held at the Ministry of Agriculture and Fisheries and put forward by Mr. Maurice, and remarked that it was also gratifying to hear that those engaged in the fishing industry now realised the usefulness of scientific investigations.

Mr. Maurice briefly replied, explaining that collaboration in fisheries research was on the high road to being achieved between England, Scotland, and Ireland, the three countries settling their schemes and policy by quarterly inter-Departmental conferences.

The president (Prof. Stanley Gardiner) suggested that the Section might arrange for a full day of discussion at its meeting in Edinburgh in 1921, and circularise the various fishery federations and associations to see if their members would be inclined to attend the meeting of the Association and put up their own facts and problems for friendly discussion with the scientific members of the Association. The position of the Scottish capital as a common meeting-ground for the four greatest trawler ports—Aberdeen, Fleetwood, Grimsby, and Hull—seemed to him to offer an eminently favourable opportunity for such discussion.

Protozoa.

Prof. C. A. Kofoid described recent observations by himself and his pupils on the neuro-motor system of ciliate and flagellate protozoa. The perfection of the Barber micro-dissection apparatus, which can be operated with great delicacy of action under an oil-immersion objective, has made possible the demonstration of the existence in certain protozoa of a complicated fibrillar system comparable with the nervous and muscular systems of higher animals. This integrated neuro-motor system is connected with the nucleus, and plays an important part in the division of the organism into two. Experimental proof of the conducting function of the fibrillar system in the ciliate Euplotes was established recently by Dr. Taylor, who succeeded in cutting the fibrils in the living animal. He observed that in these cases there was interference with the integrated co-ordinated movements of the animal. Cuts of similar extent made in other specimens, but which did not sever the fibrils, did not produce interference with co-ordination.

Prof. Kofoid pointed out that many of the flagellates are asymmetrical, and generally have a sinistral or left-handed torsion. The origin of bilateral symmetry which prevails in Metazoa, composed of many cells, appeared to him to be bound up with two features of the structure of protozoa: (1) The co-ordinating mechanism, already referred to, in the protozoa and its persistence in the form of fibrils connecting the constituent cells of the Metazoa; and (2) the production during division into two of a sinistral and a dextral daughter-cell, the latter due to a reversal of the primitive sinistral symmetry and forming a mirror-image of the left one, the maintenance of the union of these two cells thus providing the first step in the origin of primitive bilateral animals.

Prof. R. W. Hegner discussed the relations of nucleus, cytoplasm, and external heritable characters in the genus Arcella, in which the nuclei can be seen and measured in the living animal and the chromatin mass accurately determined. Pure lines of *Arcella dentata*, obtained during vegetative reproduction from "wild" specimens by pedigree breeding methods, differed from one another in size and spine-number, which are closely correlated—the larger the shell, the greater the number of spines. These two characters were found to be correlated also with chromatin mass, for uninucleate descendants of halves (obtained by cutting into two) of binucleate animals were only about half as large as binucleate specimens belonging to the same line. The uninucleate descendants of halves of binucleate specimens always regained the binucleate condition after a few generations. The later descendants were always binucleate, but the size and spine-number of the typical binucleate were reached only after three or four more generations, during which the diameter of the shell and the number of spines increased gradually, *i.e.* the great change within—the doubling of the chromatin mass—was accompanied externally by small changes in a definite direction. If the internal condition had not been known, the conclusion would have been reached that the change in external heritable characters was due to several gradual modifications instead of to one large mutation.

Messrs. E. Heron Allen and A. Earland read a paper on protoplasm and pseudopodia, based on observations on Foraminifera. They conclude that protoplasm is capable of almost unlimited extensibility and attenuation by imbibition of water, and that pseudopodia are not extended as such, but formed from protoplasm surrounding the shell. They claim for the pseudopodia a rudimentary nervous reaction to stimuli.

Prof. Kofoid exhibited a series of plates for a forthcoming monograph on the unarmoured Dinoflagellata, and Miss C. Herdman exhibited living specimens of Amphidinium from Port Erin.

The Influence of Salts on Growth.

Dr. Cresswell Shearer read a paper on the influence of salts on growth. He described experiments which show that living bacteria offer considerable resistance to the passage of ions of various salts; dead bacterial protoplasm offers no resistance. There is something peculiar to the living state that conditions this resistance, and this should be kept in mind in all applications of the results of protein chemistry to living protoplasm.

Annelids.

In a communication on the polyphyletic origin of genera in the Oligochæta and its bearings, Prof. J. Stephenson showed that the genera of the Megascolecidæ can be arranged in the form of a phylogenetic tree. The differentiating characters are few, *e.g.* in the majority of genera of the sub-family Megascolecinæ they concern only the setæ, prostates, and nephridia. The evolutionary changes in these systems have demonstrably taken place more than once, and the differentiating characters and their various combinations are few enough to render it probable that the same combination, *i.e.* the same genus, has been reached in more than one way. Apart from probability, there is anatomical and geographical evidence that the genus Megascolex has arisen from both Notoscolex and Perionyx, and from Notoscolex more than once. The multiple origin of Microscolex from Notiodrilus has also been demonstrated, and there is some evidence of the multiple origin of Pontodrilus. To assert the polyphyletic origin of a genus is, however, unorthodox; writers obviate it by merging the genera concerned, but this is to evade the difficulty. The answer given to the question of polyphyly has a bearing on geographical distribution. A number of genera of the sub-family Megascolecinæ occur both in India and Australia; the Octochætinæ occur only in India and New Zealand. These distributions are explained by assuming land-bridges between India and Australia and between India and New Zealand. But such connections cannot have existed since the Eocene, or Eutherian mammals would have entered Australia and New Zealand. Earthworms are, however, a recent group, and such a genus as Megascolex is among the phylogenetically youngest earthworms; its origin, and probably that of other genera common to the two regions, must have been recent (since the Eocene). Land connections are thus apparently insufficient to explain the distribution, and a double origin of at least the phyletically younger genera seems worthy of consideration.

Prof. Pierre Fauvel sent a summary of the results of his examination of the marine annelids collected in the Abrolhos Islands by Prof. Dakin. Sand- and mud-dwelling Polychæta were absent; Aphroditidæ and Eunicidæ were plentiful, together with Amphinomidæ and a few Nereidæ—a small fauna of Polychæta creeping on the stones and corals. Of the nineteen species from the Abrolhos, five are known only from the warmer parts of the Indian Ocean, eleven belong to the tropical area, but often extend beyond it northwards and southwards, and three belong to the Australian coast. The Polychæt fauna of the Abrolhos is probably the same as that of most of the coral-reefs of the Indian Ocean, with the addition of a few species belonging to the Australian coast.

Hookworm and Human Efficiency.

Prof. Kofoid, in an address on hookworm and human efficiency, described investigations made in the United States Army in connection with the elimination of hookworm infection among recruits. Examination revealed an infection of about 10 per cent. among men from the Southern States, and a slightly higher rate among whites than among blacks. A statistical investigation of the incidence of disease among 24,000 men at Camp Bowis, Texas, over a period of eight months (including that of the measles-pneumonia epidemic of the winter of 1917–18) showed that men in whom hookworm infection had been detected had a much higher sick-rate, and were more often sent to hospital for severe infections. Regiments with more than 10 per cent. infection by hookworm had a much higher death-rate from pneumonia than regiments with less than 10 per cent. infection by the worm. A comparison of the mental ratings obtained by the tests of the Psychology Board of the U.S. Army in the case of 10,000 recruits from the hookworm area showed that white able-bodied men with hookworm infection have a lower average rating than men in whom the infection was not detected. The mental deficiency thus measured was nearly 25 per cent., and affected all grades of intelligence from the highest to the lowest, but the latter somewhat more severely. Hookworm infection, even in cases when it is light, is a matter of great educational, sanitary, and economic importance.

Physiology of Migration.

Prof. A. Meek discussed the physiology of migration. He stated that the passive denatation of the egg, larval, and young stages of fish may be, and usually is, succeeded by an active down-current migration which is accompanied by seasonal on-shore and off-shore movements. But the periodic migrations of the species are markedly interrupted when the call of maturity comes. Then the migration is contranatant, a longer or shorter distance according to species and circumstances, due to the effects of an internal secretion or hormone which exercises a profound influence on the central nervous system, and may also produce somatogenic results. The only invertebrate which is definitely known to react in this way on the approach of spawning is the crab—the females migrate contranatantly at that period—but it may be presumed that other large, active Crustacea and Cephalopoda respond similarly. Prof. Meek referred to Amphibia as being similarly affected at the spawning season, the hormone bringing about a return to gregariousness as well as somatogenetic effects which characterised the period. The same appears to be true of aquatic reptiles, birds, and mammals, and Prof. Meek suggested that this pointed a way of approach to the subject of aerial migration. In the discussion following, Prof. Lloyd Morgan directed attention to the breeding habits of lapwings, and suggested that they were to be explained as due to hormone action, and other speakers proposed that attempts should be made to isolate and experiment with the hormone. Prof. Garstang discussed the question with reference to plaice, and Prof. Meek replied, pointing out in this case the distinction between the periodical and the spawning migrations.

Embryological Studies.

Prof. J. E. Duerden gave an account of the pineal eye of the ostrich (for a summary of this paper see NATURE, vol. cv., pp. 516–17), described a caudal vesicle in ostrich embryos, and recorded the presence of Reissner's fibre. In embryos of about ten days' incubation a prominent vesicular swelling is present at the tip of the tail or on the dorsal surface near the tip. The cavity of the vesicle, in which the central canal of the spinal cord terminates, varies much in size and shape in different specimens. The ventral wall of the spinal cord lines the floor of the cavity and terminates somewhat abruptly, and the dorsal wall of the cord merges gradually into the mesenchymal tissue which constitutes the dorsal and lateral walls of the vesicle, without, however, showing any differentiation into an epithelial layer. The cavity is filled with a coagulable fluid in which cellular tissue in process of degeneration frequently occurs, and occasionally much black pigment is present. The external enlargement persists for only a short time, rarely lasting after the twentieth day of incubation. A similar vesicle has been found in several reptiles, and is well-developed in the penguin and the puffin, though in these it is not so large as in the ostrich. It is suggested that the vesicle in the ostrich, which varies so much in size, is in some way concerned with the regulation of pressure of the cerebro-spinal fluid at this early stage. Longitudinal sections of the caudal region show the presence of Reissner's fibre and its posterior attachment to the mesenchymal tissue. Reissner's fibre has been found to occur within the central canal of the spinal cord of vertebrates from the cyclostomes to the primates.

Mr. J. H. Lloyd dealt with the early development of the pronephros in Scyllium and Chrysemys, and supported Mr. Burlend's view that the pronephros arises as a non-segmental groove from the somatic layer of the mesoblast, and that the anterior portion of the duct is formed by constriction from this groove, and not by fusion of the distal ends of tubules. The evidence, as presented by the illustrations, was not convincing, and was subjected to considerable criticism.

The Movements of the Sea.

At a joint meeting of Sections D and E, Dr. E. C. Jee gave a paper on the movements of the sea. He pointed out that the temperature of the deep waters surrounding the British Isles is essentially due to the Atlantic circulation. He dealt in some detail with the northern North Sea current, and stated that no significant correlation has yet been demonstrated between the variations of this current and fluctuations in the landings of fish. The current which enters the English Channel from the Atlantic affects the fisheries of the south-west area, and its strength seems to show the following variations: A winter maximum and a summer minimum, and a two-year, a six-year, and a twelve-year periodicity. It is probable that the fluctuations in the landings of pilchards are correlated with the variations in strength of the Channel current. The periodicities referred to are now being investigated by the International Council. The examination of numerous samples of sea-water and the liberation of surface and bottom drift-bottles are being undertaken with the object of obtaining information for a study of the migrations of mature plaice to and from their spawning-grounds in the Flemish Bight and the probable drift of the pelagic plaice eggs and the location of the fry in their various stages of development.

Prof. E. B. Poulton gave a preliminary account of the hereditary transmission of a minute, extremely variable, and generally asymmetrical marking in the forewing of the currant moth (*Abraxas grossulariata*).

J. H. ASHWORTH.

University and Educational Intelligence.

BIRMINGHAM.—At the last meeting of the council the Principal reported that the Staffordshire Education Committee is increasing its grant to the University from 450*l*. to 1000*l*. per annum. The Worcestershire County Council recently increased its annual contribution from 300*l*. to 500*l*.; and the Dudley Town Council has informed the University that it will include an annual sum of 50*l*. in its estimates.

Messrs. Dorman and Co., of Stafford, have presented a 20-h.p. petrol engine, and Messrs. Sturge and Co. an old beam engine. The Pro-Vice-Chancellor, Alderman Clayton, is providing 100*l*. towards the cost of removal and re-erection of the latter.

The University is affording facilities in the department of pathology to enable Prof. Shaw Dunn to take part in the training of the Naval and R.A.M.C. *personnel* required for the physiological department of the Chemical Warfare Section at Porton.

Mr. R. W. W. Sanderson has been appointed a demonstrator in physics for the current session.

Mr. R. G. Abrahams has been appointed honorary assistant curator of the pathological museum, Section of Surgery.

CAMBRIDGE.—By the time that this issue appears the vote on the admission of women to membership of the University will have taken place. Both sides are hopeful of the issue, and a fairly close vote is generally anticipated. Something of the vigour of the earlier fighting on this question has vanished, perhaps because the "old guard" realise that they are fighting a losing battle. If they hold their privileged position this time they know that their flanks are in the air, and that it is only a short time before they are liable to be overwhelmed in an attack from another quarter. Somewhat late in the day, many of them are holding out a promise of a place where everybody may go if only the Senate will throw out the present proposal. But no details are given, and the fact that some of the signatories in favour of the new and unknown scheme have been on a syndicate for twelve months charged to prepare a suitable scheme, and have so far failed to meet their own and their friends' requirements, does not inspire much confidence in their future operations. The results of the vote and a forecast of the later developments will appear in the next issue of NATURE.

DR. J. N. PRING, reader in electro-chemistry, University of Manchester, has been appointed head of the Physical Chemistry Branch, Research Department, Royal Arsenal, Woolwich.

SIR RICHARD GREGORY will deliver an address on "Scientific Fact and Popular Fallacy" to the students of the Journalism Diploma course at the University of London, South Kensington, S.W.7, on Monday, December 13, at 5 p.m. The chairman will be Prof. C. H. Lees.

IN connection with the London County Council lectures for teachers, a lecture on "The Antiquity of Man" will be given by Prof. Arthur Keith at the Regent Street Polytechnic, W.1, on Saturday morning, December 18, at 10.30 o'clock. The chair will be taken by Major J. E. K. Studd.

THE University College (University of London) Committee will shortly elect a Quain studentship in biology. The studentship is open to past or present students of the college who have taken a course in botany. The value of the studentship is 150*l.* per annum for three years. Candidates should communicate with the Secretary, University College, Gower Street, W.C.1, before December 16.

THE annual meeting of the Geographical Association will be held at the London Day Training College on Friday and Saturday, January 7 and 8, 1921. There will be a discussion on Historical Geography, opened by Mr. J. Fairgrieve and Capt. W. W. Jervis, and one on Geography in Continuation Schools, opened by Mr. L. Brooks and Capt. V. A. Bell. Dr. Unstead will lecture on The Study and Teaching of International Relations, and Dr. Haddon on Racial and Cultural Distributions in New Guinea. The presidential address by Prof. Gilbert Murray will be delivered on the afternoon of January 8.

AT a time when almost every university and technical institution in Great Britain has to close its doors to new students because of their already congested condition, it is difficult to believe that any circumstances could justify the extinction of a college which has been a pioneer of the most effective type in the work of technical education. Such, however, is the position of Finsbury Technical College, and a defence committee has been formed to consider the possibility of helping in any way to carry on the work of the college and thus to obviate its contemplated closing in July next. The college was given its distinctive character by Profs. Armstrong, Ayrton, and Perry, who were followed by Profs. Meldola and Silvanus Thompson, and the educational methods they introduced were both practical and sound, with the result that every student who took advantage of the opportunities afforded him was well equipped for his work in life. The college was founded by the City and Guilds of London Institute, and has in every way been worthy of its founders. In the last financial year the expenditure was about 12,400*l.*, of which about 7600*l.* was contributed by the institute and 4800*l.* was received in students' fees. It will thus be seen that the students' fees were nearly 40 per cent. of the income expended, which is a much higher ratio than in universities and colleges generally. The average proportion of tuition fees in universities and colleges in receipt of State aid in England and Wales is 28 per cent., and in the United States 10 per cent. Assuming that the City and Guilds Institute contribution is continued, a sum of at least 5000*l.* a year additional is required to enable the college to continue its work, and double that annual amount would not be too much to pay to secure its development. The defence committee has a strong case to put before the City Companies and the public, and it invites all who are interested in the preservation of the college to become members. Applications, with an entrance fee of 2*s.* 6*d.*, should be sent to Dr. Atkinson, Finsbury Technical College, Leonard Street, E.C.2.

Societies and Academies.

LONDON.

Royal Society, November 25.—Sir J. J. Thomson, president, in the chair.—Prof. L. **Hill**: The growth of seedlings in wind. Mustard-and-cress seeds have been grown on lamp-wicks in a continuous wind of approximately 5 metres a second, and the control seeds in still air. The seeds grown in the wind are stunted and bent, and contain less water, more ash, less protein, and, presumably, more cellulose. To counterbalance the drying effect of the wind the seeds have been irrigated with water, and to balance the cooling effect of the wind due to evaporation this water has been warmed, so that a part of the irrigated wick in the wind has been as warm as, or warmer than, the control wick. By the combining effect of thorough wetting and warming the growth of the seeds in wind has been made much more nearly equal to that of the control. While the right amount of moisture is the most important factor, the cooling of the germinating seeds by the wind is also a factor in explaining the stunting of growth in wind-swept places.—Prof. P. T. **Herring**: The effect of thyroid-feeding and of thyroparathyroidectomy upon the pituitrin content of the posterior lobe of the pituitary, the cerebro-spinal fluid, and blood. (1) Neither thyroid-feeding nor thyroparathyroidectomy in cats affects the pituitrin load of the posterior lobe of the pituitary body as tested by the action of similar strengths of extract upon the rat's uterus and the blood-pressure of the pithed cat. (2) There is no evidence of the presence of pituitrin in the cerebro-spinal fluid of the fourth ventricle in normal, thyroid-fed, and thyroparathyroidectomised cats. (3) The defibrinated blood of normal, thyroid-fed, and thyroparathyroidectomised cats has no appreciable action on the rat's uterus. The blood of thyroid-fed cats has a greater depressor action upon the circulation of an anæsthetised cat than has the blood of the normal animal. The blood of thyroparathyroidectomised cats has a pressor effect upon the circulation accompanied by contraction of the kidney and a diminution in the secretion of urine.—W. A. **Jolly**: Reflex times in the South African clawed frog. The reflex times of the homonymous and heteronymous reflexes in the hind limbs of the spinal clawed frog have been measured at temperatures ranging from 14° C. to 30° C. The average heteronymous time (66 observations) is 18·7 σ (0·0187 second). The average homonymous time (68 observations) is 14·9 σ. That is to say, the crossed reflex time is longer than the same-side reflex time by 3·8 σ.—Prof. J. A. **Gunn** and R. St. A. **Heathcote**: Cellular immunity. Observations on natural and acquired immunity to cobra venom. (*a*) *Natural Immunity*.—

The minimum lethal dose of cobra venom for the cat is twenty times that for the rabbit (by subcutaneous injection per kg.). (*b*) *Acquired Immunity.*—When a rabbit is immunised to cobra venom the isolated heart and intestine, perfused with Locke's solution so as to remove the serum, withstand higher concentrations of venom than the heart or intestine of a normal unimmunised rabbit.—L. T. **Hogben**: Studies on synapsis. III.: The nuclear organisation of the germ cells in *Libellula depressa*. (*a*) The nuclear organisation of the germ cells in *Libellula depressa* is investigated with a view to further knowledge of (i) relation of kinetic processes in premeiotic and meiotic phases, and (ii) bearing of nuclear emission in oocyte upon integrity of chromosome complex in meiotic phase. (*b*) In the premeiotic telophase the chromosomes spin out into finely granular loops, displaying initially a polar disposition, becoming increasingly more attenuated in the spirophase, and first recognisable individually in the prophase at attenuated convoluted filaments. (*c*) The Leptotene bouquet is regarded as owing its character to the polarisation of the normal telophase. (*d*) The behaviour of the "double nucleolus" has been thoroughly studied; the plasmosome is independent of the chromatin organisation of the nucleus.

Zoological Society, November 16.—Prof. J. P. Hill, vice-president, in the chair.—Dr. W. A. **Cunnington**: Fauna of the African lakes, with special reference to Tanganyika. After referring to certain physical and geological features which have a bearing on the subject, the nature of the various animal forms inhabiting the lakes was dealt with. Tanganyika was shown to have a very distinctive fauna, in that (1) it includes many more different types than any of the other lakes, (2) an extremely large proportion of them are not found elsewhere, and (3) certain forms (notably Gasteropoda) are considered to have a marine-like appearance. The view previously put forward which regarded the lake as the remains of an old Jurassic sea was considered untenable, since many of the types thought to be marine and primitive belong to essentially fresh-water groups and show signs of specialisation. The Jurassic hypothesis proves likewise incompatible with recent geological evidence. After discussing various other theories, it was suggested that Tanganyika probably owes its remarkable organisms to a prolonged period of isolation, coupled, perhaps, with the effect of an increased salinity which isolation would involve.—H. F. **Carter**: Descriptions of the adult, larval, and pupal stages of a new mosquito from Lord Howe Island, South Pacific.—Prof. C. L. **Boulenger**: Filariid worms from mammalia and birds in the society's gardens, 1914–15.

Institution of Mining and Metallurgy, November 18.—Mr. Frank Merricks, president, in the chair.—C. **Brackenbury**: An automatic counting machine for checking tram-wagons. At a quarry in which the workmen were paid on piecework, their wages depending chiefly on the number of wagons of material sent to the dump and over the weighbridge, the author devised a simple scheme for registering each wagon as it passed up the incline. The upline was provided with catch-rails for the purpose of derailing runaway wagons, and as each wagon passed the open switch the wheel-flanges moved the rail. Suitable levers and wires connected the switch with an automatic counting machine situated in the office, with the result that every complete movement of the switch-rail registered a new unit on the counter. In this manner both the management and the workmen were satisfied that a correct record of the movements of the tram-wagons could be kept.—H. C. **Robson**: Converting high-grade matte in magnesite-lined converters. This paper contains a record of work done at the Spassky Copper Mine, Siberia, where in 1915 two 10-ft. "Great Falls" magnesite-lined converters were installed in place of three 5-ft. acid-lined converters. From the start the new converters were run with the idea of keeping a protective coating of magnesite on the brick lining. This was effected by blowing to white metal a 5-ton charge of matte with flux, followed by a similar amount without flux and 1½ tons of cold matte, the whole being blown to blister-copper. One of the chief difficulties in converting high-grade matte is keeping the tuyères open, especially with slags high in iron and low in silica. From his experience the author can see no reason why any commercial grade of matte should not be treated if correct working conditions be maintained; with matte assaying between 55 and 60 per cent. of copper it was not possible to produce a slag containing less than 6 per cent. of copper. A blister-copper assaying about 98·8 per cent. of copper with a small percentage of sulphur was always produced; attempts to produce copper of a higher grade caused difficulties by the cooling of the charge. The paper contains tables showing respectively the operating data of the converters, analyses of the converter products and by-products, and particulars of the operating temperatures in three trial charges.

Linnean Society, November 18.—Dr. A. Smith Woodward, president, in the chair.—Prof. E. S. **Goodrich**: A new type of teleostean cartilaginous pectoral girdle found in young Clupeids. In the young of *Clupea sprattus*, *C. harangus*, and *C. pilchardus*, about 20–30 mm. in length, the right and left coracoid regions fuse to a solid cartilaginous ventral bar, which becomes bent and again subdivides in later stages. This fusion is probably a specialisation to strengthen the support of the pectoral fins before the complete development of the dermal bones of the pectoral girdle.—Dr. J. C. **Willis**: Endemic genera in relation to others. In a paper of 1916 the deduction was made that in general endemic species of small area were not relics, but species in the early stages of spreading, and much evidence has since been brought up to show the truth of this. It is now proposed to extend this deduction to endemic genera, and to endeavour to show that there is no appreciable difference between a local endemic and an allied genus of wide distribution (of course, working always with groups of genera) other than age. The author has added up all the endemic genera of all the islands in the world, and for comparison also those of (1) West Australia, South Africa, and Brazil (the mainland areas richest in endemics); (2) of Australia, Africa, and South America; and (3) of the world. Examination of the tables thus obtained soon shows that if one takes the families in groups of ten in order according to the number of genera they contain in the world (*i.e.* beginning with Compositae and ending with monotypic families), the proportion of island genera to the total is closely the same throughout the list, and the same holds for all the four areas mentioned. Thus the first ten families contain 40·1 per cent. of the genera of the world, 39·4 per cent. of those of Australia, Africa, and South America, 40·5 per cent. of those of West Australia, etc., and 38·3 per cent. (606 genera out of 1582) of the endemic genera of islands. And the approximation is equally close all down the scale, so that the curves produced almost coincide. Comparison shows with equal clearness that the proportional representation among the endemic genera of islands decreases as one goes down the scale. The first 100 families in the world have island endemic genera in 92, the genera being 12·9 per cent. of the total genera in the families. The intermediate 92 families are represented by 45 only, with 9·28 per cent. of their genera, and the last 100 by 13, with 8·72 per cent.

EDINBURGH.

Royal Society, November 22.—Sir Alfred Ewing, vice-president, in the chair.—Prof. W. **Peddie**: Fechner's law and the self-luminosity of the eye. This law states that the change of visual perceptivity is proportional to the fractional change in the intensity of the light. At weak intensities a term, regarded as constant, has to be added to the intensity of the external light on account of the self-luminosity of the eye. By integration over the whole stimulated part of the retina Helmholtz obtained an expression for the perceptivity which agreed with observation in so far as the general nature of the relation between perceptivity and external stimulus is concerned. There was, however, a measurable difference for a certain range of intensities. A close correspondence can be obtained by assuming that the self-luminosity term in Fechner's expression is itself a simple function of the external stimulus, rising rapidly to a maximum, and thereafter slowly falling to a steady value.—Dr. H. S. **Allen**: Æther and the quantum theory. Although some supporters of the principle of relativity reject the idea of æther, most physicists still employ the æther conception in describing electric and magnetic phenomena. Certain classes of physical facts appear to contradict the laws of classical mechanics, and the quantum theory has been developed by Planck and others to meet such cases. It is argued in this paper that the quantum theory necessitates the physical existence of lines or tubes of magnetic force as discrete entities, and yields a quantitative estimate of what must be the fundamental unit magnetic tube. This unit magnetic tube is determined by the ratio of Planck's constant, h, to the charge, e, of an electron, and is equal to $4{\cdot}12\times10^{-7}$ c.g.s. units. Consequently, one c.g.s. line (one maxwell) contains $2{\cdot}43\times10^{6}$ "quantum tubes." On this theory æther may be regarded as an assemblage of lines of force in accordance with the representation given long ago by Faraday and Maxwell.

PARIS.

Academy of Sciences, November 15.—M. Henri Deslandres in the chair.—C. **Moureu** and A. **Lepape**: The rare gases in natural gases of Alsace-Lorraine. The natural gases examined included five from petroleum wells of Pechelbronn, one from the Wittelsheim potash mines, one firedamp from the Sarre-et-Moselle coal mines, and two from mineral springs (Niederbronn and Soulzmatt). The carbon dioxide, oxygen, combustible gases, and nitrogen (including rare gases) were determined and then the nitrogen was analysed separately. The rare gases were separated into two groups: argon with traces of krypton and xenon, and helium with traces of neon. The argon–nitrogen ratios found varied only between 0·91 and 2·48, but the helium–nitrogen ratios varied much more widely, 23·8 to 2·6.—P. **Théodoridès**: The thermal variation of the coefficient of magnetisation of some anhydrous chlorides and an oxide in the solid state: the magneton theory. Measurements were made on the anhydrous chlorides of cobalt, manganese, and nickel and on manganous oxide at temperatures ranging between 0° C. and 550° C. For the chlorides of nickel and cobalt the results conform to the magneton theory, but this is not the case for the determinations with manganese chloride and oxide.—R. **de Mallemann**: The rotatory power of tartaric and malic acids in solution. Study of the variations in rotatory power produced by the addition of benzene to alcoholic solutions of tartaric acid; the rotations are to the left for all colours, and the dispersion is normal. In aqueous solution this acid reverses its rotation in presence of calcium chloride, and the dispersion, at first abnormal, becomes normal after a certain quantity of the salt has been added. Malic acid resembles tartaric acid and shows similar variations, but in the inverse sense.—E. **Darmois**: The dispersion of the refraction of hydrocarbons. If n and n' are the refractive indices of a given hydrocarbon for two colours, the difference $\frac{n'-n}{d}$, where d is the density, is called the specific dispersion. For different classes of hydrocarbons the differences in the specific dispersion are sufficiently great to be of service in the analysis of mixtures such as occur in petrols.—A. **Bolland**: The micro-chemical reactions of iodic acid. A description of the crystals obtained with iodic acid and salts of thallium, silver, barium, strontium, calcium, and rubidium.—P. **Fleury**: The catalytic decomposition of an alkaline solution of sodium hypobromite by copper sulphate. The opposing action of iodine. The decomposition of the hypobromite solutions was measured by the amounts of oxygen evolved in 1, 2, and 4 days. As little as 0·25 milligram of copper per litre of solution was found to exert a marked catalytic action. This effect can be completely counteracted by adding small quantities of iodine.—C. **Dufraisse**: The ethylene isomerism of the monobromostyrolenes in the lateral chain.—P. H. **Fritel**: The presence of the genera Gangamopteris and Schizoneuta in the grits of Ankazomanga (south of Madagascar). The presence of these plants indicates a lower level of the Permian in Madagascar than that recognised by M. Boule in the Sakamena Valley.—G. **Bertrand**: Observations on the properties of tear-producing substances and the measurement of their activity. Comments on the method used by MM. Dufraisse and Bongrand in a recent communication on the same subject. There are difficulties in the exact definition of the limiting concentration producing effects on the eyes; moreover, the sensibility of the observer varies with the time of day. The mode of attack by the different irritating substances is not the same in all cases; chloropicrin, for example, acts suddenly, whilst the effect of other substances, of which monochloroacetone is an example, is progressive.—A. **Bach** and Mme. Sophie **Zoubkoff**: Contribution to the study of the indices of the blood enzymes. The estimation of catalase, peroxydase, and etherase in one drop of blood.—E. **Kayser**: The influence of luminous radiations on a nitrogen fixer. Cultures of *Azobacter agile* were grown under shades of coloured glass and the nitrogen was assimilated by the bacteria determined. The maximum nitrogen assimilation was under yellow and green light.—J. Y. **Heymans**: *In vivo*, as *in vitro*, micro-organisms pass through the walls of a filter.—L. **Léger**: The endogenous multiplication of *Chloromyxum truttae*.

ROME.

Reale Accademia dei Lincei, June 4.—A. Ròiti, vice-president, in the chair.—S. **Pincherle**: Iterated function of a rational integral one.—G. **Fano**: Surfaces of the 4th order with infinite discontinuous groups of birational transformations, i. The author commences this series of papers with the F/4 containing two skew lines, the first example of the complete study of a group for which Severi's quadratic form is ternary.—G. **Ciamician** and C. **Ravenna**: Considerations regarding the function of alkaloids in plants.—

A. **Angeli** and C. **Lutri**: Black compounds of pirrol, viii.—H. S. **Washington**: Italite, a new leucitic rock. This was discovered by Baron G. A. Blanc and F. Jourdain on the western flank of the volcano of Rocca Monfina in a lava-current more than 100 metres in length.—G. **Andreoli**: Some functional inequalities leading to developments in series.—T. **Boggio**: Lines of force in a stratified spheroid.—C. **Mineo**: Transference of co-ordinates along a geodetic. The formulæ established by the author are applied to a numerical example in geodesy previously calculated by Pizzetti, and are found to agree with his results.—M. **Pascal**: Resultant pressure on a wing of an aeroplane. This is a solution of a hydrodynamical problem in two-dimensional stream-line motion by means of a conformal transformation.—G. **Aliverti**: State of contraction of electrolytic metal deposits, i. Stoney's method is applied to test whether the contraction is or is not due to thermic effects.—E. **Oddone**: Determination of the seismic hypocentre. An empirical formula is established connecting the depth of the hypocentre with the period of the waves of maximum length. As applied to recent earthquakes, this formula gives values for the hypocentric depth of from 9 to 13 km., agreeing fairly well with the known results obtained by more exact methods.—E. **Clerici**: Pelagosite from Canalgrande (Iglesias). This mineral, which was discovered in the form of encrustations on a cavern excavated by the waves, was found to agree in its properties with specimens obtained from Argentario.—L. **Pieragnoli**: Pathology of *Ursus spelaeus* from the caves of Equi. These remains, which were excavated by Prof. Carlo de Stefani, were found to be greatly affected by tuberculosis, showing these animals to be liable to the same diseases as man, and this to an extent which may have been instrumental in causing the extinction of the species.—C. **Artom**: Biology of the genus Artemia.—L. **Petri**: Cause of arrested development of the ovary in the olive. According to Dr. Pirotta, olive-trees could be classified into four distinct types, characterised by the presence or absence of sterile or fertile flowers, flowers with imperfectly developed ovaries, or mixtures of these forms. The author disagrees with Dr. Pirotta's theory, and maintains that the arrested development of the ovary is a phenomenon common to all varieties of wild and cultivated olives, which may be brought about by extraneous temporary causes of recent date. The conditions favourable to the production of the different forms of flowers remain to be determined.—A committee, consisting of L. Luzzatti, G. de Marchi, and R. Pirotta (recorder), presented a report on Dr. Girolamo Azzi's proposals for dealing with meteorological and geographical problems relating to agriculture.

The Practical Teaching of Science.

THE resumption by the Board of Education of the publication of memoranda prepared for the Office of Special Inquiries and Reports is to be welcomed. Before the war a constant stream of valuable information on educational progress and experiment at home and abroad issued from this source, and if not much more came of each individual contribution than is expected from the reports of most Government inquiries, these memoranda were, in the mass, sensibly affecting educational thought and practice. The war inevitably checked the stream in its course, and it is one more encouraging sign that we are, however slowly and painfully, returning to a time of peaceful development, or at least preparing for such a return, when we note that the stream has begun to flow again.

The recent appearance of a modest pamphlet, in the familiar green paper covers, entitled "Some Experiments in the Teaching of Science and Handwork in Certain Elementary Schools in London,"[1] is of peculiar value at the present moment. It is true that the experiments described were cut short by the war, but it is important that the conclusions to be drawn from them should be studied now, when not only in elementary and central and secondary schools, but also in the new day continuation schools, we are faced by the problem how best to combine efficiency and economy in the effort to stimulate intellectual development through science, not as an isolated study, but as a branch of the humanities. Before 1914 we had tended to give up the idealistic dream that if all schools were fitted up with laboratories, or had access to laboratories, equipped for the academic study of chemistry and physics, progress was assured. The view was winning acceptance that for perhaps most young people the best approach was through the motor activities, through carrying out in practice the general idea of "teaching science by making things," or, in other words, discovering scientific principles by solving practical problems. The idealist had come to earth, and we may hope that if his head remains in air his feet will continue to feel the ground he walks upon.

In the report which we have now before us the claim is made that the experiments carried out in the higher classes of elementary schools and in central schools, the latter of which take young people on to about sixteen years of age, go to show that a scheme of instruction in science which is based largely on handwork, and makes no excessive demand on theory, is far wider in scope than has hitherto been suspected. But the report only confirms the lessons to be drawn from two earlier reports—the invaluable "Manual Instruction in Public Elementary Schools," issued in 1910, and, on a higher plane of studies, the "Report on Science Teaching in Public Schools," issued in 1909—the most striking scheme in which was one where handwork and brainwork went on together.

The claim now definitely made is one which is entitled to respect because it is enunciated, not by any mere theorist spinning theories as he contemplates the ceiling through a cloud of tobacco smoke, but by skilled observers speaking on behalf of actual practitioners in the art of teaching. The principle involved is commended to the earnest consideration of those who are anxiously thinking out what kind of practical rooms and what sort of laboratories are to be installed in the new part-time day continuation schools for young people between the ages of fourteen and sixteen who spend most of their time in the office or workshop and only a precious seven or eight hours a week in school. They have the choice between text-book instruction supplemented by a modicum of experiment in a formal laboratory and practical instruction in a workshop which is equipped with the essential fittings of a laboratory. They may well come to the conclusion that,

[1] Educational Pamphlet No. 36. Pp. 34. (H.M. Stationery Office.) Price 1s. net.

while for those who have before them years for continuous study the former method is to be commended, with those who have but an hour or two a week in which to quicken their scientific appreciation a sound working knowledge of a far wider range of scientific phenomena, *with a bearing upon daily experience*, can be gained under a system which combines the workshop and the laboratory than by the conventional text-book treatment of science.

Such is the problem before us, and a possible solution, stated in their simplest terms. As regards elementary education, the question is settled so far as Governmental authority is concerned by the requirement of the Act of 1918 that every local education authority must make suitable provision for the practical instruction of older children. If this practical instruction is to have an educational significance beyond the mechanical repetition of manipulative exercises, however useful in themselves, then the illustration, the working out in concrete materials, of scientific principles or formulæ must be the very basis. For the older children in elementary schools, and also on the industrial side of central schools, such a compromise between the laboratory and the workshop is inevitable. In county boroughs and urban districts, where large, well-equipped centres are possible, the laboratory and the workshop may be separate rooms, provided that the intimate relation of one to the other is recognised, so that the problem set and illustrated in the laboratory is worked out at the bench, or, conversely, the process employed in the workshop is dissected and its principle revealed in the laboratory.

This is precisely what is going on in the one new type of school which has been evolved in this twentieth century of ours. Junior technical schools are very different from the preparatory trade schools or pre-apprenticeship schools which they are generally supplanting. Their purpose is to give a young person intending at sixteen to take up an apprenticeship in some branch of the engineering or building trades or professions, even architecture or naval architecture, not only a humanistic training in English subjects (and, for the brighter intelligences, in a foreign language), but also a firm foundation in mathematics, in mechanical drawing, and in the abstract principles underlying that branch of applied science popularly known as "mechanics," on which they may build their careers—some going no further than to become the foremen of industry; others, during or at the end of their apprenticeship, proceeding to university courses and becoming the Kelvins and Moultons of the future.

Even in the sphere of adult education which is opening out before us there is scope for work on these comparatively simple and unambitious lines. The intelligent artisan who awakes to deficiencies in his early education and is anxious to improve his scientific equipment will often find the initiation into natural philosophy easier by way of the laboratory workshop than through the lecture theatre and the merely experimental laboratory. But here the argument must not be pressed too far, for the greatest is he who is able on reaching man's estate to venture into strange seas of thought alone, and the man of science is great who approximates to that higher and more abstract ideal.

Vitalism versus Mechanism.

The System of Animate Nature: The Gifford Lectures delivered in the University of St. Andrews in the Years 1915 *and* 1916. By Prof. J. Arthur Thomson. (In two volumes.) Vol. i. Pp. xi+348. Vol. ii. Pp. v+349-687. (London: Williams and Norgate, 1920.) Price 30*s*. net two vols.

THE subject of the Gifford lectures was intended by the founder to be natural theology regarded as a natural science and treated, just as astronomy or chemistry would be, with entire freedom from any prepossessions whatever. This rather difficult task has been attempted by two biologists, Dr. Hans Driesch in 1907–8, and Prof. J. Arthur Thomson in 1915–16. The first of these lecturers tells us that he set out to follow biology along its own path—that is, from its nineteenth-century "naïve realism" towards its transition to "a branch of the philosophy of Nature," and such a progress he accelerated in no small degree by a method of treatment that was both critical and constructive. It was critical inasmuch as it included a penetrating analysis of the nature of the transformations that occur in living substance, thus leading to the rejection of the notion of a peculiar "vital energy form," and—which is equally important—it involved also a thorough criticism of the "pseudo-psychology" that had been employed in the study of animal behaviour. But it was also constructive in that it developed an old concept—that of "entelechy"—deriving from this a series of "psychoids" which were regarded as factors in organogenesis, metabolism, and behaviour. The Drieschian psychoids are not energetic agencies, but they function, as Leibnitz suggested in regard to the human soul, like a wise prince among his subjects, or a good father in his household, by directing, suspending, and releasing activities rather than by exerting them.

Now, after this strong and tough fare purveyed by Driesch, Prof. Thomson's book may almost be called "light reading"; clearly it could not have been written from an easy chair, but it can easily be read in such. The aim of a study of animate Nature, Prof. Thomson tells us, "is to state the general results of biological inquiry which must be taken account of if we are to think of organic Nature as a whole in relation to the rest of our experience," and it is just such a survey that he presents to us in a most agreeable manner. There is no inclination to make, or adopt, a system, and the criticism is seldom very penetrating. One is told what is meant, in contemporary literature, by the ideas of "Body and Mind," "Organism and Mechanism," "Adaptiveness and Purposiveness," "Disharmonies and Shadows" that prevent us from seeing, in the organic world, "the True, the Beautiful, and the Good," and so on. But, in the main, the discussion centres round the contrasted hypotheses of mechanism and vitalism.

What is vitalism? There are at least three grades, the author says. First there is a recognition that the physico-chemical processes that go on in inorganic materials cannot explain animal behaviour; knowing only the former, we cannot predict the latter. This is the "very thin edge of vitalism." Next there is the view that some particular "vital force," or mode of energy, operates in living substance, but not elsewhere. Lastly, it has been thought that the organism is the seat of a non-energetic factor, or entelechy. This is "thorough-going vitalism." In addition to these hypotheses there is Mr. E. S. Russell's "methodological vitalism"—a biological fact, such as a migration, is a unique activity which has to be explained. It is not explained by decomposing it into an infinity of physico-chemical reactions, for then the fact itself disappears, and we are left only with a great number of little, partial views or aspects of it, which are, no doubt, expressions of a mechanism of matter and energy, but not the thing itself. We must, therefore, study animal behaviour, not as a series of energy-transformations or even as the result of the operation of mind, but as irreducible data to be dealt with by themselves. This Prof. Thomson regards as the most satisfactory attitude yet suggested, and there can be little doubt about that; it is a method rather than an "ism," and its outcome is investigation.

What is mechanism? As usually understood, the mechanistic conception of life states that the activities of organisms are physico-chemical —and nothing else. The notion comes down to us from Descartes, who recognised nothing in the organic world but matter and its configurations and motions (for, even when he placed the "sensitive soul" in man, he did not regard that as essential to animality). Now, matter, when *our* hypothesis of mechanism was elaborated, meant the chemical atoms; its configurations were chemical compounds, and its motions the expressions of energy-transformations. How to deal with consciousness on this hypothesis was always difficult, but, as a rule, the thorough-going mechanist ignored the condition, and regarded as "realities" only objective things and processes. This was called "monistic panhylism" —which sounds well, at all events.

Whichever of these attitudes one takes up (for a biologist is expected to be either a mechanist or a vitalist) depends on one's education and its media, and also upon one's temperament. Thus Prof. Thomson "confesses to some sympathy with those who ask why there should be all this straining and striving to remove organisms from the domain which includes the stars and precious stones, Northern Lights and dewdrops"; but he does not think that mechanism "exhausts the reality of the earth and the heavens, still less that of the flower in the crannied wall." On the other hand, Prof. D'Arcy Thompson is "not ashamed to uphold" that "the earth itself and the sea, the earth with its slowly changing face and the sea multitudinous with all its tides and currents and great and little waves, constitute a mechanism; the heavens themselves, the sun and moon and all the little stars, are a glorious mechanism." Obviously, having to make the choice induces sentiment. Now it would not be rash to say that the difference between mechanism and vitalism may suggest that between the Homoousians and the Homoiousians, but, like Gibbon when he wrote about the Arian controversies, one fails to trace any "real and sensible distinction" between the "isms" that concern us here. What does one find if he tries to think it all out in the light of strictly modern, physical speculation? Does "determinism" mean anything at all in science? It is "strict" only when we deal with mathematical functionality, and even then is not that just because the human mind, *having made the rules*, expects the answer? Obviously, this "ism" is a method, and not a result. Then, again, it is still very convenient to speak about atoms, etc.; but in pure speculation (which is our field just now) we must get down to bedrock conceptions. *Then* the ultimate data of science are not even space-time coincidences, and not even the *dx's*, *dy's*, *dz's*, and *dt's* (for these can have significance only when they are referred to other *dx's*, etc.), but the relations between these unsubstantial ghosts of reality and other similar ghosts. And are not these relations most obviously the products of the mind? If so, is not our mechanism at the same time also vitalism?

Plainly, then, there is occasion for strong and resolute thinking in biology, as well as in physics, and until that has been done there ought to be an end to these back-number controversies. One fails to find this in Prof. Thomson's book, but, none the less, it is a book that most certainly ought to have been written. It takes stock, so to speak, of the situation of speculative biology at the beginning of a new phase in science, and it does so in a manner that is candid, comprehensive, and most attractive. Even to have compiled the bibliography, for which a host of young biologists will be thankful, is worthy of the gratitude of both students and investigators. J. J.

A Study of Weeds.

Weeds of Farm Land. By Dr. Winifred E. Brenchley. Pp. x+239. (London: Longmans, Green, and Co., 1920.) Price 12*s.* 6*d.* net.

IT is a healthy sign of the broad-minded, practical way in which agricultural research is being conducted that this handsome book on weeds should come from Rothamsted. It is necessary to employ the utmost refinements of mathematical and physical discussion in order to determine the water-retaining power of soil particles, and to make recurring counts of the bacteria and other organisms present in a gram of soil, if the expert is to be furnished with the data he requires in order to advise the farmer on the manuring and cultivation of his soil. But the best of manures will fail of effect if the land is not clean, and agricultural investigators run the danger of performing harmonics on the academic string if they do not constantly vitalise their thinking by watching the farmer at work and learning from him where the real difficulties arise.

Dr. Brenchley's book deals with weeds, and introduces us straightway to a big, and as yet an unsolved, problem—that of competition among living plants. As Rothamsted showed years ago, all the improvements in our agricultural plants, that selection for immense vegetative capacity which makes them such excellent productive machines, have not fitted them in the least to stand competition. When the wheat crop on a part of the Broadbalk field was left unharvested to sow itself and recur to the wild life of struggle, it persisted for only three seasons. By that time the weeds had taken possession of the land, and the wheat could hold its own no longer. A weed is nothing more than a plant which can scratch a living under the stress of competition with cultivated crops and in spite of the wholesale destruction wrought by tillage operations.

Dr. Brenchley begins her book with a description of the devices by which weeds ensure their continuance and distribution. Some, like the poppies, depend on the abundance of their seed; others, like the dandelion, have developed a plume or other device to spread wide their seed; others, again, like the creeping thistle or couch grass, possess a creeping underground stem which will yield a plant from every fragment. This part of the philosophy of weeds is easy; we can see why particular weeds are abundant, but why other equally well endowed plants do not become weeds is less evident. As in other domains of thought, teleology is a fine weapon of argument until someone reverses it. There are other factors in competition we do not in the least understand. Why should certain plants, chiefly European, harmless enough at home, have such a deadly power of spreading and becoming weeds in the worst sense when they are let loose in Australia or America? The prickly pear has rendered millions of acres unusable by man or beast in Queensland; every new country shows some invader in impudent possession, "having the time of its life."

The factors in competition are as yet beyond our summing; some slight reaction to soil or climate may depress or improve the "constitution" of the plant to a degree that is not apparent and certainly not susceptible of measurement, yet that slight change does determine whether the plant can or cannot stand competition. Dr. Brenchley supplies an example in point. Spurrey and sheep's sorrel are perhaps the most useful of indicator weeds—sure signs of soil acidity and lack of lime. Spurrey may be said never to be seen on chalk soils; on the sour Bagshot sands it will overwhelm the wheat. Yet these plants, when grown in pots and plots free from competition, grow better in limed or chalky soils than in their natural medium. The same thing has been observed with the calcifuge leguminous plants.

The latter part of Dr. Brenchley's book is occupied with a discussion of the association of particular weeds with soils, especially arable soils, a question of which she has made the first systematic study, and thereby upset a good many statements that had been put out on insufficient observation. Many of the results are still contradictory and far from conclusive; in fact, this is a field of applied ecology demanding further study. Within a given climatic zone we ought to be able to associate soil types with weeds, and so prepare a soil map accurate enough for working purposes from surface observations of the arable land flora alone, with quite a limited amount of checking by analysis.

Another question to which Dr. Brenchley devotes a good deal of attention is that of the viability of seeds as bearing on the unexpected flora which often appears on the bared surface of a railway cutting, a newly ploughed field that has been long in grass, or even the spoil heap of subsoil from a well or a ditch. Rank luxuriant charlock almost invariably springs up, yet it is difficult to see either how that somewhat heavy seed could be carried there, or that it could have been dormant in the soil. Charlock has been observed to cover a piece of newly ploughed moorland, broken up for the first time in its history so far as was known, and remote from any other arable land. The oldest inhabitants always know that certain fields will be smothered with charlock if they are ploughed deep, or broken up from grass after a long term of years. Yet the viability of seeds when stored is not great, nor do Dr. Kidd's experiments on the retarding effect of carbon dioxide on germination quite decide the question. Under ordinary conditions a seed continues to respire as long as it is alive; in the long-stored wheats at Rothamsted, for example, the embryo is burnt out, as it were. But under suitable conditions—say, of the carbon dioxide content of the air—can the seed assume a static condition and yet retain its germinating capacity, its life, for an exceptional term of years? Dr. Brenchley's figures for the number of arable seeds that germinated in samples of soil from different depths taken from land which had been down in grass for various periods indicate a progressive dying off of the buried seed, the numbers being comparatively few after thirty years of grass. But the subject would repay further study, especially as regards charlock.

One of the best of Dr. Brenchley's chapters deals with the prevention and eradication of weeds; they may be summed up in good cultivation and a sound rotation; smother crops are only effective to keep, not to make, land clean. Chemical methods have their occasional uses, like spraying with copper sulphate solution for charlock, but no farmer should need them after he has once got his land in order.

Dr. Brenchley's book should find its place in all agricultural libraries; it has the vividness and interest of the record of personal observation and thought that no mere compilation ever possesses. A word of praise should also be given to the illustrations; the photographs of parasitic plants attached to their hosts will be of interest to many botanists, while the drawings are new and characteristic.

A. D. H.

Facts and Theories for the Social Worker.

(1) *An Introduction to Sociology: For Social Workers and General Readers.* By Prof. J. J. Findlay. Pp. xi+304. (Manchester: At the University Press; London: Longmans, Green, and Co., 1920.) Price 6*s.* net.

(2) *The Social Worker.* By C. R. Attlee. (The Social Service Library.) Pp. viii+286. (London: G. Bell and Sons, Ltd., 1920.) Price 6*s.* net.

(1) "THE 'unit' in sociology is the group." Throughout this "Introduction to Sociology" the author holds fast to this basal conception, and amid his many excursions into varied fields of study he is constantly turning back to the "group," unfolding its many implications, and by its means striking a path "through the jungle of social questions."

In this treatment of the group conception emerges the author's view that "the political philosophers have been far too prone to present an antithesis between The State and The Individual, whereas the conflict should always be viewed as between The State and The Voluntary Group." The former method gives a false superiority to the State, and begs the question of the place of the other groups in the life of the community. But if we throw over the supreme authority of the State we are left with two alternatives, neither of which seems satisfactory. We may elevate some other group to the highest place; the Syndicalist, for example, would make the group of producers supreme. That way lies no solution, for the association of producers is less representative than the State as it exists at present. We may, on the other hand, with Mr. G. D. H. Cole, attempt to balance the producers' association (The National Guild) by a consumers' association; but even so we are driven to look for a third group with authority over both; and Mr. Cole's *tertium quid* resolves itself into something not unlike our present State. Prof. Findlay does not aim at a final solution of this problem. "A new region," he says, "now awaits to be explored; . . . the various groups which, under the ægis of the democratic State, have developed self-consciousness and power, must now be brought into harmonious relation with each other and with the

State which claims to be their master." But in his discussion there is much that is suggestive and illuminating.

In his chapter on occupation and leisure the author finds the contrast between profession and trade to lie in the fact that the former is based on service, the latter on exchange, and he sees hope for the future in the thought that "society has never accepted the economic basis." Industry must be professionalised. This can be done—it was done during the war—through the trade unions and the employers' associations realising that they exist "to do the work of the trade, to produce the goods."

The book is fresh, alive, and interesting. The author holds that we "must begin with the present: describing and defining what we witness with all the power of abstraction we possess." Hence we find less in this book about the Todas and more about the League of Nations than in most treatises on sociology. Perhaps for an "Introduction" its very facility will prove to some extent a drawback. The simplicity of outline which the beginner demands is lost in the wealth of illustration and in the multitude of apt comments in many spheres of present and past experience. But the system is there if the reader has the wit to come by it; and the student of sociology who reads the book will go back to his task with renewed vigour.

(2) It is not very long since the only picture called up by the term "social worker" was that of an unprepossessing female, of uncertain age, but of undoubted respectability, who periodically descended from her refined atmosphere to view the lives of those strange beings "the poor." But the rapid extension of the sphere of State activity; the devolution of administrative functions to local bodies, and of advisory, and sometimes of executive, functions to workers, voluntary and official, paid and unpaid; the quickening of the social consciousness of the Church; and, perhaps most of all, the awakened self-consciousness of the working classes, no longer content to be experimented upon, but resolved to work out their own solution of whatever social ills they are heir to—all this has made the ordinary citizen aware to a fuller extent than ever before of his social responsibilities. If we are not all "social workers," we have at least come to pay tribute to the value and the difficulty of the services which the "social worker" performs.

Major Attlee in his book explores the wider denotation of the term. He reviews the opportunities for social service, in the charitable society, the prison, the mission, and the Church; in connection with the Poor Law, the Labour Exchange, the Care Committee, the Public Health bodies; and even in the trade union, the friendly society, and the co-operative society. All these are grist to Major Attlee's mill; and rightly so. The social fabric has become self-conscious through and through, and since in this new age these activities must be performed, it is desirable that they should be performed with intelligence and enlightenment. The book is full, racily written, and made alive with interesting first-hand illustration. Not only to the aspiring social worker, but also to those who are old in the service, and to the ordinary citizen, the book should prove a mine of information and a particularly inspiring example of the spirit in which the social worker should pursue his task.

The volume is the first of a series to be entitled "The Social Service Library" and edited by the present author. We look forward with interest to the publication of the other volumes in the series.

Our Bookshelf.

A Dictionary of Scientific Terms: Pronunciation, Derivation, and Definition of Terms in Biology, Botany, Zoology, Anatomy, Cytology, Embryology, Physiology. By I. F. Henderson and Dr. W. D. Henderson. Pp. viii+354. (Edinburgh and London: Oliver and Boyd, 1920.) Price 18*s*. net.

THE present work contains definitions of about 10,000 terms, including several hundred lately coined expressions, many of which have not hitherto appeared in a dictionary. In a first edition all the attempts at definition are not likely to be happy: "cœlom" is "a cavity of the body derived from the mesoblast"; "cœlomoduct," "the duct leading directly from the genital cavity to the exterior in Cephalopods and in Annulates"; "nephridium," "any excretory organ, usually the excretory organ of Invertebrates"; "micronephridia" is not given, though the obsolete and misleading "plectonephridia" appears; "sclerotome," "a partition of connective tissue between two myotomes"; "notochord" is not given, though "vertebra" is; "acanthin," "a substance like chitin, strontium sulphate, forming the skeleton of the Radiolarians"; "nanoplankton," "microscopic plankton"; "entelechy," "the realisation of forms in plant and animal life which have the power of reproducing their kind."

Alternative pronunciations are frequently given, as "different centres of learning have different types of pronunciation"; but one may seriously question the admissibility of many of these—*e.g.* of accenting "abdomen" and "gluteus" on the first syllable, or "popliteal" on the second, or "madreporite" and "mediastinum" on the third; while the only pronunciations given for "lorica," "vesica," and "posticous" (on the first syllable) are frankly impossible. To neglect the established "rules of the game" in this matter is merely to encourage anarchy. "Anlage" should be accented on the first syllable.

The preparation of a dictionary of so many different sciences and subsciences is a formidable undertaking for two authors; the writers have, however, attained a considerable measure of success.

The Evolution of a Coast-line: Barrow to Aberystwyth and the Isle of Man, with Notes on Lost Towns, Submarine Discoveries, etc. By W. Ashton. Pp. xvi+302. (London: Edward Stanford, Ltd.; Southport: W. Ashton and Sons, Ltd., 1920.) Price 10s. net.

The author gathers every possible kind of evidence to prove that there has been a widespread downward tendency in the land levels of the western coast of Britain, which has continued from a beginning, one gathers, after Neolithic times. He has read widely and with profit, though not always with discrimination, but his book will be of value to students, especially if they also have Sinel's "Geology of Jersey" to consult alongside it. The coast is considered section by section with, frequently, a popular geological introduction. The author works out a conjectural map of some ancient coast-lines, such as that of Cardigan Bay, which he suggests was once all lowland, and the land of the famous story of the Lowland Hundred or Cantref y Gwaelod retold by T. L. Peacock in "The Misfortunes of Elphin." In this he is almost certainly right in the main, though some of the scraps of evidence quoted are conjectural, and it is doubtful whether enough is allowed, either in this section or in others, for the consolidation, with the lapse of time, of the boulder clay which formed the main part of the lost lowlands. It is rightly stated that there has been distinct loss of land within historic times, but protection at the public expense is difficult, because the public does not appropriate land gained from the sea, and this, in the last thirty-five years, has been more than seven times the land lost. Even on the west coast gains have counterbalanced losses. The reproductions of old maps and prints are a valuable feature of the book.

Has the North Pole been Discovered? By Thomas F. Hall. Pp. 539+maps, charts, etc. (Toronto: Richard G. Badger.) Price 2.50 dollars.

The Peary-Cook question still arouses controversy in the United States, and the author of the book before us, a former captain in the American Merchant Service and a past member of the Nebraska Legislature, has elaborately cross-examined the various narratives by Peary and his colleagues. He concludes that there is no conclusive evidence that either of the two claimants reached the North Pole. He states that he began his investigation with full faith in Peary; if so, his feelings have been so strongly roused that his statement is marked by the appearance of bitter personal bias. He maintains that the speeds claimed by Peary in his last marches are impossible, that Peary's photographs are shown by incompletely obliterated shadows not to have been taken in the latitudes claimed, and that Peary's different narratives are inconsistent and contradicted on essential questions by those of his negro companion, Henson. The author also claims that recent ascents of Mount McKinley show that Cook must have achieved the ascent of that mountain.

Whether the author's criticisms of Peary are fundamental, or based merely on honest errors in the narratives, on inconsistencies due to haste in publication, and on photographs which were prepared as book illustrations, and not as evidence, will doubtless be ultimately settled by the opinion of competent and impartial American geographers.

The Mystery of Life as Interpreted by Science. By R. D. Taylor. Pp. 176. (London and Felling-on-Tyne: The Walter Scott Publishing Co., Ltd., 1919.) Price 3s. 6d. net.

Most readers of Nature seek enlightenment on "The Mystery of Life as Interpreted by Science"; but whether they will find it in the little book which Mr. R. D. Taylor presents under this title is open to question. All life is psychic in its essential being, and every atom is "a psychic" endowed with super-consciousness defined as native cognition, determinative and directive, inbred in the structure of every atomic centre. This super-consciousness is the law of its being. In accordance with this law every atom radiates attractional emanations into the related atom of next lower radial potency, and coincidently receives radiations from the next higher. The "radial-attractional law of gravitation," which is not only the act of tending towards a centre, but is also coincidently the act of developing towards a source (and thus includes all human aspirations), is the theme of a book the metaphysical implications of which call for no further notice here.

Directions for a Practical Course in Chemical Physiology. By Dr. W. Cramer. Fourth edition. Pp. viii+137. (London: Longmans, Green, and Co., 1920.) Price 4s. 6d. net.

In the present edition of this laboratory manual the arrangement and method of treatment adopted in previous editions have been retained, while the subject-matter is also largely the same as that in the edition reviewed in Nature of March 25, 1915. Two additions have been made—a simple experimental arrangement for demonstrating cell-respiration, which was devised by Dr. Drew, is described, and a section has been added on the balance between acids and bases in the organism. In the latter a brief account is given of the elementary facts of the physical chemistry of acids and bases, and simple experiments by which they can be verified are described.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Heredity and Acquired Characters.

IN his letter headed "Heredity" published in NATURE of November 25 Sir Archdall Reid has not done justice to himself or to your readers. He endeavours to gain attention once more for a jocose misrepresentation of the meaning of the term "acquired characters," and in order to do so neglects to mention the fact that in NATURE, vols. lxxxviii. and lxxxix. (1911 and 1912), the matter was very fully treated in letters from himself and others, including two from me (vol. lxxxix., p. 61 and p. 167). It is the simple fact that in those volumes Sir Archdall Reid had his fling in attempting to mystify your readers with a facetious misrepresentation of the proper use of the term "acquired characters." The fictitious nature of the case presented by him was exposed at that time, and he adds nothing to it to-day. It would be sufficient to refer your readers to that correspondence, the mention of which is avoided by Sir Archdall Reid on the present occasion, were it not difficult for many people to obtain the volumes in which it occurs.

I may, therefore, state here that Sir Archdall Reid's joke or trick consists in ignoring the special and definite significance which has been given (originally, I believe, by Wallace) to the term "acquired characters," namely, that of an English equivalent or code-term for Lamarck's words "les changements acquis." He, on the present occasion, as in 1911, deliberately and professedly treats the statements of accredited writers concerning "*acquired characters*" as though they were using those two words in what he calls their "natural sense," and not (as they themselves declare they are using them) in the special Lamarckian sense as a "code-term." He thus creates confusion and mystification. He declares that *every* character which makes its appearance in the course of development from the egg-cell to the end of life is in the natural sense of those words an "acquired character," and he charges writers who maintain that "acquired characters" are not transmissible with making a statement which is "purely nonsensical." "There is," says Sir Archdall Reid, "absolutely no meaning in the Neo-Darwinian statement that acquired characters are not transmissible. It is like a declaration that five miles weigh five pounds." To that the obvious reply is: "If you, without any warrant, alter the established signification given by the Neo-Darwinian to the chief term in his statement, you can, of course, convert it into nonsense, and your proceeding is merely farcical."

Though many readers of NATURE are undoubtedly acquainted with Lamarck's "Philosophie Zoologique" and the careful definition given by him of what he meant by his words "les changements acquis," it is desirable to cite here what Lamarck said, since Sir Archdall Reid, in order to give an air of sincerity to his little joke, poses as an ignoramus, and possibly others really do not bear in mind Lamarck's statements. Sir Archdall Reid says (November 25): "I daresay I am wrong, but I should be glad to learn just how I am wrong." Further, he writes: "If it be thought that I am mistaken as to all this, can anyone tell us in precise terms what in the world the Lamarckian controversy was *about?*" It is difficult to suppose that Sir Archdall Reid has not read his Lamarck, and still more difficult to believe that he has forgotten the letters published in NATURE in 1911 and 1912, where he was plainly told "just how he is wrong," and also what the Lamarckian controversy was, and is, about. In any case, I will now quote what Lamarck wrote about "les changements acquis" and state what the Lamarckian controversy was, and is, about. Lamarck enunciated in his "Philosophie Zoologique" (Martin's edition, vol. i., p. 235) two laws, the first of which postulates the production of departures in shape and structure of the organs of an animal from the shape and structure normal to the species in normal conditions—when the animal is subjected to what were hitherto unusual conditions; whilst the second asserts that the changes thus acquired ("acquired characters" of English writers) are transmitted in generation to offspring. The limitations given by Lamarck's own words must, of course, be carefully observed. Lamarck writes:

"PREMIÈRE LOI.—Dans tout animal qui n'a point dépassé le terme de ses développements, l'emploi plus fréquent et soutenu d'un organe quelconque fortifie peu à peu cet organe, le développe, l'agrandit et lui donne une puissance proportionnée à la durée de cet emploi; tandis que le défaut constant d'usage de tel organe l'affaiblit insensiblement, le détériore, diminue progressivement ses facultés, et finit par le faire disparaître.

"DEUXIÈME LOI.—Tout ce que la nature a fait acquérir ou perdre aux individus par l'influence des circonstances où leur race se trouve depuis longtemps exposée et, par conséquent, par l'emploi prédominant de tel organe, ou par celle d'un défaut constant d'usage de telle partie; elle le conserve par la génération aux nouveaux individus qui en proviennent, pourvu que les changements acquis soient communs aux deux sexes, ou à ceux qui ont produit ces nouveaux individus."

Those are Lamarck's two laws. The first is universally admitted to be a correct statement of observed fact in numerous cases, though it is not to be accepted as formulating a primary or fundamental property of living matter.

The second law—stating that "les changements acquis" (for which words, in the exact sense in which Lamarck used them, the English term "acquired characters" was many years ago adopted and established as an equivalent) are preserved by generation to the new individuals born from the parents which have acquired those changes in accordance with the first law—has been challenged by many naturalists and accepted by others. Lamarck makes it abundantly clear that the characters transmitted to a new generation—with which he is concerned—are *changes* in form and structure acquired by the parents as a result of *more frequent and sustained use* of some organ or of *constant disuse* of such organ resulting from the influence of circumstances to which their race has been for a long time exposed. It would have rendered misapprehension more difficult had the term "acquired changes" been adopted instead of "acquired characters" as the English equivalent of "changements acquis." The distinctive attribute of the acquired characters so indicated and defined is that they are departures (either increase or decrease) from the usual or normal size, form, or structure of this or that part, arising in an organism "which has not yet passed the limit of its [individual] development" when that organism is submitted to novel conditions. They are *novelties* which arise under *novel* conditions, departures from the normal which occur when the environment ceases to be—*in certain important par-*

ticulars—that which is associated with the normal form of the species.

The "Lamarckian controversy" about which Sir Archdall Reid affects to be ignorant was, and is, as to whether the changes of structures set up in the manner indicated in Lamarck's first law are ever transmitted by generation to progeny. It has been demonstrated that such changes do occur, but no satisfactory evidence of their transmission by generation to progeny has been produced. It is admitted that, so far as we know, such a transmission is *possible*, and, in the period at which Lamarck wrote, the assumption that such transmission occurs was a reasonable one. But hitherto all attempts to give convincing demonstration of its occurrence have failed, though such attempts have been, and still are, made by able biologists.

Before concluding this letter, may I direct the attention of readers of NATURE to the correspondence on this subject which was started by Sir Edward Fry in 1894 (vol. li., p. 54), to which I contributed a long statement? Sir Edward, owing to his lack of acquaintance with Lamarck's writings, was genuinely misled by the term "acquired characters," then less familiar than it is to-day. E. RAY LANKESTER.

December 8.

IN NATURE of November 25 there appears a long letter from Sir Archdall Reid on the subject of heredity. In this letter he seeks to show that the whole controversy about the inheritability of acquired characters—perhaps *the* controversy of most vital importance in biology—is a mere "pother" about "words full of sound and fury, signifying nothing." "All the characters of the individual," he assures us, "are innate, acquired, and inheritable in exactly the same sense and degree."

Sir Archdall Reid must have a singularly poor opinion of the intelligence of his co-workers in the field of biology if he thinks that they have wasted, and are still wasting, their time in a meaningless controversy. The list of such "wasters," moreover, must include the honoured name of Darwin himself, who had a very clear idea of what was implied in the term "inheritance of acquired characters," only he termed it the "inheritance of the effects of use and disuse."

The fact is that the whole of Sir Archdall Reid's letter rests on a mere play with words. I recollect reading of a lawyer who, in defending a client on a charge of slander, maintained that "villain" was a perfectly harmless epithet, since logically and etymologically it only signified a servant employed on a farm.

Sir Archdall Reid begins by stating that all characters are acquired in response to external conditions, since there are no characters, but only potentialities, in the formless germ, and these potentialities will not be realised unless conditions are favourable. Did Sir Archdall Reid imagine that this was doubted by any biologist? Is it not, on the contrary, so elementary and self-evident that every biologist, in discussing genetic questions and assuming an irreducible minimum of intelligence in his hearers, takes it for granted?

If, however, Sir Archdall Reid thinks that such an assumption is unjustifiable, let me try to make the issue a little clearer.

The egg of any animal will only develop its innate possibilities as manifested in the features of the adult animal if the surroundings are favourable, but the development results in a definite type. If the surroundings are unfavourable the type may not come to fruition, but there will be an obvious attempt to attain it; the egg of the shrimp, for instance, never shows any tendency to develop into the same form as the egg of a fish. There is, of course, for every egg a particular combination of circumstances which is especially favourable and may be termed the normal environment, and the normal life of the animal and the function of its organs consist in answering the demands made upon it by this environment.

If, now, the environment be altered to such a moderate extent that the animal is still able to respond to it, then the use of certain of the animal's organs and their growth will be altered. On that point all are agreed; the difference between opposing schools of biologists begins when the question is raised as to what will be the characters of the offspring of the altered individual.

The Neo-Darwinian or Weismannian school maintains that the germs produced by the altered animal will be precisely like the germ which gave rise to that animal. If they develop in the normal environment of the species they will give rise to individuals conforming to the normal specific type; if they develop in the same circumstances as their immediate parent they will show similar divergences from the specific type.

The Lamarckian school, on the other hand, contends that the germs of the altered animal *become themselves slightly altered*, so that if they are allowed to develop in the normal specific environment they may still in their earlier stages of growth show a trace of the altered structure of their parent; and, on the other hand, if they are allowed to develop in the same circumstances as their parent they will manifest the altered structure acquired by the parent *more rapidly and in stronger degree than did the parent.*

I have already had occasion to direct the attention of readers of NATURE to the fact that certain experimenters on the Continent claim to have established the truth of these two essential postulates of Lamarckism. This claim may be ill-founded or well-founded—that is a matter for argument—but no reasonable Neo-Darwinian would fail to admit that if the claim proves to be well-founded the Lamarckian position will be established.

Sir Archdall Reid states that, "apart from variation, like exactly begets like when parent and child develop under like conditions." Leaving aside for the moment the quibble about the word "variation," the Lamarckian contention is that like does not "exactly beget like," but that the influence of conditions on the character of the individuals composing a species *is cumulative from generation to generation.* There is a rapidly accumulating body of evidence in favour of this view; for a piece of evidence to which my attention has recently been directed I am indebted to my friend and colleague, Prof. Dendy. It is as follows: The peach in Europe is a deciduous tree. Transplanted to Réunion it has become an evergreen in the lowlands of that island, but has remained deciduous in the highlands. If a seed be taken from the evergreen tree and grown in the highlands it will still in the first generation give rise to an evergreen tree, although its ancestors were undoubtedly deciduous.

Finally, I should like to say that the sense in which I understand the word "variation," and the sense in which I think it is understood by the majority of my co-workers, is a divergence from the normal appearing among the offspring of a normal individual *when the normal environment remains unchanged*, and in that sense it should be used by Sir Archdall Reid. Imperial College of Science, South Kensington, London, S.W.7, December 8.

The Energy of Cyclones.

IN NATURE for December 2, p. 436, Sir Napier Shaw remarks: "There can be no doubt, I suppose, that solar and terrestrial radiation are ultimately responsible for the kinetic energy of the winds." If we include other possible radiations from space and the effects of high-velocity cosmic matter striking the upper limits of the atmosphere, few will fail to agree. Not many years ago the theory mentioned by Mr. J. R. Cotter (NATURE, November 25, p. 407), "that the energy of a cyclone is derived from the heat-energy of the earth's surface," would have been considered as most probably correct. However, Mr. W. H. Dines, with the aid of about 250 soundings of the upper air with self-registering balloons, proved that the lower central parts of cyclones are actually cooler and denser than the surrounding parts. That his conclusion is of general application so far as western Europe is concerned the daily Upper-Air Temperature Charts issued by the Meteorological Office show.

Fig. 1 shows the distribution of temperature in cyclones found by Mr. W. H. Dines, and in the face of such a distribution it appears to be impossible to attribute their growth and disappearance to the heat-

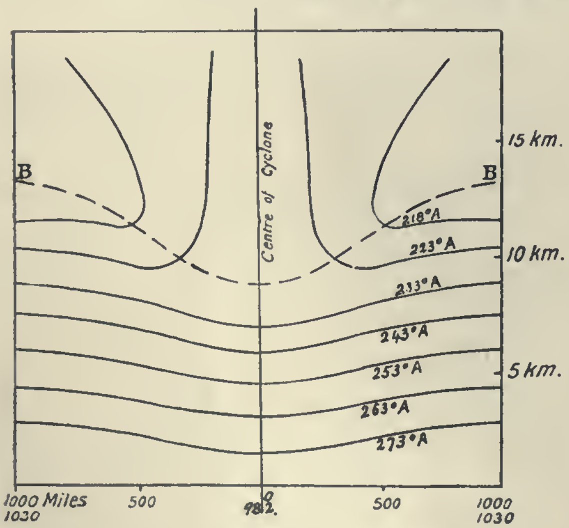

FIG. 1.

ing and cooling of the troposphere. Local heating of the atmosphere near the earth's surface does cause up-rushes of air, resulting in thunderstorms, etc., but they never seem to result in cyclones.

In view of the actually determined distribution of temperature in cyclones being as shown in Fig. 1, I suggested (*Phil. Mag.*, July, 1915, April, 1916, and March, 1918) that the upper, as well as the lower, limits of the atmosphere become irregularly heated, and that the general and local winds of the earth result from the interaction of the movements set up by these two layers of heated air. Referring to Fig. 1, it will be noticed that the line of division BB between the stratosphere and the troposphere is lower at the centre of the cyclone than at its margins, and that the temperature at the centre of the depression is lower than near the margins. So marked is this lowering of temperature that, in spite of the lower pressure, the central air is denser than that surrounding it, and there is, consequently, no tendency for the column of air to rise. On the other hand, above BB the temperature of the stratosphere at the cyclonic centre is higher than it is at the margins at similar levels, and the pressure at the centre being lower as well, there is a strong lifting power exerted upon the troposphere by the stratosphere. So long as such lifting action is in operation the cyclone persists.

With regard to the general circulation upon which the travelling cyclones are superimposed, all the registering balloon ascents yet made indicate that the temperature conditions of the greater cyclonic circulations of the polar areas are similar in nature to those of the smaller ones; nor is there as yet any evidence suggesting that the conditions of decay in cyclones differ in anything but degree from their conditions of growth.

Sir Napier Shaw has pointed out that rain and many other weather conditions are very often due to the "embroidery" of the cyclone rather than to the rising air in the centre of the cyclone itself. The Daily Weather Charts show that, especially near the margins, the effect of the oncoming or growing cyclone, impressing its circulation upon already existing winds, is often to cause damp, warm air-currents to mount over dry ones, and thus to produce rain and cloud. Mr. W. H. Dines (NATURE, November 18, p. 375) may be quite correct, therefore, in holding that cyclones do not result from warm air of the troposphere flowing over cold air near the earth's surface; and Lt.-Col. Gold (*ibid.*, November 11, p. 345) may be equally correct in believing that rain is often due to such conditions obtaining in cyclones. However, such movements are secondary phenomena, and may add some energy to an already existing cyclone, for the reasons given by Sir Oliver Lodge (*ibid.*, November 25, p. 407).

The formation of a cyclone, as Sir Napier Shaw (*ibid.*, December 2, p. 437) states, shows that "the region covered by a cyclone has simply lost a certain part of the air which it normally possesses. In one example I estimated the loss as equivalent to 40,000 cubic km. at sea-level. Beyond all doubt or question air had gone; it was not piled up in anticyclones fore and aft, as we used to think the convected air of our cyclones must be; it was gone clean away." According to my conception, the upper limit of the atmosphere is often heated locally by radiant energy or high-velocity matter from without. Heated protuberances are thus formed at the upper effective limit of the atmosphere. The air of these protuberances then flows away in all directions, leaving cyclonic conditions below the area where the protuberance was formed.

Tintagil, Kew Gardens Road, Kew, Surrey, December 4.

Name for the Positive Nucleus.

MAY I ask in what way "the hydrogen nucleus or unit of positive charge," for which Sir Oliver Lodge (NATURE, December 9, p. 467) provides us with a choice of brand-new names, "proton, ambron, merron, uron, prime, centron, and hylon," differs from our very old friend "hydrion," the familiar hydrogen ion of the physical chemist? The point occurred to me when Sir Ernest Rutherford suggested the new name "proton" for it in Section A of the British Association this year. Its new hypothetical *rôle* as "the brick of which all atoms are built up, electrons acting as cement," although probably more acceptable to chemists than the curious inversion of this which afforded to a past generation of physicists such peculiar æsthetic and intellectual gratification, ought not to be allowed to obscure the fact that there is nothing hypothetical or protonic about the particle itself. In 1920 hydrogen ion, as the common constituent of that very common class of substances called acids by the chemist, surely does not need a choice of seven brand-new names. In fact, one Faraday did some very important work indeed in the subject generations before the modern hydrophobic school, with its inveterate aversion to "anything wet," had arisen. FREDERICK SODDY.

The Stereoscopic Appearance of Certain Pictures.

DR. EDRIDGE GREEN'S explanation on p. 375 of NATURE of November 18 does not go quite far enough. It is true that a picture in correct drawing and perspective will be correct only for one eye, but the eye must be situated at a certain point which is geometrically defined by the elementary rules of perspective. A photograph taken by a pin-hole camera or with any good lens is in true perspective. It should be viewed at the same angle as that with which it was taken; in other words, it should be viewed from a distance equal to that of the pin-hole (or a certain point in the lens combination) from the plate.

Photographs and illustrations are generally viewed at too great a distance. With an angle of view of 55° the eye should be at a distance approximately equal to the longest dimension of the picture. If this is considerably less than 250 mm. to 350 mm. (say 10 in. to 14 in.) a lens must be used, not for magnification—which is a disadvantage in the case of coarse-grained process blocks—but to enable the eye to be used at approximately the right position. Exactness is not necessary, as the eye is so easily pleased. An ordinary reading-glass may be used for the illustrated papers, but it must be held close to the eye. The result is sometimes very striking. Photographs of complicated instruments or of complicated machinery in a factory, which are scarcely intelligible when viewed in the ordinary way, stand out almost as solid as with a binocular stereoscope. Partly because photographs, illustrations, and pictures are generally viewed with both eyes, and partly because the distance is usually much too great, accurate perspective representation, as a rule, produces no stereoscopic illusion whatever.

A. P. TROTTER.

Ajaccio, Corsica, December 3.

Luminosity by Attrition.

THE following workshop observations may throw some additional light on luminosity by attrition, the subject of recent correspondence in NATURE:

Blocks of optical glass are cut into slabs by means of a soft steel circular saw, the edge of which is usually charged with diamond-dust, a copious flow of a lubricant such as petrol, paraffin, or soapy water being employed.

Within the block of glass at the line of contact with the saw there is often visible a blue-tinted white light, limited to the acting portion of the edge of the saw. The light is not thrown downwards in the direction of motion, as in the case of a shower of sparks or of an ordinary flame.

The bluish-white light is most apparent when the cutting is forced, when the saw is blunt, and when an insufficient amount of diamond-powder is used. When the saw is working well the light can only be seen with difficulty by excluding extraneous light.

There is no evidence of any temperature cracking over the cut surfaces, and I know of no instance in which the petrol or paraffin has been ignited even when the saw is cutting at the extreme edge of the glass in contact with the air.

When carborundum is used instead of diamond-powder—the carborundum, however, being injected with compressed air and a water lubricant employed—a dull reddish light appears. It is difficult to say if this reddish light is accompanied by any characteristic heat cracks, as the cutting action with carborundum is more complicated, there being a secondary side abrasion at the surfaces of the saw which might obliterate minute heat-cracks.

JAMES WEIR FRENCH.

Anniesland, Glasgow, December 8.

Tragic Death Feint of a Snake.

ON Sunday morning, May 30, about 10 o'clock, I noticed a common western hog-nosed viper, about 20 in. in length, basking on the lawn in the warm sunshine. I approached the serpent in company with a friend to make some investigation of it, and only to interfere with it enough to keep it from crawling away. The creature went through the usual feint of being a dangerous snake that is peculiar to this species, and quickly began to coil and recoil and to hide its head under its body. After it had done this a short time it turned on its back, but continued to writhe as though injured severely. Gradually it assumed a position simulating that of a dead snake lying on its back, with its mouth completely inverted and bleeding. This was done in such a way that the head appeared to be completely mashed or severed. The exudate of blood from the entire surface of the mouth was perfect. It was the most complete and well-carried-out feint of a tragic death that I have ever witnessed, and all without the least torture or stroke of any kind from me. I only detained the snake by placing my foot in front of it and turning it back once at the beginning. We left the creature in this apparently killed condition, only to see that it disappeared in a very short time.

My observation of this genus Heterodon (hog-nosed viper), which is not a viper at all, has shown me that it always puts up the tamest kind of bluff before hiding its head, but never before have I observed this complete performance with a bloody exudate from the inverted mouth. I am convinced that it will not often be carried out thus completely unless the conditions of season, the weather, and the development of the snake are just right. In other words, I think that it must be a peculiarity of some maturity of growth, and that the full vigour of a warm day in late spring or early summer must enter into it.

W. E. BARTLETT.

Belle Plaine, Kansas, U.S.A., November 22.

The Alkaloids of Senecio jacobæa.

IN the Notes in NATURE of November 4, p. 321, reference is made to "*Senecio jacobaea*, the source of the disease in sheep in Nova Scotia." It should read "cattle" instead of "sheep," for although injurious to sheep it has not been fatal to them as it has been to cattle. The "Pictou cattle disease" has in some quarters led to change of the common name "St. James ragwort" to "cattle-kill"—a term analogous to "lamb-kill" for *Kalmia glauca* and *K. angustifolia*, supposed to be poisonous to young sheep.

The alkaloids of *Senecio jacobaea* were, under the auspices of the Nova Scotia Institute of Science, planned to be investigated by the late Dr. Eben MacKay, of the University of Dalhousie, on the chemical side, and by Prof. C. L. Moore on the biological side. A. H. MACKAY.

Education Office, Halifax, Nova Scotia, November 22.

Instruments for the Navigation of Aircraft.

By G. M. B. DOBSON.

THE design of instruments to aid the navigation of aircraft, like all other branches of aeronautics, has been greatly accelerated by the war, though many of the instruments required are only now reaching their final stages of development, and instruments to effect navigation—as distinct from pilotage by the aid of landmarks—were scarcely used during the war.

Before and during the earlier stages of the war the errors of the magnetic compass as used on aeroplanes were the subject of much discussion, and numerous designs were tested with the view of overcoming its defects, which are, unfortunately, really inherent. The gyroscopic turn indicator has now solved this problem by taking over some of the original duties of the compass. Provided the aeroplane be flying straight, the compass shows the direction of flight correctly, but as soon as a turn is started it immediately becomes untrustworthy. It must be remembered that in a cloud the pilot of an aeroplane has no means of knowing whether he is turning to right or left, or flying straight. Thus previously the compass was used both to keep a straight course and to obtain the bearing of that course. The gyroscopic turn indicator—originally due to a suggestion by Prof. J. B. Henderson—is now available in several forms, all of which work well, and enable a pilot to turn and straighten out again while in a cloud almost as easily as in clear air. With the presence of this instrument the compass is required only for showing the direction of flight during the time the aeroplane is flying straight.

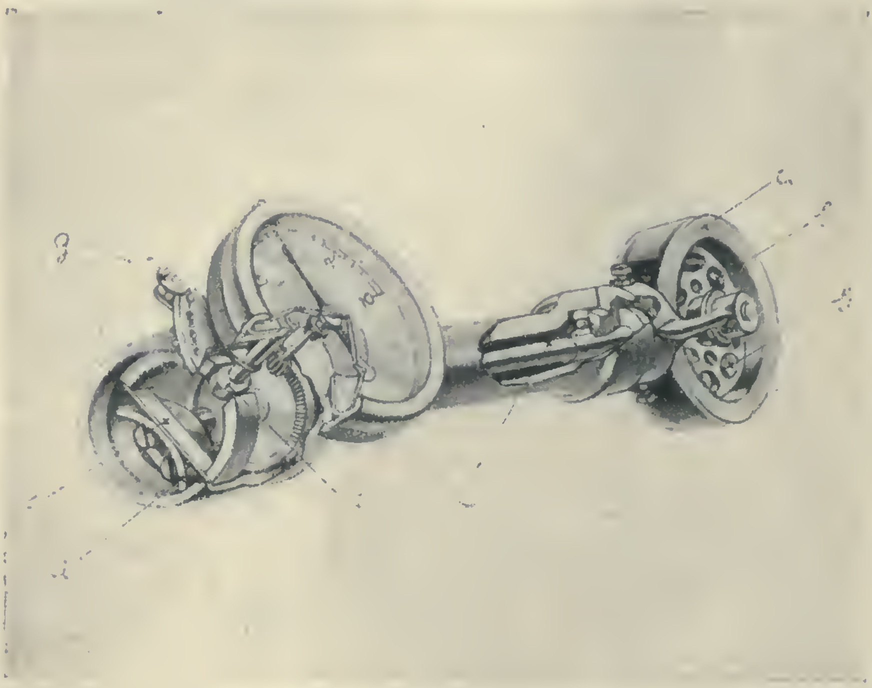

FIG. 1.—R.A.E. gyro turn indicator Mark V. *a*, gyro wheel; *b*, *b*, oblique holes for air-drive; *c*, shaft carrying gyro wheel communicating motion to pointer; *d*, cam on shaft *c*; *e*, controlling spring; *f*, cam altering tension of spring *e*, worked by lever *g*.

The gyroscopic turn indicator depends for its action on the precession of a rotating gyroscope against suitable controlling springs, when its axis of rotation is changed. One simple form is shown in Fig. 1. The gyro wheel seen on the right is

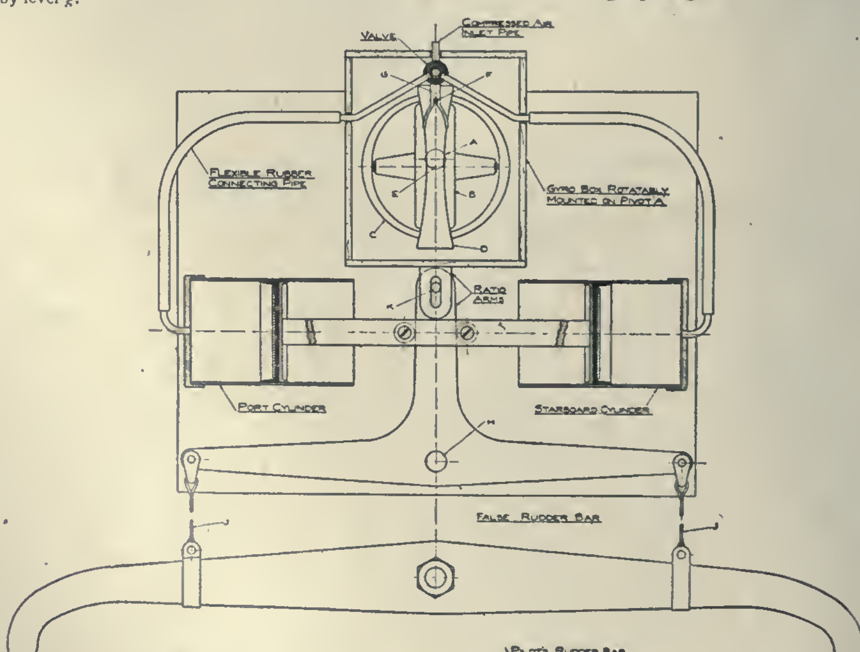

FIG. 2.—Gyro rudder control. B, gyro wheel; C, D, gimbal rings of gyro; F, G, pin and link connecting outer gimbal ring to valve.

mounted outside the aeroplane, and spun at 10,000 to 15,000 revolutions a minute by the relative wind. The central cylindrical portion passes inwards through the side of the aeroplane and carries the dial, which is in front of the pilot. By means of a cam marked *f* the tension of the control spring *e* can be varied at will over a large range, and thus the sensitiveness of the instrument can be changed to suit different machines or different atmospheric conditions.

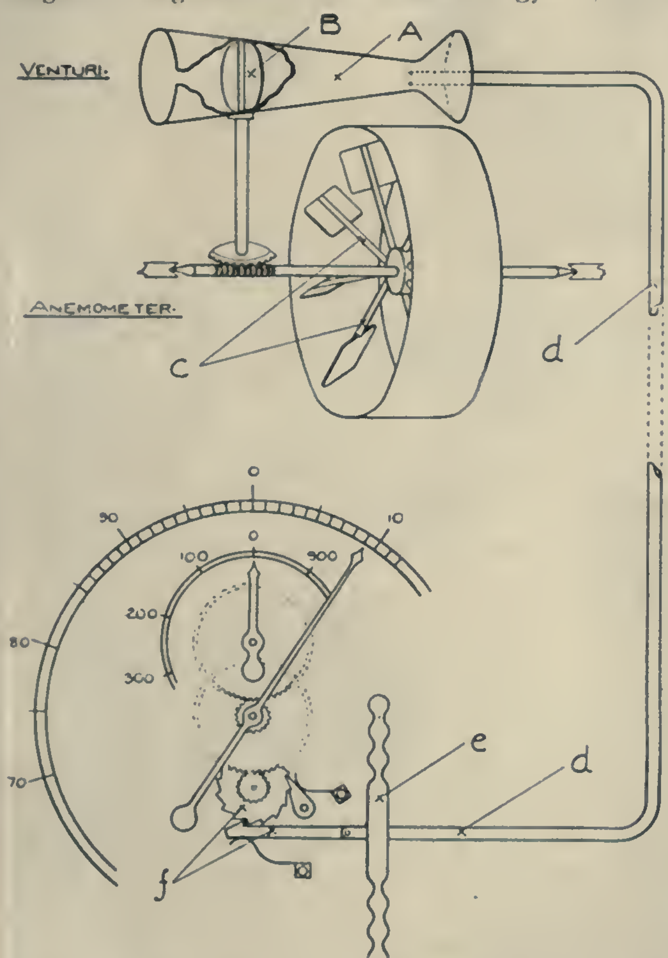

FIG. 3.—R.A.E. pneumatic air log. A, Venturi tube exposed to wind; B, disc in exit cone revolved by wind nill C; *d*, pipe connecting throat of Venturi to diaphragm *e*; *f* ratchet and wheel.

Another gyroscopic instrument which has been designed during and since the war is the gyroscopic rudder control. This is intended to relieve the strain on the pilot during a long flight by controlling the aeroplane's direction. With it the pilot need only check the course once every five to ten minutes. The instrument consists of a gyroscope hung freely in gimbals and carefully balanced. With good workmanship such a gyroscope will keep its direction within a degree in ten minutes. Any movement of the aeroplane relative to the gyroscope immediately operates a valve controlling a pneumatic servomotor, which puts over the rudder so as to turn the aeroplane back to its original course. It is also fitted with a simple "follow-up gear," so that the deflection of the rudder is proportional to the amount the aeroplane is off its true course. The apparatus is shown diagrammatically in Fig. 2. The gyroscopes are about 3 in. in diameter, and spun at about 15,000 revolutions a minute by compressed air.

Until recently the only method of finding the distance an aeroplane had travelled through the air was to note the length of time flown and the average reading of the air-speed indicator. The latter reading, being dependent on the density of the air, must be corrected for the density at the height flown, as well as for a small error due to interference of the air-flow by the neighbouring parts of the aeroplane. To eliminate this trouble, an air log was designed, which should record continuously the actual distance travelled through the air. This is shown diagrammatically in Fig. 3. A windmill type of anemometer is employed, since this has the advantage that it needs no correction for change of density. As the windmill must necessarily be fixed on an exposed part of the aeroplane, it must be made to transmit its indications to the pilot. This is conveniently arranged by mounting a Venturi tube alongside the windmill. The exit of this Venturi tube is alternately opened and closed by a rotating disc, say once every 1000 revolutions of the windmill. The pressure at the throat of the Venturi tube is thus alternately above and below atmospheric pressure, and a pipe led from the Venturi tube to the indicator transmits these alternations of pressure, which operate the counting gear through the agency of a small diaphragm. The addition of a small adjustable baffle behind the windmill allows the interference error to be eliminated once for all for any aeroplane.

The use of ordinary sextants in the air is largely ruled out by the fact that the true horizon is nearly always obscured by haze. The top of this layer of haze is generally nearly horizontal, and has, therefore, sometimes been used instead of the real horizon. As, however, it may occasionally be inclined to the horizontal by a degree or more, such results are untrustworthy.

The use of bubble sextants has been attended by greater success than was at first expected. On aeroplanes the mean of six readings will generally give the altitude of the sun or star correctly within about ten or fifteen minutes of arc. On airships much better accuracy seems possible. The design of bubble sextants for use in the air is largely a matter of making them convenient to use. The image of the sun and bubble must move together across the field if the instrument be tilted, and the size of the bubble must be adjustable. The general principle of a bubble sextant is shown diagrammatically in Fig. 4. By means of a lens and prism (not shown), which are fixed above the bubble lens, the horizon can also be seen in the field of view, as well as the bubble, so that the instrument may be used as an horizon sextant if required.

The problem of the rapid calculation of sextant observations appears to have been solved completely by the cylindrical slide-rule due to Mr. Bygrave. With a slide-rule about 7 in. long results can be obtained in three or four minutes' time which are accurate to within about three minutes of arc. With larger patterns greater accuracy in obtained.

The accompanying illustrations are from a lecture on "The Design of Instruments for the Navigation of Aircraft," read to the Royal Geographical Society by the author on May 10 last, and published in the *Geographical Journal* for November.

Industrial Research Associations.

VI.—THE GLASS RESEARCH ASSOCIATION.

By EDWARD QUINE.

THE Glass Research Association has been established for investigation into the problems of the glass industry in accordance with the scheme of the Committee of the Privy Council for Scientific and Industrial Research. The association received its Certificate of Incorporation on August 11, 1919, and held the first general meeting on October 14 following.

The objects of the association are to conduct scientific and technical investigations relating to glass and its manufacture, and to disseminate among members technical and other information bearing on these subjects and on the production of articles made wholly or partly of glass.

The rate of development of the glass industry in this country is largely influenced by difficulties in the matter of technique, works organisation, production and equipment, and, in order that the industry may attain a high degree of efficiency, it is necessary for investigations to be directed towards overcoming these difficulties, in addition to investigations of fundamental principles and search for new knowledge. To ensure that greater economy in production and more satisfactory products may be obtained, improved methods must be introduced, and the works practice of the industry brought into line with the advanced methods found operative in other countries. Until recent years no comprehensive research work relating to the industry had been carried out in this country, but the need for a deeper and more extensive knowledge of the fundamental facts underlying the various processes of manufacture is now appreciated. The association is consequently endeavouring to secure that the fundamental principles and their application shall be thoroughly investigated by systematically conducted researches, so that, side by side with the modernising of works practice, and the introduction into the industry of the scientific control of the various operations, new knowledge may be acquired which may ultimately lead to industrially valuable developments.

The investigations of the association cover the problems of all sections of the glass industry other than those of optical glass, research work in which is being undertaken by the British Scientific Instrument Research Association.

The membership of the association is limited to British corporations and British subjects carrying on business in connection with the manufacture of glass, and other trades and industries allied therewith or accessory thereto. Individuals ineligible for membership or not desiring admission as members, who are interested in the glass industry and willing to subscribe to the objects of the association, may be admitted by the council as associates. At present there are 135 members and seventeen associates.

The management of the association is vested in the council with an executive committee; the council consists of a majority of elected members together with a limited number of members co-opted because of their special knowledge and experience, and members nominated by the Department of Scientific and Industrial Research. The chairman of the first council is Mr. George E. Alexander, whose support and direction have been largely responsible for the successful establishment of the association.

The organisation and direction of research work is entrusted to a director of research, and the association has appointed to this post Mr. R. L. Frink, formerly of the Frink Laboratories, Lancaster, Ohio, U.S.A., who took office on March 1, 1920.

The director of research works in close consultation with seven research committees, which have been appointed by the council to survey the field of research in relation to glass and the glass industry. The terms of reference of these committees are:—

(1) Chemical and physical properties of glass (at all temperatures). (Chairman: Dr. W. Rosenhain.)

(2) Fuels, refractories, furnaces. (Chairman: Mr. S. N. Jenkinson.)

(3) Glass-making materials, glass-founding—temperature measurement and control; annealing and finishing other than decorative and marking operations. (Chairman: Mr. C. C. Paterson.)

(4) Glassware-forming operations—hand and mechanical; glassware-making machinery. (Chairman: Mr. J. Forster.)

(5) Lamp-working. (Chairman: Mr. F. Cossor.)

(6) Design, lay-out, and equipment of glass factories. (Chairman: Mr. R. S. Biram.)

(7) Glass decorative and marking operations. (Chairman: Mr. E. J. Purser.)

The programme of research covers a wide range of subjects, including investigations into the following problems:—

(1) The dependence of fusibility, range of viscosity, colour transparency, brilliancy, refractivity, heat conductivity, expansibility, electrical conductivity, tensile and crushing strength, hardness, brittleness, elasticity, working properties in the blow-pipe flame, resistance to chemical action, and devitrification upon the chemical composition of the glass.

(2) The examination and treatment of clays and bricks, the composition and methods of manufacture of refractory materials, the firing of pots, and investigations in regard to refractory materials.

(3) The design, construction, and operation of furnaces, tanks, pot arches, lehrs, kilns, glory-holes, etc.

(4) The relative value and efficiency of coal, coke, oils, tar, and other combustible mixtures, gas and gas-producers for various types of furnaces and lehrs, and the investigation of electrical methods of heating.

(5) The most suitable raw materials by means of which to introduce certain chemical elements in the best and most economical forms.

(6) Methods of batch mixing.

(7) Measurement and control of temperature during founding, chemical and physical changes during founding, determination of most suitable rates of charging and founding different types of glass, effect of furnace gases upon the various types of glass during founding; methods of aiding the fining process.

(8) Examination and improvement of the methods and conditions under which molten glass can be conveyed to the forming apparatus; moulds and their treatment; mechanical processes of forming glass.

(9) Investigation of annealing temperatures, rates of annealing, effect of annealing on physical and chemical properties; methods of detecting and measuring strain.

(10) Cracking off, grinding, etching, enamelling, decorating, graduating and marking, lamp-working machinery, and other mechanical processes of finishing.

(11) Ventilation of works.

(12) Efficiency and health of operators as related to industrial operations.

Apart from the general problems of the industry, members of the association may, on terms to be decided by the council, have special information given to them by the director or staff of the association, or may have special investigations or researches made for them.

In March, 1920, the association secured the lease of 50 Bedford Square, W.C.1, and these premises have been equipped as offices and laboratories, in which eight research assistants are carrying out intra-mural investigations. Difficulties have been met with regard to the equipment of these premises, thus causing much delay in the work; but now the required equipment is being rapidly assembled.

The full activities of the association have as yet been of short duration, but during this period it has consummated agreements and arrangements with certain of its members whereby it has been made possible to construct an experimental tank furnace for the development of certain types of glasses, and a method of their formation into chemical, table, lighting, and other classes of ware, which, it is hoped, will effect not only a great economy in cost of manufacture, but also increase the production. The construction of a new type of lehr is also contemplated under a similar arrangement, and it is hoped that the results of this work will assist in solving, or even solve completely, many of the technical problems in the annealing of various classes of ware at a greatly reduced cost in construction and operation, and at the same time place annealing under more scientific and positive control. Moulds for forming glassware, their composition, construction, and methods of use are being studied, and the results will shortly be experimentally applied in the works of members.

A number of improvements and inventions, for some of which applications have been made for patents, are being completed, and will in due course be placed in operation. These improvements and inventions include a method of cooling tank-furnace walls, an instrument for indicating and recording viscosity of glasses under practical working conditions, temperature-control apparatus, furnace-controlling instruments, paste for moulds, etching and acid polishing solutions, instruments for classification of colour values of glasses, and others of minor importance.

It has been the policy of the association so far as possible to utilise existing facilities in scientific institutions, and in accordance with this policy the National Physical Laboratory is proceeding with researches on behalf of the association, and it is contemplated that during the coming year the volume of researches at this institution will be considerably increased. Investigations are also proceeding at the Department of Glass Technology, University of Sheffield. Negotiations are pro-pressing with universities and institutions which are specially equipped and adapted to investigate specific problems on behalf of the association.

The association is completing a working agreement with the British Refractories Research Association whereby large-scale researches into the fundamental principles underlying the manufacture of refractories for the glass industry and their industrial application will be carried out by the British Refractories Research Association working in consultation with a joint committee formed of members of both associations and the Directors of Research.

Working arrangements have been made with the British Scientific Instrument Research Association whereby problems common to both associations will be investigated jointly, this association co-operating with the British Scientific Instrument Research Association to the fullest possible extent.

The council has considered the advisability of conducting research investigations into psychological and physiological problems affecting organisation and productive operations of the industry, and, believing that such investigations will be of great benefit both to the operatives and to the manufacturers, has referred this matter to the appropriate research committee for action.

Apart from work to be undertaken by associations and scientific institutions and at factories of members on behalf of the association, arrangements have been made for men of science who have specialised in certain branches of scientific investigation as applied to this industry to undertake researches.

Extensive investigations on "The Bloom and Dimming Effect upon Lamp-working Glass" have been made on behalf of the association by Mr. J. H. Gardiner. A first report has been received which has led to fruitful suggestions for further investigations, which are proceeding. A valuable contribution has been made to the association by Messrs. F. Twyman and A. J. Dalladay upon "Methods of Differentiating Cords in Glass," and further work is being done on this subject in the laboratories of the association.

A vast amount of work lies before the association, and, while realising the limitations of universities in their relation to industrial research and appreciating their services to industry in furnishing both ideas and trained investigators, the council is, in its endeavours to solve such of those problems of the glass industry as lend themselves to investigations along academic lines, anxious for the close co-operation of those universities and scientific institutions having equipment and facilities available, and it is hoped that as its work progresses the association may become the centre of scientific and industrial research into problems of the glass industry for the Empire.

The Quantum Theory.

PROF. MAX PLANCK was awarded the Nobel prize for physics this year, and his address [1] on the occasion of receiving it makes extraordinarily interesting reading. He describes in some detail the way in which he was led to the discovery of the quantum, and to anyone engaged in research the description will be very encouraging, for it shows through what darkness the mind of a great discoverer must grope, and what false tracks he will follow, before he sees the light of the truth. At the time of his discovery few physicists would seem to have appreciated the fundamental importance of the unknown relation connecting the energy of radiation with its wave-length and temperature, perhaps because this relation can be obtained only by a denial of some of the chief articles of their scientific creed. Thus the late Lord Rayleigh had already stated correctly the radiation formula as it ought to be—and as it is for the longer wave-lengths; but he does not appear to have attempted to explain its hopeless failure in the region of the visible spectrum and beyond. The rival formula was that of Wien, far less sound theoretically, but giving good agreement with observation in the visible spectrum.

Planck started on Kirchhoff's idea that if he could find the emission and absorption for a single ideal radiating substance, the true radiation formula would result. He naturally worked on dynamical principles, and inevitably got a result equivalent to no result at all, for it led to the

[1] "Die Entstehung und bisherige Entwicklung der Quantentheorie." Von Max Planck. Pp. 32. (Leipzig: J. A. Barth, 1920.) Price 4 marks.

impossibilities of Rayleigh's formula. He next turned his attention to the thermodynamical aspect, and this illustrates at its best the groping process, for in fact thermodynamics does not contain the answer at all; and yet this track guided him to the right solution. He was led to study a certain thermodynamic function (the reciprocal of the second differential of the entropy with regard to the energy!), and was struck by the fact that, with Wien's formula, it was proportional to the energy itself—a fact that is really quite accidental. For Rayleigh's formula it was proportional to the square of the energy, and Planck was happily inspired to combine the two forms into one. The result gave him the true formula. It remained to find a theory to account for it.

In the course of his efforts to get this theory, Planck turned to the deeper meaning that is attributed to entropy on the kinetic theory, which connects it with probability, and once this was tried it gave the result more simply than might be expected. For in considerations of probability one is bound to work with discrete quantities, and not with continuous; and so one must adopt the idea of atoms of energy for the calculations, though with the ultimate intention of making them infinitely small. But this intention is frustrated, because the formula is obtained without going to the limit at all. This was how Planck arrived at his theoretical explanation of the radiation formula, and by comparison with experiment he was enabled to deduce two universal constants. From the first were obtained the earliest really good values for the charge of the electron and the associated constants. The second, he confesses, perplexed him a good deal, and indeed it would have been surprising if it had not. It was the quantum.

The remainder of the address is occupied with the later history of the quantum, and it is scarcely too much to say that this is simply the history of modern physics. Of all its applications, photoelectric effect, specific heats of solids at low temperatures, specific heats of gases, etc., he not unnaturally gives pride of place to Bohr's spectrum theory. The address concludes with some speculations as to what may be the solution of the almost impossible difficulties with which we are faced. The success of the quantum theory has been, and continues to be, so enormous that it often appears as if writers had forgotten that the whole present system of physics is based on a perfectly definite set of mutually contradictory axioms. So it is particularly interesting to hear some views on this question by one of the great authorities. Unfortunately, Planck does not seem nearer the solution than are the rest of us, for in one place he throws out the discouraging suggestion that the quantum theory is now in the state in which Römer left the theory of light, so that we may expect to have to wait a long time for the Maxwell of the subject to appear and reconcile the seemingly irreconcilable.

Obituary.

SPENCER PICKERING, F.R.S.

BY the death of Percival Spencer Umfreville Pickering at Harpenden on December 5 English science loses one of its most original and attractive personalities. His death was not unexpected; for more than a year his friends had known that Pickering was in a precarious condition, holding on to life by little more than his courage.

Pickering was born in 1858 of good family, and educated at Eton and Balliol. His earliest paper was published while still an undergraduate, and it is not uncharacteristic that it was polemical, directed against one of his dons, and concerned with a basic compound. But his real activity began with his appointment as professor of chemistry at Bedford College in 1881. He began to work upon the constitution of double and basic salts, and passed on to determinations of thermal phenomena accompanying the formation and solution of salts. Naturally enough, this work led to a general consideration of the process of solution, especially as it was about this time that the Van't Hoff theory of osmotic pressure and the dissociation into ions of salts in aqueous solutions was beginning to revolutionise the conceptions of chemists. Pickering would have none of this theory; his work lay at the other end of the scale among strong solutions and powerful electrolytes, and he saw solution as a process of association with formation of hydrates. In a voluminous paper published by the Chemical Society in 1889 he examined with an extraordinary wealth of detail the density, conductivity, heat of dissolution, heat capacity, and expansion of mixtures of sulphuric acid and water, demonstrated breaks of continuity in the graphs representing these properties, and isolated definite hydrates to match the breaks.

Controversy with the supporters of the ionic hypothesis grew intense, for Pickering was turning out an enormous volume of experimental work, and was standing for his hydrate theory almost *Athanasius contra mundum*. Between 1889 and 1896 he printed no fewer than fifty-six papers on solution with the Chemical Society alone, many of them of great length, and involving a vast number of exact determinations, all of which were done single-handed and without assistants. The tide was, however, running against Pickering; he and Ostwald were looking at different sides of the shield; but, though Pickering's work has since fallen into its proper place, at the time it lacked that pragmatic justification of leading to discovery which made the dissociation hypothesis so generally acceptable to the chemists of the day. In disgust Pickering forsook chemistry, the rapid flow of papers ending abruptly in 1896.

Pickering, however, as a younger man had, in order to regain his health, put himself to work as a labourer on the Experimental Farm at Rothamsted, and thus acquired an interest in the application of science to the problems of the cultivator. He had as early as 1894 designed a series of experiments upon the growth of fruit, and had persuaded the Duke of Bedford to set up a trial garden at Ridgemount in Bedfordshire. Results soon began to appear and to arouse dissent; not easily did the practical fruit grower, accustomed to old grass orchards, accept the doctrine of the injurious effect of grass upon tree growth. This subject occupied Pickering to the end of his days; the complexity of the problem grew with extended knowledge; but Pickering maintained his first explanation that the grass roots excrete something specifically poisonous to fruit trees. Much other ground was broken—the effects of pruning, methods of planting and preparing the soil for planting, manuring, insecticides—there is no part of the fruit grower's routine on which Pickering did not inaugurate investigation.

The conclusions published from year to year and gathered together into a final volume, "Science and Fruit Growing," in 1919, have been the occasion of much controversy. The unsuitability of soil and situation, and some defects in management in the early years, hindered their acceptance, but the Woburn trials will remain as the most substantial contribution of the last hundred years to the study of fruit-tree development, one full of stimulus to new workers. His work on spray fluids led Pickering back to chemistry and his earliest interests—basic salts; after a ten years' silence papers began to reappear on such questions as the basic copper salts of Bordeaux mixture, on emulsions (with his strange discovery of a method of solidifying paraffin), and on quadrivalent copper salts.

In his horticulture, as in his chemistry, Pickering was essentially the amateur of genius; he often seemed to be careless of, and even but moderately equipped with, the knowledge that was common form, academic or practical. But he had a disconcerting habit of making discoveries which contradicted that common form. Either from policy or from temperament, he never disguised these antagonisms; where another man might have looked round to find hints and anticipations in previous experience, Pickering would say roundly, "All men who have hitherto expressed opinions on this point have been entirely wrong," even in such a matter as the way to plant a fruit tree. He loved truth, and he pursued it all his life like an artist, for the interest it had to himself; there was also something of the artist's disdain in the way he presented it to the world.

Never in robust health, an accident that deprived him of the sight of an eye probably helped to keep him out of general society, nor had he any of the ordinary man's amusements. At one time he used to walk a great deal with his inseparable companion, his wife, but he seemed to get most pleasure out of the company of a few friends in his Harpenden garden, and it is there, among his fruit trees, or indoors at his piano, that one will remember Spencer Pickering, handsome, imperturbable, a fine and rare presence among men.

A. D. H.

WILLIAM ARTHUR HAWARD.

WILLIAM ARTHUR HAWARD, who accidentally met his death on Monday, December 6, whilst making some final experiments in an important investigation upon gaseous combustion under high initial pressures, upon which he had been engaged during the past two years as a Salters' research fellow in the Imperial College of Science and Technology, was passionately devoted to the cause of scientific research. There is every reason to believe that, had his career not been thus so tragically cut short, he would at no distant date have achieved great distinction as a scientific discoverer. Even during the research which he was completing at the time of his death he had, by most skilful experimental work, discovered a series of facts which pointed to an important new fundamental development in the science of combustion. Indeed, the actual experiment upon which he was engaged when the accident occurred was intended to test a new theory which had been suggested to account for some of his remarkable experimental results. In due course, when the results of his research are published, the importance of them to science will at once be apparent. He undoubtedly laid down his life in the cause of science.

The various stages in Haward's all too brief, but very distinguished, career were as follows: Entering the Royal College of Science in October, 1912, he took the associateship two years later, and also his London B.Sc. degree with first-class honours in chemistry. He thereupon commenced a course of post-graduate study and research in the department of chemical technology, under the direction of Prof. W. A. Bone. It was soon apparent that he was unusually gifted as an experimentalist, for he made some remarkable experiments upon certain aspects of surface combustion, which have yet to be published. During two of his summer vacations, in the years 1915 and 1916, he made investigations under the direction of Dr. R. V. Wheeler at the Eskmeals Home Office Experimental Station upon (1) the propagation of flame in mixtures of hydrogen and air, and (2) the uniform movement of flame in mixtures of acetylene and air, the results of which were embodied in two papers that were published in the joint names of himself and two others (who had assisted him) in the Trans. Chem. Soc. for 1916 and 1917.

In June, 1916, Haward was elected to a Beit research fellowship tenable at the Imperial College; but this was relinquished some six months later in order to join the chemical staff of H.M. Explosives Factory, Gretna, where he remained until shortly after the armistice. He then obtained a Salters' research fellowship, with which, at his own desire, he undertook the particular investigation which he was completing at the time of his death. Though a man of gentle disposition, and very modest in his demeanour, Haward undoubtedly was conscious in the right way of his experimental powers, which excited the daily admiration of those whose privilege it was to watch their rapid development. He had in a marked degree the instinct of the true artist, which was never satisfied with anything less than the best. He was twenty-six years of age, and was married only fifteen months ago.

ANOTHER Kew veteran has passed away in the person of JOHN READER JACKSON, who died on October 28 at his house at Lympstone, near Exmouth, Devon, aged eighty-three. Mr. Jackson was born in 1837 at Knightsbridge, but his family removed about 1843 to Canterbury, where he received his early education, returning in 1851 to school in London. Through the influence of Prof. Thomas Bell, then president of the Linnean Society of London, he was given charge of the museums at Kew, then in process of development under Sir William Hooker, and for nearly twenty years he discharged his duties single-handed, until in 1879 he received the help of an assistant. His work left him but little time for literary diversion, but we owe to him not a few contributions in applied botany in various journals, as in those of the Linnean and Pharmaceutical Societies, the *Technologist*, *Gardeners' Chronicle*, and the like. Mr. Jackson brought out a new edition of Barton and Castle's "British Flora Medica" in 1877, and in 1890 appeared his excellent "Commercial Botany of the Nineteenth Century." He was elected an associate of the Linnean Society in 1868, and was the senior on the list at the time of his death.

WE regret to record the death of DR. CHARLES INFROIT, late head of the radiological service at the Salpêtrière Hospital, Paris. The death of Dr. Infroit adds one more to the list of victims to X-ray dermatitis. A pioneer in the subject of X-rays in medicine, he was injured through over-exposure to the rays at a time when these dangers were not fully appreciated. Despite the disabilities by which he was handicapped, he made numerous contributions to the literature of the subject of radiology, especially from the diagnostic side. So recently as last year a paper appeared by him on the subject of concretions in the lung simulating the presence of a foreign body. A joint communication with Pascalis upon the surgery of the bones of the head appeared in the *Journal de Chirurgie*, 1912. Dr. Infroit designed and put into use a localiser of foreign bodies, which was used very considerably during the war; details of this instrument and the results obtained by its use may be found in the *Bulletin de l'Académie de Médecine*, 1915.

NEWS has just been received of the death of HOFRAT ALEXIUS MEINONG, on November 27, after a short illness, at the age of sixty-seven. Professor of philosophy at the University of Graz, to which he was appointed in 1889, Meinong was well known to philosophical students throughout the world by his important contributions to a special branch of study which he named "Gegenstandstheorie." His earliest published work was "Hume Studien," 2 vols., 1877. His principal work, and that by which he is best known, is entitled "Ueber Annahmen," published in 1902, and a second edition of which appeared in 1910.

WE regret to announce the death, on December 13, at seventy-two years of age, of DR. ALEXANDER MUIRHEAD, F.R.S.

Notes.

THE position of scientific men employed in the Government service has long exercised the minds of scientific workers. The responsibility for the National Physical Laboratory and for the Geological Survey has been handed over to the Department of Scientific and Industrial Research. Kew is still under the Ministry of Agriculture and Fisheries. The Government Chemical Laboratory and the British Museum, with its Natural History Branch at South Kensington, remain distinct institutions for which the Treasury is responsible. All these institutions are largely concerned with the preservation and routine examination of specimens, testing, and the standardisation of methods, and do not serve solely for research. The Ministry of Agriculture has farmed out its research work to institutions such as Rothamsted, the Imperial College of Science and Technology, Cambridge and Oxford, etc.; it still retains, however, on its fisheries side a Research Division. Dissatisfaction has long been felt at the positions, rates of pay, and prospects of promotion in all these offices. Scientific men claim that the positions offered to them should be at least equal in rank, in prospects, and in pay to those offered in the regular Civil Service. The matter came up for discussion at the meetings of several Sections of the British Association at Cardiff. It was referred to the council of the Association, which has now unanimously passed the following resolution and forwarded it to the First Lord of the Treasury:—"That the council considers that no scheme of payment of professional scientific men in the service of the State is satisfactory which places them on a lower level than that of the higher grade of the Civil Service." It is clear that the Treasury must agree with this resolution if the services of scientific men of the first grade are to be obtained for research purposes.

IN addition to revolutionising the methods of wireless telegraphy and rendering possible the practical development of wireless telephony, the thermionic valve promises to have a far-reaching effect on long-distance line telephony in furnishing a telephonic relay of remarkable powers. On long lines considerable difficulties are caused by attenuation of the current-waves and distortion of their form in transmission. Sufficient audibility could be obtained only by going to commercially impracticable expense in the provision of copper in the line, and sufficiently true reproduction of the wave-form for recognisable speech could be reached only by loading the line with artificial inductance to counteract its natural capacity. It is true that various forms of telephone relay have been experimented with from time to time in the endeavour to diminish the amplitude of the current-waves necessary to an extent which would bring the cost of copper within reasonable limits, and at the same time to lessen the troubles due to distortion, but until the advent of the thermionic valve no instrument was found which combined the requisite ratio of amplification with truthfulness of reproduction. A set of thermionic telephone repeaters working on an artificial cable circuit is being demonstrated at the office of the Western Electric Co. at 62 Finsbury Pavement, E.C.2, which represents the state of development arrived at by this company in conjunction with the American Telegraph and Telephone Co. It is interesting to notice in the next column of the *Times* to that in which appears the announcement of this demonstration an account of another example of the use of the thermionic valve in a wireless telephone demonstration between Geneva and London organised by the Marconi Co.

THE following are the lecture arrangements at the Royal Institution before Easter of next year:—Prof. J. Arthur Thomson, a course of lectures on The Haunts of Life, adapted to a juvenile auditory, to begin on December 30; Sir Gerald P. Lenox-Conyngham, two lectures on The Progress of Geodesy in India; Sir James G. Frazer, three lectures on Roman Life (Time of Pliny the Younger), London Life (Time of Addison), and Rural English Life (Time of Cowper); Dr. Arthur Keith, four lectures on Darwin's Theory of Man's Origin; Dr. W. A. Herdman, three lectures on Oceanography; Mr. F. Balfour Browne, two lectures on Mason Bees and Wasps; Dr. G. C. Simpson, two lectures on The Meteorology of the Antarctic; Dr. Percy C. Buck, three lectures on The Madrigal, with musical illustrations by the English Musical Singers; Prof. A. Fowler, three lectures on Spectroscopy; and Sir Ernest Rutherford, three lectures on Electricity and Matter. The Friday evening meetings will commence on January 21, when Sir James Dewar will deliver a discourse on Cloudland Studies. Succeeding discourses will probably be given by Sir Frank Benson, Dr. A. D. Waller, Dr. F. W. Aston, Mr. Solomon J. Solomon, Dr. John Buchan, and Sir Frederick Bridge, among others.

THE meeting of the American Ornithologists' Union in Washington, D.C., on November 8–11, was one of the largest in the history of the union. The election of officers for 1921 resulted as follows:—*President:* Dr. Witmer Stone, Philadelphia. *Vice-Presidents:* Dr. G. B. Grinnell and Dr. J. Dwight, New York. *Secretary:* Dr. T. S. Palmer, 1939 Biltmore Street, Washington, D.C. *Treasurer:* Mr. W. L. McAtee, Biological Survey, Washington, D.C. The single vacancy in the council was filled by the selection of Dr. W. H. Osgood, of Chicago. The programme of nearly forty papers, five of which were illustrated by motion pictures, covered a wide range of subjects relating to North American birds, and also included papers on the birds of Argentina, Nicaragua, Peru, Europe, and Madagascar. In connection with the meeting an exhibition of drawings, paintings, and photographs of birds by American artists, supplemented by a series of prints showing the development of zoological illustration as applied to birds from the earliest times down to date, was arranged in the division of prints in the Library of Congress.

IN the House of Commons on December 8 Sir Philip Magnus asked the Prime Minister:—"Whether, having regard to the urgent necessity of securing for laboratory and other purposes a sufficient supply of the different kinds of glass used in the manufacture of optical and other instruments, and having regard to the importance of encouraging the production in this country of such glass, he will arrange for the introduction at an early date of a Bill prohibiting for a time, except under special licence, the importation of such varieties of glass and of such scientific instruments as may or can be produced in this country?" Sir Philip Lloyd-Greame, who replied, said that the President of the Board of Trade had stated during the debate on December 7 that the Government intends to introduce the Bill dealing with key industries, other than the dye industry, as the first measure next session.

THE four hundredth anniversary of the discovery of the Straits of Magellan is to be celebrated this month. According to the *Scientific Monthly* for November the festivities will centre in Santiago and Punta Arenas, where the occasion will be marked by the inauguration of several important public works, including port improvements, lighthouses in Smith Channel, and the laying of the foundation-stone of the University of Punta Arenas. Great Britain, Spain, Portugal, and the nations of America are to be invited to join Chile in the commemoration of the anniversary.

THE *Times* of December 15 publishes a communication from its Paris correspondent describing a paper read before the French Academy of Sciences on the use of X-rays for the examination of old paintings, and the message refers to a picture by an old Dutch master in which a woman had been painted in over the picture of a monk. There is, however, nothing new in the report given in the *Times*, and this particular application of X-rays was described and illustrated in NATURE of February 26 last (vol. civ., p. 699).

IN a letter published in NATURE of September 30 Mr. C. S. Garnett gave an account of some interesting mineral deposits which had been investigated by him in Derbyshire. It is now announced that three miles south of Matlock, near Wirksworth, Mr. Garnett has discovered a new deposit of fluorspar which is reported to be a mile in extent and 30 ft. in thickness.

THE thirty-third annual Report of the Bureau of American Ethnology for 1911–12, published in 1919, shows no evidence of the effects caused by the war on many scientific societies in Europe. The activities of American anthropologists continue unabated, and the format of the report, with its abundant illustrations, is fully up to the pre-war standard. One of the most important investigations carried on by the Bureau is the transcript by Mr. F. W. Hodge, the Ethnologist-in-Charge, of a series of inscriptions recorded by the early Spanish explorers on El Morro, or Inscription Rock, in the Zuni district, which have an important bearing on the early history of the Pueblo tribes. Opportunity was taken to explore an interesting Pueblo site in the Jemez Valley. It was the custom of the inhabitants to throw large stones into the graves of the dead, thus destroying the pottery deposited with the remains. Numerous fragments discovered will enable these jars to be reconstructed. It is satisfactory to learn that the progress made by Mr. W. H. Holmes in compiling his "Handbook of Archæology" has been satisfactory.

THE *Museums Journal*, recently compelled to double its price, has managed to set against this an increase in the number of pages and plates and the enlistment of high authorities in its staff of reviewers. The improvement seems particularly marked in the domains of art, archæology, and cultural anthropology. The educational use of museums has been much discussed of late by the Museums Association, and the December issue of the journal contains an article, "The Child and the Mummy," by Mr. Peart, Director of Education for the City of Winchester, who suggests ways in which the dead objects in a museum may be made more alive for younger pupils. He would permit some handling, would add colour to backgrounds and labels, would connect the demonstration with knowledge already possessed by the child, and would lay stress on the human associations of each specimen—the romance of collecting and so forth. In the same issue Mr. Charlton Deas pleads for "an Imperial Department of Illustrated Public Information"—the home propaganda of war-time continued in peace.

THE report on the Government Museum at Madras for 1919–20 has just been received. The new superintendent, Dr. F. H. Gravely, announces a large number of additions to the archæological collections, chiefly in the form of copper-plate grants. Among these the most interesting is a set of thirty-one found in an underground chamber at the temple of Tiruvēlāngādu, Chittoor district, and recording the grant to that temple of the village of Palaiyanūr by King Rājēndra-Chōla in A.D. 1016. A sword-fish, *Histiophorus brevirostris*, 5 ft. 1 in. in length, has lately been procured. The specimen 4 ft. 4 in. long mentioned by F. Day ("Fauna of British India," Fishes, vol. ii., p. 133) has disappeared from the museum, and it would be interesting to know where it now is.

THE Wistar Institute of Anatomy and Biology (36th Street and Woodland Avenue, Philadelphia) issues abstract library cards, of standard size for card-catalogues, of all papers appearing in the *Journal of Morphology*, the *Journal of Experimental Zoology*, the *American Journal of Physical Anthropology*, and the six other periodicals which it publishes. Since the abstracts are distributed to subscribers before the appearance of the complete papers, they serve for preliminary notices as well as for permanent records. Individual investigators may find them useful, and societies compiling bibliographies in these sciences would save themselves trouble and expense by taking the complete series.

THE *Meteorological Magazine* for November states that forecasts can be obtained by communication with the Meteorological Office by telegraph or telephone to cover a period of twenty-four hours, also the state of the weather in various parts of the United Kingdom or the Continent. The Office is open day and night, including Sundays. The discussions of recent work of foreign meteorologists held at the Meteorological Office, South Kensington, which take place fortnightly during the winter months, and have continued since 1905, are now noticed in the magazine, and, indeed, for the first time in the public Press. The opening discussion this season was on "New Methods of Forecasting," based on two papers by Prof. Bjerknes. A record of 35,030 metres (22 miles) was alleged to have been established by a balloon at Pavia on December 7, 1911, but doubt is now thrown on the results, and it is suggested that the barograph was not working properly, which renders it probable that the greatest height attained was 18,900 metres—little more than one-half of the alleged height.

A NEW geographical journal has appeared in Italy. *L'Universo* is published every two months by the Istituto Geografico Militare in Florence, and is devoted mainly to researches in astronomy, geodesy, and cartography, but contains several articles on regional geography. The issues which have appeared maintain a high standard, and are well illustrated with plates and coloured maps. An article in No. 2 (March–April) gives a useful account of the Topographical Service of the Turkish Empire, and is illustrated with specimens and keys of the maps of various scales.

THE Meteorological Service of the Dominion of Canada is issuing a series of monthly weather charts. Each chart shows the mean temperature, the difference from the average mean temperature, and the total precipitation of the month throughout southern Canada. The highest and lowest temperatures at various stations are given in tabular form. Weather and agricultural reports for nearly 100 stations are added. There are also notes on the probability of gales on the Great Lakes in the month of publication.

THE problem of determining the forces which will act on a part of an actual aeroplane when in flight by observations on a model in a wind-tunnel is a very difficult one. An attempt at a solution of part of the problem has been made at the Bureau of Standards at Washington by Mr. H. L. Dryden, to whose work Scientific Paper No. 394 of the Bureau is devoted. By measuring the distribution of pressure on the surface of a cylinder with its axis at right angles to the wind-stream in a tunnel, Mr. Dryden shows that the decrease of pressure at the back of cylinders of small diameter is greater in proportion than the increase in front, and that, in consequence, the distribution of velocity is not similar about cylinders which are "dynamically similar"—that is, for which the product of the diameter, the speed, and the reciprocal of the dynamical viscosity of the wind has the same value. After showing that the size of the wind-tunnel, the effects of the guards, and of the gap between them and the cylinder cannot explain the difference, Mr. Dryden concludes that it is due to some unknown property of the air in the vortex motion behind the cylinder. He proposes to test this by taking photographs of this portion of the moving air.

THE second Report of the British Scientific Instrument Research Association, covering the work of the association from July 1, 1919, to June 30, 1920, is interesting reading. It is a striking example of the importance of applying scientific research and knowledge to the comparatively small things in life. The staff of the association, whilst preparing for a number of important researches, has been carrying out a series of investigations which, whilst small in themselves, are of importance to the scientific instrument industry. A polishing powder and some abrasives have been developed which have desirable properties, and which, it is hoped, will be manufactured commercially in this country. A research into tissue-papers has resulted in a specification which will enable opticians to obtain paper in which optical glass may be wrapped without tarnishing the glass. The association has produced a solder, fusing at a temperature of 195° C., capable of being used with aluminium, and this in itself is no small achievement. The report impresses the reader that every effort is being made to get into close touch and co-operation with other research organisations, such as the National Physical Laboratory, and at the same time the requirements of the users of scientific instruments are being continually studied. The future work of the association will be eagerly awaited by all makers and users of scientific instruments.

THREE papers on notched-bar impact tests were read at the Institution of Civil Engineers on November 30. The paper by Messrs. T. E. Stanton and R. G. C. Batson gives particulars of a series of tests made at the National Physical Laboratory with the view of investigating (*a*) the effect on the work of fracture and the consistency of the results obtained of a variation in the angle and sharpness of the notch in 10 mm. by 10 mm. specimens, and (*b*) the sensitivity of the various types of **V** notch in revealing faulty heat treatment. It was found that the shape of the bottom of the notch has an important effect, and the work of fracture has least value when the angle at the bottom of the notch is as nearly zero as can be obtained. Variations in the results of individual tests are not inherent in the method of test, but are due to a lack of homogeneity in the material. M. Charpy has found that by taking extraordinary care in heat treatment to ensure homogeneity it is possible to obtain a degree of uniformity in the results of notched-bar tests which is higher than any other mechanical test to which the material can be subjected. The National Physical Laboratory tests indicate that the 10 mm. by 10 mm. specimen developed by the Aeronautical Insoection Directorate, having a 45° notch with a radius of 0·25 mm. at the bottom, is as effective in the detection of faulty heat treatment as the Charpy specimen. Other tests on the dimensional effect with specimens of varying sizes indicate that the value of the impact test, as at present understood, lies not in discriminating between the impact resistances of different materials, but as a means of ensuring that the impact strength of any given material is at its highest. The paper by Messrs. R. H. Greaves and H. Moore also deals with notch radii, and that by Messrs. R. M. Jones and R. H. Greaves discusses tests made with the view of investigating the effect of overstrain.

THE use of wire-rope conveyors of the class having more than one rope has hitherto been restricted. This is owing to the fact that it has been the practice to attach the ends of the slats or their mechanical equivalents to separate ropes. Since it is not possible to splice separate endless ropes so that they shall all be of exactly the same length, strains are set up in the working which are fatal to success. This objection has been obviated in the Roe cable conveyor—described by Mr. G. F. Zimmer in *Engineering* for November 19—by fixing one end only of the slats or transverse carrier-bars to one endless rope, and the other end merely rests upon the other rope or ropes without being attached thereto. Thus two or more endless ropes of differing lengths may be used to provide a satisfactory support for the conveyor slats. In the conveyor illustrated in the article the total length is 1800 ft., and the difference in altitude between loading and unloading points is 15 ft. Ten brake-horse-power is required to drive the conveyor under full load at 150 ft. per minute. It is of interest to note that the invention owes its existence to the requirements of the War Office.

SOME particulars of the canal now under construction by the Hydro-Electric Power Commission of Ontario, Canada, are given in *Engineering* for December 3. The canal, which is said to be the largest for water-power purposes in North America, is about 8·5 miles long, and involves the removal of about 19,000,000 cubic yards of earth and rock. Water will be taken along the Welland River for about 4·5 miles from Chippawa, and thence through the canal proper to Queenston at the edge of the cliff marking the limit of the Niagara River Gorge. The power-house will be located at Queenston, where the net head available will be 305 ft. The actual difference in level between Lakes Ontario and Erie is 326 ft., and the present power plants at Niagara utilise heads of 150 ft. to 200 ft., which is the height of the falls alone. The additional fall in the new scheme is obtained by using a site beyond the rapids. The canal is designed to carry sufficient water to generate more than 400,000 h.p.

THE Journal of the British Science Guild for November contains an account of the annual meeting held in June last, when addresses were delivered by Lord Sydenham (the retiring president), Lord Montagu of Beaulieu (his successor), and others. Since then the Guild has lost by death its founder, Sir Norman Lockyer, and a past-president, Sir William Mather. In the account of the administrative activities of the Guild attention may be directed to the contribution by Dr. J. W. Evans, chairman of the Committee on the Utilisation of Science in Public Departments. Some interesting evidence of the results of undue centralisation in various Departments has been collected, and the need for a Royal Army Scientific Corps, with which should be associated a special research institution, is strongly emphasised. It is interesting to observe that the Admiralty now possesses a Scientific Research Department, and a specially contributed account of this new organisation appears in the Journal. Among recent papers on the Guild's objectives reference may be made to "The Human Factor in Industry," by Mr. Alexander Ramsay. An account is given by Prof. C. S. Myers of the work of the Institute of Industrial Psychology, which he represents as a *liaison* member on the Guild's executive committee. It is stated that the catalogue of British scientific and technical books in preparation by the Guild is now complete, and contains about 6000 titles. The scheme of forming provincial groups of the Guild appears to be making progress, the first local committee having been already set up in Aberdeen, with Prof. Alex. Findlay as secretary.

A COMPREHENSIVE and valuable catalogue (No. 408) of works relating to South Africa has just been circulated by Mr. F. Edwards, 83 High Street, Marylebone, W.1. It contains upwards of 700 titles. Many of the volumes are rare and difficult to obtain. Among the items offered for sale is the Godlonton correspondence—Sir Harry Smith: "A Collection of Fifty-one Autograph Letters, Signed, to the Hon. R. Godlonton," mostly marked "Private" or "Confidential," and wholly unpublished. The catalogue is one to be seen by librarians and others interested in the development of South Africa.

PROF. J. F. DOBSON, professor of Greek in the University of Bristol, and Dr. S. Brodetsky, lecturer in applied mathematics in the University of Leeds, have nearly completed their translation of the "De revolutionibus orbium celestium" of Nicholas Copernicus. The translation will be accompanied by a Life of Copernicus and some account of his influence and the history of the views connected with his name.

Our Astronomical Column.

TIDAL FRICTION AND THE LUNAR ACCELERATION.—Mr. G. I. Taylor contributed a paper to Phil. Trans., A, vol. ccxx., on tidal friction in the Irish Sea, from which it appeared that fifty Irish Seas would provide sufficient dissipation of energy to account for the secular acceleration of the moon. Dr. H. Jeffreys returns to the subject in Phil. Trans., A, vol. ccxxi., examining the various seas where such action is probable, and obtaining details of tides and currents from Admiralty publications. The seas that contribute most are largely enclosed, but an opening is required sufficient to admit the tide. The Mediterranean, Red, and Baltic Seas are thus excluded. Bering Sea is by far the largest contributor. It is concluded that two-thirds of the total action takes place there. The Yellow Sea, Malacca Strait, and the American North-West Passage come next. The famous tides of the Bay of Fundy contribute somewhat less than the Irish Sea.

The total rate of dissipation of energy is $2{\cdot}2\times10^{19}$ ergs per second. Taking the excess of the moon's secular acceleration above the portion due to diminution of eccentricity of the earth's orbit as 9″ per century per century (equivalent to 4½″ on the usual erroneous method of measuring by space gained instead of velocity gained), the equivalent dissipation is $1{\cdot}4\times10^{19}$ ergs per second. It is noted, however, that several of the data used were spring-tide values. Allowing for this, the agreement is quite as good as could be expected. It is the first time that a satisfactory estimate of the tidal friction has been made, and the author notes that it seems capable of satisfying all the quantitative demands made on it. He had previously expressed doubts on this point, but he had not then realised that the land-locked seas, not the open ocean, were the chief contributors.

Dr. Jeffreys also notes that the diurnal tides have a slight effect on the obliquity of the ecliptic, reducing it to $1/e$ of its original value in about 10^{11} years. The effect within historic times would be quite inappreciable.

THE SOLAR SPECTRUM FROM 6500 Å. TO 9000 Å.—Vol. vi., No. 3, of the Publications of the Allegheny Observatory contains an investigation of the red and infra-red region of the solar spectrum made by Mr. W. F. Meggers using plates stained with dicyanin and a large plane grating lent by the Johns Hopkins University; it was ruled by Prof. J. A. Anderson, and has 15,000 lines to the inch. The spectra of the opposite limbs of the sun were photographed in juxtaposition, the Doppler effect thus produced serving to distinguish solar and telluric lines. A large number of the latter are assigned (some tentatively) to water-vapour. The region 6500 to 7300 overlaps Rowland's table, the two tables being printed side by side. This region contains 473 solar lines and 596 telluric lines, while the region 7300 to 9000 contains 495 solar and 838 telluric lines. The infra-red spectra of many of the elements are still uninvestigated, but more than half of the solar lines in this region have been identified. In particular, the evidence for the presence of potassium in the sun is strengthened; besides the line at 4044 already known, lines are found at 7664 and 7699. The former partly overlaps a strong line in the A band of oxygen (telluric), but the Doppler effect permits it to be seen separately. There is a general absence of elements with high atomic weights; in explanation of this a sentence is quoted from Abbot's "Sun" (p. 253) stating that these elements would probably lie at too low a level for their lines to be seen at the limb. Seven elements (rhodium, ruthenium, palladium, gallium, europium, helium, and oxygen) are added to the thirty-six solar elements in Rowland's list. Oxygen is shown by the lines 7771, 7774, 7775, and 8446 (doublet); these lines have Doppler displacements.

Anthropology at the British Association.

ON the whole, the proceedings of Section H (Anthropology) at the Cardiff meeting may be counted as successful. The number of papers presented was fewer than usual—several contributors were obliged to withdraw at the last moment—nor did they all offer the opportunity for discussion which normally has been a prominent feature in this Section. There were, however, a number of communications of importance, and the attendances were good, notwithstanding the comparatively small number of members at the meeting.

Turning to the consideration of the chief communications in detail, attention may be directed to Prof. F. G. Parsons's paper entitled "The Modern Londoner and the Long Barrow Man," which was mainly a criticism of conclusions arrived at by the president of the Section (Prof. Pearson) and the late Dr. Macdonell. In a paper published some years ago the latter had given it as his view that the modern Londoner approximated to the type of the Long Barrow man. Prof. Parsons had examined skulls of Londoners of the eighteenth and nineteenth centuries, the Rolleston and Thurnham Long Barrow skulls, and numerous Anglo-Saxon and Mid-European skulls. As a result he maintained that when the modern Londoner departs from the Anglo-Saxon type it is in the direction of the Alpine folk rather than in that of the Long Barrow folk. An interesting fact which had emerged in the course of the investigation was that broad-headedness appeared to be on the increase in the modern population.

Prof. H. J. Fleure summarised the results of his investigation of the Welsh physical type. He finds that there are nine distinct physical types in Wales, and that, generally speaking, the Welsh people show more long-headedness and more dark pigment and are of shorter stature than the English, but that both are a complex mingling of different breeds.

A paper of great importance in the elucidation of problems of the early ethnology of the Mediterranean area was offered by Mr. L. H. Dudley Buxton. His communication "On the Physical Anthropology of Ancient Greece and Greek Lands" was based upon a study of the cephalic index, stature, upper facial index, and pigmentation of the modern population, and a comparison with the scanty early material available. The mean cephalic index varies from 79·20 in Crete to 87·51 among the Bektash of Lycia. The modern Greeks are slightly more brachycephalic than the ancient inhabitants of the same places. In Crete it would appear that there had been an immigration or extension of long heads in early times, which was later supplanted by a mixed round- and long-headed population. Tentatively he concluded that (1) the cranial index shows sufficient variety to suggest ethnic admixture; (2) this admixture has not been evenly distributed, and local and distinct sub-races have been formed; and (3) the admixture is early, possibly Neolithic in Leukas, and Bronze age (or earlier) in Cyprus or Crete. In regard to stature, large numbers are available from Crete and Cyprus only, but the same conditions appear to make for heterogeneity; the modern stature appears to be slightly greater than the ancient; but, owing to the small numbers represented, caution is needed in ascribing high or low stature to any race in the area. At both boundaries of the Greek world there are two racial types of comparative homogeneity; the intermediate people, who present local divergences, are very variable. The Greeks are a combination, probably early, of Alpine and Mediterranean stocks.

Miss Tildesley, in a communication on the Burmese skull, established by means of a co-efficient of racial likeness that the Burmese skull is closely akin to the Malayan and less closely to the Chinese, while being widely removed from the Caucasian type.

In Ethnography Dr. W. H. R. Rivers, in a communication on the statues of Easter Island, suggested that these may represent the hypertrophy of one element in an association similar to that found in San Christoval, where stone images represent the dead chief buried in the pyramidal structure with which the images are associated. The presence of this hypertrophy in Easter, Pitcairn, and Lavaivai Islands suggested that immigrant workers in stone thus obtained a means for the expression of religious and artistic impulses to which the fuller life of the larger islands of Polynesia and Melanesia gave other outlets. The crowns of red vesicular tufa, he held, represented hats rather than hair, either natural or in the form of wigs, as has been suggested, and might be compared with the hats which are prominent symbols of the dead in Melanesian societies which practise the ghost cult.

Capt. L. W. G. Malcolm dealt with the anthropogeography of the Cameroons, and in particular with that of the area in which the Bantu-speaking peoples came into contact with the Sudanese; and Prof. E. H. L. Schwarz described certain elements in the culture of the Ovambos, to which he endeavoured, upon somewhat slender evidence, to find analogues in the customs of early historical races which were in contact with Africa.

A very successful afternoon session was devoted to primitive music, with special reference to Wales. Dr. H. Walford Davies, in a paper on "Euphony and Folk Music," pointed out that the pentatonic scale, the simplest known form, which recurs all over the world, epitomises the simpler tone-relationships, and is the basis of the Dorian mode, in which so much of the British folk-music is written. Dr. J. Lloyd Williams, in describing Welsh national music, pointed out that while a considerable body of the music shows the influence of the harp, in vocal music, of which an unexpected wealth had recently been discovered, a considerable proportion was in the Dorian and other modes. Of traditional lyrics the best were the very numerous penillion; these, and the singing of penillion according to North Wales style, constitute unique features in Welsh song.

Archæological papers furnished the most interesting section of the programme. Prof. W. M. Flinders Petrie described recent discoveries of the British School in Egypt, which included a series of tombs of every variety of type of the First to Third Dynasties; the tomb of the royal architect of King Senusert II., whose gold uræus was found in his pyramid; and a large alabaster jar with a magic inscription to provide all offerings required. Three inscriptions of the Twelfth Dynasty, in alphabetic signs, show that the prehistoric system of personal marks had by that time grown into regular writing, independent of any Semitic system.

Mr. P. E. Newberry, in his communication "Early Egypt and Syria," suggested that the parent culture of the early civilisations of the Nile and the Euphrates should be sought in Syria. The ox, the sheep, and the goat were introduced into Egypt through Syria, and the crook and the flail, the royal insignia of dynastic Egypt, were both of Western Asiatic origin, the former being the crook of the goatherd, and the latter, it was suggested, an instrument used by goatherds for gathering ladanum from the cistus bush, which was not found in Egypt. The cults of the *neter*-pole and the *ded*-column, both of which were originally coniferous tree-trunks, must have been of Syrian origin. The traditional home of Isis and Osiris was between Byblos and Damascus, and there the vine and wheat and barley grew wild. The Egyptian house was obviously derived from a wood-built dwelling, and both Egypt and Babylon are known to have drawn their timber from the Lebanon area.

Mr. R. Campbell Thompson, in a paper on "Prehistoric Dwellers in Mesopotamia," maintained that a proto-Hamitic section of the Mediterranean race which migrated at an early time into Arabia was the forerunner of the Semitic peoples.

Mr. S. Casson described the recent excavations at Mycenæ of the British School of Archæology at Athens, which had been carried out in the light of a reconsideration of Schliemann's discoveries. The Grave Circle, as well as a stratified platform of earth outside the Acropolis, the site of a part of Mycenæ in the period 2000–1500 B.C., showed traces of a Bronze-age civilisation, and even of Neolithic remains. It seemed certain that there was a continuous mainland civilisation stretching back at least to the beginning of the second millennium B.C. In the replanning of Mycenæ by the later kings, such as Atreus, by whom the Lion Gate and the Acropolis wall were built, the burial-ground of their forerunners was enclosed by the Grave Circle. This was used as an ossuary, outlying graves being cleared and their contents placed within the circle.

Mr. Joseph S. S. Whitaker's paper on "Recent Anthropological Research at Motya" described the remains brought to light on the Island of San Pantaleo, on the north-west coast of Sicily, which is undoubtedly the site of the ancient Phœnician colony of Motya, and, owing to its complete and sudden overthrow in 397 B.C., probably shows more remains of an old Phœnician town than any other known site. Excavation has revealed that the island was originally fortified by a wall all round, and the north and south gateways have been discovered. The north gate consists of an outer gateway formed of two apertures, recalling the Athenian Dipylon Gate, and a second, twenty-two metres behind it, of six apertures in pairs. In a cemetery—the first to be discovered—the prevailing method of disposal of the dead was incineration, although in the later cemetery on the adjacent mainland inhumation was chiefly practised. One burial-place belonging to the last period contained only the remains of animals, mostly ruminants, in single urns. An interesting mosaic pavement showed a combination of Phœnician picture-panels and Greek decorative borders.

Signor G. Bagnani dealt with the results of recent archæological investigations in Rome, some of which had not hitherto been described, including the Roman basilica at Porta Maggiore, the tomb on the Via Ostiense, and the tombs found under the Church of San Sebastiano.

Dr. T. Ashby, in a joint communication by himself and Mr. Robert Gardner, described further observations of the Roman roads of Central and Southern Italy, in particular of the Via Valeria, through the Abruzzi, the Via Latina, and the Via Cassia, through Etruria. An attempt to trace the Via Herculia between Venusia and Potentia was unsuccessful.

Mr. G. H. Garfitt's paper on a recent discovery of rock sculptures near a stone circle in Derbyshire described cup- and ring-markings and two sculptured stones found near the circle on Eyam Moor. On the latter are represented a deer-horn pick and a plough. A comparison with dolmenic sculptures in Brittany suggests an association with the Ægean goddess of fertility, whose cult may thus have extended to Derbyshire. Mr. MacRitchie brought forward evidence to show that early references to Greenland must be taken to denote some European country, probably the area between West Sweden and the Urals, and indicated the bearing of this conclusion on European ethnology. Mr. Kidner described certain round barrows in the New Forest which do not conform to the three standard types; and Mr. Willoughby Gardner described his recent excavations in the Dinorben hill-fort near Abergele, which had fully confirmed previous conclusions as to the character and construction of the fort.

An afternoon session was devoted to an expedition to the site of the Roman city of Venta Silurum at Caerwent under the guidance of Dr. T. Ashby, who was in charge of the excavations carried out with the assistance of the Association on that site some years ago. As a preliminary to the excursion Dr. Ashby also gave the Section an account of the results of these excavations.

E. N. F.

Smoke Abatement and Housing Schemes.

A SUPPLEMENT to the *Lancet* of November 20 contains the annual report of the Advisory Council on Atmospheric Pollution for the year April, 1919–April, 1920. The number of stations sending in full returns is nineteen, of which fifteen are divided between London and Glasgow, the other four being Malvern, Rothamsted, Southport, and St. Helens.

It will be seen that the number for the whole country is very limited, and some of the dirtiest industrial centres, where a comparison of the conditions of the atmosphere from year to year might be of some advantage to the local authorities, are entirely unrepresented. This arises, no doubt, partly from the complete indifference shown in many localities to the smoke nuisance, and partly from the troublesome and tedious analytical method of estimating atmospheric impurities. Something in the way of an automatic recorder or an apparatus not requiring much supervision would probably induce many places which at present send in no returns to adopt the system.

It should be pointed out that the Council fully recognises this desideratum, and the report shows that a considerable amount of research has already been carried out with no little success in simplifying the apparatus for recording both solid and acid impurities. That the prevalence of the latter impurity is the main factor in the disintegration of the stonework of many of our ancient monuments has been proved beyond question, and some check on the quantity is a matter of great importance.

It is to be presumed that it is no part of the Council's business to advance the cause of smoke abatement apart from the registration of statistics, yet it seems to us that a systematic propaganda against smoke pollution might form a useful adjunct to its other activities.

Under the new housing schemes emanating from the Ministry of Health an opportunity is offered for the erection of houses in such a way as to diminish considerably the output of smoke, and, in fact, under the auspices of the Ministry a Committee was summoned to inquire into and report on the subject. The report of this Committee was issued some months ago, but it appears from a statement made in the House of Lords by Lord Newton, chairman of the Committee, that neither the Department for which it was prepared, nor the local authorities for the benefit of which it was issued, appear to have paid any attention to its practical application.

We would suggest, therefore, that the various schemes referred to in the report, and generally approved by competent persons, should be taken up by the Advisory Council on Atmospheric Pollution, who should bring it before the notice of the public in the form of active propaganda. It seems useless to make yearly records of air pollution when no serious steps are being taken, publicly or privately, to diminish the evil.

J. B. C.

Work of the Analytical Laboratory, Cairo.

SEVERAL features of more than passing interest are shown in the undermentioned report.[1] Covering as it does the period of the war, it chronicles work—such as the making of special incendiary bombs and chemical igniters for flares—which is rather unusual for the analytical laboratory, but is an indication of versatility in time of need. Passing, however, to more normal activities, with a bare mention of the excellent routine work done, it is interesting to note that research has taken a definite place in the programme of the department; the authorities are evidently alive to the importance of encouraging the application of chemistry to arts and manufactures. Thus an investigation of Egyptian crude petroleum has been made, the results of which have proved that good yields of Diesel fuel-oil can be obtained from this source, besides the customary petroleum spirit and kerosene, and a pitch which will be invaluable for road-making. A Government refinery to deal with this crude petroleum is to be erected at Suez.

An inquiry into the possibility of cement manufacture in the Sudan was also undertaken. As a result a cement factory is now being constructed at Makwar, where 50,000 tons of cement per annum will be made; the fuel difficulty has been overcome by using a mixture of locally made charcoal and imported coke.

Among the chemico-legal cases dealt with was an interesting one in which a claim was made against the Government for land valued at about 16,000,000*l*. Unfortunately for the claimant, however, it was found that out of the 168 documents on which the claim was based no fewer than 163 were forged.

It is noted that an entirely new method of assaying gold has been devised, whereby the Assay Office was enabled to cope with a very considerable increase of work resulting from the new assay law, which provides for the compulsory hall-marking of gold and silver. The report indicates useful work and steady progress.

The Problem of Soaring Flight.[2]

THE source of energy used by birds in soaring flight is not yet clearly known. Attempts have been made to achieve this form of flight artificially, and, according to Gustav Lilienthal, a flight of 500 metres up wind, in which a height of 40 metres was attained, has been made by a man-carrying glider not provided with a motor, but having wings constructed on the pattern of those of a soaring bird.

The extraordinary regularity with which cranes, when flying in a group, keep their distances from one another affords a proof that such soaring flight is either due to undiscovered wing-movements or to some condition of the air which is widely and uniformly distributed. The observation that certain dragon-flies, and also flying-fishes, employ soaring flight has led to discoveries that throw a new light on the subject. Dragon-flies can adjust their abdomens and hind-legs, and flying-fishes their pelvic fins, in such a way that these organs act as a brake to check speed when flying. The brake is used in certain conditions in continued flight to keep their speed at a required minimum. This use of an air-brake yields a proof that these instances of soaring flight are not due to undiscovered wing-movements. Dragon-flies habitually avoid ascending currents when in soaring flight so long as the sun is shining. If isolated clouds are crossing the sky these insects collect in the neighbourhood of a convenient ascending current, entering it whenever the sun is obscured, and gliding beyond its range so soon as the sun comes out. That soaring flight is not due to the lifting effect of lateral gusts is proved by the fact that the flying-fish when at highest speed carries its wings inclined so that the wing-tips are on a lower level than the body. In this case, if lateral gusts were operative, their only effect would be to drive the fish under water

Certain facts suggest that turbulent motion is, in some unknown way, the source of the energy of soaring flight. But light objects, such as feathers or aerial seeds, may be seen floating in the air in the neighbourhood of soaring birds, and exhibiting only slow and equable movement. What form of turbulent motion can be imagined that enables a bird weighing 10 lb. or more to glide without effort to a height of 2000 metres or to travel horizontally for indefinite distances at a speed of 50 miles an hour, and yet is unable to disturb the course of a piece of thistledown? Thus the facts of the case appear to offer insuperable difficulties to all theories that have hitherto been put forward as an explanation of soaring flight.

University and Educational Intelligence.

CAMBRIDGE.—The proposal to admit women to membership of the University on equal terms with men was rejected on December 8 by 904 votes to 712. The next step, presumably, will be a vote on Report B, the alternative proposal offered by the recent syndicate. This is, in effect, a suggestion on the part of the University that it would welcome the foundation of a separate University for women at Cambridge, and would extend to it the same facilities for educational purposes as are at present offered to the members of Girton and Newnham Colleges. This proposal does not in any way meet the greater number of the difficulties that were raised in connection with the rejected scheme, in particular the question of numbers and accommodation. It has already been rejected by the women's colleges, which have declared that they have no intention of taking action in the matter of forming a separate University even if Report B is passed. Already three of the six signatories of Report B have, in a sense, abandoned it for some scheme which shall more nearly meet the women's needs, a scheme the details of which have yet to be worked out. It does not look as though the adoption or rejection of Report B by the University will bring the problem nearer to an agreed settlement. In the interests of the University as a whole, and of the women's colleges in particular, an early settlement must be reached, and it looks as though the next move must lie with "the party of thirteen," who have in view a scheme which will give the women the full privileges of membership of the University without any control over the men's education. If they take early and effective action they may be able to justify

[1] "Report on the Work of the Government Analytical Laboratory and Assay Office, 1913–1919." (Ministry of Finance, Egypt.)

[2] Abstract of a paper by Dr. E. H. Hankin and F. Handley Page read before the Cambridge Philosophical Society on November 22.

the vote of last Wednesday; otherwise, this vote must bring a reaction which may, in due course, sweep much farther than the original proposals.

Mr. J. Gray, fellow of King's College, has been elected Balfour student.

LONDON.—Mr. F. R. Fraser has been appointed for a period of four years as from October 20 last to the University chair of medicine tenable at St. Bartholomew's Hospital Medical School. In 1912 Mr. Fraser was appointed assistant in medicine at the Rockefeller Institute for Medical Research in New York, and two years later instructor in clinical medicine at Columbia University. During the war he served with the R.A.M.C., and on demobilisation was appointed assistant director of the Medical Clinic and assistant physician at St. Bartholomew's Hospital. He is the author of publications on electrocardiographic changes and acute poliomyelitis.

OXFORD.—Mr. R. T. Gunther, fellow and tutor of Magdalen College, has been elected by that college to a research fellowship in order to continue his researches on land levels in the Mediterranean. A science tutorship at Magdalen will thus become vacant, and it will certainly be acceptable to biologists in Oxford if another biologist be elected to succeed Mr. Gunther. Magdalen College has long been favourably distinguished for the support it has given to scientific study and research, especially in subjects connected with the sciences of life.

PROF. J. C. IRVINE, professor of chemistry in the University of St. Andrews, has been approved by the King, on the recommendation of the Secretary for Scotland, as Principal of the University in succession to the late Sir John Herkless.

APPLICATIONS are invited by the council of Bedford College for Women, Regent's Park, for a scholarship in sociology tenable at the college for two years, and of the yearly value of 80*l*. Candidates must be women holding a university degree or its equivalent. The latest date for receiving applications is January 15.

THE Association of Science Teachers will hold a general meeting on Tuesday, January 4, at University College, London, when the presidential address will be delivered by Miss M. B. Thomas, Girton College, and a lecture on vitamines will be given by Dr. J. C. Drummond, reader in physiological chemistry, University College. The hon. secretary of the association is Miss E. M. Ridley, 10 Gresley Road, London, N.19.

THE Salters' Institute of Industrial Chemistry has awarded five fellowships for post-graduate study in the laboratories indicated:—Mr. A. H. Adcock (Liverpool University), Mr. J. A. Gentle (Oxford), Mr. S. J. Saint (Reading), Mr. C. B. Taylor (Imperial College of Science and Technology), and Mr. Donald Turner (Sheffield). Scholarships have been awarded to Messrs. M. D. Forbes and G. M. Lowe (Imperial College of Science and Technology), A. W. Pritchard and F. W. Turner (East London College). Forty-five grants in aid have been awarded to chemical assistants occupied in factories in or near London to facilitate their further studies

ANNOUNCEMENT has been made that four fellowships of 1000 dollars each have been established through a co-operative agreement between Yale University and the Bishop Museum of Honolulu, Hawaii. The fellowships are available for graduates of any institution, but are primarily designed for students who have already attained the degree of doctor of philosophy. Preference will be given to applicants who desire to carry on research in anthropology, botany, zoology, geography, or geology in Hawaii or other parts of Polynesia. Detailed information may be obtained from the Dean of the Graduate School, Yale University.

THE annual meeting of the Mathematical Association will be held at the London Day Training College on Tuesday, January 4. The programme includes the following papers and discussions:—Relativity, Prof. A. S. Eddington; Aeroplane Mathematics, Dr. S. Brodetsky; The Teaching of Mathematics to Boys whose Chief Interests are Non-Mathematical, the Rev. S. H. Clarke; Some Unsolved Questions and Topics for Research, Prof. E. T. Whittaker; Results of Visits Paid to Lycées of Paris and other Centres, and the Study of Education there, particularly from the point of view of Mathematics, Miss E. M. Read. January 17, 1921, will be the fiftieth anniversary of the first recorded meeting of the association.

PROF. DONNAN gave an interesting address on "The Finance of Research at Universities" at a meeting convened by the London branch of the National Union of Scientific Workers at University College on December 9. He said that scientific research must be financed mainly out of Treasury funds, and as the Treasury is influenced greatly by public opinion, it behoves scientific workers to create the right atmosphere. The Government, no less than the general public, is apt to overlook the fact that there are three equally important factors in the creation of wealth. Two of these, new knowledge and trained men to apply it, are the right products of the universities; increased production is not merely a question of the hours of labour of the manual worker. The nation has already reached a time of financial stress which will probably continue for another five years. Hitherto the Government has treated educational institutions as charities, to be given doles in times of prosperity, to be ignored at the call for economy. Unhappily, this attitude is unchanged, and the prospect of universities receiving the necessary financial assistance from the Treasury for research workers is a poor one unless the Department of Scientific and Industrial Research realises in time that this is the more productive field for cultivation, and unless those best equipped and best entitled to benefit by grants, viz. the junior teaching staffs, are aided to undertake research work instead of being forced by inadequate salaries to make ends meet in other ways. Prof. Donnan concluded by paying a tribute to the work of the Department of Scientific and Industrial Research in fostering industrial research associations, but expressed the doubt as to whether it would not have been the more profitable investment to have started with the university research workers.

ANYONE who understands the best possibilities of the kinematograph, or has seen some of the instructive films now available, must realise that the instrument may be made a very valuable educational aid. In scientific instruction, for example, the slowing down of ultra-rapid pictures enables movements to be analysed most clearly; or, on the other hand, a film may show in a few minutes the life-history of a plant or animal, and thus synthesise changes which may extend normally over several months. Whatever can be said in favour of the use of pictures in text-books can be applied with far greater force to the motion picture, for movement impresses itself upon the mind much more deeply than still-life. This is particularly true of geographical subjects, the aim of which is to give pupils clear ideas of the characteristics of countries and peoples in various parts of the world. It has hitherto been difficult to obtain instructive films of this kind for exhibition except by applying to a number of different firms. The Macmillan Educational Film Co., Ltd., 32 Charing Cross, S.W.1, has now, however, made a collection of educational and scientific films which they are able to offer for hire. We have before us a list of such films relating to geographical, industrial, Nature-study, and other subjects, and a copy can be obtained by anyone upon application to the company. There are also lists of suggested programmes—one of a varied kind, and another in which geographical subjects are appropriately grouped together. It may be hoped that local education authorities will avail themselves of such assistance as is afforded by these lists to give a new character to kinematograph displays in local picture-houses. In the United States thousands of schools make use of the moving picture for educational purposes, and there is a great opportunity for its wise employment here when existing prejudices have been overcome.

Societies and Academies.

CAMBRIDGE.

Philosophical Society, November 22.—Prof. Seward, president, in the chair.—F. A. **Potts**: A note on vital staining. In studies which have been made on the penetration of neutral red into the living body of the soil nematode Diplogaster it is found that most of the stain makes its way through the mid-gut and none through the skin. In the mid-gut a zone of granules arranged peripherally round the lumen of the gut takes up the stain particularly.—W. F. **Lanchester** and A. G. **Thacker**: Preliminary note on the superior vena cava of the cat. Thirty cats were dissected to observe the point of entrance of the internal jugular, which in every case except one fell into the external jugular. Observations were also made on the length of the superior vena cava in twenty-one adult cats, and the length appeared to be varying round more than one mean.—Miss M. D. **Haviland**: Preliminary note on a Cynipid hyperparasite of Aphides. Charips (Cynipidæ) is a hyperparasite of Aphides through Aphidius (Braconidæ). The female pierces the Aphidius larva while the latter is lying inside the living Aphid, and deposits an egg within its body. The first-stage larva of the Cynipid is hypermetamorphic, with a thick chitinous skin and tail, but during development, which takes place within the Aphidius, the larva gradually assumes the form usual among parasitic Hymenoptera. Shortly before metamorphosis the hyperparasite leaves its host, the remains of which it devours, and its tracheal system becomes functional. It afterwards pupates within the cocoon previously woven by the Braconid.—Dr. E. H. **Hankin** and F. Handley **Page**: The problem of soaring flight (see p. 518).—Sir George **Greenhill** and Dr. G. T. **Bennett**: The rotation of a non-spinning gyrostat.—E. V. **Appleton**: A method of testing triode vacuum tubes. A dynamic method of measuring the slope of the principal voltage-current characteristic of a three-electrode thermionic tube is described.—W. B. **Frankland**: The astronomical bearing of the Einstein theory.—Dr. W. **Burnside**: The representation of the simple group of order 660 as a group of linear substitutions on five symbols. Except in the cases of two and of three variables, the explicit forms of groups of linear substitutions have been given only in a few cases. Thus it is hoped that the explicit forms in the case referred to may be of interest. The existence of a cubic three-spread, in space of four dimensions, admitting a group of 660 collineations into itself may be compared with the more familiar case of Segre's cubic three-spread which admits a group of 720 such collineations.

MANCHESTER.

Literary and Philosophical Society, November 2.—Sir Henry A. Miers, president, in the chair.—Dr. W. J. **Walker**: The polytropic curve and its relation to thermodynamic efficiency (with a note on the theory of the uniflow steam-engine). An inquiry made into the reason for the diminution of internal-combustion engine efficiencies when the value of n in the equation, pv^n = constant, for the compression line is reduced by water injection or other means.—W. H. **Pearson**: Notes on a collection of Hepatics from the Cameroons, West Coast of Africa. The collection, made by Mr. W. G. Travis from logs of ebony in the Liverpool docks, contained the following species: *Aneura Travisiana*, n.sp., Pears.; *Lophocolea Newtoni*, St.; *Mastigolejeunea* . . . ?; *Homalolejeunea excavata* (Mitt.), Sp.; *Ceratolejeunea Saxbyi*, n.sp., Pears.; and *Cheilolejeunea Principensis*, St. The type-specimens are in the Manchester Museum.

SHEFFIELD.

Faraday Society and Institute of Metals (Sheffield Section), November 19.—Afternoon session, Prof. C. H. Desch in the chair.—Dr. L. **Aitchison**: Electroplating for the prevention of corrosion. The paper dealt more especially with the protection of iron and steel and their alloys. The conditions for proper protective coatings were defined and the value of the various protective coatings was discussed with relation thereto.—W. A. **Thain**: Some applications of electrodeposition in aeronautical engineering. Three cases of the electro-deposition of copper were considered, viz.: (1) As a protection against carburisation in case-hardening practice; (2) as a means of increasing heat conductivity; and (3) as a means of building up a definite constructional detail.—B. **Carr**: The electrodeposition of cobalt. From a bath containing 4½ lb. of cobalt sulphate crystals, 5½ oz. of boric acid, and 2½ oz. of sodium chloride per gallon, and used at 34° C., excellent hard, adherent deposits of cobalt were obtained, provided that these were not too thick, with 150 and 72 amperes per sq. ft. for periods of immersion not exceeding 2 and 4 minutes respectively. The deposit is exceedingly resistant to atmospheric corrosion, and superior to nickel in the rapidity of deposition and hardness.—W. E. **Hughes**: The use of colloids in the electrodeposition of metals.—S. **Field**: The commercial electrolysis of zinc sulphate solutions. Commercial electrolysis aims at the maximum extraction of zinc with a minimum of energy. The greater the extraction the smaller the volume of liquor which circulates through the extraction plant, and the smaller the proportion of zinc which demands repeated purification. A limit to this extraction is set by the cost of increased energy necessary to take out zinc from dilute liquors. Current efficiency is dependent upon a number of factors, including current density, amount of zinc present, temperature, and the presence of impurities.

Evening session, Mr. E. A. Smith in the chair.—W. R. **Barclay**: Electro-silver plating and its technical development. This paper dealt with the history of technical investigation and research into the electro-deposition of silver so far as the more practical aspect of electro-plating is concerned. Emphasis was laid on the necessity for careful co-ordination of the factors of metal and free cyanide content to that of current density. It was shown that though considerable latitude is allowable in practice, the best results and highest efficiency lie within fairly well defined limits. It was pointed out that silver solutions in existence more than sixty years still continued to yield excellent results, and that, generally, old solutions yielded better deposits at higher current densities than those newly made up from pure materials. This was due in a great measure to the presence of substances other than the simple double cyanide of silver and potassium, especially potassium carbonate.—G. B. **Brook** and L. W. **Holmes**: The chemical composition of old silver-plating solutions, with observations on their working properties. The paper dealt with a large number of solutions varying in age from one to fifty years, furnishing historical, chemical, and physical data with regard to each, and correlating the composition with the working properties in actual works practice.—F. **Mason**: A new maximum current density in commercial silver-plating. With a free cyanide content in excess of that usually advised, and with potassium carbonate in considerable quantities, not only can the current density be increased enormously, but the deposit is of an exceptionally fine texture and takes a high finish.—G. B. **Brook**: The crystalline structure of electro-deposited silver.—S. **Field**: The deposition of gold-silver alloys. A series of experiments has been carried out in order to trace the influence of varying conditions on the composition of the gold-silver alloys deposited in the well-known "green gold."

DUBLIN.

Royal Dublin Society, November 23.—Dr. F. E. Hackett in the chair.—Prof. H. H. **Dixon** and Nigel G. **Ball**: A determination, by means of a differential calorimeter, of the heat produced during the inversion of sucrose. The heat of inversion of sucrose in presence of invertase was determined by means of a differential calorimeter in which the temperature was measured with a sensitive thermocouple. Two vacuum flasks were employed, in one of which the reaction took place, while the other was used as a control, one junction of the thermocouple being in each flask. The enzyme solution was contained in a capsule of paraffined paper immersed in the sugar solution to secure that both were at the same temperature. In the control flask a similar arrangement was used, but the enzyme solution had been previously heated to 100° C. These capsules could be ruptured without opening the flasks. The temperature effects of dilution of the sucrose were eliminated by these arrangements. Stirring was effected by shaking the flasks. A value for the heat produced during the inversion of sucrose by invertase was obtained which agrees closely with that previously given by Brown and Pickering, the mean of the results being 3·83 calories per gram-molecule.

PARIS.

Academy of Sciences, November 22.—M. Henri Deslandres in the chair.—A. T. **Schloesing**: The separation of two salts having a common ion. In the preparation of ammonium nitrate from sodium nitrate and ammonium bicarbonate an aqueous solution of sodium nitrate and ammonium nitrate is obtained, from which the latter salt has to be extracted. Solubility curves of mixtures of these two salts have been worked out and are given in the paper and the mode of applying these to the problem is indicated.—E. **Imbeaux**: New systems of electric towing on canals. The haulage difficulties on canals with numerous locks, such as those of the Marne, Rhine, and the Sarre coalfields, are summarised, and a description is given of the systems at present in use.—E. **Ariès**: The heat of evaporation of a liquid at low temperatures. Reply to a note of M. G. Bruhat.—T. **Varopoulos**: Algebroïd functions and increasing functions.—J. **de Lassus**: The essential properties of pneumatic transmission in a closed cycle.—J. **Andrade**: The last perturbations of isochronism.—W. **Margoulis**: A new method of testing aerodynamic models in gas currents. In existing apparatus serious errors may arise, as it is impossible to observe the conditions required by the law of similitude. The author suggests the replacement of air by carbon dioxide at high pressures and temperatures, and gives formulæ showing the resulting reduction in the horse-power of the motor necessary for moving the gas.—Lord **Rayleigh**: The light diffused by argon. Remarks on a recent paper by M. J. Cabannes.—C. **Matignon** and M. **Fréjacques**: The transformation of ammonia into urea. The problem of the economical transformation of ammonia into urea is of undoubted technical interest, since it contains 47 per cent. of nitrogen as against 35 per cent. of nitrogen in ammonium nitrate, and it behaves as an excellent manure. An account is given of studies on the conversion of ammonium carbamate into urea.—A. **Muguet** and J. **Seroin**: The age of the autunites of Portugal. These minerals are of recent formation, and were formed between 1250 and 1900 years ago. The figures are based on the determination of the ratio of radium to uranium in the minerals.—G. **Denizot**: The stratigraphical position of the Montabuzard limestone.—A. **Rolland**: The existence of formations of ground called *rideaux* in Cantal.—R. **Souèges**: The embryogeny of the Urticaceæ. The development of the embryo in *Urtica pilulifera*.—A. **Chevalier**: The variations of the buds of cultivated trees and shrubs as a cause of decadence of old varieties.—J. **Barlot**: New colour reactions utilisable for the diagnosis of mycological species. The colour reaction with potash solution serves to distinguish between the poisonous *Mycena pura* and the variety *amethystina* of *Laccaria laccata* (edible). The same solution gives different colour reactions with *Gomphidius glutinosus* and *G. viscidus*.—P. **Dangeard**: Metachromatine and the tannic compounds of the vacuoles.—W. **Mestrezat** and Mlle. Marthe **Paul-Janet**: The comparative evaluation of the total nitrogen in urine by the methods of Dumas and Kjeldahl. The Kjeldahl method applied to urine gave only from 98·5 per cent. to 90·3 per cent. of the nitrogen found by the Dumas method.—A. **Damiens**: The toxicological detection of poisons containing bromine. An application of the methods described in previous communications for the detection and estimation of traces of bromine in animal tissues.—G. **Bohn** and Mme. A. **Drzewina**: Variations of sensibility to soft water of the Convoluta, according to the physiological states and the number of animals under experiment.—L. **Joubin** and E. **Le Danois**: Biological researches on the thermometry of the Atlantic off Ushant during the summer of 1920. The data obtained are represented on two diagrams, showing the distribution of temperatures in a section W.-N.W. through Ushant.—C. **Lebailly**: The conservation or disappearance of the virulence of apthous milk in the course of the manipulations following treatment. If the contaminated milk is allowed to stand for cream long enough for an incipient lactic fermentation to take place the virus is attenuated or destroyed, and young animals fed on such milk during an epidemic have either remained healthy or have had only a mild attack. When the milk is collected in large creameries and the cream quickly separated mechanically, the skim milk rapidly spreads the fever.

ROME.

Reale Accademia dei Lincei.—(Communications received during the vacation.)—G. **Fano**: Surfaces of the 4th order with infinite discontinuous groups of birational transformations, ii.—C. **Crema**: Deposits of bauxite in the Apennines, Istria, and Dalmatia (with illustration of section).—C. **Artom**: Biology and systematics of the genus Artemia, ii.—M. **Genna**: Nutrition of *Anopheles claviger*. The male feeds only on sweet juices, but the female also requires to suck blood before it can lay its eggs. The processes of digestion of the two kinds of food are not only different, but they take place in different organs in the female.

(Vol. xxix. (2), i., ii.)—S. **Pincherle**: Iterated function of a rational integral one, ii.—G. **Fubini**: Projective differential geometry.—E. **Artini**: Cassiterite and titanite of Baveno. The former mineral was represented by a small crystal 5 mm. long and 4 mm. broad, being a multiple twin crystal found by G. Codara in the granite mines, and a few fragments discovered on a later visit. Of titanite the author possesses three small purplish crystals. Both minerals are new to the granite of Baveno.—C. **de Stefani**: Siliceous fossil sponges of western Liguria. These were found mainly in crystalline schists, but also in Triassic limestone, between Genoa and Savona. The majority are Hexactinellidæ dichyoninæ, and the structure was well preserved both in microscopic sections and in specimens treated with acid.—G. **Marletta**: Abelian varieties.—P. **Nalli**: A functional equation.—M. **Pascal**: Resultant pressure on an aeroplane wing, ii. A continuation of the previous hydrodynamical problem of two-dimensional stream-line motion in an incompressible fluid. The present paper proceeds to calculate the lift.—L. P. **Eisenhart** (of Princeton University): Congruences of spheres of Ribaucour which admit of a finite deformation.—R. **Serini**: Theory of the circular plate electric condenser.—E. **Adinolfi**: Centres of absorption of coloured solutions. The author describes a method in which the absorption spectra are observed in solutions of variable density, using a cylindrical receiver which acts as a lens.—R. **Ciusa** and L. **Vecchiotti**: Nitro-derivatives and nitrohydrazones, ii.—M. **de Angelis**: Crystalline form of nitrodibromoacetanilide.—M. **Gortani**: The Permo-Carboniferous and Permian formations in the Caracorum chain.—V. **Novarese**: The Cambrian of Iglesias.—G. de A. **d'Ossat**: Chalk and American vines. The effect of chalk in giving rise to chlorosis in vines already forms the subject of abundant literature. The present experiments appear to negative the empirical results previously obtained, while they suggest that methods adequate for the requirements of practical viticulture may be comparatively easy to carry out in working.—V. **Bambacioni**: Fibrillar structures of Nemec. The protoplasmic cords present in the cells of the radical apices in most plants do not present the complex structure described by Nemec, but in *Aspidium aculeatum* structures are observed comparable with his fibrillæ.—C. **Artom**: Biology and systematics of the genus Artemia, iii.—C. **Jucci**: Differentiation of caste in the society of termites, i. The neotenics.—E. **Artini**: Presence of chrysoberyl in the dolomite of Campolongo (Canton Ticino).—G. **Marletta**: Abelian varieties, ii.—P. **Nalli**: A functional equation.—E. **Adinolfi**: Influence of dissociation on permanganate. As in the previous paper mentioned above, researches on absorption centres can advantageously be made with solutions of concentration rendered variable by diffusion. Permanganates of potash and of lime have the same absorption spectra, and dissociation has no influence on the absorption spectrum of the potash compound.—V. **Cuttica**: Thermic analysis of the system of nitrate of thallio-nitrite of thallium. In view of the thermic behaviour of fused mixtures of $TlNO_3$ and $TlNO_2$, the author excludes the formation of complexes. The two salts form a continuous series of mixed crystals and the transformation to the solid state is referable to Roozeboom's second type in the classification of binary systems with polymorphic transformations.—G. **Cusmano**: Catalytic reduction of *o*-nitroazoxybenzol.—C. **Jucci**: Differentiation of caste in the society of termites, ii. The neotenics.—M. **Boldrini**: Sexual differences of weight in the human body and organs. A table showing the relations between the medians, the probabilities of transvariation, the relations between the arithmetical means, and the intensities of transvariation for numerous series of weights of male and female individuals and organs. The table furnishes a summary of the observations of Frascani, Demoor, Benedict, Bischoff, Bean, Boldrini, and others, the subjects observed including new-born infants from Pisa, Brussels scholars, white and black Americans, Germans (both living and dead), Romans, and a few French and others.

CAPE TOWN.

Royal Society of South Africa, October 20.—Dr. J. D. F. Gilchrist, president, in the chair.—Dr. J. D. F. **Gilchrist**: Observations on living fish brought by H.M.S. *Challenger* from tropical East Africa to Cape waters. In January, 1919, H.M.S. *Challenger* brought six species of fish from Dar-es-Salaam, Port Amelia, Mnazi Bay, and Zanzibar, which were transferred to the tanks of the Government Marine Station at Simon's Bay. They throve very well until April 25, when they all died within a few days of each other. At this date there was a sudden fall in the temperature of the water. The significance of this occurrence in connection with the distribution of fish in South Africa is discussed. Some observations were made on the sleeping habits of *Balistes aculeatus*.—L. **Simons**: Detection of induced β-ray emission from substances exposed to Röntgen rays by a photographic method. A narrow beam of Röntgen rays from a Coolidge tube impinging on a film of red lead laid down on paraffin wax gives a marked effect on a photographic plate placed opposite up to a distance in air of about 2 cm. from the red lead. If a photographic plate replaces the red lead, a similar, though less intense, effect is shown on the opposite plate. This excited radiation was almost stopped by the thinnest mica and paraffin wax. β-rays seem to be more important than secondary X-rays in producing a photographic impression.—J. R. **Sutton**: A contribution to the study of the rainfall map of South Africa. The monthly and annual rainfalls for 567 stations in South and East Africa are given, and the results shown graphically in thirteen maps. The isohyets form a system which moves to and fro across the equator, following the sun with a lag of a month or more. Corresponding with the general movements of the main isohyetal system are the winter rains of the south-west, which advance inland as the summer rains retreat and *vice versa*. The paper concludes with a short bibliography of special studies of South African rainfall.—J. R. **Sutton**: Some notes on ancient ideas concerning the diamond. Various prosaic "motives" for some of the legends and stories about the diamond current in ancient times are suggested. It is argued that Pliny, when he spoke of *adamas* as a name given to a crystal of gold, was probably referring to the outside appearance of the crystallisation.—F. G. **Cawston**: Experimental infestation of fresh-water snails. Infestation of *Limnaea natalensis* was caused by Fasciola from a sheep's liver, also infestation of *Physopsis africana* by water containing the miracidia of *Schistosoma haematobium*; here the mature cercariæ were found six weeks later.—R. D. **Aitken**: The water relations of the pine (*Pinus pinaster*) and silver-tree (*Leucadendron argenteum*). The conductivity of the wood for water, rate of transpiration, total area of leaf-surface, and sectional area of wood have been determined for similar twigs of pine and silver-tree. Under the experimental conditions pine leaves exerted a much greater suction force, calculated in one instance to be about four times that exerted by the silver-tree leaves. The latter are less able to resist drying than pine leaves, in which the rate of transpiration very rapidly diminishes when the twig is not supplied with water to a much lower level than in a silver-tree twig under identical conditions.—J. W. C. **Gunn**: The action of *Eucomis undulata*. *E. undulata* contains a large amount of a saooglucoside, soluble in water and 90 per cent. of spirit. It is a powerful hæmolytic agent. Absorption of the extract from the stomach and intestines and from the subcutaneous tissues is very slow; intravenous injections are actively poisonous, and produce symptoms like other saponin bodies.—T. J. **Mackie**: A study of the *Bacillus coli* group, with special reference to the serological characters of these organisms. The paper is a detailed record of investigations on the *B. coli* group with reference to their (1) biological classification, (2) serological characters, and (3) mutations. The biological characters of 246 strains of gram-negative, aerobic, non-sporing, and non-liquefying glucose-fermenting bacilli (not including specific pathogens of this class) were studied. Four main subgroups could be recognised: (*a*) Gas-producing, indol-forming, and non-inosite-fermenting. (*b*) Gas-producing, non-indol-forming, and non-inosite-fermenting. (*c*) Gas-producing and inosite-fermenting. (*d*) Non-gas-producing (anaerogenes types). The serological characters studied were (1) the agglutination and (2) complement deviation reactions of immune sera to certain of the commoner varieties. These observations proved of great interest from the purely immunological point of view, and also threw some further light on the biological relationships of the various types of coliform bacilli. The comparative resistance of various types to brilliant green was correlated with the grouping determined by cultural and serological tests. Mutations among these organisms were investigated, and afforded some explanation of the great diversity of cultural types and of the high degree of specialisation in the serological characters of individual strains.—E. **Newbery**: Note on over-voltages. Over-voltage appears to be a function independent both of the gas liberated and of the metal in question, and completely determined by valency alone. Whether the valency of the gas is involved or not is still an open question, since all gaseous ions used were monovalent. The over-voltage compounds probably carry excess electrons, and the addition of each electron produces a definite increment in the single potential, which increment is dependent only upon the number of free valency electrons present in the atom of the electrode or ion of the over-voltage compound.

Books Received.

Manual of Tropical and Subtropical Fruits: Excluding the Banana, Coconut, Pineapple, Citrus Fruits, Olive, and Fig. By W. Popenoe. (Rural Manuals.) Pp. xv+474+xxiv plates. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd.) 30s. net.

Diary of Societies.

THURSDAY, DECEMBER 16.

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—H. Ricardo: Possible Developments in Aircraft Engines.—A. J. Rowledge: The Instalment of Aeroplane Engines.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—E. J. Prior: Some Sources of Error in Alluvial Boring. —R. E. Palmer: Some Observations on Mining by the Opencast or Stripping Method.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Discussion: Report on the Heating of Buried Cables.

CONCRETE INSTITUTE, at 7.30.—H. J. Deane: Special Applications of Reinforced Concrete in Docks, with Special Reference to the Reinforced Concrete Gates at Tilbury Docks.

INSTITUTION OF AUTOMOBILE ENGINEERS (Graduates' Meeting) (at 28 Victoria Street), at 8.—T. E. B. Whiting: Carburation.

CHEMICAL SOCIETY (at Institution of Mechanical Engineers), at 8.—Sir R. Robertson: Lecture: Some Properties of Explosives.

RÖNTGEN SOCIETY (in Physics Lecture Theatre, University College), at 8.15.—The Reduction of Radiographic Exposures to 1/25th and Less by Means of a New Type of X-Ray Plate. Part I. by Dr. L. Levy and D. W. West. Part II. by T. Thorne Baker.

HARVEIAN SOCIETY OF LONDON (at 11 Chandos Street, W.), at 8.30.—Dr. C. M. Wilson, Dr. C. Buttar, and Others: The Future of the Poor-law Infirmary.

FRIDAY, DECEMBER 17.

SOCIETY OF MEDICAL OFFICERS OF HEALTH (at 1 Upper Montague Street), at 5.—Lt.-Col. H. R. Kenwood: Presidential Address to the Navy, Army, and R.A.F. Hygiene Group of the Society.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Dr. W. J. Walker: Thermodynamic Cycles in Relation to the Design and Future Development of Internal-combustion Motors.

JUNIOR INSTITUTION OF ENGINEERS (at Royal United Service Institution), at 7.30.—Lord Weir of Eastwood: Some Reflections on our Industrial Situation (Presidential Address).

ROYAL SOCIETY OF ARTS, at 8.—Col. R. J. Stordy: The Breeding of Sheep, Llamas, and Alpacas in Peru, with a view to supplying Improved Raw Material for the Textile Trades.

ROYAL SOCIETY OF MEDICINE (Electro-Therapeutics Section), at 8.30.—Adjourned Discussion: Radio-Therapy.—Dr. R. Morton: Recent Developments in Deep Therapy.—Dr. L. Martindale: Technique of X-ray Therapy of Fibroids.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at London School of Tropical Medicine), at 8.30.—Laboratory Meeting.

SATURDAY, DECEMBER 18.

PHYSIOLOGICAL SOCIETY (at St. Thomas' Hospital), at 4.

MONDAY, DECEMBER 20.

SURVEYORS' INSTITUTION, at 7.—H. S. Logsdon: Rating as affected by Recent Legislation.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street), at 8.—Prof. T. P. Nunn and Prof. H. Wildon Carr: Discussion on Prof. Alexander's "Space, Time, and Deity."

ROYAL SOCIETY OF ARTS, at 8.—A Chaston Chapman: Micro-organisms and Some of their Industrial Uses (Cantor Lecture).

INSTITUTION OF AUTOMOBILE ENGINEERS (London Graduates' Meeting) (at 28 Victoria Street), at 8.—W. H. Wardall: Cylinder and Piston Wear.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—F. Debenham: The Future of Polar Research.

TUESDAY, DECEMBER 21.

ROYAL SOCIETY OF MEDICINE, at 5.—General Meeting of Fellows.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Dr. D. J. Reid: Further Developments in Systematic Exposure in Photomicrography.

The Dyestuffs Bill.

THE Dyestuffs (Import Regulation) Bill passed its third reading in the House of Commons on December 17 by a majority of 86 (111 votes to 25), after the Opposition had unsuccessfully challenged a division on the Government's motion to exempt the measure from the limitations of the Standing Order relating to a Friday sitting. This action on the part of the Opposition is an indication of the attitude of a certain section of the Manchester school of political economists towards the Bill; in so far as it savours of Protection, it is, of course, anathema. Their ears were apparently deaf to all arguments as to the absolute necessity of resuscitating, as much in the interests of our national security as in those of our commercial prosperity, an industry primarily of British origin. The old theoretical Free Trade arguments against the Bill failed, however, to convince all Free Traders in the House. The member for the Bridgeton division of Glasgow, as a Free Trader, had the temerity to denounce the agitation against the measure as wholly factious and bogus and as doing the greatest harm to the cause of Free Trade.

A perusal of the proceedings of Standing Committee B, which was charged with the consideration of the Bill, serves to confirm this impression. Under cover of protecting the interests of the textile and other colour-using industries, an amendment was moved which, without materially benefiting these industries, could only result in limiting the beneficent intention of the Bill as regards the dye-makers. The mover of the amendment scored one or two debating points, but the suggestion to add words to the particular subsection which prohibits importation of dyestuffs so as to imply that the safeguarding of the dye-making industry was being done at the expense of the textile industries so little commended itself to the judgment of the Committee that it was rejected by a majority of more than two to one. Such action on the part of the Opposition is not constructive legislation. There is no necessary antagonism between the colour-makers and the colour-users in this country; their mutual interests are inseparable, and the prosperity of one section is bound up with that of the other.

The same animus against the measure was displayed in a succession of amendments which were ruled out of order. Attempts were next made to restrict the prohibition to dyestuffs manufactured in Germany, but, as the Parliamentary Secretary to the Board of Trade pointed out, to confine the clause to the prohibition of importation from Germany would make the Bill perfectly nugatory. To safeguard the dyestuff industry effectually, it had to be safeguarded against competition from all outside sources. Moreover, there would be nothing to prevent the German dye-makers from establishing depôts in other countries and exporting the dyes thence. A moving appeal was made on behalf of Switzerland, which, it was contended, had continued to help us throughout the war, and, it was added, incidentally to help herself. To what extent Switzerland made herself an agent for the transmission of German-made dyes was not stated.

This character of argument was too much for the patience of some members of the Committee. Sir Philip Magnus, the member for the University of London, bluntly charged members of the Committee with the deliberate intention of obstructing the Bill; from the speeches at the first sitting it was obvious that every possible opposition would be made. This unmasking of their batteries was naturally warmly resented by the militant members, led by Major Barnes, Col. Williams, and Major Hayward, who protested, in the words of Major Wood, that they were "not out against protecting or assisting the dye industry." What they objected to were the means by which that end was to be reached. But whatever affection they might feel towards the dye industry was most effectually dissembled. In the end the attempt to restrict the prohibition to Germany was defeated by a majority of nearly three to one. Later attempts to leave out the provision as to colours and colouring matters and organic intermediate products; to direct the Advisory Committee as to the grounds of their decisions; and to provide that "prohibition shall not apply to any such goods manufactured within the British Empire," were either abandoned or were defeated by large majorities on division. A similar fate met amendments raising the question of the date of the application of the Act; the prohibition of synthetic organic products imported mainly for medical purposes; and the importation of new colours.

The longest discussion occurred on the question of the composition and functions of the Advisory Committee which the Board of Trade is empowered to set up for the purpose of advising it with respect to the granting of licences. This Committee is to consist of five persons concerned with the trades using dyestuffs, three persons connected with their manufacture in Great Britain, and three persons constituting "a neutral body"—that is, persons not directly concerned with the manufacture or use of dyestuffs—one at least of whom is to possess "high scientific qualifications"—not, as one Opposition amendment suggested, "a person of medical skill," although why such a person is needed on such a Committee is not very obvious. Various attempts were made either to enlarge the Advisory Committee or to place upon it representatives of particular trades, such as the export branches of the textile industries, the woollen and worsted industry, and the cotton industry. Nor were the claims of Labour, as such, forgotten. But the President of the Board of Trade, who throughout the four days' proceedings had discharged his responsibilities with urbanity and tact, firmly resisted all attempts to tamper with the constitution and functions of the Advisory Committee as defined in the Bill, and in the end, after repeated divisions, in which the malcontents were defeated by increasing majorities, he got his way.

As a last resource, the Opposition sought to curtail the operation of the Act. It is provided that the Act shall continue in force for a period of ten years and no longer. Successive amendments were moved to limit it to one year, then to three, next to seven years; but after the closure had been carried it was decided that the words proposed to be left out should stand part of the clause, and ten years is to be the duration of the Act, which, as afterwards stated by Sir Robert Horne, is to come into force on January 15 next. Major Wood then moved that the Act shall cease to be in force if an Order in Council, on an address by both Houses of Parliament, should so determine; but the amendment was declared to be out of order. An Act of Parliament can be repealed only by an Act of Parliament.

The debate in the House on the Report stage of the Bill was to a large extent a repetition of the proceedings of the Committee. Clauses were moved to limit the extent of prohibition on the import of dyestuffs; to limit dividends and profits by manufacturers of synthetic colouring matters; to curtail the currency of licences; and to alter the constitution of the Advisory Committee; but, after repeated applications of the closure, these several amendments were defeated by even larger proportional majorities than they had met with in the Standing Committee.

On the third reading a last despairing effort was made to reject the Bill, but the appeal to Cæsar met with no success, and the twenty-five stalwarts were beaten by a majority of nearly five to one.

The Meteorology of the Antarctic.

British Antarctic Expedition, 1910–1913. *Meteorology:* Vol. i., *Discussion.* By Dr. G. C. Simpson. Pp. x+326+v plates. Vol. ii., *Weather Maps and Pressure Curves.* By Dr. G. C. Simpson. Pp. 138+23 plates. (Calcutta: Thacker, Spink, and Co., 1919.)

It was a fortunate day for meteorology when Capt. Scott invited Dr. Simpson to join his last expedition as meteorologist. The Antarctic has always provided a fascinating field on account of the symmetry of its general circulation combined with remarkable local phenomena; but never before has a meteorologist and physicist of the first rank studied Antarctic meteorology on the spot and presented to the world the digested results of observations planned and executed by himself.

The two volumes now published contain a comprehensive discussion of Antarctic meteorology in 1911–13, and a series of weather maps at 8 a.m. and 8 p.m. daily (presumably 180th meridian time) from April 1 (1911?) to January 2 (1912?), a period of nine months. A third volume will include detailed tables of the results of observation. The printing was done in Calcutta and is good, but the registration of the synoptic charts is frequently indifferent.

In a brief preface tribute is fittingly paid to the people of Derby for the provision of funds for instruments and to the other members of the expedition for indispensable assistance in maintaining the records; the author proceeds modestly to disclaim ability or interest in statistical meteorology; nevertheless, the book abounds in means and averages, frequency curves and Fourier coefficients, correlations and probable errors, and dispels, by its completeness, the suspicion engendered by pp. vi and vii of the preface that the author was approaching his task under the impression that the function of meteorology was to "attempt" the questions of a Saturday morning problem paper rather than to record facts and to set them in order for the information of mankind.

The observations on which the discussion is based were made at the base stations Cape Evans and Cape Adare, at Framheim (Amundsen), and for shorter periods at different places on the Barrier and the plateau by the various parties. Two very instructive maps in the introductory chapter show the surroundings of Cape Evans and Cape Adare, and indicate that the situation of neither station was very good from the meteorological point of view: an indication which is supported by the records of wind. At Cape Evans 43 per cent. of the winds were below ten miles per hour, and the direction of the wind bore so little relation to the general distribution of pressure that on a large number of occasions it appeared to be blowing *out* of the centre of low pressure. At Cape Adare, the northern extremity of a promontory twenty miles long, 72 per cent. of the winds were below five miles per hour, whereas at a well-exposed station in the British Isles only about 10 per cent. of the winds come into this category; and in a similar situation further west in the Antarctic Mawson found an average wind speed for the year of fifty miles per hour.

The main discussion is divided into nine chapters dealing with temperature, wind, cloud and precipitation, pressure and its relation to winds and weather, general circulation, the upper air, the height of the Barrier and the plateau, and atmospheric electricity. Each chapter contains not merely a discussion of the results of the observations and a rational explanation of the facts revealed, but also some new contribution (such as, for example, a study of the gustiness of the wind) which was rendered possible only by the new instruments and methods not previously available in Antarctic work.

The annual and diurnal variations of temperature are shown to be, on the whole, due to insolation, but two features present difficulty. There is a diurnal variation of temperature during the months when the sun is completely below the horizon, and the "day" hours are, on the whole, warmer than the "night" hours. No rational explanation is given of this effect. The suggestion that it arises from scattered radiation from the upper layers of the atmosphere which come into the sunshine during the "day" hours is not mentioned, and it appears to be excluded by the fact that the effect is more marked on cloudy than on clear days, and by the further fact that on clear days there are two maxima at about 4 a.m. and 4 p.m., the time of minimum pressure in the semi-diurnal barometer oscillation. The unusual feature in the annual variation is roughly this: on the Barrier the amplitude of the variation is "oceanic" and the phase "continental," while in the Arctic the amplitude is "continental" and the phase "oceanic." The explanation put forward is, roughly, that the continents of Asia and America control the amplitude in the Arctic Ocean, and the Antarctic Ocean controls the amplitude on the Barrier; the argument is well stated, but it is not entirely convincing.

The records from the Dines pressure tube anemometer, many of which are reproduced, add greatly to the interest of the chapter on wind, and, indeed, to that on temperature, too, by the light they throw on blizzards and other sudden changes. The winds at Cape Evans were found to be about 50 per cent. more gusty than the winds at Scilly and Holyhead; but the gustiness decreased as the speed of the wind increased, indicating, according to Dr. Simpson, that the high value was due, not to the exposure, but to the interaction between a warm upper current and a cold surface layer which are co-existent in the Antarctic more frequently than in England.

Pressure-waves travelling outwards from the centre of the continent are Dr. Simpson's contribution to the explanation of the synoptic charts of the Antarctic. He rejects Lockyer's scheme of travelling cyclones, and pours scorn on the suggestion that the motion of the air in a blizzard is part of a very large cyclonic system. "A depression with its centre in 60° S. able to produce a blizzard of 40–60 miles per hour in 78° S. is of course quite inconceivable. Whatever blizzards may be due to, they are certainly not part of the circulation around a cyclone the centre of which is more than 1000 miles away." He appears here to be doing less than justice to Lockyer's scheme, which may represent the broad features of the pressure distribution, even although all the cyclones do not adhere rigidly to the 60th parallel of latitude.

The theory of pressure-waves will undoubtedly provoke much discussion; facts are marshalled in an imposing array to support it, and theoretical synoptic charts are produced which are wonderfully similar to the charts based upon actual observations. The pressure-waves are apparently not sound-waves; they are described as "true pressure-waves traversing the upper atmosphere in the same way that water-waves travel across the sea"—*i.e.* they are waves formed at a surface of discontinuity. As the waves appear to be at least 500 miles from crest to trough, there cannot be very many of them—probably, in fact, not more than one—in existence at a time, so that the comparison ought to be with one long wave in shallow water (*e.g.* a tidal wave) rather than with "water-waves travelling across the sea"; it appears doubtful if it is possible at the surfaces of discontinuity, which certainly exist in the Antarctic, to get waves 500 miles long travelling at forty miles per hour, and having pressure amplitudes of 20 millibars at sea-level. The horizontal transference of a large mass of air naturally suggests itself as an alternative explanation, but the adjustment of the motion to the pressure gradient presents difficulties.

In his discussion of the general circulation Dr. Simpson arrives at conclusions agreeing in some respects with Hobbs, and in others with Meinardus. Broadly speaking, he makes the whole continent an anticyclonic area surrounded by a broad band of low pressure about lat. 65; but at 10,000 ft. the plateau alone is anticyclonic, while a very marked cyclone is centred over the part of the Antarctic which is near sea-level. The upper winds deduced from cloud observations and from Erebus's smoke fit in well with the scheme.

The free atmosphere over the Antarctic had never been explored before Dr. Simpson sent up his *ballons-sondes*; the results of this first attempt are remarkably good, although the stratosphere was not reached. Out of twenty-one ascents, fourteen instruments were recovered, of which twelve furnished good records; but three of them referred to different times on one day, November 19, 1911. In six cases of summer ascents the temperature decreased steadily upwards at a rate of about 6° C. per kilometre; in four cases of winter ascents temperature rose at the commencement of the ascent, and began to fall only after a height of one or two kilometres had been reached. The lowest temperature recorded in these ascents was $-46°$ C. ($-51°$ F.) at a height of 6750 m. (22,000 ft.) on Christmas Day, 1911. The lowest temperature recorded on the Barrier was $-60°$ C. ($-76°$ F.) on July 6, and this is the lowest temperature recorded anywhere in the Antarctic.

The observations on atmospheric electricity led to interesting conclusions on the effect of drift-snow, which, however, could not be put to the crucial test owing to Dr. Simpson's unexpected recall to India. One is, indeed, forced to observe that the Government of India was decidedly less than generous throughout. It might well have lent Dr. Simpson's services in such a glorious cause, seeing that a proper knowledge of Antarctic meteorology is vital to an understanding of those great currents of the atmosphere to which monsoons belong; instead, it granted him "leave without pay," and then recalled him in the middle of the enterprise.

The work is a notable contribution, not merely to Antarctic meteorology, but also to meteorological science; it is an enduring monument to the great leader of the expedition through whose foresight and scientific spirit the enterprise was made possible.

Imperial Mineral Resources.

(1) *Imperial Mineral Resources Bureau. The Mineral Industry of the British Empire and Foreign Countries. War Period. Arsenic.* Price 6*d.* net. *Felspar.* Price 6*d.* net. *Chrome Ore and Chromium.* Price 1*s.* net. *Fuller's Earth.* Price 6*d.* net. *Magnesite.* Price 1*s.* 3*d.* net. (London: H.M. Stationery Office.)

(2) *Tungsten Ores.* By R. H. Rastall and W. H. Wilcockson. (Imperial Institute: Monographs on Mineral Resources, with Special Reference to the British Empire.) Pp. ix+81. (London: John Murray, 1920.) Price 3*s.* 6*d.* net.

(1) THE necessity for complete and accurate information about the mineral resources of the British Empire has repeatedly been emphasised in these columns and elsewhere. Even before the war this need had become evident, and it was felt to be a serious reflection upon British statisticians that the most trustworthy source of such information was to be found in an American publication. During the war, the gravity of this deficiency naturally became accentuated, and the formation of the Imperial Mineral Resources Bureau has been the result. This bureau has now been organised, and is entering seriously upon its labours, the result being made public in the form of a succession of pamphlets, each dealing with one particular mineral. Those hitherto issued relate to minerals of relatively minor importance, and include arsenic, felspar, chrome ore and chromium, fuller's earth and magnesite. The

scheme of all these pamphlets is identical; they commence with a general description of the mineral discussed, its composition, uses, and chief sources of supply. The world's output of the mineral is then given, and this is followed by a detailed description of the occurrences in the United Kingdom and the rest of the British Empire, together with statistics of production, followed by similar information concerning foreign producers. References to technical literature on the subject are given in an appendix, and in some cases there is an additional note on some important application of the mineral; for instance, the pamphlet on magnesite contains a note on the production of magnesium chloride and its use in the manufacture of Sorel cement. It should be added that the statistics and information relate in each case to the "war period," 1913-1919. These publications thus form a continuation of those formerly issued by the Home Office, and known as part iv. of the Report of the Chief Inspector of Mines. It would probably have been more convenient for most users of these pamphlets if the statistics had been taken rather further back, and given, say, for the last ten years, and if decennial tables were included in all future annual issues. There is some information as to costs and prices, though not sufficient for those interested in the industries, but no doubt in future years these figures will be given in more detail; it is also stated that in future issues data concerning labour, safety, etc., will be included.

The work of compilation has been well and carefully done, upon the whole; it would be easy to point out small errors and omissions, but these are inevitable in the first issue of a publication of this kind, which involves a vast amount of minute and painstaking research amongst a large number of different sources of information, which are often of very unequal value so far as trustworthiness is concerned. Perhaps the least satisfactory feature is the fact that a number of different standards of weight are employed; it is true that a footnote points out that metric, long and short tons are employed, and the equivalent of each of these is given, but this is not quite enough; it should not be necessary for anyone using these pamphlets to make a calculation before he can compare the statistics that he finds on adjoining pages; probably the best plan is to give in every case the tonnages as reported in the original source of information, and in a parallel column these weights in metric tons, which latter are being largely employed by scientific statisticians.

(2) Simultaneously with the issue of these publications by the Imperial Mineral Resources Bureau, the Imperial Institute has issued another volume of its series of monographs on mineral resources, the present one being on tungsten ores, written by Messrs. R. H. Rastall and W. H. Wilcockson. In its general scheme this pamphlet is identical with those produced by the Imperial Mineral Resources Bureau, and its execution is quite satisfactory, though perhaps the economic aspect of the subject receives even less attention here than in the other series of publications. The question that evidently obtrudes itself, however, is whether there is anything at all gained by this duplication of effort. The issue seems to be unusually simple; the Imperial Mineral Resources Bureau has been organised, and is maintained out of public funds for doing just the very work that the Imperial Institute is taking up. If the bureau does not do its work completely and efficiently, it should be called upon to mend its ways; but if it does do the work entrusted to it satisfactorily, it is surely to the public interest that the Imperial Institute should employ the funds entrusted to it in some more useful manner than in duplicating this work, and it cannot be suggested that there are not plenty of other important Imperial problems needing investigation.

H. LOUIS.

New World Zoology.

Zoölogy: A Text-book for Colleges and Universities. By Prof. T. D. A. Cockerell. (New World Science Series.) Pp. xi + 558. (Yonkers-on-Hudson, New York: World Book Co., 1920.) Price 3 dollars.

TEXT-BOOKS of zoology are legion, and they are by no means all bad. Some of them, indeed, like "Marshall and Hurst," are almost perfect specimens of their kind. Yet we can understand the growth of the list, for every experienced professor of the science has his optimistic moments when he thinks that his particular way of teaching the subject is worthy of presentation to an audience wider than that in his classroom. But the unfortunate fact seems to be that few writers of text-books have managed to fulfil their intention. In many cases the individuality ends with the preface, the whole book sinking to conventional competence on familiar lines.

But this is not true of Prof. Cockerell's "Zoölogy," for it has an individuality. "The biology or zoology for the average individual who has no thought of specializing in the department should not be too morphological, too rich in detailed facts of structure and classification. Experience shows that such minutiæ are not remembered, and do not necessarily leave as a residue any broad and useful conceptions." So the author has space for many interesting stories, which are crowded out of most books, such as Mendelism, "linkage" and "crossing over," artificial fertilisation, Protozoa and disease, social insects, the pedigree of the elephant, and the zones of life.

Another feature is the insistence on practical utility, not in any tiresomely narrow way, but with a wide horizon. Zoology is for life, not life for zoology. There are big ideas to be understood, which will influence the whole conduct of life. Most of these big ideas are difficult, but "from a psychological and pedagogical standpoint, it is surely an error to suppose that each idea must be luminously clear at the moment of presentation." Prof. Cockerell gives his students plenty to ponder over, for he deals with the living substance, the individual, "nature" and "nurture," alcohol and heredity, variation, selection, disease in relation to human evolution, eugenics, and sociology from a biologist's point of view. The chapters are freshly written, very objective, and their brevity is as psychologically sound as it is unusual. The author does not preach at all, but he suggests the responsibility as well as the happiness of playing the scientific game. He also suggests the wonder of the world. So it is not a common text-book this; it is a new presentation.

A third feature of great value is the introduction of biographical chapters. "We are too apt to receive the gifts of science without asking whence they came. . . . As the pious studied the lives of the saints, so may we pause now and then to learn how scientific heroes have won new territory for the kingdom of science. Thus, if we have anything of generous response within us, we may return to our studies refreshed, resolving that we also, in some measure, will further the good cause." So the book contains sketches of Darwin, Mendel, Linnæus, Fabre, Pasteur, and others. There are numerous illustrations, many of them new and interesting, others a little too familiar. For the general student who is not going to pursue zoology far, this is an admirable text-book; for all it is a good introduction.

The Botany of Iceland.

The Botany of Iceland. Edited by Dr. L. Kolderup Rosenvinge and Dr. Eug. Warming. Vol. ii., part i. By Ernst Østrup and Olaf Galloe. Pp. 248+5 plates. (Copenhagen: J. Frimodt; London: John Wheldon and Co., 1920.)

THE present instalment of the results of work on the botany of Iceland is devoted to the Cryptogamic flora, and contains an account of the fresh-water diatoms by the late Dr. Ernst Østrup, and a description of the lichen flora and lichen vegetation by Dr. Olaf Galloe. The former comprises a systematic list of species based on the examination of 572 samples collected by different botanists in various parts of the island. The list includes a number of new species and varieties which are figured in the five plates. The author also gives a table indicating the general distribution, and the distribution in the different parts of Iceland, of the 468 forms listed. From this table it appears that 95 per cent. of the Icelandic forms also occur in the rest of Europe; Asia and America come next with about 50 per cent.; comparing Iceland with the Arctic regions, the greatest resemblance is with Greenland, with which it has 41 per cent. in common. A classified list is also given of the species found in hot springs from thirteen localities.

Dr. Galloe's account of the lichenology of the island is based mainly on observations made by himself during the summer of 1913, when he investigated fairly thoroughly several of the coast districts, although he had no opportunity of examining the desert interior of the island. The author criticises the methods of systematic lichenologists, who have endeavoured to diagnose species on lines similar to those followed in dealing with flowering plants. This, he maintains, has led to the establishment of a large number of species, many of which would probably be shown by culture experiments to be forms of one and the same species. Unfortunately, this experimental method would be difficult and tedious, and there is little hope of its being successfully carried out. In the meantime it is urged that lichenologists should publish extended descriptions of "one single individual" of each type in order to leave no doubt as to the form which it is intended to describe.

A classified list of the species is given, but the greater part of the work deals with the biological and ecological aspect of the lichen flora. The means of propagation and of dispersal of the Iceland lichens are discussed, and an account is given of the chief biological conditions in which they occur. They are classified under three associations—the bark-lichen, the earth-lichen, and the rock-lichen. The conclusion is drawn that Iceland (like other Arctic countries) is poorer in species according to its area than temperate and subtropical countries, but as regards frequency-number and abundance the Arctic regions and Iceland are probably richer than other regions. No doubt this is chiefly on account of the slight competition to which the lichens are subjected.

Our Bookshelf.

Scientific and Applied Pharmacognosy. By Prof. H. Kraemer. Second edition, thoroughly revised. Pp. xxviii+741. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) Price 33s. net.

OF all the American works on pharmacognosy, none is so well known in this country as Prof. Kraemer's, and every pharmacognosist will welcome the appearance of a second edition as affording the author an opportunity, of which he has taken full advantage, of increasing the scope of the work and bringing it up to date. In nearly all the descriptions of the drugs the inner (microscopical) structure is included, and also the characters of the powder; more attention has been devoted to the chemistry, and, in the case of those containing important alkaloids, glucosides, or other definite constituents, these are very fully described and characterised. Many of the numerous illustrations are original, particularly those of the sections and the microscopical characters of the powders, the value of which, it must be confessed, would have been enhanced by a statement of the magnification. Pyro-analysis of drugs, carried out by examining sublimates obtained at comparatively low temperatures, to which a good deal of time has been devoted on the Continent during the last few years, has also received attention, although most pharmacognosists will probably agree that its real value has still to be proved. The section on animal drugs is very interesting, particularly the description of cochineal. In the tables arranged for the identification of a powdered drug, the author still adheres to a primary classification based upon the colour, although this has not found general acceptance.

The work is well printed and freely illustrated; it contains a mass of information, much of which is not otherwise readily accessible; and it should therefore find a place in the library of every pharmacognosist.

The Groundwork of Modern Geography: An Introduction to the Science of Geography. By Dr. A. Wilmore. (Bell's Geographical Series.) Pp. xv+396+xxvii plates. (London: G. Bell and Sons, Ltd., 1920.) Price 6s. net.

AMONG text-books of geography this volume is noteworthy, because it has a fresh outlook and strikes new ground, the author having the courage to depart from many of the time-honoured conventions of school geography. The subject is divided into three parts—structural, climatic, and biological geography—the last rightly including the elements of human geography. Economic considerations are kept well to the fore, which helps to dispel the fallacy of regarding economic geography as a distinct subject.

There is here no medley of scraps of geology and meteorology, but a true geographical treatment of land-forms and climate. The only fault we have to find with the sections on climate and vegetation is that in their brevity they tend to overlook causal relations, and lapse at times into mere descriptions. These chapters might well have been extended by the sacrifice of the chapter on the distribution of animals, a subject that in most of its aspects is not required in the geographical synthesis, since comparatively few wild animals directly influence human activities and migrations. The absence, on the other hand, of any notice of the distribution of disease-bearing insects is a serious omission. Useful bibliographies are given to all chapters, and there are some well-chosen illustrations. R. B.

A Course of Modern Analysis: An Introduction to the General Theory of Infinite Processes and of Analytic Functions; with an Account of the Principal Transcendental Functions. By Prof. E. T. Whittaker and Prof. G. N. Watson. Third edition. Pp. vii+608. (Cambridge: At the University Press, 1920.) Price 40s. net.

THE first edition of this admirable and well-known treatise was the single-handed work of Prof. Whittaker, and was published in 1902. Into the second edition, which was published thirteen years later and reviewed in NATURE for June 8, 1916, the results of Prof. Watson's collaboration entered very largely. The scope of the work was then considerably extended. The present, or third, edition appears at a much shorter interval, and contains fewer changes, chiefly represented by corrections and a fuller apparatus of references. But a valuable chapter on ellipsoidal harmonics is an entirely new feature. This fine work is now far larger and more complete than in its original form, and it is inevitable in present circumstances that the price has been considerably advanced. The only complaint that can be suggested in this connection is that, at the high price, paper of a rather better quality might have been provided.

Medical Electricity: A Practical Handbook for Students and Practitioners. By Dr. H. Lewis Jones. Eighth edition. Revised and edited by Dr. L. W. Bathurst. (Lewis's Practical Series.) Pp. xv+575. (London: H. K. Lewis and Co., Ltd., 1920.) Price 22s. 6d. net.

THE seventh edition of this valuable treatise on medical electricity was reviewed in NATURE for June 20, 1918. Since that date the subject has expanded in various directions; the war provided a mass of new material for electro-therapeutists, and in the present edition indications of these advances have been inserted. The effects of Röntgen rays are dealt with in discussing physiological and pathological considerations, but there is no mention of the technical apparatus used in this work, for the reason, as Dr. Bathurst states in his preface, that "Röntgenology" is now a separate department of medical work. A chapter on ultra-violet radiation, and new matter relating to ionisation, diathermy, and the electrical testing of muscles, have been incorporated in the text.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Heredity and Acquired Characters.

ALTHOUGH agreeing entirely with Sir Ray Lankester's and Prof. MacBride's criticisms (NATURE, December 16, pp. 500–1) of Sir Archdall Reid's letter, I venture to add a few words on two points.

First, I will attempt to explain to Sir Archdall Reid why it is held that a head is "more innate and germinal and less acquired and somatic than a scar" (*ibid.*, November 25, p. 405).

It is reasonable to suppose that, at least up to hatching, the nurture of the chicks of all domestic races is the same. The differences between their heads are therefore due, not to nurture, but to nature. Nurture is an essential condition of their development, but, being uniform, it cannot be a cause of diversity.

A scar is the precise opposite of this. Its cause is the blow or other external force inflicting injury, an essential condition being the existence of organic matter incapable of resisting the force and with limited powers of regeneration. This condition is uniform over a large part of the body surface, and can never explain the infinite variety in the appearance and position of scars.

We therefore rightly maintain that everything distinctive of the normal head, everything which we can describe, measure, or figure, is *inherent* or *blastogenic*, although appropriate external conditions are necessary for its development; and that, similarly, every feature by which one scar is distinguished from another is *acquired* or *somatogenic*, although germinal potentialities are necessary for its existence.

One other consideration arises out of Sir Ray Lankester's letter. Although I entirely agree that acquired characters are commonly "departures (either increase or decrease) from the usual or normal size, form, or structure of this or that part," yet—as I pointed out in reply to similar definitions by Sir Francis Galton and Prof. Lloyd Morgan—it is "a mistake to make too much of abnormality, or to import it into a definition. Some of the most marked, and certainly the most easily studied and tested, of acquired characters are the differences between the effects of alternative environments, all of which are normal, upon the individuals of a single species. The green colour of a larva of *Amphidasys betularia*, if fed upon broom, is an acquired character, as is the dark colour it would assume upon oak, etc. I think, therefore, that a more satisfactory definition of, at any rate, a large class of acquired characters may be framed as follows: 'Whenever change in the environment regularly produces appreciable change in an organism, such difference may be called an acquired character'" (Proc. Ent. Soc. Lond., 1904, p. cviii.).

Oxford, December 19.

Environment and Reproduction.

SEVERAL attempts have been made to show that spawning in the sea and in fresh waters, and also in terrestrial conditions, is regulated by temperature. Many examples could be quoted to demonstrate that the rule is for a species to spawn earlier and to develop more quickly in warm water; that, in other words, the period of spawning is early in tropical seas and conditions, and later to the north and south of the tropical belt, and that the period of growth is increased with lowering of temperature. The factors at work, however, are more deep-seated than they appear to be at first sight. That this is so is at once clear from two correlated considerations: (1) There is a period, sometimes a long period, of ripening with reference to which spawning is the culmination, and during which somatic changes and migratory results are produced; and (2) all the adults do not participate in the ripening and spawning.

In the case of the Protista and the Metazoa which reproduce rapidly, an annual phase may be postulated which closely follows the rise and fall of temperature, but in each generation reproduction follows growth, and does not take place until the growth of the cell or of the soma has reached a certain condition. When the growth is represented by a curve the point of inflection may be said to mark the period when, in the case of the cell, the impulse is conveyed to prepare for division, and in the case of the Metazoon the call arrives to the gonad to develop. Now amongst the Metazoa we get all stages, from the rapid reproduction of such forms to those which reproduce twice a year or once a year, and to those which reach maturity after several years of growth and do not necessarily thereafter spawn annually. In each case we have to observe that the somatic need must be satisfied before maturation is introduced. There are aquatic and terrestrial species which in one situation reproduce once a year, and in warm seasons or in warmer situations reproduce twice a year. But we understand by that statement that the conditions have allowed the early generation to grow

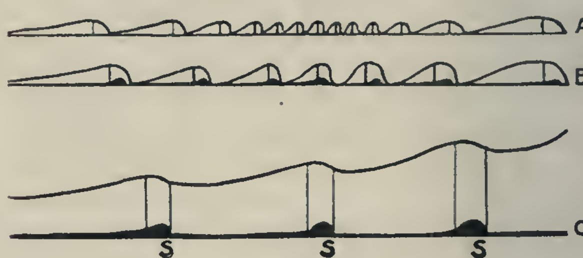

FIG. 1.

sufficiently fast to permit of a second generation in the same season.

In the accompanying diagrams (Fig. 1) an attempt is made to indicate the effect of summer and winter on Protozoa (A) and on Metazoa which have many generations a year (B). Lowering of temperature in these cases would restrict growth, and therefore the number of generations. The diagrams also depict the acceleration and retardation of growth and reproduction of planktonic species passing to and from tropical seas. In (B) the history of the gonad is indicated by the black curves. This is also done in (C), which is meant to show the periodical changes in a species which spawns regularly.

With regard to the last, we must first differentiate between the individual and the crowd. The spawning period may be a long one in the tropics, but it is periodic for the individual, and, indeed, spawning seasons are in many cases sharply indicated in tropical species of all groups. If, with reference to such an example as (C), the season of the commencement of maturation of the gonad be approximately constant, the effect of lowering of temperature would be manifested by a later spawning. Such considerations go, therefore, a long way to explain the observed results, and they also serve to explain the length of the tropical spawning season and the more restricted season of temperate, and especially of Arctic, regions. Without reference to other environmental factors, it may be granted therefore that growth and reproduction vary in length and periodicity with temperature. Nevertheless, the fact that the spawning season may be postponed makes us feel unsatisfied with an explanation which transfers in a general way, as, say, by the physical condition of the circulation, the function of intimating to the gonad that it can proceed with its development. Besides, the regularity of the spawning seasons, the manner in which summer and winter are impressed upon the most sedentary animals, the influence of warmth and density in promoting larval life, and other similar considerations, bring us back once more to the question of environment.

There may be said to be, as is shown in the accompanying diagrams, three phases of life in all animals: immaturity, maturity, and spawning. If the act of spawning is not followed by death, then there succeeds a series of similar phases. If we are prepared to recognise that the phase of immaturity is not ended alone by the attainment of the requisite somatic growth, then it is regulated by an organ which acts as an inhibitor of the next phase, and continues to act, not merely until the soma is in the requisite condition, but until the environment is also favourable. Such an organ must be placed in a convenient situation for receiving impressions from the environment and for communicating to the blood a hormone the function of which is to inhibit the development of the gonad. In the case of aquatic animals we naturally turn to the gills to see if such an organ is provided, and it is already apparent that the thymus has been developed for this purpose. The thymus is a larval organ which develops in association with the gills, and it is already known that its secretion inhibits the growth of the gonads. A thymus-like secretion will probably be found to be at work in this manner in all animals. In the Craniata the thymus is removed from its primitive position in the gills, but it lies near the gills of fishes, and in them and the higher Craniata continues to exercise its function of controlling the period of adolescence.

When the thymus ceases to supply its secretion to the blood the gonad commences its period of growth, and it is probably then that the thyroid comes into action to control in similar manner the growth of the gonad. The thyroid has an interesting history, and in the higher animals at least its relationship to the gonad has long been known. It is developed in the floor of the gill-chamber, and therefore is in a favourable position not only for helping in the straining of the food by the gills, but also for intimating to the blood the reception of the food, and even other environmental changes. The thyroid, then, probably controls the second phase; and if the thymus, so to speak, during the first is constantly intimating to the gonad that it is not time yet to commence growth, that the environment is not in the right condition, so can we imagine the thyroid controlling the degree of growth until temperature and other conditions are favourable for spawning. Both these ecological organs may be presumed to influence the growth of the soma according to the environmental changes. The gonad itself during its period of growth contributes messages to the blood which influence growth and produce migrations.

With these organs we have to associate the pituitary body, which arises from the ectoderm of the roof of the mouth, and the parathyroids, which are developed in the gills. The former appears to be very like the thyroid in function, and the latter are yet little understood. Until we know more of these organs it would be idle to speculate as to their primitive functions. The actions of such organs of the environment may tend to be automatic, as has been suggested, but it is probable that direct impulses are introduced producing adaptation to changes in salinity and temperature. For example, there are widely distributed species, but restricted to tropical and temperate seas, and others which with little or no modification manage to live in every kind of water from equatorial to Arctic. Many of the species, therefore, which have with great difficulty been differentiated amongst holoplankton will likely turn out to be more physiological than morphological in character.

We have yet a lot to learn from biochemical inquiry and from experiment as to these fascinating ductless glands. I have, in the meantime, tried to show that some of them are concerned in conveying impressions of the environment to the soma and to the germ-cells by a series of impulses carried by the blood, and leading to a primitive but effective internal and external integration. It is probable that reproduction in general in Protozoa, and in the cell as in Metazoa, is so controlled, and that such fundamental effects may have a profound pathological bearing.

Mode of Feeding and Sex-Phenomena in the Pea-Crab (*Pinnotheres pisum*).

The pea-crab which lives inside mussels, cockles, and sometimes even oysters, has been an object of general interest since the days of the Pharaohs, and many legends have been invented of the way in which it feeds and of its relation to its host. Calman gives an account ("The Life of Crustacea," by W. T. Calman, London, 1911, p. 217) of many amusing habits attributed to this crab by many writers. For instance, the pea-crab has been stated to warn its host of the approach of enemies or of the entrance of prey between its gaping valves, but it will be seen from what follows that the bivalve and crab depicted in Egyptian hieroglyphics to symbolise the dependence of man on his friends is indeed an appropriate symbol.

A search of modern literature, however, reveals that only vague accounts exist of the manner in which this crab feeds and lives. Recent work on the mode of feeding in bivalve molluscs and other plankton feeders suggested a possible way in which crabs imprisoned in these animals might obtain their food. It will be remembered that in those animals which feed on plankton—floating organisms—by using the gill as a food-sieve, the food-material is collected generally into cylindrical masses by means of mucus, and such is the case in mussels, cockles, oysters, and other bivalves. Thus animals living in the unoccupied space between the valves of these bivalves have ready access to a concentrated supply of food. Now it is easy to watch a pea-crab inside a mussel by cutting a window in the shell of the bivalve and allowing a crab to creep inside it. This has been done, and the bivalve fed on concentrated plankton. It was found that a hungry crab soon begins to feed in the manner described below.

The larger pea-crabs generally sit on the middle of the bivalve, with a pair of the bivalve's gills on each side. The smaller crabs may be found in any position inside a mussel, but are generally somewhere on the gill. When a crab is observed through a window in a mussel-shell it is seen that such a position is taken up generally so as to bring the edge of a gill-leaflet up against the abdomen of the crab. Now as the edge of a gill-leaflet is one of the main food-paths in a bivalve, it will be seen that when the mussel is feeding cylindrical masses of food will automatically pass along the edge of the gill-leaflets, and therefore along the part of the gill to which the crab has approximated its abdomen and within easy reach of its claws. When feeding the crab moves, or rather scrapes, its claws over the gill, and by means of the hairy nature of its claws easily catches hold of the mucus-strings entangling the food and transfers them to the region of its mouth. The claw is now scraped over the region of the mouth, and the specially hairy mouth-parts of the crab, working in an opposite direction, comb off the strings of food and press them into the mouth. The claw of this crab is apparently specially modified to enable it to be flexed about the middle of its length for giving the unusual scope of action required for the scraping movements.

It is thus seen that the pea-crab is a parasite, and no advantage of its presence to the host has yet been detected, unless it be the occasional association of the palps with the crab, for in this case the crab would be relieving the host of the necessity for transporting and expelling undesirable food; on the other hand, the crab would appear to do no more harm to the mussel than to make it collect food faster or for a longer time than would be necessary in an abundant supply of food if the crab were not there.

There is thus good reason to believe that those allies of the pea-crab which are known to live in plankton-feeding animals—for example, other bivalves and Ascidians—will be found to feed in the same way as this crab.

In the search for these pea-crabs during the summer it was observed that berried females were frequently found alone in a mussel, and that males appeared to be scarce; the method of fertilisation, therefore, was not understood, and appeared to be worth investigating. It is well known that in this crab there is a marked sexual dimorphism, the males being small, very hairy, and, it may be added, very active, while the females are large, relatively smooth, and extremely passive. Moreover, tiny females have apparently never been described. There was thus the additional problem of interest of the whereabouts of the tiny females—if, indeed, tiny females should exist. The whole of the phenomena suggested protandry—a suggestion that was strengthened by my obtaining a tiny female form moulted from a minute supposed male crab with a carapace only 2·7 mm. wide. This tiny female form—now 3·3 mm. in diameter—however, was found to have enormous spermothecæ crammed full of mature spiked sperm and only a trace of gonad, which was, however, obviously female. The moult of this specimen was now carefully examined, and found to possess the full number of abdominal appendages characteristic of the female, although otherwise not recognisable externally from a male.

Many other male-like tiny female specimens have been obtained, and also a series of moults which leave no doubt that the young male-like female attains the adult characters through a succession of moults. It is an interesting fact that all the larger females examined have been found to have their spermothecæ always full of mature sperm. It would therefore appear that this pea-crab copulates precociously at an extremely early age before settling down to its later sedentary life, and, so far as my observations have gone, it would seem that no further meeting with a male is necessary, although males have been found in the autumn inside the same host as large females; a newly moulted female, however, appears to have no charm for a male. Sexual dimorphism in the species is thus seen to be accompanied by dimorphism of the females, and the change from the male-like form of the female to the adolescent young-bearing female form appears undoubtedly to depend upon, and to occur after, copulation. It would also appear that copulation normally takes place inside the host, and that the males visit mussels in their search for females, since unwary male crabs have been found with their legs or bodies trapped by the mussel closing its shell before the crab could get inside. These crabs survive the rough treatment by reason of their extraordinarily strong carapace, and creep inside the mussel later when it must perforce relax and open its shell in order to breathe. The male-like female has a similarly hard carapace which prevents the animal being crushed to death if unluckily trapped by the mussel destined to become a host. Individual crabs have been found to be lacking a leg which might very well have been lost in this dangerous operation.

The life-story of this animal is probably not yet complete, since the tiny male-like female appears to possess a different sexual apparatus from the older forms, and a single male form has been found with a carapace closely resembling that of a female. It is hoped, therefore, to complete the investigations in the near future. J. H. ORTON.

The Energy of Cyclones.

MY objection to Mr. Deeley's suggestion (NATURE, December 16, p. 502) that cyclones are caused by an access of warmth in the stratosphere is that in that case the troposphere ought to bulge upwards over the cyclone, whereas, in fact, it bulges downwards. The inversion at the boundary renders it certain that the interchange of air between the troposphere and the stratosphere is very slow, and for the few days of the life of a cyclone we may, to get a clear idea, imagine a light but impermeable film to exist at the boundary. If a patch of air above the film were warmed by any means it would expand outwards and reduce the weight on the film, which should, in consequence, rise. If, on the other hand, the film were drawn downwards, the temperature of the air above it would rise, because each air-particle as it lost in height would come under an increased pressure, and be warmed adiabatically. If, then, the air is drawn outwards horizontally from a cyclone in the upper part of the troposphere, the conditions as to temperature and the position of the top of the troposphere that are known to prevail are readily explained.

The point mentioned by Sir Oliver Lodge in his letter in NATURE of November 25 has been, I think, put forward by von Besold and others, but Sir Oliver seems to have overlooked the result of the heat set free by the condensation of the vapour. Could a cubic metre of damp air be confined in an adiabatic but extensible balloon and the vapour be condensed by any means, the result would be an increase of volume, for the expansion due to the heat produced by the condensation would far more than balance the contraction due to loss of pressure. If, indeed, the heat-energy due to the latent heat of vapour all took the form of kinetic energy in the atmosphere, quite a trifling rainfall would suffice to produce over the same area the most violent cyclone ever recorded.

W. H. DINES.

Benson, Wallingford, Berks.

The Mechanics of Solidity.

IN NATURE of November 18 last Mr. J. Innes pointed out that if a number of substances be arranged in order of increasing coefficient of linear expansion, then they are very nearly in a series of decreasing hardness, as shown by Brinell's, Moh's, or Auerbach's test, and he has, therefore, suggested, that it should be possible to obtain a fair idea of the so-called mechanical properties of substances from an inspection of their more fundamental physical constants.

It seems highly probable that there is some simple relation between the many physical constants of substances, and, indeed, many formulæ connecting them have been put forward, viz.:

(1) Sutherland (*Phil. Mag.*, 1890 and 1891) proposed to find the characteristic frequency of the atoms of elements by the formula

$$\nu \propto \frac{\sqrt{\frac{T_s}{A}}}{aT_s V^{\frac{1}{3}}},$$

where ν is the characteristic frequency of the atoms, T_s the melting point on the Absolute scale, A atomic weight, a mean coefficient of linear expansion between 0° Abs. and T_s° Abs., and V atomic volume $=A/\rho$, where ρ is the density.

(2) Einstein (*Ann. d. Physik*, 1911) has proposed

$$\nu = k\sqrt{\frac{V^{\frac{1}{3}}}{K.A}},$$

where ν, V, and A have the same significance as above, K is the bulk modulus of elasticity of the body, and k a constant which Einstein's theory demands should have the value $2\cdot8\times10^7$, but for which the empirical value $3\cdot3\times10^7$ seems to agree much better with observation.

(3) Debye (*Phys. Zeits.*, vol. xviii., p. 276, 1917, and *Ann. d. Physik*, vol. xiv., p. 789, 1912) asserted that ν is the frequency of vibration of those elements in a substance which determine the velocity of sound in it, and he has therefore calculated ν from E, and σ, where E is the Young's modulus of elasticity of the body and σ its Poisson's ratio.

If, now, the ν of Debye and that of Sutherland or Einstein are identical in their physical significance, we may write

$$\frac{\sqrt{\frac{T_s}{A}}}{aT_s V^{\frac{1}{3}}} \propto \nu \propto \sqrt{\frac{V^{\frac{1}{3}}}{K.A}} \propto F(E.\sigma),$$

where $F(E.\sigma)$ is Debye's function for the determination of ν in terms E and σ.

It is of interest to note that Debye's formula does not involve an empirical constant, and that the constant of proportionality in Sutherland's formula is $\sqrt{P}$, where P is Dulong and Petit's constant, *i.e.* the product of the specific heat and atomic weight of the element.

Other formulæ have been put forward by Planck, Lindemann, and Grüneisen, but it is not considered necessary to add them here.

For a discussion of the agreement of these formulæ with experimental results the reader is referred to *Phil. Mag.* for December, 1917, "Atomic Frequency and Atomic Number, Frequency Formulæ and Empirical Constants," by Dr. H. S. Allen.

Perhaps these formulæ are of the type of which Mr. Innes is in quest.

It will be observed that, in the foregoing, reference to the "hardness" value has been omitted; it is now proposed to justify this omission.

The moduli of elasticity, the ultimate strength, and the coefficients of expansion of a substance are, without doubt, the mathematical expression of certain body or bulk properties, and their magnitudes will depend on the state of equilibrium of the molecules within and throughout the body, as well as on those on the surface. On the other hand, the hardness of a substance was defined in *Engineering* for December 12, 1919, as "the resistance of a surface to deformation by mechanical means," and is, therefore, a surface effect and not a bulk effect. If this is admitted, then the hardness number of a surface is probably closely related to its surface energy, and is, perhaps, a measure of a property analogous to the surface-tension property of a liquid. In this connection proposals put forward by Frenkel (*Phil. Mag.*, April, 1917) on "The Surface Electric Double Layer of Solid and Liquid Bodies" are of interest. In that paper it is maintained that every free surface is a parallel plate condenser the outer plate of which is negatively charged, and consists of electrons in the outer half of their orbits about their positive nuclei which form the positive plate. The charge per unit-area of this condenser is calculated from (1) the number of positive nuclei per unit of area of surface, (2) the number of electrons moving in orbits about one nucleus, and (3) the electronic charge.

The distance between the plates is obtained from the mean radius of orbit of the electrons of any one atom. Thus the energy per unit-area of surface can be calculated. Results obtained in this way were shown to be in agreement with the known surface energy and contact potential of the various elements considered.

It seems to the present writer that attempts to obtain formulæ connecting the mechanical constants of elements with their fundamental physical constants must be along this line if the hardness number is the main object of the search. Many difficulties, however, remain to be overcome, for it appears that the plasticity of a substance must have a much greater effect in determining the "Brinell hardness" than it does in determining the "Moh hardness" of any given substance.

Needs of Polish Universities.

I AM travelling in East Galicia, and have only just seen Mr. H. G. Wells's remarks on the needs of scientific workers in Russia (see NATURE of November 11, p. 352). Using Mr. Wells as a text and applying it to Russia's neighbour, I should like to enter a plea for the Polish Universities of Krakow, Lwów (Lemberg), and Warsaw, which stand in the greatest possible need of American, English, and French scientific and technical literature. From the middle of 1914 to 1918 such literature was unobtainable, and since 1918 the rate of exchange—to-day 1500 Polish marks to 1*l.*—has placed it beyond the possibility of purchase by the three impoverished universities. For some months the Friends' Relief Mission has been making an effort at home to arouse practical interest in the problem, and recently we received some volumes of NATURE. These I took to the librarian of Warsaw University, who showed me over the library. The new English books could have been counted on the fingers of the two hands, and in the periodical-room not a single English periodical was being received, and only two in French. Similar conditions obtain in Krakow and Lwów, capitals of West and East Galicia, and two of the most important intellectual centres in reunited Poland.

CUTHBERT E. A. CLAYTON,
Sec. in the Field of the French Poland Unit.
Nadworna, East Galicia, November 24.

WE believe that the Anglo-American University Library for Central Europe exists to supply the need to which Mr. Clayton refers. The address of the secretary is London School of Economics (University of London), Clare Market, W.C.2.—ED. NATURE.

Domestic Fires and Fuels.

THE Air Pollution Board—a sub-committee appointed by the Manchester Corporation in 1915 to study the smoke nuisance—initiated an investigation of the domestic coal fire by Mrs. M. W. Fishenden. In 1917–18 the Department of Scientific and Industrial Research made grants in aid of the work, and now the Fuel Research Board has, with the concurrence of the Manchester Board, published the results,[1] expressing the opinion that "the investigation into the efficiency of the open fire has yielded a collection of carefully ascertained data, from which it is believed that a new departure can be made in dealing with the whole question of the use of smokeless solid fuel in domestic fires."

It is even yet not sufficiently recognised how grave an offender is the domestic coal fire in the production of the smoke nuisance in regard not only to the quantity, but also to the quality of smoke, although this was shown by Prof. J. B. Cohen many years ago. The Manchester Board was doubtless right in basing the work, as the chairman, Mr. E. D. Simon, points out in his introductory summary, on a scientific study of the domestic grate, about which an astonishing lack of precise information was found. If fires could be rendered more efficient, it was argued that a reduction in coal consumption and in the corresponding smoke production would automatically follow. It was hoped at first to draw up a standard of efficiency in fireplaces which might be enforced by local by-laws. This hope, however, proved illusory, as will be shown later. Determinations were first made of the "radiant efficiency" as the most important property of coal fires of different types—*i.e.* the proportion of the heat of combustion of the fuel which was radiated into the room. Here Mrs. Fishenden was able to start with the methods already elaborated for the study of gas fires by a joint committee of the Institution of Gas Engineers and the University of Leeds. It was found possible to adapt the so-called "Leeds test" to the more difficult problem of the solid fuel fire. The figures given are for the total radiation of heat from lighting to dying out, although from the point of view of the users of a fire the heat evolved in the early period and at the end is of little value. This emphasises the fact that solid fuel fires are less satisfactory for intermittent use or for short periods.

The results obtained were unexpected. The grates examined did not differ much in radiant efficiency. Fed with ordinary bituminous house coal from the Yorkshire Haighmoor (not "Haighmore") seam, all gave figures between 20 and 24 per cent. The superior radiant efficiency of the grates of modern construction proved to be a myth. How is this to be reconciled with the common experience that the newer fires appear to give more warmth in the room for less coal? It seems to be due to the constriction of the opening into the flue, which prevents the flow of an excessive quantity of heat-conveying air into the chimney. Strong draughts are avoided, and comfortable conditions in the room can, therefore, be maintained by a smaller consumption of fuel. Moreover, massive iron bars and cheeks with their cooling action are avoided; fireclay is substituted so as to promote the maintenance of a small fire, while the fuel burns more slowly and more completely. The draught below the fire can be restricted, and that in itself puts a great check on the fire.

The advantages are thus real, but not in the direction which is popularly supposed. It was shown that the mere removal of the bars from a grate has only a negligible effect on the radiant efficiency of a fire. Of course, the ventilating effect of the fire is reduced if the opening to the flue is lessened, but this seems generally to be an advantage. Here one looks expectantly, but vainly, for measurements of the ventilating effect of the newer types of grates. Mrs. Fishenden's measurements were made on an old-fashioned grate provided with an adjustable flue damper. With unrestricted draught it was found to move up the chimney as much as 25,000 cub. ft. per hour, although by regulation of the damper this was reduced to one-tenth. Such measurements on the new types of fire would have been specially valuable for the comparison of different systems of domestic heating. In domestic architecture in this country heating and ventilation go together. There seems to be no practical alternative to the chimney flue, simple, cheap in upkeep, and automatic in action, for the ventilation of smaller houses. The recognition of this led to careful measurement of the ventilating action of gas fires by the joint committee of the Institution of Gas Engineers and the University of Leeds, and similar measurements for modern coal grates would be very valuable.

The experiments on different fuels burnt in the same grate are specially interesting. When burning coal, the radiant efficiency was found to be 24 per cent. With anthracite the figure was 27 per cent. With dry gas coke 28·5 per cent. of the heat was radiated, but this advantage over coal was lost if more than 10 per cent. of moisture was present. Two dry cokes produced by low-temperature carbonisation radiated respectively 31 and 34 per cent. of their heat, but here again the presence of moisture was found to have a deleterious effect. Briquettes of coal proved relatively inefficient with only 19 per cent. radiation. The figures point a moral to producers of coke—*i.e.* the desirability of preventing the degradation of an excellent fuel by excessive moisture, although there are technical difficulties in eliminating moisture altogether. The results for low-temperature coke are striking, and "confirm the fact accepted by all smoke-abatement reformers that it is exceedingly desirable that a fuel of this nature

[1] "The Coal Fire. A Research by Mrs. M. W. Fishenden for the Manchester Corporation Air Pollution Board." Fuel Research Board. Special Report No. 3. Pp. 112. (H.M. Stationery Office.) Price 4*s.* net.

should be put on the market at a reasonable price." The friability of such cokes has proved a grave obstacle, and, if one seeks to avoid it by briquetting, Mrs. Fishenden's results suggest that any superiority in radiating power would be more than wiped out, while the high cost of pitch—the natural binding material—is not helpful. The Fuel Research Board and private workers are busy with the problem.

One cannot help thinking that the real domestic smoke problem is presented, not by the grates of the type studied by Mrs. Fishenden, but by the enormously more numerous and more voracious kitchen ranges used for cooking as well as for heating. Would a smokeless fuel prove serviceable for these? The present report does not deal with the kitchen range.

Mrs. Fishenden has exploded several popular fallacies. Powders have been sold (under promising names) which are alleged to effect marvellous economies in fuel, as vouched for by people whose official descriptions ought to have implied better things. Some of these powders were examined and found to be essentially common salt coloured with iron oxide. No appreciable effect on the radiant efficiency of a fire consuming coal treated with these salts could be detected. To-day, when coal and money are so scarce, a protective publicity might well be given to these tests in the daily Press.

It appears generally from Mrs. Fishenden's work that the wastefulness of the open fire may be lessened by the use of carbonised fuel, and particularly by the cutting down of draught so as to limit the air drawn through the room and into the chimney to the quantity required for ventilation. The use of solid fuel is still cheaper than that of gaseous fuel for fires which have to be in constant use.

Not the least useful part of the report is the appendix, containing a summary of recent bibliography of work on domestic heating appliances. Attention may well be directed to earlier students of the problem—Rumford, Peclet (whose "Traité de Chaleur" still repays perusal), and more recently Dr. Pridgin Teale, of Leeds, who may be regarded as the pioneer of modern grate reform in this country. Peclet, and perhaps Rumford, seemed quite clear about the significance of excessive flue draught and the need for restricted and variable flue openings, and in reading his treatise one can only marvel that the manufacture of crude appliances has continued to the present day. Still, Mrs. Fishenden's work has placed the whole subject on a more substantial foundation of carefully ascertained data, an achievement which should prove valuable in the campaign of smoke abatement and fuel economy, and at a cost which seems to be relatively insignificant. J. W. C.

A Handbook to Roman Pottery.[1]

THE term "terra sigillata," denoting certain well-known classes of Roman pottery, may be unfamiliar to the ordinary reader, but it is gradually coming into use in place of the somewhat misleading "Samian ware" of the nineteenth-century antiquarian. The late Prof. Haverfield, indeed, stoutly upheld the use of the older term; but it is open to decided objections, being purely conventional, unhistorical, and non-descriptive. Such expressions as "Roman red-glazed ware," "Gaulish red ware," etc., may be more accurate, but are not sufficiently definitive. The authors of the work under review have, therefore, followed Continental precedent and adopted this term, which strictly denotes "clay decorated with stamped patterns" (from *sigillum*, a stamp). The ware with which they deal is the pottery produced under the Roman Empire and found in all parts of Western Europe, which is marked by the use of a fine red paste and a lustrous red glaze, and usually ornamented by means of patterns and figures in relief.

It is the first attempt made in this country to produce a handbook to the study of this pottery, which during the last twenty years has made a great advance, owing to the labours of British, French, and German archæologists, and to the more careful attention paid to the results of scientific excavations in this country. We most heartily congratulate the authors on their work, which is distinguished both by exhaustive knowledge and by scientific accuracy.

Their aim has been to arrive at definite conclusions concerning the development of Roman pottery under the Empire by a diligent study of such details of technique, form, decoration, and design as can be of assistance for purposes of dating, and to base on the results of detailed study

FIG. 1.—Vase of La Graufesenque ware (Form 29) with scroll decoration (about A.D. 40).

a general consideration of the evolution of this pottery and the sources of its inspiration.

The book is divided into ten chapters, the first two being of a general and introductory nature. Chap. iii. deals with "dated sites"—*i.e.* those where the approximate dates of occupation are known, such as Haltern in Germany (11 B.C. to A.D. 9). Chap. iv. gives a list of the potters whose names are stamped on the vessels, arranged in chronological groups. In chap. v. the vessels decorated in moulded relief are discussed under

[1] "An Introduction to the Study of Terra Sigillata: Treated from a Chronological Standpoint." By Felix Oswald and T. Davies Pryce. Pp. xii+286+lxxxv plates. (London: Longmans, Green, and Co., 1920.) Price 42s. net.

the principal forms of bowls employed. The evolution of the forms and decoration is worked out in a most lucid and interesting manner. The chronological value of this development is further described in chap. vii., and in chap. vi. we have an interesting discussion of the origin of the decorative designs. The figure-subjects are mostly to be traced to the art of the Augustan period, and the decorative motives in many cases to earlier phases of Greek art. It seems a little doubtful,

FIG. 2.—Vase of La Graufesenque ware (Form 30) combining scrolls with figure subjects (about A.D. 60).

however, whether motives and methods of decoration which were employed in early Greek art, and disappeared in the sixth century B.C., or even earlier, can have actually influenced the Roman potter. An instance is the "nautilus" ornament found on the Arretine vases and some early Gaulish wares of the first century after Christ. The nautilus certainly occurs in Minoan pottery, but its use was localised, and it is not known in Greek art. It is possible that this pattern is really intended to represent a fern-frond.

Chap. viii. is devoted to a discussion of the plain wares which have only potters' stamps without decoration, and chap. ix. to other methods of decorating *sigillata* ware by painting, incising, or *en barbotine* (patterns produced in relief by thick layers of liquid clay). The final chapter deals with the origin and evolution of *terra sigillata*, and is a general summing up of the whole subject.

There are no fewer than eighty-five excellent plates, all drawn by hand, with adequate biblio-

FIG. 3.—Vase of Lezoux ware (Form 37) with panel decoration (about A.D. 100).

graphical references, and a useful map of sites forming the frontispiece. The general and detailed bibliographies on pp. 245 ff. will also be invaluable to the student of the subject. We should have been glad to discuss this admirable work in much fuller detail, but space forbids, and we can only recommend those who have any interest in the subject to lose no time in becoming acquainted with its contents.

Our illustrations reproduce three typical forms of Gaulish vases with decoration.

Industrial Research Associations.

VII.—THE RESEARCH ASSOCIATION OF BRITISH MOTOR AND ALLIED MANUFACTURERS.

By H. S. ROWELL.

NO branch of engineering is so much the creature of taste and fashion as the automobile industry. No industry of anything like the same dimensions is so much dependent on the views, almost the caprices, of the layman. Almost certainly no industry in this country has had such a meteoric or rather rocket-like post-war career as that responsible for the manufacture of motor vehicles. These facts must be borne in mind in considering the development of the Research Association of British Motor and Allied Manufacturers.

After the armistice the release of petrol supplies, the diversion of manufacturing agencies from war work, and the natural desire of an overworked public for convenient locomotion and healthy relaxation gave the motor-car trade an unprecedented boom. Motor-car manufacturers were not only confronted with all the distracting problems of reconstruction, but, in addition, they had prospects of—several firms, indeed, had orders for—some years of work. While one or two other research associations were formed as a vital necessity to preserve the existence of the corresponding industries against foreign competition, the motor trade had at the time of the incorporation of this association in May, 1919, no such incentive. At that time to many in the motor industry it must have seemed a luxury, if not an extravagance. Those who have had to do with the inauguration of new societies, especially of societies novel in form or object, know how much work and time are involved in seeking, and often in reconciling or converting, the views of busy men. Even then much preliminary work is necessary before staff can be appointed for the necessary executive work. The Research Association of British Motor and Allied Manufacturers was formed under the ægis of the Association of British Motor Manufacturers, and it is largely to the energy and enthusiasm of

Mr. H. C. B. Underdown, president of the latter body, that the daughter association owes its existence.

The active work of the Research Association of British Motor and Allied Manufacturers began on June 1, 1920, with the appointment of the present writer as technical secretary. Since that time considerable progress has been made in organising committees and arriving at a policy by which to guide future work. A bureau of information has also been established from which are issued classified abstracts of most of the important papers dealing with matters relevant to the automobile. There is in many quarters a rooted and well-founded objection to the collection of information in this way; it is often asked: "Where will it end?" The answer to this question is neither easy nor necessary, but the fact remains that already the information bureau has been of great value. The needs of various industries are different, and the organisation of the research association must fit in with its own particular industry. In the case of one textile industry there was little or no scientific foundation on which to build, and thus the first task of its research association was to gather information. In the motor industry, on the other hand, there is a wealth of information, but it is widely spread and often hard to come at; as one example out of many we have the transmission of heat across a plate between two moving fluids. This problem has been investigated by many engineers in many countries, generally with reference to the steam boiler; the same principles must govern the radiator and heated induction pipe of the motor-car. The abstracts sent out to the members of the association not only keep their technical and design staffs in touch with new developments at home and abroad, but as they are carefully classified they will in course of time provide a basis on which research work may be founded. Moreover, they will become a work of handy reference.

Time teaches, and the views here presented are naturally subject to modification by experience. At present the tasks in front of the association may be set out as follows:—

(1) Collecting, recording, and disseminating to members accurate technical information.

(2) Consultative and advisory work for members of the association.

(3) Original research and investigation into matters of importance to the industry of which knowledge is at present unsatisfactory.

(4) Co-operation with allied industrial and scientific workers.

(5) Examination of new inventions, and, in promising cases, their experimental development.

(6) Impartial tests and verdicts.

A few words of explanation on these brief headings are fitting.

The bureau of information has already been discussed.

Regarding consultative work, it must be clear that a highly trained scientific staff is able to help works engineers and designers in many ways. There are, in any case, two main advantages to be derived from consultative work in a research association quite apart from the immediate solution of any difficulty; not only are the obstacles encountered by one firm brought to the notice of other firms in the association, thus showing them what to avoid, but also the scientific staff is kept in touch with the men in the works, thus learning their needs, their outlook and point of view, and possibly some of the manifold experience which is rarely formulated.

Co-operation with allied trades is especially necessary in motor-car research, for no other product, except perhaps that of the shipbuilder, involves so many handicrafts and sciences as the automobile. As examples, we have spring-making; lamp manufacturing; electrical apparatus for starting, lighting, and ignition; rubber tyres; upholstery; body building; and all the general work implied by mechanical engineering. It would clearly be unjust that the Research Association of British Motor and Allied Manufacturers, an association at present of chassis builders, should, even if it had the necessary resources, embark on such a wide sea of troubles. Thus the title and aims of the association have co-operation in view, and it is pleasant to know that there are now prospects of firms in the allied trades joining the association very shortly. With those allied industries that have already formed research associations close collaboration will be encouraged.

The examination of new inventions may seem to many a piece of unwisdom, since it may be concerned more often with design than with research. On the other hand, it must be admitted that an unbiassed and scientific view is necessary to do justice to the inventor; nor may we forget the epoch-marking innovations which we owe to non-technical people; the textile industry, for example, owes much to a barber and to a clergyman.

The views of men are the product of their experiences, and in the hurry and bustle of practical life notions and prejudices are acquired which time and leisure for reflection would dispel. Or, on the other hand, the natural bias of paternity may lead the designer to retain his devices when better substitutes are available. In such cases a research association can serve a useful purpose in giving an impartial, or at least a different, view. Later, as the organisation develops, it may be that the field of judgment will be extended in order to expose or confirm the various claims of blatant advertisers. In this way the true interests of the public and of the automobile industry will be served.

The objects set out above are probably not the same as those of other research associations, but the needs of various industries are different; it was sound statesmanship that led the Department of Scientific and Industrial Research to give each industry its freedom in the research movement. In considering the list of objects given above, it must not be assumed that the order adopted is that of relative importance. The great difficulty in securing suitable premises, and the congested and overworked state of university institutions, have temporarily displaced original research from its deserved place of priority. The collecting of information, on the other hand, was at once useful and feasible.

Much emphasis has been given, both in this country and in the U.S.A., to the view that industrial research associations should seek after fundamentals. Quite recently in an important publication appeared the sentence: "It cannot be stated too strongly that the main object of research associations is fundamental research, and that consequently results will usually be slow in coming." With a full sense of the profound respect due to the authors of this statement, the present writer begs leave to disagree. In his view, the main object of industrial research associations is profit, for without profit no industry can live. Disregard by men of science of this vital fact is probably responsible for much of the apathy shown towards science by men in commerce and industry. Here it must be added that the profit point of view is not necessarily a short view; let the vista be as long and as broad as economic conditions warrant, and in cases of doubt let the error lie in distance and in breadth.

The membership of the Research Association of British Motor and Allied Manufacturers represents at present only about one-third of the British motor industry, but it is the object of the council of the association to build up an organisation which shall become a representative national body in the automobile world, and, by working on a practical yet progressive policy, fully adapted to the present temper of the trade, it is hoped to convince not only the entire British motor industry, but also the various allied and accessory trades, of their interest in research. It is clear that the larger the membership becomes, so much the greater are the resources of the association and the benefits of membership. Until the entire British motor industry is included, strict secrecy will be observed in regard to any results of advantage to the trade. At the same time, the interests of research workers (in the pay of the association), to whom credit is an important form of reward, will be assured by publication of their results after members of the association have had, say, three or five years' start of non-members.

There is one difference between pure science and technical science which it is believed has not been emphasised before. When a technical worker is given a problem by industry, the answer or solution is, as a rule, wanted at once, whereas a worker in pure science has, or should have, unlimited time at his disposal. This cardinal difference imposes a totally different solution in the two kinds of work. The technologist may be called upon to eliminate a wasteful process or a dangerous condition. He is not authorised to spend twenty years in finding out a perfect process or in determining exactly what condition is just safe. He is asked to cut out as much waste as possible at once, and, if advisable, to go on improving the process, or in the other case his task is to find out what is safe enough with a reasonable margin for the various probable errors to be expected. The great majority of technical problems cannot be enunciated precisely; only a more simple analogue can, as a rule, be considered. The end in view is an immediate solution sufficiently accurate for the work in hand.

When the technical worker has solved his problem and passed the solution to the designer, he will see, as a rule, unless his scientific curiosity be dwarfed and shrunken, many interesting paths which invite his investigation had he but the needful time and equipment. It is here that he can serve pure science by handing on his boundary problems to the specially gifted men who devote their lives to the development of science as distinct from its applications. How much is handed on in this way and how much retained for investigation by the research association will depend on the ability, vision, and other resources of those concerned; the experience of industrial research organisations in Germany and in America seems to show that the short view does not pay in the long run.

Obituary.

Sir D. E. Hutchins.

The death in New Zealand was announced in the *Morning Post* of December 3 of Sir David Hutchins, the well-known forester, at seventy years of age. Sir David (with eleven contemporaries, including the late Prof. W. R. Fisher, Mr. E. C. Hill, late Inspector-General of Forests in India, and Mr. E. P. Popert, late Forestry Adviser to the Commissioners of Woods and Forests) was appointed a probationer for the Indian forest service in the spring of 1870, and sent to France for instruction in forestry. Shortly afterwards, on the outbreak of the Franco-German War, he returned and studied, with the other probationers, botany and other auxiliary subjects in Scotland under the supervision of the late Dr. Cleghorn, himself a retired distinguished Indian forest officer. After the end of the war in 1871 Sir David returned to France and studied forestry at Nancy until the autumn of 1872. He joined the Indian forest service at the end of that year, and remained in it until the end of 1885. Owing to ill-health, he was then transferred to the forest service of Cape Colony. During the latter part of his service in India Sir David was occupied with the measurement of Casuarina plantations which had been established along the Madras coast. From the statistics thus obtained, he calculated the "form factors" for the species, this being the first attempt of the kind made in India.

Sir David remained in South Africa about twenty years as Conservator of Forests, Cape Colony. During that time he introduced a variety of exotic species, principally conifers and Eucalypts, to supply the colony with the timber which the indigenous forests could not yield. He also caused similar plantations to be established in the Transvaal and the Orange Free State. These planting operations were on a large scale, so that their area amounts now to 75,000 acres; they have been very successful, especially from a financial point of view. Later, Sir David was transferred to British East Africa as director of forest operations, and in that capacity he published a voluminous report on the forests of that Protectorate. He also visited Cyprus and reported on its forests. He paid visits to the Canaries and other tropical and semi-tropical countries, making a special study of the forest vegetation of the last-mentioned. The knowledge thus acquired enabled him to recommend suitable species for introduction to other countries possessed of a similar climate.

In the year 1914 Sir David proceeded with the British Association to Australia, where he remained for two years studying the forest conditions of that country. At the end of that time the Government of Western Australia published for him, in 1916, a full report on Australian forestry and his suggestions as regards future action to be taken by the Governments of these colonies. The report attracted great attention, and Sir Ronald Munro-Ferguson, at that time Governor-General of Australia, expressed the opinion that "nobody has ever written on Australian forestry as Sir David Hutchins has done."

From Australia Sir David proceeded to New Zealand, where he examined the forests, paying special attention to the "Kauri" pine (*Agathis australis*). He urged that the small remnants of that queen of pines should be protected and enlarged. It appears that he died while passing a report on the New Zealand forests through the press. Sir David Hutchins was an enthusiastic forester, who had amassed a vast amount of knowledge on forestry subjects, and especially on semi-tropical forest vegetation. In spite of his enthusiasm carrying him sometimes too far, he did most substantial service to the Empire, and his friends were pleased to see his merits appreciated by the bestowal of a knighthood some months before his unexpected death.

SIR CHARLES BRUCE, G.C.M.G.

BY the death, at the age of eighty-four, of Sir Charles Bruce the country has lost a great scholar and an efficient administrator. The son of an Indian Civil Servant, in his early years Sir Charles devoted himself, mainly in Germany, to philological study, chiefly in Sanskrit and Zend-Pahlavi, and he did valuable work in connection with the great Sanskrit dictionary published by the Academy of St. Petersburg. He was next appointed rector of the Royal College at St. Louis, Mauritius, whence he was transferred as Director of Public Instruction to Ceylon. He returned to Mauritius as Colonial Secretary, and was later appointed Lieutenant-Governor of British Guiana. In recognition of his services he received the knighthood of the Order of St. Michael and St. George. In 1897 Sir Charles returned to Mauritius as Governor, where, with the hearty support of Mr. Joseph Chamberlain, then Colonial Secretary, he carried out important reforms in the public services, and as an administrator gained much popularity among the people of the island, until his retirement from the public service in 1903. During his colonial service of more than thirty-five years he gave much attention to ameliorating the condition of the Indian immigrants to our Crown Colonies, a task to which he devoted himself after his retirement. In 1910 he published an important work, "The Broad Stone of Empire," dealing with the problems of Crown Colony administration in the light of his wide and varied experience. Sir Charles Bruce will be regretted by many friends as a man of devout spirit and of singular independence and honesty of purpose, with much charm of manner and kindliness of heart.

Notes.

HIS HIGHNESS THE PRINCE OF MONACO has issued invitations to representative scientific workers of all countries to be present at the formal opening of the Institut de Paléontologie Humaine at 1 rue René Panhard, Paris, to-day, December 23. The President of the French Republic (M. Millerand) has promised to attend. The institute owes its origin to the munificent benefactions of the Prince, whose interest in archæological problems made possible the systematic exploration of the Mentone caves. Its work is most widely known to archæologists through the magnificent series of publications covering the exploration of Palæolithic caves, notably those of Grimaldi, Altamira, and La Pileta. Of the excavations described in these publications some have been undertaken under the auspices and at the expense of the institute. This is especially the case with those of more recent years, such as the exploration of the cave of La Pileta (Malaga), undertaken by MM. Breuil, Obermaier, and Verner. Although it did not undertake the actual exploration of the Altamira cave at Santander, carried out by Dr. Cartailhac and the Abbé Breuil, it was responsible for the publication of the results. It was through the institute and the generous assistance given by the Prince that it was possible for the authors to describe the site and its culture on a scale and with a wealth of illustration which have made the remarkable series of examples of prehistoric art familiar to archæologists who are not fortunate enough to be able to visit the cave in person.

MUCH interest has been aroused by the registration on December 16 of one of the greatest earthquakes of recent years, and the interest has been increased by the mystery which at present attends the position of its origin. The first preliminary tremors reached West Bromwich at 12h. 17m. 14s. p.m.; the second tremors arrived nine minutes later, indicating an epicentral distance of about 68° of arc. The oscillations at this station were so violent that Mr. J. J. Shaw's seismograph was thrown out of action. The epicentral distance from Oxford was estimated at 67°. From the American records it would seem that the distance from Washington was about 43°. Various positions have been suggested for the origin—China, beneath the Pacific Ocean to the north of Japan, the Atlantic between Sierra Leone and Brazil, or the South Pacific. Prof. H. H. Turner, writing in the *Times* of December 21, suggested that the place of origin was in the Gulf of Mexico, but since then he has seen evidence which indicates an Alaskan origin for the earthquake. No seismic sea-waves have been reported from any place, and this absence seems to favour an origin that is, at least in part, terrestrial. On the other hand, an earthquake so violent must have been felt to a distance of some hundreds of miles from its origin; and thus, if the origin were terrestrial, it must either be in a country from which outgoing messages have been censored or one with few observers or inadequate means of communication—such, for instance, as Yakutat Bay, in Alaska, which is, however, only about 64° from the British stations.

THE announcement that the King has approved of the appointment of Prof. J. C. Irvine as Principal of the University of St. Andrews has been received with feelings of much satisfaction by men of science throughout the country. This is not the first occasion when the chief administrative office in the oldest University of Scotland has been filled by a man of scientific eminence, for Sir David Brewster occupied the Principalship of the United College from 1838 to 1859, and his successor was J. D. Forbes. After a period of years, during which the University was guided by those men of distinction in the world of letters, John Campbell Shairp, Sir James Donaldson, and Sir John Herkless, it now falls to the lot of a chemist to direct the policy of the University of the grey city by the northern sea. The new Principal was a pupil of Prof. G. G. Henderson in Glasgow Technical College before going to St. Andrews as an undergraduate. He afterwards spent a couple of years in Leipzig, where he came under the inspiration of Wislicenus, returning in 1901 to his *alma mater*. On the retirement of Prof. Purdie in 1909 the chair of chemistry in the United College was filled by his assistant. During the past twenty years Prof. Irvine has devoted himself to research on the chemistry of carbohydrates, in which branch he may now be regarded as the leading living authority. He has been particularly successful in imparting much of his enthusiasm to his students; many of the men associated with him in his publications in the Journal of the Chemical Society are graduates in arts who, with no scientific predilections, were attracted to the study of chemistry by the personality of the professor. Principal Irvine's scientific work was recognised by his election as F.R.S. in 1918, whilst his valuable war services earned for him his C.B.E. in the present year. His many friends in academic circles both in St. Andrews and in Dundee have full confidence that in his hands the best interests of their University are in safe keeping.

THE recent reports relative to a fall of rock involving the summit of Mont Blanc, however improbable they might appear to those who have knowledge of the ground, have naturally aroused general attention. The *Daily Mail* of November 27 published a communication from Geneva correcting the idea that the summit had suffered change, but recording the fall of the face of a rock-precipice on to the Brenva glacier, and the sweeping of an ice-avalanche from this glacier through the woods of "Portud" (La Pertu). The *Journal des Débats* for November 29 quotes information given by M. Vallot, director of the Mont Blanc Observatory, to the *Eclaireur de Nice*. M. Vallot points out that the summit is composed of an ice-mass of variable level, and that the source of the avalanche could not have been determined from the Italian side. Presumably this refers to dwellers in the Val di Veni. M. A. Lacroix, permanent secretary of the Paris Academy of Sciences, very kindly informs us that accurate details are not yet to hand, and that the matter may resolve itself into an avalanche of ice rather than a fall of rock.

A SMALL expedition is being organised in the University of Oxford to visit Spitsbergen next summer with the view of conducting researches in ornithology, botany, and palæontology. Work will be confined mainly to the west coast, but if ice conditions permit the northern and north-eastern shores of the mainland will be visited and an attempt made to cross New Friesland and to ascend some of the unscaled peaks in that part of the country. It is proposed to charter two or three sealing sloops in Norway to accommodate the expedition. The first sloop would arrive in Spitsbergen early in June, making for the bird rookeries on the north and west coasts of Prince Charles Foreland; the others would arrive later for work on the north coast. The explanatory side of the expedition's programme depends largely on weather conditions, but the other researches can certainly be carried out. The staff of the expedition has been selected, and will, we understand, include the Rev. F. C. R. Jourdain, who is chairman of the organising committee. Expert advice is being taken in the preparation of the plans and in the selection of the equipment. The *Times* understands that the cost of the expedition is estimated at about 3000*l.*, towards which several generous contributions have already been promised. The expedition has the official sanction and support of the University of Oxford.

THE Forestry Commission was established in order to secure an adequate supply of home-grown timber, and many people imagine that this can be effected by State afforestation alone. The 1,770,000 acres which the Government has decided to acquire and plant with trees during the next eighty years are quite inadequate. Much of the planting must therefore be done by private owners, who control about 3,000,000 acres of woodlands. Owing to the war and other causes, the great bulk of mature timber on these estates has disappeared, and in all probability only 750,000 acres are fully stocked with trees more than twenty years old. Certainly a great part of the conifer woods has been either clean-felled or thinned to such an extent as to be no longer productive. The remedy is the encouragement of replanting by private owners, who are now deterred by high wages, the enhanced cost of plants, etc. The Forestry Commissioners are prepared to assist private owners in two ways: either by entering with them into partnership in profit-sharing schemes or by giving grants in aid of planting and of establishing a crop under approved conditions. These grants are fixed at 2*l.* per acre for conifers and 4*l.* per acre for broad-leaved trees, and are repayable whenever an owner makes ultimately a profit exceeding 4 per cent. As the new planting season is in full swing, applications for grants should be addressed direct to the Assistant Commissioner concerned: For England and Wales—30 Belgrave Square, London, S.W.1; for Scotland—25 Drumsheugh Gardens, Edinburgh; and for Ireland—6 Hume Street, Dublin.

THE annual exhibition arranged by the Physical Society and the Optical Society is to be held on Wednesday and Thursday, January 5 and 6, at the Imperial College of Science, South Kensington, and will be open both in the afternoon (from 3 to 6 p.m.) and in the evening (from 7 to 10 p.m.). Sir W. H. Bragg will give a discourse on "Sounds in Nature" at 4 p.m. on January 5. Dr. Archibald Barr will lecture on "The Optophone: An Instrument which Enables the Totally Blind to Read Ordinary Print" at 8 p.m. on January 5 and at 4 p.m. on January 6. After the lecture a demonstration will be given by a totally blind person. At 8 p.m. on January 6 Prof. C. R. Darling will give a discourse on "Some Unusual Surface-Tension Phenomena." All the lectures will be illustrated by experiments. About fifty firms will be exhibiting, and a number of experimental demonstrations have been arranged. We understand that invitations have been given to the Institution of Electrical Engineers, the Institution of Mechanical Engineers, the Chemical Society, the Faraday Society, the Wireless Society of London, and the Röntgen Society. Admission in all cases will be by ticket only, and therefore members of the societies just mentioned desiring to attend the exhibition should apply to the secretary of the society to which they belong. Others interested should apply direct to Mr. F. E. Smith, hon. secretary of the Physical Society, National Physical Laboratory, Teddington, S.W.

THE Imperial Bureau of Mycology is the outcome of a proposal unanimously adopted by the Imperial War Conference in 1918 that a central organisation should be established for the encouragement and co-ordination of work throughout the Empire on the diseases of plants caused by fungi in relation to agriculture. The committee of management consists of some of the foremost biologists in the country, with Viscount Harcourt as their chairman, and includes the following members:—Prof. I. Bayley Balfour, Dr. W. Bateson, Prof. V. H. Blackman, Prof. F. O. Bower, Mr. R. D. Cotton, Prof. H. H. Dixon, Prof. J. B. Farmer, Capt. A. W. Hill, Prof. W. H. Lang, Sir Daniel Morris, Mr. J. Murray, Mr. G. H. Pethybridge, Sir David Prain, Dr. A. B. Rendle, Mr. H. N. Ridley, Prof. R. A. Robertson, Sir A. E. Shipley, Prof. W. Somerville, and Dr. H. W. T. Wager. Dr. E. J. Butler, late Imperial Mycologist, Director of the Research Institute, Pusa, and Agricultural Adviser to the Government of India, has been appointed Director, and has started work at the headquarters of the Bureau, 17–19 Kew Green, Kew (telephone Richmond 603). The Bureau will work broadly on the lines of the existing Imperial Bureau of Entomology at South Kensington, and will aim at doing for the other great class of destructive agencies in agriculture, namely, the diseases and blights of plants caused by fungi, what the older Bureau has so successfully done in regard to injurious insects. It will be a central agency for the accumulation and distribution of information and for the identification of specimens sent in from all parts of the Empire.

DR. R. H. PICKARD, principal of Battersea Polytechnic, has been appointed director of research to the British Leather Manufacturers' Research Association.

IN the November issue of *Man* Miss M. E. Durham supplements Dr. W. Crooke's article (Journal of the Royal Anthropological Institute, vol. xlix.) on nudity in India by some notes of similar practices in North Albania. When a new house is built and ready for habitation, the hearth has to be kindled for the first time ceremonially. The fire is laid and the master of the house strips stark naked, enters the house, and ignites the fire by firing a pistol into it, after which the family takes possession of the house. When a new pair of oxen are yoked together for the first time the owner must be nude when he ploughs the first furrow. Miss Durham also notices that there is no feeling against nudity in the case of men crossing rivers by the aid of inflated sheepskins or of those in charge of ferries. The above two cases, which she regards as probably the only cases of ritual nudity in Europe, if, indeed, they are still practised in a region devastated by war, are deserving of record.

MR. C. G. E. BUNT discusses in *Ancient Egypt* (1920, part iv.) the genesis of Coptic twists and plaits, with the result that he traces them to Sumerian origin. Prof. Flinders Petrie sums up the question thus: "These conclusions on the Sumerian being the earliest forms of the twists and plaits accords with other facts of their distribution. The formula which seems to agree with all the cases is that the twist and plait is a Central Asian motive (see the wickerwork screens in Kirghiz tents); that from there it passed down the Euphrates, also into Syria, and first into Egypt under Hyksos influence. Plaits and twists were unknown in Italy until the Dacian captives were brought in and set to mosaic work; plaits were brought from the north into the basketwork capitals of Justinian, and the round plait in architecture only occurs in true Gothic work in Italy, the Lombard plait being angular, rushwork and not osiers. In Ireland the spiral is alone in the pagan age, and the plait only comes in after the Norse influences of the Christian period."

AN interesting programme was presented at the meeting of the Association of Economic Biologists held in the Imperial College of Science on Friday, December 10. Sir David Prain occupied the chair, and the first portion of the meeting was devoted to the exhibition of specimens. Dr. B. M. Bristol, of Rothamsted, showed a number of very beautiful pure cultures of algæ on solid media, obtained from the soil of the famous Broadbalk wheat-field, the algal flora of which she is studying. Dr. S. G. Paine exhibited bacteria with flagella stained by a new method, and also a convenient new pattern of incandescent lamp which he has devised for microscopic work. Mrs. Alcock showed specimens of Douglas fir attacked by *Phomopsis pithya*, Lind., a parasitic fungus new to this country; and Mr. W. B. Brierley exhibited a fine photograph of Dr. Erwin F. Smith, the eminent American pathologist. Mr. W. J. Dowson then read his paper on "Problems of Economic Biology in British East Africa," dealing especially with the relations of plant disease to climatic conditions. A second paper was read by Dr. M. C. Rayner on "Nitrogen Fixation in the Ericaceæ," in which a convincing case was stated for the fixation of nitrogen by the mycorrhizal fungus in this genus of plants. The papers were discussed by Dr. E. J. Butler, Mr. F. T. Brooks, Prof. V. H. Blackman, and Dame Helen Gwynne-Vaughan.

IN Bulletin 313 of the Agricultural Experiment Station of the University of Wisconsin Prof. L. J. Cole and Miss Sarah Jones discuss the occurrence of red calves in black breeds of cattle such as Aberdeen-Angus, Galloway, and Holstein-Friesian. They point out that red is recessive to black, and was introduced by crosses in the early days of formation of the breeds, when little selection for colour was practised. The more rigid selection for colour at present in vogue has not yet succeeded in eliminating the recessive factor for red from the germ-plasm. Such a simple account of the cause of the persistent sporadic reappearance of red is valuable for practical breeders who have no knowledge of the scientific principles of heredity. It serves to eradicate many erroneous ideas as to the nature of these occurrences.

IT was ascertained by Blacklock and Carter at the Liverpool School of Tropical Medicine in 1919 that the indigenous British mosquito, *Anopheles plumbeus*, could be infected with the malarial parasite *Plasmodium vivax*. As a consequence of this discovery the Mosquito Investigation Committee of the South-Eastern Union of Scientific Societies was asked by the Ministry of Health to aid in discovering the exact distribution of this mosquito in England and Wales. In its Circular No. 4 this committee explains the effort it is making to conduct an inquiry into the distribution of *A. plumbeus* within the areas to which the activities of its affiliated societies extend. The circular gives detailed descriptions of the egg, larva, and fly of *A. plumbeus* and of its breeding-places, illustrated by plates of figures reproduced from Lang's "Handbook of British Mosquitoes," issued by the British Museum, and from Blacklock and Carter's paper in the *Annals of Tropical Medicine and Parasitology*. These, with further information concerning habits, distribution, collection, etc., should make the circular useful to the amateur and efficient for its purpose. It is clear that the Ministry of Health has a keen ally in this committee of the South-Eastern Union of Scientific Societies.

THE October issue of the Tropical Diseases Bulletin, published by the Tropical Diseases Bureau, consists of a Sanitation Number, and comprises extracts from and notes on papers appearing in various scientific journals and official reports. The matter is divided under several heads, namely: Disease Prevention (chiefly Malaria), Conservancy, Water, Milk, Smallpox Vaccination, Rat Destruction, Disinfection, Vital Statistics, and Book Reviews. Most of the notes and extracts are very brief, but appear to bring out the more salient points of the original papers, and will undoubtedly serve as a very useful guide to the student of this particular subject. The paper to which most space is given is one by Sir Alexander Houston on water and sewage purification, reprinted from the Reports of the Progress of Applied Chemistry. This paper, dealing chiefly with water and sewage problems in this country, has, perhaps, only an indirect bearing on tropical hygiene, but it is, nevertheless, highly important from that point of view in that it deals largely with questions of chlorination of water and with algal infection. An interesting point is that the author states that he has recently discovered a means of preventing or removing the residual or, as he describes it, "iodoform" taste in chlorinated water by means of a small dose of potassium permanganate (2 lb. to 8 lb. per 1,000,000 gallons). This question of taste has always been one of the difficulties in the way of the successful chlorination of water and the cause of many complaints from consumers, and Houston's taste-eliminating process should prove an immense boon where chlorination of water is necessary. How much more pleasant it would have been to the troops during the war if this discovery had been made half a dozen years ago!

THE Geological Survey has just issued another portion of the Memoirs on the Economic Geology of the Central Coalfield of Scotland, the present volume dealing with the fourth area into which the coalfield has been divided; this includes an area of rather more than 40 square miles, extending 10 miles to the west of Glasgow, both north and south of the Clyde. The district is not of any great economic interest; the ironstones are, for the most part, thin, and practically all the workable portions have been exhausted. Most of the coal-seams, too, are thin, and the quality is in many cases inferior. There are, however, two features of high geological interest, namely, the great local thickening of one of the coals, known as the "Quarrelton thick coal," described as "certainly the thickest single accumulation of coal-matter in Britain," and the remarkable crush-zone known as the "Paisley Ruck." Both these are fully and exhaustively discussed in the memoir.

SOUTHPORT Meteorological Observations for 1919 have recently been published by the County Borough, the report being prepared by Mr. Joseph Baxendell. Hourly whole-year normals of several elements for periods ranging from ten to twenty years are given in diagram form as a frontispiece. The tabular statistics of air-pressure, temperature, sunshine, rainfall, wind direction and velocity, with other subsidiary matters, are given for several hours for each month and for the year with the differences from the normal. An outstanding feature of 1919 was the remarkable prevalence of winds from the north-westward, their duration surpassing that of winds from any other direction, which is quite unprecedented since the commencement of autographic records in 1898. The March of 1919 was the wettest experienced during the forty-eight years' existence of the observatory, and this was followed by a deficient rainfall for eight consecutive months. Atmospheric pollution is regularly measured at two different spots in Southport, and an attempt is made to compare the results with those from other places, but the observations to hand are by no means numerous. The recorded meteorological observations are of the highest order, and the report from year to year contains usually some special discussion—a feature in advance of the returns from most corporations. In the report for 1919 the special discussion is the diurnal variation of air-pressure from the averages of ten years, and associated with this is the range of the diurnal sea-breezes. Ten years are too few for such a discussion, and certain elements of irregularity cannot be eliminated in so short a period.

THE *Résumé* of the communications made to the French Physical Society on November 19 contains a short description of the spectrograph for ultra-violet work constructed by MM. J. Duclaux and P. Jeantet. The lenses of the collimator and camera are of quartz and the prism is of water between quartz plates. The whole is enclosed in a wooden box which is sufficiently gas-tight to allow non-absorbing gases to be substituted for air. With a water prism of 70° it is possible to photograph spectral lines from 6000 to 1850 tenth-metres. For light of wave-length less than 2000 water is more transparent than quartz, and throughout the whole of the ultra-violet the dispersion of water is greater than that of quartz. With a condenser spark the line 1862 may be photographed on a Schumann plate which is almost devoid of gelatine in 5 seconds. The only inconvenience of the water-prism for this work is the considerable change of the refractive index with temperature.

THE discovery of the nickel-steels of the invar type, possessing a very small coefficient of expansion, has had many valuable applications in metrology, but careful study has proved the existence of residues, temporary or permanent, much resembling the anomalies in the expansion of glass. The cause of this instability has now been proved by M. Ch. Ed. Guillaume (*Comptes rendus*, November 29) to be the carbon in the alloy. The index of instability is arbitrarily defined as the elongation, in microns per metre, of a bar submitted to a heating for 100 hours at 100° C., the only previous treatment being the air-cooling after forging. For an invar of average composition in the natural state this index has been found to be of the order of 30. The examination of a series of bars with gradually increasing and exactly determined percentages of carbon showed that the index of instability was a regular function of the carbon content, and approached the origin of the co-ordinates as the carbon approached zero. Cementite was regarded as the probable cause, and hence the addition of a metal having a higher affinity for carbon, such as chromium, tungsten, or vanadium, suggested a probable solution of the problem of removing, or at least of reducing, the cementite. Experiments made in this direction have proved successful, the addition of chromium, for example, to an invar containing 0·1 per cent. of carbon producing an alloy in which the index of instability is reduced to one-tenth of its original value. As the price of the increase in stability, the coefficient of expansion is slightly raised.

THE meeting of the Illuminating Engineering Society on December 14 was devoted to the presentation of reports on progress and to exhibits illustrating novelties in lighting. The number of committees working under the society has been increased, recent additions being committees to deal with progress in gas lamps and lighting appliances and with the measurement of light and illumination. Progress in the latter field was illustrated at the meeting by the exhibition of a new form of illumination-photometer enabling illumination to be determined by the inspection of a series of apertures of graded brightness without any manipulation being needed to secure a reading. Such instruments seem likely to be specially useful for demonstration purposes. Other features of interest among the exhibits included a demonstration of the latest form of Sheringham "artificial daylight" apparatus, which is now being made in a standardised form, and some small electrical gas-filled lamps with opal glass bulbs, shown by the Edison and Swan Electric Co. This firm also loaned for exhibition some new neon lamps of a very interesting character. Formerly such lamps, the light of which depends upon an electrical discharge through rarefied neon gas, required a relatively high voltage. But the lamps exhibited resembled an ordinary glow lamp in appearance, and could be inserted in an ordinary lamp-socket on 220 volts. The lamp exhibited was stated to consume only 5 watts, but the light consists of a relatively feeble orange glow at the negative electrode. It is thought, however, that such lamps will be useful as pilot lamps, etc., and in cases where only a very low candle-power is needed. At the conclusion of the meeting the chairman (Dr. A. H. Levy) announced that Mr. J. Herbert Parsons had accepted the presidency of the society in succession to Mr. A. P. Trotter.

THE results of recent investigations on the theory of development by Mr. A. H. Nietz, of which Dr. Mees, of the Kodak Research Laboratory, recently gave an account at the Royal Photographic Society, are given in the current (December) issue of the society's Journal. It is found that the "reduction potential" of a developer can be measured by finding the concentration of bromide required to give the same rate of change of depression of density, and this is the method for its estimation that is least subject to error. The relative reduction potentials of sixteen developing agents are given, beginning with ferrous oxalate as 0·3 and ending with diamidophenol as 30 to 40. The author says that it appears to be well founded that (1) the maximum density tends to increase with increasing reduction potential; (2) no definite relationship can be shown between the time of appearance and the reduction potential, nor is the velocity constant affected by the potential in any regular manner; (3) while the speeds of emulsions vary with the developer employed, they are apparently no function of the reduction potential; and (4) the fogging power of a developer also appears to have no relation to the reduction potential. The author also draws conclusions as to the effect of the structure of the molecule of the developer on its reduction potential. The amino-phenols are the most energetic, the hydroxy-phenols come next, and the amines follow. The introduction of a methyl group into the nucleus or into an amino-group raises the energy, but two methyl groups are not always more effective than one; nuclear substitution of a halogen in the hydroxy-phenols raises the energy, and other less general statements are deduced. The growth of the image and of the fog do not generally follow the same law; evidence was found that fog is practically absent from the high densities and increases as the image density decreases, but bromide restrains the fog more than it restrains the image. Other allied subjects are considered.

MESSRS. J. WHELDON AND CO., 38 Great Queen Street, W.C.2, have just issued a noteworthy catalogue (New Series, No. 91) of books in the various branches of zoological science. It refers to upwards of 2000 volumes, classified under the subjects of Protozoa and micro-zoology, Cœlenterata, Echinodermata, Annelida, Crustacea, Insecta and Arachnida, Mollusca and Polyzoa, parasitology, evolution, heredity, and hybridity. In addition, there is a list of sets and long runs of scientific periodicals which Messrs. Wheldon offer for sale.

A NEW edition of "The Resources of the Sea," by Prof. W. C. McIntosh, is announced for publication by the Cambridge University Press early in January. The work has been carefully revised and brought up to date. A chapter on the labours of the International Fisheries Council is promised.

Our Astronomical Column.

A NEW COMET.—Mr. Skjellerup, of Cape Town, has discovered a new comet 1920*b*; its position on December 13 at 12h. 57·4m. G.M.T. was R.A. 8h. 55m. 16·07s., S. decl. 9° 1′ 48″; daily motion + 4m., N. 1° 19′. The comet is moving towards Regulus, and coming into a favourable position for northern observers. Its magnitude at discovery was 10½. It will be remembered that Mr. Skjellerup discovered another comet a year ago; it was, however, unfavourably placed, and very few observations were secured.

Mr. Van Biesbroeck observed this comet at Yerkes Observatory on December 17d. 20h. 19·8m. G.M.T., R.A. 9h. 16m. 59·6s., S. decl. 3° 10′ 7″. The average daily motion from December 13 to 17 is +5m. 3s., N. 1° 22′. The comet is evidently not very distant from the earth; its motion is direct, and it will pass the ascending node in about ten days. It is visible in a small telescope.

TABLES DU MOUVEMENT KÉPLÉRIEN.—Ever since the enunciation of Kepler's laws efforts have been made to simplify the determination of true anomaly and radius vector in terms of the time. Many of the methods given are ingenious and useful, but none appear to give so rapid a solution as extended tables. Dr. M. F. Boquet, astronomer of the Paris Observatory, has just published a very useful volume with the aid of a grant from the Académie des Sciences; it gives for values of e ascending by intervals of 0·01 from 0·00 to 0·50, and for values of v ascending by intervals of 1° from 0° to 180°, the values of M and $\log r/a$ to three and five decimal places respectively, together with columns of differences for the variation of v and e. It is thus quite a short computation to find v and $\log r$ for a given value of M to 4″ and to the fifth decimal place respectively. Examples are also given showing how the difference-columns may be utilised to obtain seven-figure accuracy by a straightforward computation. These tables will be a boon to all who desire to calculate ephemerides of short-period comets or minor planets. *A propos* of the latter point, it may be mentioned that the ephemeris of Ceres given in NATURE of December 9 is found to need the large correction of *minus* 4m. 40s. in right ascension. This large discordance emphasises the inconvenience resulting from the discontinuance of the accurate ephemerides of the four chief asteroids formerly published in the Nautical Almanac.

THE UCCLE OBSERVATORY.—Tome xiv., fascicule iii., of the *Annales de l'Observatoire Royal de Belgique* shows that a considerable output of work went on at the Uccle Observatory even during the dark days of war. It contains micrometric measurements of 172 double stars made with the 38-cm. equatorial by G. van Biesbroeck. The mean result for Castor (epoch 1914·142) is 219·59°, 5·30″. The distance shows a marked diminution since about 1890, when the maximum, 5·76″, was reached. So far as it goes, the above observation favours Mr. Lewis's minimum ellipse, the period of which is 310 years.

The *Annales* also contain a very fine series of cometary observations extending from 1913 to 1919; for example, Delavan's comet of 1913 was observed for position on seventy-three nights, and its magnitude determined on thirty-two nights. It remained a naked-eye object for nearly six months, attaining a maximum of 2·8 magnitude in mid-September, 1914. Among other methods that of extrafocal images was largely used. The comparison stars are thus expanded into discs, which renders them more readily comparable with a diffused body like a comet.

Colloid Chemistry.

By PROF. W. C. McC. LEWIS.

COLLOID chemistry—the science which deals with the phenomena occurring at the interfaces which separate two contiguous phases, such interfaces being very large in extent relatively to the actual masses of the phases themselves—stands in a rather peculiar position. Numerous colloid problems are encountered by workers who in many cases fail to realise the significance of their observations from the point of view of colloid chemistry itself. The scope of the subject is so wide that it is not surprising to find the literature exceedingly scattered, and part of it not easily accessible. Many of the results and observations are rendered difficult to interpret, or even lose the greater part of their value, through insufficient attention having been paid to considerations which a general knowledge of colloid chemistry as a science would have suggested. For similar reasons there has been a considerable amount of overlapping and, in some cases, a distinct lack of agreement in results, which probably has its origin in unsuspected dissimilarity in the conditions employed. With the literature, scientific and technical, in this state it is evident that considerable good might be done by attempting to correlate such observations and results with the object of impressing the essential unity of the subject upon those engaged in problems apparently diverse. Such an attempt at co-ordination has been made by the Colloid Committee of the British Association, which has just issued its third report.[1]

This report, following the plan already adopted in the two previous reports, contains the subject-matter arranged under two heads: (1) classification according to scientific subject, and (2) classification according to industrial process. Under the first head the following subjects have been dealt with: Colloid Chemistry of Soap Solutions; Ultra-microscopy; Solubility of Gases in Colloidal Solutions; Electrical Charge on Colloids; and Imbibition of Gels. Under the second head we find: Industrial Applications of the Imbibition of Gels; Colloid Problems in Bread-making; Colloid Problems in Photography; Cellulose Esters; Colloid Chemistry of Petroleum and of Asphalt; Varnishes, Paints, and Pigments; and Clays and Clay Products.

Merely to read over the list of industrial subjects dealt with in this and in the two previous reports is sufficient to indicate the extraordinarily wide technical field in which colloid considerations play a decisive part. At the same time one cannot but be struck by the predominance of empiricism in almost all cases, and, consequently, the urgent need there is for each industry to investigate its own colloid problems on scientific lines. The Committee will have done something if it succeeds in emphasising this fact.

Unfortunately, at the present time the retort may well be made that broad scientific principles in colloid operations and processes are few, and that even the simplest colloid phenomenon is by no means completely understood. By way of illustration, let us take the case of the stability of a colloidal metal in a dispersing medium such as water. Are we to take it as true that small particles consisting of pure metal only are capable of permanent distribution in a pure solvent, or is it always necessary to have some "impurity" present to stabilise the system? We know that a finely divided metal such as that considered carries an electric charge, but we have not any notion of its magnitude; and although we know that it can be discharged, the mechanism is not altogether clear. Does the stability of the colloid system depend on the existence of the charge alone or upon the magnitude of the interfacial tension round each individual particle, or upon both effects; and, if so, in what manner? Is there a real limiting size to such particles, and, if so, what opposing agencies determine the size and how do they operate? In the peptisation of such particles, say by the addition of gelatin, does the peptiser form an actual coating round each individual? If so, what are its properties, and what relation does the amount of bound peptiser bear to that still left free in the liquid? We know that peptising effects are highly specific. What determines the specific nature of the effect? Again, what is the mechanism of coagulation, and why are certain coagulations reversible and others not? Numerous queries of this kind naturally occur even in connection with a problem which is only one of many included in the term "colloid chemistry," and it may be said with confidence that to answer at all adequately some of these queries will require many years of intensive scientific investigation. Further, it must be borne in mind that several technical processes in active operation at the present time depend directly upon such phenomena as stability of dispersed systems, peptisation, and coagulation. It is obvious that effective control and ultimate extension of such industries must involve a scientific knowledge of what is taking place.

Let us turn for a moment to some of those aspects of colloid phenomena upon which we may be said to possess some real *quantitative*, though necessarily incomplete, knowledge. First of all we have Willard Gibbs's theoretical investigation of the influence of an interface upon the concentration of gaseous and dissolved substances. A small section of Gibbs's work has led to the only quantitative law of adsorption by capillary forces which we possess, and it seems not improbable that other generalisations still lie unheeded in his famous essay. Next we have Donnan's quantitative investigation of the effect of a chemically inert membrane upon the distribution of electrolytes when electrolytic colloidal material is present on one side of the membrane, leading to the phenomena of membrane hydrolysis and membrane potentials. To this we must add the application of Donnan's method of treatment in the hands of Procter and of Wilson to the imbibition of gels and the process of vegetable tanning. Next we have the quantitative investigations and generalisations of McBain, of Bayliss, and of Pauli upon the composition and behaviour of colloidal electrolytes, such as the soaps and the proteins, as a function of the dilution of the system. We have, too, the work of Perrin, of Gee, and of Bancroft on the mechanism of electrical endosmose. We have the beginnings of a science of electro-capillarity in the work of Lippmann and of Helmholtz. Our knowledge of the molecular and atomic mechanism of condensation upon surfaces has been greatly increased by the novel ideas of Langmuir and of Harkins—a subject of the utmost importance in connection with heterogeneous catalysis generally. We know something, though not a great deal, about such phenomena as the viscosity of colloidal solutions, the rigidity of surface films, the mechanism of lubrication, the Liesegang phenomenon, and other typically colloid-chemical problems. The fact is that an enormous field exists the scope of which is by no means realised

by scientific investigators in general or by those actually engaged in technical problems which involve, either partly or wholly, considerations of a definitely colloid nature.

The reports of the British Association Committee on Colloids have dealt with a number of the subjects referred to above, and also in some detail with a number of industrial operations involving colloid chemistry. Several scientific subjects and technical applications have not as yet been included. It is hoped that a number of these will form the subject-matter of the fourth report.

A New Problem of Coastal Navigation.

In coastal navigation there is no problem of greater general utility than that of fixing positions by means of "cross-bearings" of two terrestrial objects. If, for instance, we have one object bearing due north and a second bearing due east, we have but to lay down the bearings reversed, south from the one and west from the other, and the point of intersection of the two lines of bearing fixes the position of the ship.

When, as is often the case, only one light is available, it has generally been assumed that no more information could be obtained from its observed bearing than a single line of bearing, somewhere upon which the ship's position must lie. But a little work recently published in Australia[1] by Capt. H. H. Edmonds, of the British Mercantile Marine, introduces us to a comparatively novel use for a single light, for he shows how by three bearings, with the intervals between the bearings noted, we may deduce that most valuable piece of information, the actual course under the influence of wind and current which is being made good "over the ground."

The problem is not wholly new, for in its most general form questions to be solved by protraction have been proposed in recent years in the Board of Trade examinations for masters and mates, but in much too complicated a form to be of service in actual work at sea. The advance effected by Capt. Edmonds lies in the application of a simple form of table, reference to which gives the course made good in a moment with no more trouble than the division of one quantity by another.

In the construction of the table it is assumed that the intervals in azimuth are equal, the times of the three observations being carefully noted. One of these being divided by the other, a "ratio" is obtained which serves as an argument of the table.

The use of the table will easily appear from one of the examples given: "A light bore N.W.; after a time-interval of 39 minutes it bore W.N.W.; after another time-interval of 21 minutes it bore W."

A portion of the table to be employed is given below:

Bearing interval 22° 30'.

Course angle.	Ratio.
31°	1·884
32°	1·839
33°	1·796

The solution is given as follows: "Dividing the greater time-interval by the lesser, we obtain a ratio 1·857; with this ratio, under bearing 22½°, we obtain the course-angle 32°, which, allowed forward of the first bearing, gives course made good N. 13° W."

The table of the text-book, as has been shown, proceeds upon the assumption that the intervals in azimuth should be equal. A still more advantageous form of table, it would seem, could be obtained by taking the observations at equal intervals of time, with differences of bearing in general unequal. This form of table presents at least two very attractive features: first, that we have no ratio to calculate, and, secondly, that it is much simpler in practice to observe a bearing at a given time by watch than to wait, watch in hand, at the compass until a given bearing comes on. For air navigation in particular such a table should be invaluable, since it is quite unnecessary to fix the identity of the particular point observed, and, indeed, the problem has already engaged the attention of some of the able men who have taken up the problems connected with the navigation of the air. In a recently published work by Lieut. Dumbleton[2] the following passage occurs, taken apparently from a lecture by Squadron-Leader Wimperis before the Royal Aeronautical Society: "How is one, then, to determine the course being made good? Perhaps the best method is to take times and bearings of the object as it passes through the points E, F, and G, such that the time from E to F is equal to the time from F to G."

The lecturer goes on to describe a method of solving the problem by protraction, suitable, perhaps, for an airship, but scarcely practicable probably for a heavier-than-air machine.

The following extract shows the form which such a table, devised for equal differences of time, would assume:

Angle of Inclination to First Line of Bearing.

Difference between first and second bearings.	Difference between second and third bearings.					
	56°	F.	54°	F.	52°	F.
38° ...	35·2°	0·74	36·5°	0·76	38·0°	0·78
36° ...	34·7°	0·71	36·0°	0·73	37·4°	0·75
34° ...	34·0°	0·68	35·3°	0·69	36·7°	0·71
32° ...	33·2°	0·64	34·4°	0·66	35·7°	0·67
30° ...	32·1°	0·60	33·3°	0·62	34·6°	0·64

The column marked F requires, perhaps, some explanation. The primary object of the table is to give the course made good. But when at first bearing the distance from light is known with reasonable accuracy, the distance in final position is obtained by multiplying first distance by factor F. The following example will serve to illustrate the use of the table:

From a ship steaming N. 25° W. 16 knots, the Smalls Light (lat. 51° 44′ N., long. 5° 40′ W.) bore N. 26° E. Twenty minutes later the Light bore N. 59° E., and again after a further twenty minutes S. 67° E. Find true course made good.

For first difference of bearing we have $59° - 26° = 33°$, and for second $113° - 59° = 54°$.

Entering table with 33° on left and 54° at top of the page, we have the angle 35° nearly.

This angle applied to the first bearing, N. 26° E., gives N. 9° W. as true course made good over the ground.

To illustrate the use of the factor F, let us suppose that by means of the line of position from a star observation or otherwise, distance at first bearing was found to be 10 miles. Then final distance $= 10 \times F = 10 \times 0{\cdot}68 = 6{\cdot}8$ miles.

[1] "Course Angle Tables for Finding a Course Made Good." By H. H. Edmonds. (Sydney: Turner and Henderson.)

[2] "Principles and Practice of Aerial Navigation." By Lieut. J. E. Dumbleton. (London: Crosby Lockwood and Son.)

The position of the Smalls Light, it may be observed, is such that it offers special advantages for the application of the proposed method. A ship rounding the Land's End, bound for the Irish Channel, after passing the Longships Light, has a run of about 130 miles for the Tuskar Light, and towards the end the tidal currents set across the mouth of the Channel with considerable velocity. In such a case observations of the Smalls Light, should it become visible on the starboard bow, would be of considerable service in checking the course laid for the Tuskar.

H. B. G.

Late Keltic Remains from a Mendip Cave.

AN important series of Late Keltic objects has been brought to light by members of the Speleological Society of the University of Bristol in the course of investigations in a cave in the Mendips. The cave was first discovered in September, 1919, and the work of exploration, which has been done on most systematic lines, has been carried on throughout the past year. The finds, which were described by Mr. L. S. Palmer at a recent meeting of the Royal Anthropological Institute, included objects of worked bone and stone, bronze hubs and bands of chariot-wheels, bronze bracelets and finger-rings, iron slave shackles, an iron key, spindle whorls, and similar objects. A considerable amount of pottery was also found which in design and technique was comparable to that found in most Late Keltic settlements. It does not, however, exhibit the characteristic curvilinear motives, the chief decorative feature being in the form of an inverted C. Only three human bones were discovered. There was a large number of bones of domestic and wild animals. A peculiar feature of the discovery is that all these objects were found either on the surface of the floor of the cave or in a thin band of mud which constituted the uppermost layer. There was no evidence of earlier occupation or any trace of Roman occupation. These facts, taken in conjunction with evidence which points to occupation of the cave having taken place in abnormal circumstances, would suggest that the cavern was used as a temporary refuge.

The discovery is of great importance in connection with the question of the relations which subsisted between this country and the Continent during the Iron age. The character of the finds, and in particular the close affinity exhibited by the pottery to that of Brittany, pointed, in Mr. Palmer's opinion, to the site having been occupied by a tribe of the Brythons who migrated to this country from the north of France. The same people built Glastonbury Lake Village, and are known to have inhabited Wookey Hole, Worlebury Camp, and some hut circles on Brean Down, all of which are within a few miles of this cave. In support of his view Mr. Palmer pointed out that the hill forts in this area all face in a northerly direction, which would suggest that they were the van of a wave of immigration from the south. On the other hand, as Prof. Keith pointed out, the type of skull usually associated with this type of culture in the west of England differs essentially from the Breton skull, and the affinity between the pottery of this area and that of Brittany may well be the result of commerce rather than of immigration. It may be hoped that the further exploration of the site which is to be carried on during the coming year may produce fresh evidence to throw light upon a period concerning which our present knowledge is all too scanty.

Physiology at the British Association.

ON Tuesday, August 24, the Section of Physiology held a joint meeting with the Sub-Section of Psychology. At this joint sitting Dr. Rivers opened a discussion on the desirability of establishing a separate Section of Psychology. The address of the chairman of the Sub-Section (Dr. C. S. Myers) was on almost the same subject. Dr. Rivers gave an outline of the history of psychology in relation to the British Association, and showed that there had been a great increase in the number of papers on psychological subjects contributed to the Association. He pointed out that psychology had developed methods and problems of its own. At the end of the discussion Dr. Rivers moved a resolution: "That this meeting of the Section approves of the constitution of a separate Section of Psychology." This resolution was passed *nem. con.*, and it was referred to the committee of the Section.

At the same joint meeting Miss M. Smith and Dr. W. McDougall read a paper on "The Effect of Drugs on Fatigue." Fatigue was induced by sitting up all night for three successive nights, and the effect was studied by means of dotting circles on a moving tape and by memory tests with related words. The first effect of fatigue was to increase the efficiency, but after the first few days the efficiency showed a marked decline and remained below the normal for from sixteen to nineteen days. This showed that the effect of the loss of sleep extended for a considerable period after the loss of sleep had occurred. The drugs were given disguised so that they could not be recognised. Most of the experiments were with alcohol or opium. The action of alcohol was to decrease the efficiency except during the period of recovery, when a stage occurred in which alcohol caused the efficiency to approach the normal non-fatigued value. Opium caused an increase in efficiency which was more marked in the recovery stage. When the dotting and memory tests were carried out together alcohol caused them to vary together, and the subjective effect was not unpleasant, but opium caused one process to improve at the expense of the other, and the subjective effect was distinctly unpleasant.

On Friday, August 27, the Section of Physiology met the Section of Botany to discuss "Biochemistry and Systematic Relationship." An account of this discussion appears in the article upon the proceedings of the Section of Botany (p. 550).

Several of the meetings of the Section were held in the new buildings for the department of physiology, when the members of the Section had the privilege of inspecting the excellent accommodation for the department. At one of these meetings Prof. Haycraft demonstrated a new pulse recorder, which consists of a mirror resting on the artery, the records being made by photographing the movement of a spot of light reflected from the mirror.

Dr. T. Lewis read a paper on "The Relation of Physiology to Medicine." This was largely a plea for the development of the subject of human physiology. He pointed out the importance of a knowledge of physiology for rational medicine, but contended that it would be of greater value if more use were made of the human subject for illustrating the facts of physiology. The use of methods of examination applicable to the human subject should be extended, but, of course, the methods must be controlled by experiments on animals. Dr. Lewis finished his paper by appealing to the citizens of South Wales for an endowment for the department of physiology. As a graduate from South Wales, he felt the handicap due to lack of accommodation and of equipment; now that a good building had been provided he hoped that sufficient money would be forthcoming for its equipment and upkeep.

As a good example of the way in which animal experiments must be used to elucidate the physiology of the human subject Dr. Lewis's paper on "Auricular Flutter" may be quoted. This was a description of experiments on the heart of the dog. The time-relations of electrical changes in the auricle were traced, and they were found to differ from those of the auricle beating in its natural way. The evidence from the time-relations of the electrical changes points to a wave of contraction passing round the superior and inferior venæ cavæ. The normal beat consists of a contraction wave which spreads over the whole auricle, but in auricular flutter the wave travels down one side of the auricle round the inferior vena cava, and returns by the other side of the auricle to the superior vena cava. This establishes a circus movement which continues indefinitely. The wave of excitation reaches each part of the auricle at a sufficient interval after the previous contraction to fall outside the refractory period; hence the series of quickly following circus movements. The normal contraction ends because the wave of contraction spreads fan-like over the whole auricle, when it reaches the limits of the auricle: it ceases because the wave of excitation is dammed by the refractory period of the contracting auricle.

Miss E. Bedale, in collaboration with others, read a paper on "The Energy Requirements of School-children." The measurement of energy was attempted in two ways. The first consisted in obtaining diet-sheets prepared by the pupils on which they recorded the weighed amounts of the various food materials eaten. These diets were evaluated by analytical data, and the energy-value of the diet was obtained in that way. The second method was to measure the energy expenditure by means of the respiratory exchange. The basal metabolism was measured during sleep. Measurements of the respiratory exchange were made during various forms of activity and the daily expenditure was estimated by a calculation involving the amount of time occupied in the different forms of activity. The two energy values did not agree, the intake of energy being greater than the expenditure. It was left an open question as to how much of the lack of agreement was due to errors in computing the energy output in the various forms of activity during the day.

Prof. Waller gave some figures on an allied subject in which he measured the energy expenditure by the output of carbon dioxide. He contrasted a man in training with an untrained man running the same distance at the same speed. Assuming that the basal metabolism of the two men was the same, the untrained man expended double the amount of energy in doing the same work.

Prof. Herring recorded measurements showing the effect of pregnancy on the various organs of the white rat. The animals were from a standard litter, and kept under identical conditions except for the occurrence of pregnancy in some of them. Most of the organs showed a slight decrease in weight; the only ones that showed an increase in weight were the liver and the adrenals. The increase in the former shows the great importance of metabolism during pregnancy. The increase in the latter is probably in the cortex, and not in the medulla.

Dr. Edridge-Green read a paper on "The Prevention of Myopia," in which he stated that the exciting cause of myopia is an increase in intra-ocular pressure. Games such as cricket, football, golf, etc., do not cause myopia, but severe strains such as lifting heavy weights, especially with the eyes pointing downwards, should be avoided.

Prof. Waller recorded some further observations on "The Emotive Response of the Human Subject." The response is usually confined to the hand and foot, but a few individuals show it on the forearm and leg. The reaction appears first on the hand (2″) and then on the foot (3″). If it occurs elsewhere it is delayed as long on the arm as on the foot (3″), and shows a longer latent interval on the leg (4″).

Prof. Waller presented the report of the Committee on Electromotive Phenomena in Plants. The zone of growth in iris is at the base of the leaf, and in anemone at the apex of the plant. When an induction shock is passed through an active growing tissue the resultant electrical change is always from the more active to the less active portion in the plant-tissue, no matter in which direction the stimulating current is passed. In dead tissues the current produced after stimulation is small, and always in the direction of polarisation.

Botany at the British Association.

THE diversified character of modern botany was well exemplified in the programme of the Cardiff meeting, and the *rapprochement* of the sciences was evidenced by the three joint discussions in which the Section took part. Joint sittings have become an important feature of recent years, and in this reflect the tendency of modern research to overstep the necessarily arbitrary boundaries of the so-called sciences and to combine with other workers on the border-line problems.

Thus it is not surprising to find botanists co-operating with zoologists and geologists to consider whether Mendelian work and palæontological evidence show as yet any sign of giving mutual support to the conclusions derived from each line independently.

The joint discussion with the physiologists and chemists entitled "Biochemistry and Systematic Relationships," presided over by Miss Saunders, president of the Botany Section, aimed at considering whether the present state of knowledge indicates any definite ratio between biochemical constitution and morphological expression—that is to say, does biochemical investigation show a chemical relationship in the forms which have long been grouped together on morphological grounds? The discussion was introduced by a paper by the Hon. Mrs. Onslow, wherein the possibility of expressing reproductive and vegetative characters in chemical terms was explored; lines of plant-metabolism were considered and suggestions made as to correlations between the evolution of the families of flowering plants and the presence of oxygenases, and the distribution of anthocyan pigments and of flavones was discussed. The papers and open discussion which followed indicated the importance of the new line of work, inasmuch as a considerable correspondence of chemical and morphological relationship had been established, but laid stress also on the necessity for extreme carefulness in its application in view of the diversity in many cases of chemical reactions in closely related forms.

Dr. F. F. Blackman contributed a paper on "The Biochemistry of Carbohydrate Production in Plants from the Point of View of Systematic Relationship," in which the distribution of the primary products of the photo-reduction of CO_2 in different groups of plants was traced, pentoses being the basis of the succulent habit, and the diversity of the condensation products, saccharose, starch, and inulin, was considered in relation to species and families. Emphasis was laid upon Reichert's work on the individuality of the starch-grains of every species of plant, and of its bearing on the chemical specificity of protoplasms. Prof. G. H. Nuttall followed with a paper entitled "Precipitin Reactions as a Means of Determining Systematic Relationships in Animals and Plants," in which it was pointed out that both animal and vegetable albumins retain certain chemical properties which persist, while the animal or plant to which they belong undergoes a phylogenetic morphological change, and that qualitative precipitin tests carried out with different albumins give a measure of the degree of relationship existing between forms that have descended from a common stock. The contribution of Mr. J. Barcroft (president of Section I) correlated the properties of the oxygen-carrying power of blood, essentially the properties of hæmoglobin, with the functions and habits of the animal in question rather than with its phylogeny, comparing in particular the oxyhæmoglobin equilibrium of fishes living in different habitats.

The semi-popular lecture which has become a feature of the Botany Section was delivered this year by Prof. Chamberlain, who came from Chicago to do so at the invitation of the committee. His eye-witness account of his adventurous acquaintance with the Cycads of the world delighted the audience no less than the beautiful lantern-slides which accompanied it.

Amongst other descriptive accounts of vegetation may be mentioned that of Prof. Chodat on some aspects of plant ecology and biology in Paraguay; that of Mr. Kingdon Ward on the distribution of floras in south-east Asia as affected by the Burma-Yunnan Ranges; that of Mr. Patton on the vegetation of Beinn Laiogh; and, lastly, a lantern demonstration of the Eastern Canadian Rocky Mountains by Prof. F. J. Lewis. Vegetation and soil surveys formed the subject of the joint meeting between the Sections of Botany and Agriculture, presided over by Prof. Keeble, president of the latter Section. Mr. G. W. Robinson dealt with the soil types of North Wales as revealed in the soil survey of recent years, and Mr. G. A. Fisher with soil acidity. Mr. Robinson suggested that, while uniformity in sampling and analytical methods should be secured, the classification of soils must depend on local conditions. In extreme humid conditions it would appear that differences due to geological factors tend to be obliterated. Large numbers of soil samples should be collected, and the types worked out from actual observations; correlation with geology may follow afterwards. The soil survey gives information as to *one* of the factors affecting plant-growth and, ultimately, agriculture in a particular area. The survey in its widest sense should take cognisance of all the other factors, including climate and soil-water conditions. The vegetation survey gives the results of the operation of all these factors.

Miss Wortham gave an account of the results of her survey of Anglesey and North Carnarvonshire, with special reference to the grass-lands, and showed that the plant-formations are closely related with the geological structure of the district. She traced the origin of grass-lands from upland moor, from woodland, and from the degeneration of lowland moor.

The botanical part of the discussion centred especially round types of grass-land, their importance in Wales and in general in agriculture, the possibility of fixing on some *standard* symbols of colours for ecological mapping, and the correlation of the various surveys. Prof. Stapledon, after discussing *Festuca agrostis* pastures in detail, laid stress on the need for a colour scheme which would allow of the representation of transition types. He also took up the question of the difficulties of the representation of arable, and suggested the possibility of using the weed flora in this connection. Lastly, Prof. Stapledon emphasised the immediate importance of hastening on the primary vegetation survey. As a result of the discussion, in which Sir Daniel Hall, Mr. T. J. Jenkin, Dr. E. N. Thomas, Mr. Morrison, and others took part, it became obvious that there existed a great need for co-operation among workers and more codification of observations. Steps were initiated with the view of bringing about this end.

The subject of geotropism, which has received considerable attention during the last few years, was considered on the Wednesday afternoon, when Dr. Harold Wager gave a paper on the geotropism of foliage leaves and their possible dia-geotropism. In a contribution entitled "Further Evidence for the Differentiation in Hydrion Concentration in Stem and in Root as the Explanation of Positive and Negative Geotropism," Prof. Small, in collaboration with Miss Rea, further developed his theory of the CO_2 balance as the cause of this differentiation in behaviour.

The only contribution to fossil botany was furnished by a paper by Mrs. Clement Reid on the history of the West European Pliocene flora as deciphered by the study of fossil seeds, in which, by the critical comparison of percentages which were then plotted as a curve, she demonstrated very clearly that seeds may be used to determine species and with strong probability for zoning purposes. Since Mrs. Reid's conclusions agree with those furnished by animal palæontology for known ages, they can be used for one unknown. The deductions from the curve based on the numerical study of plant species also agree with, and therefore support, many conclusions arrived at by stratigraphical and other evidence.

The president expressed special interest in a paper by Miss Blackburn on anomalies in microspore formation in Rosa and its possible connection with hybridity in the genus. The normal process had been examined in three species. Abnormalities were described in ten forms, two of which were known to be hybrids. The results suggested the possibility of determining the genetic constitution of forms by an examination of cytological phenomena.

Probably the most outstanding contribution of original work was supplied by Prof. Lloyd Williams, who gave a detailed account of his researches into the life-history of the Laminariaceæ, which demonstrated the existence of alternation of generations throughout the group.

Great interest was expressed in the progress reported by Mr. Martineau on the growth of pit-mound plantations in the Midlands, and a resolution was proposed by Sir Daniel Morris, seconded by Prof. Henry, and passed unanimously, urging State support for similar experiments in other parts of the country.

Notwithstanding the short time and crowded programme, the botanists were able to see something of the vegetation of the neighbourhood on their expeditions to the very beautiful country surrounding Cardiff.

University and Educational Intelligence.

LONDON.—On his resignation after twenty-seven years' service of the chair of botany at King's College the Senate of the University has conferred the title of emeritus professor of botany in the University on Dr. W. B. Bottomley.

The following doctorates have been conferred:—*D.Sc. in Geology*: Mr. H. A. Baker, an internal student, of University and Birkbeck Colleges, for a thesis entitled "On the Investigation of the Mechanical Constitution of Loose Arenaceous Sediments by the Method of Elutriation." *D.Sc. in Mathematics*: Mr. H. E. J. Curzon, an internal student, of University College, for a thesis entitled "The Reversal of Halphen's Transformation." *D.Sc. (Economics)*: Mr. E. H. J. N. Dalton, an internal student, of the London School of Economics, for a thesis entitled "Some Aspects of the Inequality of Incomes in Modern Communities."

Dr. Harriette Chick has been awarded the William Julius Mickle fellowship, of the value of 200*l*., in recognition of the important work she has carried out during the past five years on diseases due to defective nutrition.

DR. DAVID OWEN, senior lecturer in physics at the Birkbeck College, has been appointed head of the department of physics and mathematics at the Sir John Cass Technical Institute, Aldgate, E.C.3.

THE Drapers' Company has made a grant of 5000*l*. to the East London College (University of London) for the equipment of its new library. The remarkable growth and success of this University college in the Mile End Road, built up under the auspices of the Drapers' Company, form one of the outstanding features in modern educational activity. The undergraduates in the college now number nearly 600.

A MEETING for the purpose of considering the desirability of establishing a Federal Council of Associations of Teachers in Bristol, Gloucestershire, Somerset, and Wiltshire, held at the University of Bristol on December 4, was attended by representatives of numerous associations and institutions. Prof. J. Wertheimer was elected chairman, and it was decided that, subject to the approval of the majority of the associations represented, the council should be established. The objects of the council will be:—To bring together representatives of teachers of all types in order to give them opportunities of exchanging views, of becoming acquainted with one another's work, and of formulating, when desirable, expressions of opinion in regard to educational problems of general interest.

THE statement for the year 1919–20 of the Rhodes Scholarships Trust has been received. During that period 185 scholars, of whom 105 were from the British Empire and the remainder from the United States, were in residence; of this number 98 were freshmen. By the end of the year 32 of the scholars either completed the term of their scholarship or went down, in spite of which the present year opened with as many as 220 Rhodes scholars in residence. A record of the results achieved during the past year by holders of these scholarships is given, among which may be noted three students who were admitted to read for the degree of Ph.D. in natural sciences; while the books which have been published in the academic year by Rhodes scholars include a translation by Mr. H. L. Brose of Moritz Schlick's book entitled "Space and Time in Contemporary Physics."

IT is announced in the *Lancet* of December 18 that an anonymous donor has given 20,000*l*. for the endowment of the University chair of physiology at the Middlesex Hospital Medical School. The present occupant of the chair is Prof. Swale Vincent, who is well known for his publications dealing with the ductless glands and internal secretions. Prof. Vincent has one of the physicians of the hospital associated with him in his department in order to facilitate the introduction of new discoveries in the laboratories into medical practice in the clinical wards. This generous gift is a big step in the direction of the co-ordination of medical education with research and treatment which Lord Athlone, chairman of the hospital, is anxious to secure, and it will also form another bond in the relations between the hospital and London University. Of the six professorial chairs now existing in connection with the Middlesex Hospital that of physiology is the second to receive permanent endowment, the chair of physics having been endowed early in the present year.

THE first annual dinner of the Imperial College of Science and Technology, held on December 14, was an outward and visible sign of the common interests of the three constituent colleges—the Royal College of Science, the City and Guilds (Engineering) College, and the Royal School of Mines. The Marquess of Crewe, chairman of the governing body of the Imperial College, presided, and a large number of leading representatives of science and technology supported him. Several notable speeches were made in the course of the evening. Sir Alfred Keogh, rector of the college, said that long before the late conflict the college had been urging the principle of the relation of science to industry, which was the same thing as the relation of science to war, but neither the nation nor the Government had paid heed to it until the war broke out and it was found that war could not be waged without science. It was then that the three constituent colleges were able to render essential service in many fields. Lord Moulton said that science and technology were mutually complementary, science procuring the seed while technology used it to secure bountiful harvests for human needs. Sure success is built upon accurate knowledge such as the college diffuses in all its branches. The Marquess of Crewe remarked that the Imperial College has all the attributes of a university, and the courses taken by its students are no more specialised than those pursued by science students in the older seats of learning. He followed with much interest the progress of the University of London, and it was hoped that the college would advance on parallel, but not on identical, lines, both institutions agreeing to pursue the twin figures of knowledge and wisdom in still wider fields.

A CONFERENCE on recent advances in physics will be held in the physics laboratory of the University of Toronto between January 5 and 26 of the coming year. The principal event will be a series of eighteen lectures by Dr. L. Silberstein on "The Special and Generalised Theories of Relativity and Gravitation" and on some of the recent advances in spectroscopy and the theory of atomic structure. Einstein's theories of general relativity and gravitation, and the more recent theory of electromagnetism put forward by Weyl, will occupy some five or six lectures, and a similar period will be devoted to Bohr's quantum theory of spectra, Sommerfeld's relativistic theory of the structure of spectral lines, the Epstein theory of the Stark effect, and the lecturer's own theory of non-spherical nuclei. The course will be mainly mathematical in character. Dr. Irving Langmuir will deliver a short course of lectures on the theories of atomic structure and allied subjects from the chemical as well as from the physical aspect. Prof. E. F. Burton is giving a course of twelve lectures on the fundamental properties of colloidal solutions, which it is hoped will be as useful and interesting to manufacturers as to men of science. Sixteen lectures of a popular nature dealing with various aspects of recent researches on the structure of matter and on the origin and characteristics of radiation will be delivered by Prof. J. C. McLennan, who will deal chiefly with the results of the experimental investigations which have been made in numerous branches of the subject, concluding with an account of the production and uses of helium. The conference will be opened on Wednesday, January 5, by Sir Robert Falconer, president of the University of Toronto.

Societies and Academies.

LONDON.

Royal Society, December 9.—Prof. C. S. Sherrington, president, in the chair.—Lord **Rayleigh**: Double refraction and crystalline structure of silica glass. Although glasses in general have no double refraction, except that due to bad annealing, yet silica glass is found to have a doubly refracting structure which cannot be so accounted for, and must rather be regarded as crystalline. The double refraction is very weak, of the order of 1/60 that of crystalline quartz. In a mass of silica which has been melted, but not drawn or blown, the structure consists of doubly refracting grains with dimensions of about ⅓ mm., oriented at random. If the grained material is drawn out while soft, the grains are elongated into crystalline fibres or ribbons. Fused silica sometimes contains isolated, small inclusions of quartz with angular outlines which have escaped vitrification. These are conspicuous in the polariscope by the strain effects they produce in the surrounding glass.—Prof. J. W. **Nicholson** and Prof. T. R. **Merton**: The effect of asymmetry on wave-length determinations. (1) The apparent displacement of an unsymmetrical spectrum line caused by the finite resolving power of the spectroscope can be calculated on certain simple assumptions. (2) The displacement is independent of the actual widths of the lines. (3) It is considered that the general practice of measuring spectrum lines to a degree of accuracy far transcending the resolving power is not justified.—Prof. T. R. **Merton**: The effect of concentration on the spectra of luminous gases. Certain spectroscopic phenomena appear to be associated with the concentration of the radiating atoms in the source. An increase in concentration may result in a broadening of the lines, a change in the structure of the lines, and changes in the relative intensities. Sources containing lithium exhibit these three phenomena, and the broadening is familiar in sodium flames. A study has been made of the behaviour of sources containing sodium and lithium. The results seem to exclude a temporary association of atoms as the cause of the changes, for the addition of large quantities of sodium to a source containing a trace of lithium produces no change in the lithium spectra. Mixtures of hydrogen and helium have also been investigated. The broadened lines of both these elements from vacuum tubes excited by condensed discharges are accounted for completely by the electrical resolution of the lines by the electric fields of neighbouring charged particles.—Prof. E. **Wilson**: The measurement of low magnetic susceptibility by an instrument of new type. The paper deals with the design, construction, and working of an instrument for the measurement of susceptibility (of low order) over a wide range of magnetic force, and thus avoids the difficulty met with in the Curie balance, the defections of which follow the square law, and, in fact, limit the measurement of susceptibility of a given specimen to a very narrow range of magnetic force. The force due to torsion in a suspending fibre is replaced by an electromagnetic system in which the mechanical force is due to two components—one proportional to the magnetic force impressed upon the specimen and the other variable if the susceptibility varies. The expression for the susceptibility is that of the reciprocal of a resistance multiplied by a constant, and thus the instrument lends itself to great accuracy in the detection of variations in susceptibility.—Prof. W. T. **David**: The internal energy of inflammable mixtures of coal-gas and air after explosion. In the first part of this paper an empicical law of cooling of exploded mixtures of coal-gas and air contained in a closed vessel has been formulated. This is based upon measurements of the heat loss by conduction and by radiation made during the explosion and later cooling of the inflammable mixtures. In the second part the heat-loss measurements have been applied to the estimation of the internal energy of the gaseous mixtures at the moment of maximum temperature and at various stages during cooling.—Prof. A. **McAulay**: Multenions and differential invariants. The paper is a summary of the properties of a linear associative algebra suitable for electromagnetic relations, differential invariants, and relativity. There are *n* fundamental units, otherwise it is the same algebra as that considered in a paper by W. J. Johnson and read to the Royal Society on November 20, 1919.

Aristotelian Society, December 6.—Prof. T. P. Nunn in the chair.—Prof. W. P. **Montague**: Variation, heredity, and consciousness: a mechanist answer to the vitalist challenge. It was attempted to show that it is possible to point out a solution of the problems of phylogeny, ontogeny, and consciousness, statable in mechanistic terms, which provides full satisfaction to the demand of the vitalist that the purposive and psychic characters of life shall not be reduced to an epiphenomenal status of dependence upon blind processes. The occurrence of useful variations in the germ-plasm in greater frequency than is explicable on recognisable mechanistic principles may be explained by the conception of biological vectors, according to which the unpurposed, yet purposeful, products of telogenesis in the germ-plasm and in the brain, when occupied with creative imagination, are results of a system of protoplasmic stresses. The problem of the many hereditary determinants in the minute germ-cell may be met by conceiving the germ as a system of superforces or superimposed stresses which are the embodiments of a manifold of invisible intensive determinants equal in richness to the serial events of the germ's ancestral past, and capable of reproducing its pattern by induction during embryonic growth. The problem of explaining mind in physical terms was met by suggesting that the structure of conscious life is analogous to the structure of life in general, except that the system of cerebral superforces in which the past is stored up in the present is composed of traces of potential energy acquired by the brain through the transformation of the kinetic energies of sensory nerve-currents. A new category, "anergy," was proposed as a measure of the form of durational being produced whenever the energy of motion is transformed into the invisible or potential phase.

Linnean Society, December 9.—Dr. A. Smith Woodward, president, in the chair.—Prof. E. S. **Goodrich**: Hymenopterous parasites of grain-infesting insects.—L. V. **Lester-Garland**: Plants from Darfur collected by Capt. Lynes, R.N., with remarks on their geographical distribution.—Dr. B. Daydon **Jackson**: The Norsemen in Canada in A.D. 1000, with the plants they reported. The course followed by the Norsemen was narrated, from their colonies in Greenland, across

Davis Strait, to the north-east coast of Labrador, southward through Belle Isle Strait to the valley of the St. Lawrence and the tract of country on its right bank, where vines were found growing, unsown corn, and a tree called "Masur," these being regarded as *Vitis labrusca*, L., *Zizania aquatica*, L., and an Acer. The reasons why these voyages were not continued were explained as due to the weak colonies at that time in Greenland, the actual starting-point, and the opposition of the natives, termed "Skrællings," who prevented any attempts at settlements in "Vinland"—the Wineland of the sagas of Erik the Red and of Thorfinn Karlsefni—the northern part of New Brunswick.

Royal Meteorological Society, December 15.—Mr. R. H. Hooker, president, in the chair.—C. K. M. **Douglas**: Temperature variations in the lowest 4 km. The chief object of this paper is to emphasise the importance of the source of the air-supply in causing variations of the upper-air temperature, and to discuss the relationship of these variations to the weather changes, with special reference to the theories of Prof. V. Bjerknes, which the observations strongly support. The view put forward is certainly not disproved by statistical results, though the evidence for it is derived chiefly from the study of a large number of observations of temperature and humidity in the upper air, in conjunction with synoptic charts. Among the associated points mentioned in the paper the following may be emphasised: (1) Both troughs of low pressure and wedges of high pressure normally lie farther west in the upper air than at the surface. (2) The pressure in the upper air may be regarded as being partly a consequence, and not purely a cause, of the temperature of the underlying column. (3) Very powerful wind-currents are observed at great heights between the polar and the equatorial air at those levels.—A. P. **Wainwright**: A sunshine recorder (mechanical type). The new type of sunshine recorder is in the form of two mercury thermometers similar to one another and of fairly large capacity. The bulb of one thermometer, which is contained in a vacuum, is exposed to the direct rays of the sun, while the other is contained in the shade of a Stevenson screen. The difference in expansion of the mercury in each bulb is recorded mechanically by means of a pointer on a clockwork drum, and denotes the varying intensity of the sun's radiant heat at any hour of the day. The object of this instrument is to obtain a more detailed record of sunshine, and in particular to show the total intensity of the sun's rays for the day as apart from the number of hours during which the sun has actually put in an appearance.—Lt.-Col. J. E. E. **Craster**: An investigation of river-flow, rainfall, and evaporation records. Measurements of the flow of the Shannon show a fluctuation due to variations in the amount of rainfall and evaporation in the Shannon basin. Rainfall records for the Shannon basin are few, and there are no evaporation records, so that it is not possible at present to determine the amount of rainfall and evaporation by direct methods. But the monthly variations of the rainfall and evaporation, expressed as fractions of the total annual rainfall and evaporation, are constant over large areas. Records of evaporation from the soil have been kept at Rothamsted for many years, and in the absence of any Irish records it has been necessary to employ these. By using the monthly variations of rainfall and evaporation as described above it is possible to determine the minimum annual rainfall and evaporation in the Shannon basin, which will account for the fluctuations in the river flow. The minimum annual rainfall has been found to be 45·71 in., and the minimum annual evaporation from the soil 16·88 in.

MANCHESTER.

Literary and Philosophical Society, November 16.—Sir Henry A. Miers, president, in the chair.—A. E. **Heath**: The disinterested character of science in view of certain of its working maxims. The object of this paper was to show that Mach's "principle of economy" and Occam's "principle of parsimony" are not—as would appear on the surface—contradictory. It was contended that the sciences are synthetic, and consist in the setting up of conceptual constructions for the complete description of the fields of primary fact in each science. When alternative conceptual constructions are possible Mach's principle is used to decide between the alternatives. But the constant reference back to the field of primary fact removes from its use any menace to the disinterested character of science. Occam's principle, however, is a maxim applicable only to a process opposite in direction to the synthetic advance of the sciences, namely, the analysis of the field of primary fact itself. It is, therefore, not contradictory, but complementary, to the principle of economy.

Literary and Philosophical Society (Chemical Section), October 29.—Mr. J. H. Lester (chairman) in the chair.—J. H. **Lester**: Address on "The Textile Chemist." The value of a thorough training in physics was emphasised, and the importance of a post-graduate training in a technical college considered. The chemist in a dye-making works is only a textile chemist when he deals with the textile process of dyeing.

November 29.—Mr. J. H. Lester (chairman) in the chair.—H. E. **Potts**: How can the results of chemical research be best protected by patents? If the patent agent studied the subject sufficiently to criticise freely and intelligently the research programme, the requirements of the law could be met and the research at one and the same time assisted.

EDINBURGH.

Royal Society, December 6.—Prof. F. O. Bower, president, in the chair.—Miss A. **Mann**: Observations on the behaviour of the endodermis in the secondarily thickened root of *Dracaena fruticosa*, Koch. The paper demonstrated the effect of cambial activity in disintegrating the endodermis and establishing channels for direct ventilation between the cortex and the pith, which are otherwise isolated by the continuous endodermal sheath. Frequently where such a disintegration takes place the endodermis is not so easily recognised. Here it is a strongly indurated layer of cells, so that the detail of the disintegration can be accurately followed. The physiological result is that the large roots where secondary thickening occurs have a common ventilating system; but small roots, where the point is less vital, have the cortex strictly delimited by the endodermis from the central pith.—L. F. **Spath**: Cretaceous Ammonoidea from Angola collected by Prof. J. W. Gregory (with notes by the late G. C. Crick). These Ammonites formed part of a collection that included the Brachiopoda and Mollusca dealt with by R. B. Newton in a paper already published (Trans. R.S.E., vol. li.). The fauna was there described as belonging to the Vraconnian stage of the Cretaceous series, which includes the zone of *Schloenbachia inflata*. Since there is great confusion about this more or less universal "zone" and about the Ammonites found in it, an attempt had to be made to trace the interrelations of the numerous keeled Ammonites of the Gault and their ranges in time. Some new genera are proposed in addition to a classification of the Hoplitids in general, and a subdivision of the various horizons of the Upper Albian is offered. The specific descriptions deal with sixty different forms belonging to twelve genera. Some of these represent new, indeterminable, or doubtful species; but the genus to which *A. inflatus* itself belongs includes 50 per cent. of the total number of specimens. An analysis shows that half the number represent local types, some also occurring in the Albian of North Africa; but all the types common with Madagascar and India also occur in the European Gault—that is to say, what intermixture of Indian or American elements there is must have taken place *via* Thetys. The Ammonites do not include a single Cenomanian form. Some new facts of importance obtained from the study of various unworked collections in the British Museum from Angola, Nigeria, South and East Africa, and other localities are incorporated in this paper.

PARIS.

Academy of Sciences, November 29.—M. Henri Deslandres in the chair.—H. **Le Chatelier**: The phase rule. Some recent criticisms of the phase rule are based on misconceptions. A summary of Gibb's demonstration is given and some particular cases are examined in detail.—C. E. **Guillaume**: Cause of the instability of nickel-steels: its elimination (see p. 545).—C. **Sauvageau**: New observations on *Ectocarpus padinae*. The megaspores of this parasite on *Padina pavonia* can live and reproduce outside the plant acting as host; an alternation of generations between a summer parasitic plant and a winter plant of independent life is not improbable, although as yet unproved.—M. J. L. Breton was elected a free Academician in succession to the late M. Ad. Carnot.—R. **Birkeland**: The solution of the general equation of the fifth degree.—B. **Gambier**: The imaginary application of two real or imaginary surfaces. The corresponding real cyclic systems or triply orthogonal systems.—G. **Reboul**: A new property of substances feebly conducting electricity. If a photographic plate is covered with a sheet of black paper and placed in a dark box, and if two insulated electrodes with a potential difference of 1000 volts are brought into contact with the paper for a period of twenty-four to forty-eight hours, on developing the plate the fibres of the paper are found to be reproduced, and the equipotential lines also appear. If the paper is divided, or replaced by a sheet of metal or of mica, the effect is *nil* or confined to the electrodes. The effect can be modified by altering the conductivity of the sheet of paper.—S. **Procopiu**: The electrical dichroism of smoke and the dichroism of diffraction gratings.—S. **Posternak**: The constitution of the paramolybdates.—R. **Cornubert**: The spectrochemical study of the α-allyl and α-allylmethyl*cyclo*hexanones. The results are in agreement with the theory of Auwers on the influence of the double groups on the value of the molecular refraction.—C. **Dufraisse**: Remarks on the so-called dibenzoylmethane of J. Wislicenus. The author considers that the substance regarded by J. Wislicenus as dibenzoylmethane is, in reality, an ethylene oxide of the constitution

$$C_6H_5.CH-CH.CO.C_6H_5.$$
$$\diagdown O \diagup$$

—P. **Landrieu**: Researches on the acid and polyacid salts of monobasic acids: the potassium and lithium dibenzoates.—Mlle. Augusta **Hure**: The Lutecian limestone in the Yonne.—E. **Passemard**: The persistence of *Rhinoceros Mercki* in an Upper Mousterian deposit in the Basses-Pyrénées.—A. **Guilliermond**: New researches on the vacuole apparatus in plants. The vacuolar system in the embryonic cells of the higher plants frequently presents forms resembling mitochondria. These pseudo-mitochondrial forms do not show the histo-chemical characters of mitochondria, and should be definitely separated from the chondriome. The author considers the views of M. Dangeard with regard to the relation between these forms and the chondriome of the animal cell as erroneous.—L. **Daniel**: Researches on the grafting of Solanum.—L. **MacAuliffe** and A. **Marie**: The anthropometric study of 127 Spaniards.—M. **Baudouin**: The variations in the flattening of the tibia in infants and adults of the Neolithic races.—A. **Pézard**: Intrapuberal castration in cocks and the generalisation of the parabolic law of regression.—F. **Vlès** and J. **Bathellier**: The numerical laws of the pedal waves in the movements of Gasteropods.—P. **Wintrebert**: The comparative value and the determinism of the principal signs of aneural myotomic contraction observed in the embryos of *Scylliorhinus canicula*.—G. **Truffaut** and N. **Bezssonoff**: The characters common to the β bacterium, symbiotic with *Clostridium pastorianum* and *B. aliphaticum non liquefaciens*. The development of these two bacteria suggests that they belong to similar races, possibly to the same race.—G. **Odin**: A new method for the diagnosis of syphilis. Serum from the blood of the subject is mixed with physiological serum and a small proportion of sodium fluoride. The serum thus produced when injected into the patient increases all the syphilitic symptoms and makes a certain diagnosis. The method has been applied to more than a hundred cases without a single failure.

The Nile, Egypt, and the Sudan.

THE latest publication of the Public Works Ministry of Egypt is of more than usual interest, for it not only appears at a time when work is being resumed after being stopped, or at least largely restricted, during the war, but it also sets forth a large collection of data relating to projects which have met with criticism in some quarters during the last three years. A year ago the Nile Projects Commission was appointed to report upon the physical data upon which the engineering plans were based, and this Commission has now unanimously accepted Sir Murdoch MacDonald's evidence and approved his designs for the series of irrigation works described in the report before us.

A small amount of rain falls annually on the Mediterranean shore of Egypt, but this diminishes rapidly as we go southwards, so that it is of no value to agriculture, except for the winter crops raised by nomad tribes west of Alexandria. All the water that the increasingly intensive cultivation of Egypt demands must be supplied by the Nile, and recent surveys have established that there are about 7½ million acres which can be perennially cultivated if the necessary water is forthcoming at all seasons.

Fed by the summer rains on the Abyssinian tableland, the Nile begins to rise in Egypt in June, and reaches its maximum level in September, after which it falls slowly, the contribution of the White Nile delaying the reduction of the levels to a very appreciable extent. The task, therefore, of those in whose charge the control of the Nile water rests is to utilise the surplus water of the flood or of the river in the early stages of its fall in order to supplement the supply in the early summer, when the discharge is wholly inadequate to meet the demands of agriculture. From 1886, the earliest year for which statistics of the cultivated areas are available, there has been a steady increase in the area perennially cultivated, until now the area is greater by one-third, or more than a million feddans,[2] than it was in 1886 As some land is double-cropped, the total crop area now requiring water is somewhat more than 7½ million feddans.

While this rapid extension of the area under cultivation has been taking place, the population of Egypt has been increasing at a notable rate, and while it stood at 7½ millions in 1886, it numbered 12¾ millions in 1917; consequently, the cultivated area per head of population, which in 1886 was 0·65 feddan, in 1917 was 0·42 feddan, and the crop area had fallen from 0·89 feddan to 0·60 feddan. Thus one result of an improved administration of the country has been to increase the demands upon its irrigation in much the same proportion as new projects could be designed and carried out.

For the first decade after the reconquest of the Sudan in 1898 the lands bordering on the Nile and those areas where the summer rains made cultivation practicable sufficed for the support of the population which remained after fifteen years of Dervish rule. In 1903 experiments were made to test the feasibility of producing, with the aid of irrigation, crops suitable for export, such as wheat, sugar, and cotton; and the area which might be so cultivated in the Sudan was fixed at 10,000 feddans, an amount which was increased to 20,000 feddans when the Aswan Dam had been raised to its full height. It was now evident that the Sudan could in time utilise a much larger area of the fertile Gezira, the tract between the Blue and White Niles, if sufficient water could be taken from the Nile without prejudicing the supply required by Egypt; and the projects now described, which have been in preparation since before the war, have been designed to supply water for an area of 300,000 feddans in the Sudan, while safeguarding at the same time Egypt's requirements.

Accurate gauging of the volume discharged by the Nile at all stages was of the first importance,

[1] "Nile Control." By Sir Murdoch MacDonald, Adviser, Ministry of Public Works, Egypt. (Cairo: Government Press, 1920.) Price 20 P.T.

[2] A feddan is equivalent to 1·038 acres.

and much criticism has been directed against the tables of discharge which the Public Works Ministry has published; but there are no valid grounds whatever for doubting their correctness, and the accounts given of the rating of current-meters in this report, the accuracy of the discharges measured with them, and the method of measuring the volume discharged through the sluices of the Aswan Dam, show that the greatest care has been taken to obtain as high an accuracy as possible. The report of the Nile Projects Commission, which has just been issued, affords a complete vindication of the accuracy of these measurements.

In the early days of the British occupation of Egypt the reorganisation of the irrigation of the country was recognised as being of the first importance, and every improvement that was achieved produced large returns in the shape of increased economic prosperity. But as the margin of possible improvement grew narrower with each advance, greater precision of measurement became necessary, and for some years a special branch of the Public Works Ministry has been engaged upon the scientific investigation of all the problems of Nile hydrography. The necessity for this was clearly shown in the exceptionally low flood of 1913, and in the consequent deficiency in the supply in the following spring and summer. The volume discharged by the river in this exceptional year was only 41,000 million cubic metres, whereas the total requirements of Egypt and the Sudan by 1955 are estimated to reach 56,000 million, so that additional works must be constructed, even though such an extraordinarily low flood occurs but rarely. The Blue and White Niles, from which this additional supply must be obtained, differ fundamentally in their hydrographic character. The Blue Nile, with a comparatively short course of approximately 1500 kilometres and a fall of 1400 metres, carries a heavily silt-laden flood past Khartum which may reach and even exceed 9000 cubic metres a second. The White Nile, on the other hand, has deposited most of its load in the marsh region of its upper reaches, or on the plains of the Sobat River, so that its waters are clear and can be stored in a reservoir; also the shallow valley of the White Nile, with its exceedingly low slope, allows a very large volume to be held up by a work of moderate height.

The present scheme provides both for a dam across the White Nile valley at a short distance upstream of Khartoum, and for a dam on the Blue Nile near Sennar. The site selected for the White Nile dam is at Gebel Aulia, 45 kilometres upstream of Khartoum, where the valley is wide and shallow. A continuous masonry dam 5 kilometres long and further extended by 1½ kilometres of an earthen dam with a masonry core wall will hold up the waters of the White Nile to a height of 8 metres above summer river level, and to 9·5 metres in years of high flood; it will thus provide an additional 4000 million cubic metres of water for the development of Egyptian agriculture and for the reclamation of the northern shore of the Delta; it will also act as a protection work in high floods by holding up water until the crest of the Blue Nile flood has passed and the White Nile water can be released without danger. Evaporation over the surface of the reservoir which will be formed by the dam will be large, for the maximum area is 540 square kilometres, and observations show that it will amount to 11 mm. per day in April, and to 2·4 mm. in the rainy season when allowance has been made for the rainfall. The loss by absorption over the area of the reservoir must also be considerable, and 1 cubic metre of water per square metre of surface has been allowed for this.

For meeting the requirements of the Sudan, a dam is proposed on the Blue Nile near Sennar, and the one which has been designed will be a solid masonry structure of granite, with sluices and spillways sufficient to discharge 15,000 cubic metres per second. By the control which this dam will afford, such water as is needed for use in the Gezira can be withdrawn from the Blue Nile from July 15 to January 18, after which the reservoir upstream of the dam will supply the further requirements of the Sudan in order that the water flowing in the Blue Nile may pass on to Egypt without diminution.

The data relating to both these schemes are set out fully in the report, from which the amount of water which is required for the agricultural development of different regions at each season can be seen, and the provision for meeting these requirements by means of the storage and control provided by the dams at Aswan, Gebel Aulia, and Sennar can be readily examined.

Some subsidiary works will be needed, and one of these is a barrage at Naga Hamadi, in Upper Egypt. One effect of filling the new storage reservoir by means of the White Nile dam will be to lower slightly the maximum of the flood at Aswan, and, consequently, to make the watering of the higher lands of Upper Egypt more difficult. The conversion of land in this part of

Egypt from basin to the perennial system of irrigation is now due, and to meet these needs this barrage will have to be constructed.

Besides these works which are about to be constructed on the Blue and White Niles, two other projects of which the need in the future can be foreseen to complete the control of the Nile supply are briefly discussed. One of these is the Lake Albert dam, by means of which it is proposed to hold up a reserve store of water in the Albert Lake, which will be conveyed to the White Nile by a channel or channels so planned as to avoid the loss of water which now takes place in wide, shallow valleys where the sadd marshes are situated. The other scheme, which is even more briefly outlined, is the provision of a dam on the upper reaches of the Blue Nile to store 7000 million cubic metres of water, of which part would be kept as a permanent reserve in case of low floods, and the balance used to irrigate the cotton crop on one-third of a million feddan area in the Sudan. Nothing has yet been done on either of these projects, and no details are published in the report; they are only indicated as works which must eventually be undertaken to provide the necessary water for agriculture in arid and semi-arid areas of the Nile basin.

The report contains a large amount of valuable information on the utilisation of water under the special conditions which prevail in Egypt. The requirements of agriculture are fully stated by the responsible authorities of Egypt and the Sudan; detailed estimates of the amount of water which is available at various seasons are also given as the result of a long series of measurements which have been made in recent years. This collection of hydrographical data brings those which were previously available up to date, and supplements them by much information of greater accuracy on which the present projects have been based.

With a rapidly increasing population the occasional occurrence of such disastrously low floods as that of 1913 has carefully to be guarded against; on the other hand, the growing demands of cultivators in Egypt, and the needs of the Sudan, which will be increasing for years to come, call for the most careful investigation of the hydrography of the Nile, for, while the supply of water is shown to be sufficient to meet all anticipated requirements, this can be done only by a full control of the supply and a careful regulation at all seasons by suitable works.

Poynting's Scientific Papers.

Collected Scientific Papers. By Prof. J. H. Poynting. Pp. xxxii+768. (Cambridge: At the University Press, 1920.) Price 37*s.* 6*d.* net.

THESE papers make a stately volume of considerably more than 700 pages, and our thanks are due to the editors, Mr. Guy Barlow and Dr. Shakespear, for the ability with which they have performed their work, a work which, as old pupils of Poynting, must have been to them a labour of love. The volume contains an excellent portrait, and the type, paper, and binding are worthy of the Cambridge University Press. I think everyone, even though he may have thought himself well acquainted with Poynting's work, will find here something which he sees for the first time, for the volume includes not only papers from such normal sources as the Transactions and Proceedings of the Royal Society and the *Philosophical Magazine*, but also others from the *India Rubber Journal*, the *Hibbert Journal*, the "Encyclopædia of Biblical Literature," the *Mason College Magazine*, and the *Inquirer*. In addition to the classical papers on the flow of energy in the electromagnetic field, on the pressure of light, and on the density of the earth, there are others on the drunkenness statistics of the large towns, on the fluctuations in the price of wheat, on the experiences of one who overtook the waves of light, a criticism of Herbert Spencer's "First Principles," and a paper on physical law and life. To those who knew Poynting, these informal papers have a special charm, for they will find in them much that will recall memories of long-past talks; they recall his quiet humour, the freshness of his views, his courtesy in debate, his dread of saying or doing anything that could hurt the feelings of anyone who did not hold his own views on the point at issue. Among the seventy papers in this book, there are not more than two or three that could be called controversial, and it is characteristic of these that he criticises his opponent as if he loved him; and, even when the author under notice has laid himself more than usually open to criticism, Poynting is not content with pointing out the unsoundness of his statements; he suggests that he must really have meant something else, something much more reasonable.

Another feature of the book is that running throughout the papers is a view of the philosophy of physics which is now very prevalent, but which Poynting was one of the first in this country to adopt. This view is summarised in the paper on "Physical Law and Life"; and though this paper was not published until 1903, he had then held the views expressed in the following quotation for a long time:—

"I have no doubt whatever that our ultimate aim must be to describe the sensible in terms of the sensible. But I see, too, what gulfs there are still separating one part of our knowledge from another, and I see no harm in throwing temporary bridges of hypotheses across these detached gulfs to connect what would otherwise be detached regions. They allow us to pass to and fro with ease, and have been, and are, of enormous help to us in our exploration of Nature. But we must bear in mind that we may have many types of connecting bridge, many forms of hypothesis equally serviceable, all perhaps to be broken down and abandoned when we have filled in the gulfs which they crossed, and have made firm roadways built of sensible fact."

As another illustration of the modernness of his point of view, I may take a sentence from his address as president of Section A at the meeting of the British Association at Dover in 1899:—

"Another illustration of the illegitimate use of our hypothesis as it appears to me is the attempt to find in the ether a fixed datum for the measurement of material velocities and accelerations, a something in which we can draw our co-ordinate axes so that they will never turn or bend. . . . We could only fix positions and directions in the ether by buoying them with matter. We know nothing of the ether except by its effects on matter, and, after all, it would be the material buoys which would fix the position, and not the ether in which they float."

Poynting's scientific work concentrated in the main on three subjects: the flow of energy in the electromagnetic field, researches on gravity, and on the pressure of light. It is by the first of these that he is perhaps most widely known, and with which "Poynting's vector" will always associate his name. It was Poynting who introduced the idea that the energy in the electromagnetic field flows in the direction of a vector now known as "Poynting's vector," which is at right angles to both the electric and the magnetic forces, the rate of flow being proportional to the product of these two forces and the sine of the angle between them. Thus, whenever there are both electric and magnetic forces, there is flow of energy unless the two forces are in the same direction, and wherever there is flow of energy there are both electric and magnetic forces.

The importance we attach to this result will depend upon the view we take of the localisation and identification of energy. If we confine ourselves to the dynamics of a system of bodies acted upon by assigned forces, we may regard the kinetic and potential energies of the system as names for certain functions of the velocities and co-ordinates of the bodies which satisfy a sufficient number of equations to enable the co-ordinates of the system to be determined at any time if the co-ordinates and velocities at some previous time are known. The idea of localisation of energy is foreign to this point of view, for the amount of kinetic energy possessed by any member of the system will depend upon the choice of axes to which the velocities are referred, while when we regard the potential energy of two charges separated by a distance r as $-ee'/r$, the idea of localisation of energy is unmeaning and immaterial. When, however, we discard the idea of action at a distance, and regard the space between bodies as the seat of the influences they exert on each other, the question of the localisation of energy at once becomes prominent. Thus, to take a definite case, we may regard all energy as molecular in structure, and made up of a large number of units, all the units possessing the same amount of energy, and the energy of each unit remaining unchanged as the unit moves about. Thus the amount of energy in any region is proportional to the number of units of energy in that region, and changes in this amount are due to the motion into or out of this region of units of energy. From these points of view the motion of these units is what governs the behaviour of the system, and the flow of these units is represented by Poynting's vector. Poynting's work on the pressure of light and his determinations of the density of the earth by an ordinary balance are great tributes to his skill and insight as an experimenter. The method with the ordinary balance is, as he himself acknowledges, inferior to that employed by Boys, and yet Poynting was able to get, by care and skill, a result comparable in accuracy with that obtained by the better method.

Poynting's experimental skill and his power of devising simple apparatus which could be made in the laboratory and yet give results of the highest accuracy were quite remarkable, and the simplicity of the means by which he got his results was not surpassed either by Stokes or by the late Lord Rayleigh.

To read through everything that a man has published during forty years of scientific work, extending over a period remarkable for new discoveries and the introduction of new ideas, is a severe test for his reputation; it might be expected that much would seem musty and out of date; this, however, is not so with Poynting's papers, for in them there is little or nothing which in any way conflicts with modern ideas.

Poynting's researches, important as they are, form but a part of his life's work. He was a very successful teacher, and as professor of physics at Mason's College from its foundation he created and developed the flourishing school of physics at the University of Birmingham. He took his full share of the large amount of business and organisation required to carry on the work of his university and the scientific societies with which he was connected, and as a magistrate he took part in the civic life of Birmingham. Everyone who met him in these capacities found him the most delightful and courteous of colleagues, while to many he was the beloved and valued friend. J. J. THOMSON.

Scottish County Geographies.

(1) *Banff and District.* By Allan Edward Mahood. Edited by Dr. E. I. Spriggs. Pp. xvi+388. (Banff: *The Banffshire Journal*, Ltd., 1919.) Price 10*s.* 6*d.*

(2) *Orkney and Shetland.* By J. G. F. Moodie Heddle and T. Mainland. Pp. xii+167. (Cambridge: At the University Press, 1920.) Price 4*s.* 6*d.* net.

(3) *Caithness and Sutherland.* By H. F. Campbell. Pp. ix+168. (Cambridge: At the University Press, 1920.) Price 4*s.* 6*d.* net.

(4) *Kirkcudbrightshire and Wigtownshire.* By William Learmonth. Pp. ix+149. (Cambridge: At the University Press, 1920.) Price 4*s.* 6*d.* net.

(5) *Dumbartonshire.* By Dr. F. Mort. Pp. viii+155. (Cambridge: At the University Press, 1920.) Price 4*s.* 6*d.* net.

(1) DR. MAHOOD'S "Banff" belongs to the best class of local guide-book. It is the result of a careful study of the area by a number of enthusiastic students; the bulk of the material has been collected by Dr. Mahood, of Duff House Hospital. Chapters have been contributed by various local authorities, and the whole has been condensed and edited by Dr. E. I. Spriggs, and its stores of information are rendered accessible by an excellent index. The book is a compendium of the geography, history, and antiquities of the district, and should add greatly to the profitable enjoyment of a stay there by any intelligent visitor; and, as it gives practical guidance to the special points of interest, it should stimulate the study of the local archæology and natural history.

The walks around Banff are classified according to their length, and the programme of longer excursions refers to the numerous antiquities and to such features as the musical sands, the dunes of Culbin, and the remarkable southerly deflection of the plumb-line at Cowhythe, which would indicate a position nearly a fifth of a mile in error. Banff Museum is rich in local material, and the chapter on it is a useful introduction to the local archæology and history. Banff was the home of Thomas Edwards, the self-made naturalist with the Smiles-made reputation, who, amongst other contributions to science, demonstrated that the shell beds on the 25-ft. raised beach at Boyndie is a Neolithic kitchen-midden.

The geology of the area includes much of interest, and special attention has been recently directed to it by Mackie's discovery of the plant-bearing cherts of Rhynie, which have been proved by the researches of Kidston and Lang to be the oldest known land flora, and to contain, exquisitely preserved, the plants of the period when land was being first clothed with vegetation. The discovery of this flora is the most epoch-making in palæobotany in recent years. The account of the geology is well up to date; it recognises the Old Red Sandstone as a river-made deposit, but that view need not have been assigned to America, as it had been previously advanced in this country. A remark on the work of Prof. Jehu and D. Campbell on the Highland Border Series may be misunderstood as implying that some of the Highland schists have been thus proved to be Lower Palæozoic, whereas that work strongly strengthens the case for the pre-Palæozoic age of those schists.

(2–5) The volumes of the Cambridge University County Series suffer in contrast with that on Banff by the absence of references, as even a short bibliography would be of great assistance to the students for whom these admirable manuals would be of special service. Moreover, the one author deals with all branches of the subject—history, geography, archæology, ethnology, geology, natural history, and economics—and has to write on some questions with which he is not fully familiar. Consistency between the manuals and complete accuracy are possible only by editorial supervision. In this series the authors appear to be given entire independence provided they conform to the prescribed plan.

A student who turns to these volumes to compare the evidence on some question from different parts of Scotland finds puzzling inconsistencies. Thus the circular megalithic towers known as brochs, the most remarkable of Scottish antiquities, are attributed in the account of those in Caithness and Sutherland to the early Iron age, and therefore to be pre-Roman; whereas the volume on Orkney adopts the older and less probable theory that they were built as shelters against

Norse vikings, and would therefore be post-Roman. The advantage the volumes would gain from expert supervision may be illustrated by the sections on geology. Thus the Old Red Sandstone is still attributed in the volumes on Orkney and Shetland and on Caithness and Sutherland to lakes, whereas the work on Banff adopts the fluviatile explanation. The table of the geological succession in Caithness and Sutherland (pp. 13–15) states that the Upper Trias is absent from England, and that the Upper Cretaceous consists of "chalk and ware," whatever "ware" may be. The summary of the Carboniferous suggests an erroneous correlation of the English and Scottish divisions; the metamorphic rocks and schists are described as Silurian and Ordovician, and as younger than the Cambrian quartzites; while the discovery of Olonellus in beds above the Torridon Sandstone did not "fix the age of the Cambrian," but fixed those beds as Cambrian. The geological map of Kirkcudbrightshire and Wigtownshire omits the Permian of Loch Ryan, and marks the Permian Sandstones west of Dumfries as "blown sand and alluvium." The rainfall maps of Scotland in different volumes present marked differences in fact.

The four new volumes cover areas representative of the chief geographical types in Scotland—the highlands, the industrial localities of the Midland Valley, and the agricultural districts of the southern uplands—and the authors express clearly the characteristic features of the districts.

The Orkneys and Shetlands are the most exceptional area in the British Isles, which is differentiated by geographical structure, by the far northern position which led to the occasional visits of walrus until the destruction of the Spitsbergen herds, and by the Norse influence to which St. Magnus Cathedral is a striking witness. The population is pure Norse, except for the modern immigration of lowland Scots. The archipelagoes are graphically described by Messrs. Heddle and Mainland.

The recent story of Sutherland and Caithness is one of the saddest in the British Isles. Sutherland is the fifth in size of Scottish counties, and has the sparsest population of any British county. Its population reached its maximum in 1851, and that of Caithness continued to increase until 1861. There was a slight decline until 1871; then with the great extension of the deer forests followed swift and steady decline. Mr. Campbell describes Sutherland as "a desolate wilderness," and says that "one can behold in every direction miles upon miles of country destitute of any sign of human occupation." One result of the depopulation is the increasing difficulty in administration. The outlay on the roads, according to Mr. Campbell (p. 149), now amounts to an eighth of the total rental of the county. Roads suitable for local needs are quite unable to withstand motor traffic, and the upkeep of 500 miles of road at modern standards is beyond the local resources. The financial problems of the county are still unsolved.

The Galloway country, including Kirkcudbrightshire and Wigtownshire, the two southernmost counties in Scotland, presents problems of a different order. The one industry is farming, and mainly dairying; it is the home of the famous Galloway cattle. Farming has been greatly improved by co-operative systems, of which two local varieties are kaneing and bowing. In both the farmer provides land, stock, equipment, and fodder; labour is supplied by his associates, who take the produce and pay for the use of the cows, the kaner in cheese, and the bower in cash. The development of central butter and cream factories, which pay the farmers on the basis of the quantity of butter-fat in the milk supplied, is a more familiar co-operative method, and is proving very helpful.

The volume on Dumbartonshire, by Dr. F. Mort, is most attractively written, and especially good on the physical geography, although that subject is unusually difficult, as the county consists of three very dissimilar areas. It is part of the district known as "the Lennox," and it would have made a more natural geographical unit if it had been combined with Stirlingshire. The western part is an irregular strip of land running across the grain of the country, and its structure can be understood only by reference to the adjacent counties. The most important parts are that along the north bank of the Clyde from Loch Lomond to the western suburbs of Glasgow, and the detached eastern portion which extends south of the Kelvin further east than Stirling. It is owing to the industrial activity of these two areas that the population of the county, in spite of its sparseness in the rest, is fifty-seven times as dense as that of Sutherland, and has been growing at an accelerated rate from the decade when the Highland counties began their decline.

Dr. Mort discusses the proposed Forth-Clyde Ship Canal, and though the text refers to the Kelvin Valley route, which is that regarded with most favour in Glasgow, the only route marked on the sketch-map as for a ship canal is that through the Forth Valley. With present costs of labour and material, the estimate quoted would be quite inadequate, and a canal large enough to fulfil its proposed functions is probably at present financially impracticable. J. W. GREGORY.

Conifers.

Conifers and their Characteristics. By Charles Coltman-Rogers. Pp. xiii + 333. (London: John Murray, 1920.) Price 21*s*. net.

CONIFERS, like ferns, stove-plants, orchids, alpines, and the ignoble carpet-bedding, have had their high tide of popularity. The fashion for them owed its origin chiefly to the work of the collectors Jeffrey and William Lobb in western North America in the middle of last century, and to that of John Gould Veitch in Japan in the early "sixties." From these areas, especially the former, our gardens have obtained their noblest conifers. We are told that, from fifty to seventy years ago, so keen was the desire to plant them that many beautiful flowering trees were destroyed to provide the necessary space, and that gardens in general lost much of their brightness and seasonal charm by the displacement of deciduous trees in favour of the heavier, gloomy, unchanging conifers. Inevitably, the craze came to an end, for a good proportion of them were found to need particular conditions which many localities where they were planted did not provide; and there is no more distressing object in the garden than a sickly conifer. In course of time the pendulum swung so much in the opposite direction that conifers in recent years have been overmuch neglected.

To one who contemplates a serious and exhaustive study of the group, Mr. Coltman-Rogers's book cannot be regarded as anything more than a *hors d'œuvre*; but it is admirably adapted to stimulate a budding interest in these trees, and that probably was the author's chief aim. For this reason it would be scarcely fair to grumble at its shortcomings from the scientific point of view. At times Mr. Coltman-Rogers is apt to be discursive, not to say garrulous, but, on the whole, his gossip is pleasant and humorous, and his book will find many readers who would be repelled by a more technical work. It certainly contains much solid information, and the careful reader will find many curious and interesting peculiarities of the species pointed out which, unaided, he might very easily overlook. No detailed descriptions are given, but the last forty pages are devoted to a series of tables which contain a great deal of accurate information in condensed form; these will be a useful help in identifying species, and especially in differentiating those which are closely allied.

The book suffers from careless proof-reading, and the reader is apt to be irritated by the number of errors, trifling though they may be. On p. 97, for instance, the Douglas fir is said to have been discovered by Menzies in 1792 and introduced in 1828; and then overleaf the respective dates are given as 1791 and 1827. It was not necessary to repeat the information, but at least the two accounts should tally. Kaempferi is spelt "Kaemferi," which jars one with whom the golden larch is a favourite tree. The invariable use of capitals as the initial letter for specific names is contrary to accepted practice, but perhaps the author has his private reasons for this.

On the whole, the book is pleasant and instructive, admirably printed, and light to handle, and may be recommended to those who contemplate the planting or study of one of the noblest and most interesting groups of the world's trees.

Physiology for Students and Practitioners.

A Text-book of Physiology: For Students and Practitioners of Medicine. By Prof. Russell Burton-Opitz. Pp. 1185. (Philadelphia and London: W. B. Saunders Co., 1920.) Price 32*s*. 6*d*. net.

TO add to the already numerous text-books on physiology is presumably to have the conviction that one is supplying what is lacking in those already in existence. The striking thing about Prof. Burton-Opitz's "Physiology" is that its author makes no such claim. In the first edition of a new book a claim for being really up-to-date would perhaps have been its best for recognition at a time when even some of the better-known books are somewhat delinquent in this respect.

If the author aspires to anything, it is to brevity, although his book has some 1140 pages of text. His object has apparently been to collect all the classic facts and theories and put them into new words. In this he has succeeded admirably, and his book, on the whole, compares well with its rivals. On controversial subjects he states fairly the different aspects of the case, and no pains have been spared in collecting facts and ideas for which free acknowledgment is made of the obvious debt to other text-books. The book reviews the whole subject in the most comprehensive manner. The greatest zeal for the explanation of phenomena is shown; indeed, to the physiologist there is just a suspicion of unnecessary explanation; but, on the other hand, the giving of elementary facts renders the book all the more readable by students commencing the study of the subject or by practitioners who have forgotten such matters. Students, however, using the book in preparation for examination should be warned that principles are more important than data. The giving of references at the bottom of each page is excellent, but, although it is realised that a full bibliography is impossible, fuller references to the more recent work, especially in regard to the nervous system, would have been a distinct advantage.

The logical way in which the facts are put forward, the short allusions to the history of the subject and to comparative physiology, together with a freedom from any attempt to compile a book for examination purposes, will recommend it to the purely scientific worker.

Generally, the book is well written and produced, but the language, which contains many Americanisms, leaves no doubt as to its nationality, and does not enhance its literary value. The author does not acknowledge any help in the preparation of the volume, which must have entailed an enormous amount of work. We congratulate Prof. Burton-Opitz on its completion, and wish his excellent and ambitious text-book every success.

Our Bookshelf.

The Planting, Cultivation, and Expression of Coconuts, Kernels, Cacao, and Edible Vegetable Oils and Seeds of Commerce. A Practical Handbook for Planters, Financiers, Scientists, and Others. By H. Osman Newland. (Griffin's Technological Handbooks.) Pp. vi + 111 + xi plates. (London: Charles Griffin and Co., Ltd., 1919.) Price 6*s*. net.

Mr. Newland scarcely gave himself a fair chance when, to quote his introduction, he was "prevailed upon to issue as a separate book the chapters on 'Ground Nuts,' 'Palm Oil and Kernels,' 'Cacao,' and 'Shea Nuts,' which originally formed part of a volume on *West Africa*." In doing this he has added chapters on coconuts and other edible oil-nuts found throughout the Empire, and has adopted for the whole a comprehensive title, the promise of which it would require unusual skill in compression to fulfil in a book of 111 not very closely printed pages. Moreover, the space at the author's disposal is not well distributed; thus the important oil-seeds soya bean, cotton-seed, and sesame are disposed of in one chapter of seven pages, whilst an equal number of pages are given to reprinting Imperial Institute reports on strephonema, n'gore, n'kamba, n'kula, kamoot, and dika nuts. Interesting though these products may be, they are not of commercial importance at present, and reference to them is out of place in a book of this description. The illustrations are the best feature of the volume. T. A. H.

The Flora of Chepstow. By W. A. Shoolbred. Pp. x + 140. (London: Taylor and Francis, 1920.) Price 10*s*. 6*d*. net.

In number and quality the local Floras of this country probably excel those of any other, and afford a satisfactory measure of the enthusiasm with which systematic botany is pursued by British naturalists, including a large number of amateurs who are wholly free from any stigma of superficiality.

Indeed, the greatest authorities on the species of the British flora are nearly all amateurs, very few professional botanists, outside the great museums, having either the time or the inclination to devote themselves to this specialist study.

Among these authorities Dr. Shoolbred holds a place, and his "Flora of Chepstow" is a praiseworthy addition to floristic literature. The area of the lower Wye has long been a favourite hunting-ground among botanists, for its position and topography give it an uncommon richness.

While the author takes a thoroughly exclusive view of the size of species, still, a list of 974 Angiosperms alone is pretty good for an area of, roughly, 65 square miles, now seriously threatened by industrialism.

The critical genera are fully treated, and Dr. Shoolbred has had the advantage of assistance from such men as Marshall and Ley in dealing with their many difficulties. Mosses are also included, a feature worthy of further resuscitation.

Electricity and Magnetism: Theoretical and Practical. By Dr. C. E. Ashford. Third edition. Pp. xii + 303. (London: Edward Arnold, 1920.) Price 4*s*. 6*d*.

The chapter on Röntgen rays which has formed a part of previous editions of this school text-book has been replaced in the present edition by one on the passage of electricity through gases. In this some account is given of the broad generalisations which have followed from the work of Sir J. J. Thomson and his school, and the application of these theories in the thermionic valve. A few articles have been rewritten, and an appendix on Ohm's law has been substituted for the original description of apparatus. The popularity and worth of this book are reflected in the fact that it has been through the printers' hands no fewer than thirteen times since the first edition was published in 1903, and during that period has been twice revised to meet new requirements of theory and practice.

A Text-book of Geology. By Philip Lake and R. H. Rastall. Third edition. Pp. xiv + 508 + xxxiii plates. (London: Edward Arnold, 1920.) Price 21*s*. net.

A complete revision of this standard work has been carried out since the first edition was reviewed in Nature for June 22, 1911. The account of coral reefs has been modified in accordance with modern theories, the chapter on ore-deposits has been rewritten, and sections on concretions, petroleum, and natural gas have been added to that on sedimentary rocks. In the stratigraphical section of the book the account of the Carboniferous system has been largely rewritten, and Mr. Rastall has contributed a new chapter on the history of igneous activity in the British Isles. Numerous other minor alterations have also been made.

Recent Advances in Organic Chemistry. By Prof. A. W. Stewart. With an introduction by Prof. J. N. Collie. Fourth edition. Pp. xvi+359. (London: Longmans, Green, and Co., 1920.) Price 21s. net.

ALTHOUGH the previous edition of this book was reviewed in NATURE so recently as in the issue for February 20, 1919, Prof. Stewart has written one new chapter, and made several additions to those already existing. The former directs attention to some of the problems which are still open to solution, such as the reason why carbon among all the elements is pre-eminent in its capacity for forming long atomic chains; the addition reactions of the aldehydes; molecular stability, etc. The chapter on polypeptides has received the addition of a section which attempts to trace in outline the connection between the synthetic materials and the naturally occurring proteins and their derivatives. A number of sections have also been added to various chapters with the object of bringing the book up to date.

Letters to the Editor.

The British Association.

LIKE Prof. Armstrong, I have followed with much interest the discussion about the British Association. I have had a long and intimate acquaintance with it, and have a strong affection for it. For one thing, it is so truly British—so far from perfect, yet so adaptable. I am not sure that my most earnest prayer for it is not that it may be saved from the reformer, especially the type of post-war reformer who threatens to organise, systematise, advertise, and Teutonise every British institution on which he can lay hands. It is surprising that no one has suggested the Association should be put under the Department of Scientific and Industrial Research.

I have heard the British Association abused all my life; my own Section has always been the worst that ever was and hopelessly mismanaged, except in the year when I was its president—at least, so I have always been assured. But all the time the British Association has been bringing me—a rustic—into the possession of troops of friends in all quarters of this country and of foreign lands. I have gained more scientific help from it than I can well acknowledge, and I am sure a vast number of my contemporaries will say the same.

As to the intelligent public, I doubt whether the Association ever did so much as some people affirm. It does a little, if only in letting a hospitable *bourgeoisie* see that men of science are well-meaning human beings, more like themselves than you would have supposed. At one period the Association fluttered the theological dovecotes and gave excellent copy for the Press. There has scarcely been a year in my time when the newspapers have not remarked ruefully that the president's address lacked the interest of Tyndall's at Belfast. It is not easy to see how the Association can give scientific enlightenment to those who have not even the elements of scientific knowledge. In these days it can scarcely hope to appeal to the Press except by its indiscretions.

I should be sorry to be open to any just taunt of unprogressiveness, and, indeed, I have read carefully and reflected upon all that has been said by your correspondents. But it is difficult to discern agreement on any clear and practicable plan of reform. The British Association is an organism, not a machine. It seems to me to have grown, and grown well—not overgrown. I would say: "Let it grow, my friends; most of you have had fair fruit from it. Let us be chary of root-and-branch reform." The Association is very flexible; a great deal must depend on the personalities of the men in charge. To be a local secretary at the elbow of the late Mr. George Griffith when he was arranging a meeting and managing his superior officers was a memorable and impressive experience. Everyone will be able to recall a run of success in a Section when an exceptional man had a spell of office as recorder. I am sanguine enough to believe that exceptional men, capable and disinterested, will still be found; and that if, as I am not prepared to admit, we are unfortunate at present, we may safely count on recovery.

Lastly, as to the masses, it should be remembered that science is not the novelty it was. It is astonishing how many of them have seen phosphorus burn in oxygen. Anyone who has been in the trade knows that the old type of science lecture for the people, when a serious effort was made to illustrate the methods and topics of science, is a drug on the market. You find yourself as powder among the jam of overt or covert entertainers. In this direction let us hope the Workers' Educational Association may bring about results that can never be attained by isolated popular lectures during a British Association week.

I trust that nothing in the foregoing may appear disrespectful to those who have expressed opinions on the same subject. It is, no doubt, of great value to have comments and suggestions from such competent observers. I have only intervened because it seemed to me that bare justice has scarcely been done to what is undoubtedly good and great in the Association as it stands, and to the ruling powers who have an exceedingly difficult task to perform.

ARTHUR SMITHELLS.

December 19.

Science and Fisheries.

No one will gainsay Mr. H. G. Maurice's fundamental premise (NATURE, November 25, p. 419) that scientific fisheries investigation is primarily a matter for the State—if the authorities have a due sense of their responsibility in selecting for the task scientific men whose training and ability specially fit them for the complex work. It has long been advised that the three centres of the kingdom should have an adequate scientific fisheries staff, at the head of which a trained scientific expert of wide views should be placed.

Under Mr. Maurice's second head it is asserted that statistics could not be secured, say by the Marine Biological Association at Grimsby or at any other port; but whilst there is no doubt that the best channel for these, as in the case of the Fishery Board for Scotland, is the fishery officers of the Government, Mr. Holt's work alone at Grimsby shows that the statement needs qualification. The excellent method of the Scottish Board, which was in 1884 inaugurated by Lord Dalhousie, should be followed. It would also be well that returns by all fishing crews should be sent to the central office through the same agents, as was recommended in the scientific Report on Trawling in 1884. Mere enumeration of the sizes of fishes on board the ships, however, is insufficient. The observers should take in the whole surroundings of the products of the areas so as to be able to contrast them with others. It is also uncertain if the proposed comparison of the yield of the North Sea with pre-war days will result in any trustworthy information. Nature is superior to any influences on that head, Dutch statements notwithstanding. Again, the fact that much of the supply of fish-food for the public of this country comes from extra-territorial waters should not be held as a reason for international co-operation in fishery researches. Friendly co-operation between Governments is right, but it does not seem to be necessary in scientific fisheries researches. Britain did not attain her pre-eminence in the sea-fisheries by international aid, nor will international co-operation help her to maintain that position. The work of the Dutch alone is a sufficient criticism on the supposed necessity for international co-operation.

Mr. Maurice thinks that science has not yet proved the ineffectual and unnecessary nature of the closure of areas of the open seaboard, such as the Moray Firth. He has still to study the work of the *Garland* and other ships, as well as various experiences since Lord Dalhousie's Commission. Instead of the view of the futility of one nation working alone at scientific fisheries work, it may be that this is just where progress can best be made; and, besides, fisheries publications rapidly spread information over the world. Moreover, fisheries investigations are best carried out at marine laboratories in the midst of fishing-boats and in touch with the sea. That Great Britain continued to subsidise the international scheme during the war is, perhaps, of less moment than it appears when the results (chiefly statistics of fishes collected at ports, compiled by subordinates, and treated by the chiefs on land) are duly weighed.

There is little fear of the serious depletion of the stock of fishes in the ocean, and less of man successfully adding to it. Again, little is to be gained by a fortuitous prophecy as to good or bad seasons. The fishes are there to be captured in their seasons, though there is still much to be learned about them in marine laboratories and on board fishing vessels. There are not a few points for investigation, for instance, to be found in criticisms of the International Council at its inception (1902–3). A perusal of the British fisheries from early times may also be suggestive.

Mr. Maurice is to be commended for his friendly view of independent fisheries research and of giving a wide margin to Departmental work. If the Secretary for Scotland in 1896 had embraced similar broad views, one laboratory at least where the pioneer scientific fisheries researches of this country were done would not have been closed to-day and the supply of trained young men for the Department cut off. Mr. Maurice's closing words are excellent, only a Council for the National Exploration of the Sea should be substituted for the International Council.

W. C. McIntosh.

I thank you for the opportunity afforded me of commenting on Prof. McIntosh's letter, and him for his friendly criticism. I may, perhaps, be permitted, without discussing all his points in detail, to develop somewhat my views regarding international co-operation in scientific research, which Prof. McIntosh has not, I think, quite understood.

I cordially endorse the statement that "Britain did not attain her pre-eminence in the sea-fisheries by international aid, nor will international co-operation help her to maintain that position." Britain will maintain her pre-eminence, I think, in the future, as in the past, by the enterprise of her fishermen and fishing-vessel owners. But their enterprise is directed solely to the catching and marketing of fish. The practical object of research, as I conceive it, is mainly conservation and development. I think we must admit that, under existing conditions, there is a real danger of the depletion of the fishing-grounds up to the point at which fishing will be unremunerative, with all the undesirable results which must follow from that state of things. Whether we seek to forestall the danger by mere restriction of fishing operations, or by measures of development, or by a combination of the two, what we shall in fact be aiming at is the practical application of the results of scientific work on fishing-grounds which are open to all nations. No such measures as are here suggested can be effective unless they have the support of all the nations which have access to fishing-grounds. Such support is most likely to be accorded as a result of partnership in investigations and of agreement as to the conclusions to be drawn from them. The International Council does not claim to be above criticism, but if the necessity for international co-operation be admitted, it is entitled to support until a more effective organisation for combined research can be substituted for it.

That is one aspect of the matter, but there is another. As a layman I am greatly impressed with the vastness and the complexity of the problems of the sea. In order to solve them it does not seem to me to be sufficient that the different nations should be working independently at scientific fisheries work. Where so wide a field is to be covered, co-ordinated effort in a concerted programme must surely be of unusual value; in some inquiries simultaneity of observations is, I understand, of great importance. "The view of the futility of one nation working alone at scientific fisheries work" is not one that I have expressed; and if I believed that there was a serious risk of national work being subordinated to the requirements of international agreement, I would not urge international co-operation. I do, however, hold strongly that the value of much of the work of each nation depends upon its co-ordination with the work of others and upon the fact that it is part of an intelligently concerted programme of joint investigations. Whether as an outcome of our investigations we shall eventually be able, not merely to conserve fisheries, but even to develop them, remains to be proved. I will not embark upon prophecy, but I know that some of my scientific friends believe that this end will eventually be reached.

In his opening paragraph Prof. McIntosh refers to the proposal to form a central scientific fisheries staff for the United Kingdom. He will be interested to learn that an arrangement has now for some time been in operation under which the staffs of the Scottish Fishery Board, the Irish Department, and the Fisheries Department of the Ministry of Agriculture and Fisheries meet at regular intervals to frame their scientific programmes and to report progress, and that these meetings are generally attended, to the great advantage of the work, by a certain number of the distinguished men of science attached to our chief marine biological stations.

I am not sure whether I am to understand that Prof. McIntosh holds that science has proved closure of areas of the open seaboard to be ineffectual and unnecessary. I have not consciously expressed an opinion upon this subject, because, as a layman, I am unwilling to rush in where even a scientific angel may be disposed to tread delicately. As a Government official I am discreet enough not to venture on a public discussion of the merits of so controversial a topic as the closure of the Moray Firth.

December 21. HENRY G. MAURICE.

Propagation of a Finite Number of Waves.

IT has been stated as a general proposition by physicists that it is impossible to propagate a finite number of simple harmonic waves without change of type, the reason being that the discontinuity of motion at the beginning and end of the train of waves cannot be represented by a simple sine or cosine function.

The proposition as stated is too general, and should be qualified. It would be true, however, to say that a finite number of simple harmonic waves cannot be propagated without change of type if the mean pressures in the wave-train and in the undisturbed medium are the same.

That a finite train of waves of unchanging type can actually be propagated in a medium in which the wave-velocity and group-velocity are the same may be seen from the following illustration:

Let the medium be enclosed in an indefinitely long pipe containing a piston on which a simple harmonic motion of amplitude a may be imposed. Let the medium and piston be at rest when the latter is in one of the *extreme positions*. If the motion is then started there is no discontinuity either in the velocity or in the acceleration. So long as the motion of the piston is maintained, simple harmonic waves are propagated through the tube in both directions, the mean pressure in one set being $p_0(1+a/\lambda)$ and in the other $p_0(1-a/\lambda)$, where p_0 is the undisturbed pressure.

At the moment when the motion is started the pressure on both sides of the piston is p_0, and this is the maximum or minimum pressure in each wave series, according as the direction of motion of the piston tends to dilate the medium or to compress it. The necessary increase and decrease of mean pressure in the two wave series are automatically supplied by the work done by the exterior force which must be applied to the piston to generate the successive waves. If the motion is stopped where the piston is in the same extreme position in which it was started, a finite number of simple harmonic waves are left travelling along the tube in opposite directions.

A. MALLOCK.

Solar Variation and the Weather.

MR. CLAYTON's representation in NATURE of December 9 that, apart from seasonal and diurnal changes, the "chief, if not the only," cause of weather change lies in solar variations overlooks an important source of variation in the atmosphere which could not be allowed for on the lines of his investigation. No one will dispute that if Mr. Clayton finally substantiates his correlation results, which have been severely criticised in America by Dr. C. F. Marvin (*Monthly Weather Review*, March, 1920) they will be of great value in forecasting deviations from the normal of particular elements, such as temperature and rainfall, in coming seasons. But they will not help us to foresee the actual *sequence* of atmospheric phases embodying the combination of all elements which we call weather; and it is the precise sequence of changes, not the departure of one or more elements from normal during a given period, which, after all, is the primary aim in weather forecasting.

It seems almost certain that however closely types may recur, the atmosphere is never twice in the same condition, and this, I believe, is a prominent conviction in the minds of those meteorologists with a lengthy experience of daily weather maps. If a series of phases in the circulation of the atmosphere be represented by $A_1 B_1 C_1 D_1$ . . ., it is conceivable that by an odd chance there might be a recurrence some time later of the particular phase A_2; but unless, which seems almost infinitely improbable, all the external forces acting upon the atmosphere at the moment A_2 are identical with those which were in operation at the moment A_1, there will be no cyclic repetition $A_2 B_2 C_2 D_2$ . . . to be maintained for a longer or shorter period. In place of the repeating cycle a very different series of phases might emerge; and it is on this principle that no two seasons are ever alike in the actual sequence of phases.

In other words, once set a fluid system like the earth's atmosphere in motion and change, it will possess an internal source of variability because identical dispositions of external forces never act upon identical phases. No doubt, with a sufficient number and quality of simultaneous observations, meteorologists could so diagnose the condition of the atmosphere as to be able to calculate what phase would grow out of a present phase a few hours later; but the prevision of distant phases, which is really at the root of the weather problem, seems at present quite impossible.

L. C. W. BONACINA.

27 Tanza Road, Hampstead, N.W.3, December 19.

Name for the Positive Nucleus.

WHILE the word "hydrion" does strictly express the meaning conveyed by the symbol H+, yet in the minds of chemists it connotes all those properties associated with its hampered state in solutions, especially aqueous solutions. Even if hydrion is not hydrated like other ions, yet there is probably some sort of electrical double layer which modifies its properties. The "wet" physical chemist might abandon his term "hydrion" and the symbol, recognising that the real hydrion (H+) will have entirely different properties if ever these are known. He is in possession, however, and is not likely to do this unless, perhaps, some variant term, such as "hydro-ion," might be found acceptable. The alternative symbol H is, of course, already to hand, and, indeed, more widely used than H+, which could be left to the physicists.

In spite of these minor difficulties, it appears to me that Prof. Soddy's suggestion (NATURE, December 16, p. 502) should be acceptable to chemists, largely because it is provisional in character and avoids the multiplication of words and symbols. Although it expresses a view as to the ultimate constitution of matter which may not prove correct, yet it is only the existence of such a view which necessitates a word and a symbol. If the other words suggested are to be taken as entirely non-committal, then the choice of one is less important at present, and, if effected, the word will probably soon acquire different meanings when used by different schools of thought.

University College, Nottingham, December 18.

The Physical Meaning of Spherical Aberration.

MAY I correct an obvious mistake of mine which I notice in my letter on spherical aberration appearing in NATURE of December 9? The second expression for intensity should read:

$$I = \text{const} \times \left[\left\{ \int_{a=0}^{a=a_1} J_0(\alpha a) \cos \eta_a \, d(a^2) \right\}^2 + \left\{ \int_{a=0}^{a=a_1} J_0(\alpha a) \sin \eta_a \, d(a^2) \right\}^2 \right].$$

L. C. MARTIN.

Imperial College, S.W.7, December 17.

Man and the Scottish Fauna.[1]

IN undertaking an estimate of the manner and degree in which the fauna of Scotland has been affected and modified in consequence of human occupation, Dr. Ritchie has brought together a very large array of facts, and, on the whole, he is laudably cautious in deduction therefrom. He begins by an attempt to visualise what is now Scotland as it was when man first settled there. Here is plenty of room for speculation, and we cannot but think that some lines in the sketch are drawn more firmly than is warranted by the evidence.

The earliest traces of the primitive peoples in Scotland are associated with the so-called fifty-foot beach. Their canoes, simple dug-outs of pine, have been found at Perth in the Carse clays of this period, and frequently in similar deposits in the Forth and Clyde valleys (p. 9).

Among the very numerous canoes exhumed in Scotland during the nineteenth century (seventeen dug-outs have been recorded from the Clyde valley alone), not one has consisted of any material but oak, the only native timber that remains sound for an indefinite period; but, accepting "pine" as *lapsus calami* for "oak," is Dr. Ritchie justified in assuming such a high antiquity for these canoes? Passing on to p. 20, we get a glimpse of a landscape scarcely likely to produce either oak or pine big enough for a dug-out.

Partial and incomplete as our survey of early Scotland must be, it yet affords a reasonably accurate picture of the country when Neolithic man . . . founded his most northern settlements in the British Isles 9000 or more years ago. It was a country of swamps, low forests of birch, alder and willow, fertile meadows and snow-capped mountains.

A difficulty arises in the stress laid by the author on the 50-ft. beach as the cradle of the human race in Scotland. He never mentions the 25-ft. beach which, being thousands of years younger than the other, is far better defined and more extensively preserved, especially on the west coast. Take, for example, the shores of the Bay of Luce; while the 50-ft. beach can only be traced here and there in fragments, the 25-ft. beach runs unbroken for miles, forming the terminal moraine of the land ice, without any margin between its ancient high-water mark and the base of the ground moraine—a mantle of boulder clay in places 100 ft. thick. The difficulty consists in accounting for the existence of men, or at least for the preservation of their traces, in the older 50-ft. beach; whereas it is clear that the land ice was grinding over all after the elevation which formed the younger 25-ft. beach.

Passing to later times, Dr. Ritchie takes us on firmer ground, and will meet with no dissent from his proposition that the main factor in the extinction of some indigenous mammals and birds was the destruction of the primeval forest, the woodland which survived longest being consumed as fuel for iron-smelting in the eighteenth century. The squirrel has found its way back as plantations increased; so have the great spotted woodpecker and the jay; while the capercailzie, which became extinct towards the close of the eighteenth century, was successfully re-established at Taymouth in 1837–38, and now abounds in several counties. We still await the return of the beautiful green woodpecker (not mentioned by Dr. Ritchie), which Thomas the Rhymer listened to long ago on Tweedside.

FIG. 1.—Soay sheep—a primitive domesticated breed preserved only in Scotland. From "The influence of Man on Animal Life in Scotland."

> In a mery mornynge of Maye,
> By Huntle bankkes myself allone,
> I herde the jay and the throstle cokke,
> The mawys menyde hir of hir song,
> The *wodewale* beryde as a belle,
> That all the wode abowte me ronge.

While game-preserving is responsible for the disappearance of the polecat and the goshawk, our loss of the osprey and the erne must be laid to the account of egg-collectors. On the other hand, Dr. Ritchie enumerates many species of beast and bird that have increased with the ad-

[1] "The Influence of Man on Animal Life in Scotland: A Study in Faunal Evolution." By Dr. James Ritchie. Pp. xvi+550. (Cambridge: At the University Press, 1920.) Price 28s. net.

vance of agriculture—moles, for instance, and field voles, besides both insectivorous and grain-eating birds.

The author follows the late Dr. Günther in giving specific rank to what are now recognised as no more than local varieties of the brown trout

FIG. 2.—Cheviot sheep—a modern result of selective breeding (champion, Highland Show, 1914.) From "The Influence of Man on Animal Life in Scotland."

—*Salmo fario* (misnamed *S. trutta* on p. 278). The signal success which rewarded the acclimatisation of this fish in New Zealand was first achieved with trout, not from Lochleven, but from the Wooburn at High Wycombe. A few slips and misprints await correction in a future edition. Loch Askaig (p. 134) should be Loch Arkaig; Loch-an-Eilein on the same page appears as Loch-an-Eilan on p. 192, the correct Gaelic being Loch-an-eilain. Dr. Ritchie would probably wince if we were to write about "Northumberlandshire," just as we did when we read "Sutherlandshire" on p. 126.

Few of the numerous illustrations are worthy of Dr. Ritchie's interesting treatise. The beaver (Fig. 37) and the bittern (Fig. 64) are mere caricatures, and poor at that. Some of the figures, however, serve well to illustrate the influence of domestication and selective breeding upon primitive types of mammal, as in the case of the sheep. Although it may not be possible to define with precision the various species which have contributed to produce the modern breeds, sheep, though a race almost exclusively Palæarctic and Nearctic, are peculiarly liable to modification by food and environment, and are more plastic in that respect than cattle, horses, or swine.

While indicating some hesitation in accepting all Dr. Ritchie's conclusions, we congratulate him on his useful contribution to zoological literature, and we are grateful for the excellent index to the book.

Some Problems of Lubrication.[1]

By W. B. HARDY, F.R.S.

IN lubrication, a fluid or other body is used to decrease the friction between opposed solid faces. The lubricant may act in one of two ways. It may separate the faces by a layer thick enough to substitute its own internal friction, modified by the mechanical conditions in which it finds itself, for that of the solid faces; or it may be present as a film, too thin to develop its properties when in mass, which reacts with the substance of the solid faces to confer upon them new physical properties. In the latter case the solid faces continue to influence each other, not directly, but through the intermediation of the film of lubricant. There are indications that these two types of lubrication—one in which the solid faces intervene only owing to their form, rate of movement, etc., and not by their chemical constitution; the other in which the chemical constitution is directly involved—are discontinuous states in that one cannot be changed gradually into the other by simply thinning the layer of lubricant. The change from the one to the other is probably abrupt.

It may by no means be asserted that resistance to relative motion is always least when the solid faces are floated completely apart; it would, indeed, probably be truer to say of the best lubricants that friction is least when the "boundary conditions," to use Osborne Reynolds's phrase, are fully operative.

This address is concerned wholly with "boundary conditions," and we get directly to the heart of the problem by certain simple experiments. If a glass vessel, such as a bottle, is placed upon an inclined pane of glass at a certain angle it slips smoothly down. The glass plate is an ordinary plate cleaned with a cloth. In the usual sense of the word, the plate is not lubricated; the surface is "dry." The lower half of the plate is then wetted with water, and the bottle is now found to slip on the unwetted part, and to be pulled up sharply by friction when

[1] A Friday evening discourse delivered at the Royal Institution on February 27, 1920.

it reaches the wetted part. It is not sufficient, therefore, to interpose a liquid film between solid faces to get lubrication; indeed, as the experiment proves, water increases the friction; it is an anti-lubricant for ordinary faces of glass.

Is, then, the quality of lubricant a property of a fluid? Does water fail to act merely because it does not possess that property to which the name "oiliness" is sometimes given? Another simple experiment supplies the answer. Instead of a glass plate, let us use a plate of ebonite. The glass plate does not readily slip on this. The angle at which slipping occurs is steeper than when a glass plate is used. Now, when the lower half of the ebonite plate is wetted, it is found that a glass bottle encounters relatively high friction on the unwetted part, but slips quite freely on the wetted part. Water, in short, is an admirable lubricant for glass on ebonite. Here is another plate, picked up at random in the laboratory of the Royal Institution. Its composition is unknown. Tested in the same way, water has no detectable influence on the friction between glass and the surface of this plate.

It will be well to confess at once that these simple experiments raise questions which are as yet without an answer, and that much of what follows concerning them is merely tentative. They seem to establish two things, the first being the curious paradox that a film of fluid introduced between two surfaces does not always decrease friction—it may, indeed, very much increase it. The second is that the quality of "oiliness"—the quality, that is, which enables a substance to act as a lubricant—seems to be not the property of a given fluid, but only of that fluid considered in reference to a particular surface.

It is necessary at this stage to clear away a possible explanation of the paradox. When two solid faces are separated by a thin film of fluid, capillary forces operate, and, in certain cases at any rate, these forces act so as to resist slipping. They will so act, for instance, when the movement of one face past the other increases the area of the free surface of the film. Water has a high surface-tension; the capillary forces to which it gives rise are usually large; therefore it is pertinent to ask whether, when a layer of water diminishes the facility for the slipping of glass on glass, it is owing to capillary action. A qualitative answer is to be found in the fact that water does in some cases, as when glass is applied to ebonite, increase the facility for slipping; and the late Lord Rayleigh furnished the quantitative answer. He calculated the magnitude of the capillary effect and found it negligible compared with the actual friction of glass on glass wetted with water. An appeal to capillary forces of this type will not solve the paradox.

Some light is thrown upon it when we inquire into the state of the surface of glass that has its friction increased by water. Surfaces of glass "cleaned" in the ordinary way by rubbing with a glass cloth, or glass faces which have been simply exposed to the air, are in point of fact not clean, but highly lubricated with a film of matter derived from the cloth or condensed from the atmosphere. This "grease" film is of invisible thinness. It is probably of the order of 1 $\mu\mu$ in thickness—that is to say, one-millionth of a millimetre. It can be removed by soap and water, which in turn must be removed by a stream of water, and the plates dried in clean air out of contact with solids. The film reforms quickly—very quickly in London air, and less quickly in the country. A "grease" film also creeps over a cleaned glass face from ordinary solids with which it may be in contact. Still, when due precautions are taken—and they are many—it is possible to get a glass face which seems to be really clean.

The first property of clean faces is that their friction, one for the other, is very high; indeed, it is impossible to make them slip past one another. One glass plate may be forced past another, but true slipping does not take place; they tear at the point or points of contact. It is easier, in short, to disrupt the actual substance of the glass itself than to get the surfaces to slip over one another. Clean glass faces "seize" when they touch.

When chemical substances are tested as lubricants on clean glass faces, a remarkable fact emerges—namely, that some are quite neutral in that they do not alter the resistance to slip in the least; such are water, alcohol, benzene, and strong ammonia. Other substances have some lubricating action, great or small—that is to say, they decrease the force needed to produce slipping; such are the alkalis, trimethylamine and tripropylamine, the fatty acids—*e.g.* acetic acid—and the paraffins. Those fluids which act as lubricants are not necessarily fluids of any considerable viscosity; indeed, a high viscosity is compatible with the absence of any lubricating action other than flotation. Thus glycerine facilitates the slipping of clean glass on clean glass only when it is present in quantity sufficient to float the surfaces apart. On the other hand, acetic acid and tripropylamine—substances of low viscosity—are admirable lubricants of glass.

None of the fluids tested was found to raise the friction of clean glass faces. They were either neutral, or decreased friction to a greater or less extent. The power of increasing the friction of glass faces which neutral fluids, such as water, possess is due, not to their action on the glass itself, but to the fact that they interfere with the action of the invisible grease film. Water on an ordinary glass face acts as an anti-lubricant; on really clean glass it is "neutral."

All solid faces, however, do not distinguish chemical substances into those which are "neutral" and those which possess lubricating properties. Nearly one hundred substances have been tested on burnished faces of bismuth, and in every case some decrease of friction was observed.

A comparison of the lubricating action of simple chemical substances on clean faces of glass or of bismuth would seem to show that the quality of oiliness is due to some reaction between the substance and the solid face. Much is still obscure, but certain facts seem to be capable of interpretation in no other way. Thus water and ethyl alcohol have no detectable lubricating action on clean glass, whilst both are moderate lubricants for clean bismuth.

The thickness of the layer needed to lubricate is astonishingly small. It is quite invisible, and probably only one or a very few molecules thick. To discuss this adequately would take too long, but the fact may be instanced by an experiment of great beauty. A tiny drop of, say, acetic acid or tripropylamine is placed near one corner of a plate of clean glass 6 cm. square; nothing detectable by the senses happens; the drop is there, and that seems to be all. But the whole surface of the plate has, in fact, been changed fundamentally. It is now fully lubricated by an invisible film which has spread rapidly over it from the drop. The presence of this film may be detected by measuring the friction or by following the migration of two drops of fluid over the face of the plate. It will be found that the drops attract one another under conditions which point to the cause being the contractility of the invisible film.

This brings me to the second part of my subject—namely, the relation of lubricating power to chemical constitution.

In particular experiments with bismuth, a slider having a curved surface was applied to a plain surface of metal, both surfaces being highly polished, and the force required to initiate movement was measured. This force measures what is usually called static friction as opposed to the kinetic friction when the surfaces are in relative motion. The static friction was found to be a function of the weight of the slider. Therefore, the ratio of the weight of the slider to the friction was used as a relative measure. The results appear in the following table:—

Static friction 0·5 when the faces were clean.

CHAIN COMPOUNDS.

Alcohols.

	Static Friction.		Static Friction.
Methyl	0.29	*iso*Propyl	0.32
Ethyl	0.32	*iso*Butyl	0.30
Propyl	0.34	Allyl	0.29
Butyl	0.30	Glycol	0.30
Amyl	0.27	Glycerol	0.22
Octyl	0.25	Penterythritol ...	0.40
Cetyl	0.17		

Acids.

	Static Friction.		Static Friction.
Formic	0.45	*n*-Octane	0.32
Acetic	0.40	Stearic	0.15
Propionic	0.31	Oleic	0.10
Valeric	0.28	Ricinolic	0.02
Caprylic, fluid ...	0.19	α-Lactic	0.20
Caprylic, frozen on plate	0.05	Glyceric	0.22

	Static Friction.		Static Friction
Acetone	0.32	Ethyl ether ...	0.33
Methyl ethyl ketone	0.29	B.P. "Paraffin"	0.20
Ethyl acetate ...	0.36	Solid paraffin, m.p. 30.5°	0.09
Ethyl valerianate...	0.35	Solid paraffin, m.p. 46°	0.07
Tristearin	0.24	Carbon tetrachloride	0.43
Triolein	0.14	Chloroform ...	0.30

Tripropylamine ...	0.26		

It will be seen that static friction is a function of the molecular weight of the lubricant, and in a simple chemical series of chain compounds, such as fatty acids and alcohols or paraffins, a good lubricant will be found if one goes high enough in the series; but it is not a simple function. The friction, for instance, rises sharply in moving from $CHCl_3$ to CCl_4, and from phenol to catechol and quinol. The influence of molecular weight is overshadowed by the influence of chemical constitution.

In some simple chemical series the relation appears to be a linear one. Examples are paraffins and the series benzene, naphthalene, anthracene.

The relation of lubricating qualities to viscosity broadly resembles that to molecular weight. In a simple chemical series lubrication and viscosity change in much the same way with molecular weight, but that there is no fundamental relation between viscosity and lubrication is shown by the following figures:—

	Viscosity at 20°.	Static Friction.
Carbon tetrachloride	0.0096	0.43
Chloroform	0.0056	0.30
Acetic acid	0.0122	0.40
Octylic acid	0.0575	0.19
Benzene	0.0065	0.39
Toluene	0.0058	0.28
Benzyl alcohol	0.0558	0.31

Fluidity of the lubricant has no constant significance. The curves for acids, alcohols, and paraffins show no break where, with increasing molecular weight, the lubricant becomes a solid at the temperature of observation. Compare also benzene, naphthalene, and anthracene, menthone and menthol, thymol and carvacrol.

Perhaps the most unexpected result is the distinction between ring and chain compounds. The simple ring compounds, benzene, naphthalene, and anthracene, show the linear relation to molecular weight, and values are much the same as those for paraffins of the same molecular weight. The similarities, however, end here, for any change in the molecular structure produces opposite effects according as it takes place in a chain or a ring. Thus a double bond decreases the lubricating action of a ring compound, but increases that of a chain compound. As examples, compare naphthoic acid with double-bonded oxygen, with naphthalene, menthone with menthol, *cyclo*hexanone with *cyclo*hexane, benzoic acid with benzene. As examples of double-bonded carbon, compare cinnamic ester with hydrocinnamic ester, dipentene, having two unsaturated carbon atoms, with menthol and *cyclo*hexane. Also the more saturated cyclic compounds are better lubricants than the less saturated ring compounds. When a ring and a chain are joined, as in butyl xylene, the result is a better lubricant than either.

The esters occupy a quite unexpected position. The simple aliphatic esters are worse lubricants than their related acids and alcohols. The ring esters, on the contrary, are better lubricants than are their related acids (*e.g.* ethyl benzoate and benzoic acid).

Perhaps the most interesting substances are the hydroxy-acids with CH and COOH groups. This conjunction produces a remarkable increase in the lubricating power of a chain compound (lactic acid and ricinolic acid), and almost destroys lubricating action in the case of the ring compounds (salicylic and benzylic acids).

In the ring compounds the replacement of hydrogen decreases lubricating power in the case of N, :O, or .COOH, and increases it in the case of other groups in the order $C_2H_5 < CH < OH$.

The effect of a second group of the same or of a different kind is to decrease the effect of the first. Compare, for instance, toluene with xylene; catechol, quinol, and cresol with phenol; and methyl *cyclo*hexanol with *cyclo*hexanol. The simpler the group, the more effective it is. Compare cymene with toluene or xylene, and benzyl alcohol with phenol.

When the atoms are disposed with complete symmetry about a carbon atom, the result is a very bad lubricant, as we see in carbon tetrachloride and the alcohol penterythritol

$$C(CH_2{\cdot}OH)_4.$$

It will be noticed that no ring compound is a good lubricant. Even cholesterol with the molecular weight 366 is no exception.

The group SH acts much as the group OH, thiophenol, $C_6H_5{\cdot}SH$, and benzyl hydrosulphide, $C_6H_5{\cdot}CH_2{\cdot}SH$, resembling phenol and benzyl alcohol respectively.

Concerning one matter—and that the most fundamental—some conclusion must be reached, even though it be upset later. What is friction due to? The "Encyclopædia Britannica" is in no doubt as to this. Friction, it says, is due to inequalities of the surface. This conclusion cannot, I think, be accepted. Why, if it be true, should clean burnished faces of glass or bismuth refuse to slide over one another? It does not even accord with such simple facts as we now know. For instance, the friction of an optical face of glass was found to be the same as that of ordinary plate glass within the limits of accuracy aimed at; and both the optical face and the ordinary plate were found to give higher values than ground glass.

The subject cannot be fully discussed here, but I think we may conclude with some confidence that the friction both of lubricated and of clean faces is due to true cohesion—to the force, that is, which binds together the molecules of a solid or of a fluid. If there were no seizing, there would be no friction. The function of the lubricant is to diminish the capacity for seizing by saturating more or less completely the surface forces of the solid. In some cases it seems to abolish it completely, so that static friction vanishes.

The subject of lubrication is of interest to the engineer, but it is perhaps of more interest to the physicist, for it offers a means of exploring the most difficult regions of the physics of boundary zones—namely, the surface energy of solids. It will, for instance, I believe, enable us to prove that the simplest chemical change at the surface of a metal takes place only when the surface energy is decreased thereby. The film of oxide of sulphide which forms on copper acts as a very effective lubricant, and it acts also like a grease film in preventing water from wetting the surface; and from both of these facts we may conclude that the presence of the film lowers the surface energy of the metal.

Obituary.

Prof. Italo Giglioli.

Among the famous band of workers who built up a scientific agriculture in the nineteenth century the name of Italo Giglioli will take a high place, not only for what he did himself, but also for what he inspired others to do. Both his father and his grandfather had become exiles from Italy in the turbulent days of the early revolutions; the father came to Edinburgh, took a medical degree, and then settled in London to practise. The revolution of 1848 attracted him back to Italy, where, in 1852, at Genoa, a son was born to him to whom the name Italo was given as the first to be born in the native land.

Italo Giglioli devoted himself to the teaching of scientific agriculture, which he believed to be his country's great need. He was elected professor at the age of twenty-four, and taught, first at Portici, and then at Pisa, where he stayed until his death, on October 1, at sixty-eight years of age, playing a great part in the development of these two schools to their present honourable position. For this work he was well fitted. He had an unusually good knowledge of English and of other languages besides his own, and was thoroughly familiar not only with the investigations of Lawes and Gilbert at Rothamsted and of other British agriculturists, but also with the French and German work. In 1888 he drew up a long report for the Italian Ministry of Agriculture on British agricultural education (*Annali di Agricoltura: Educazione Agraria Britannica*, Rome, 1888), written with full knowledge, and containing much information that the student could obtain elsewhere only with difficulty. He kept up his interest in English investigations throughout his working life, and was usually appealed to by English workers who desired information about Italian agriculture.

Giglioli's published work covers a wide range; on the physiological side it deals with the functions of essential oils in plants (*R. Accad. dei Lincei*, 1911, vol. xx.); the biological absorption of methane, in which he confirmed the conclusion of Söhngen and Kaserer that methane is oxidised by certain micro-organisms (*Studi e Richerche*, Pisa, fas. 22, 1909-14); and the resistance of seeds to chemical agents. It is not, however, as a worker on abstract laboratory problems that Giglioli will be remembered. His more important investigations were on the agricultural side. He carried out experiments at the Experimental Station at Suessola on the cultivation of wheat, summarised in "Il Frumento: sue varietà e concimi" (Portici, 1888), and in later reports. In these he dealt with varieties, manuring, and such special cultural treatments as the effect of electrification, of manganese, etc. He also dealt with the cultivation of the cork tree ("La cultura del Sughero," Portici, 1902); the effects of chemical manures in arid climates; phylloxera; and silage—all important subjects in Italian agriculture.

Giglioli's best work was probably as a teacher, and some of the tributes paid by his students are very touching. His book, "Chimica agraria campestre e silvana" (Naples, 1884 onwards to 1902), was much used in Italy. The more general agricultural questions are discussed in his well-known "Malessere agrario ed alimentare in Italia" (Portici, 1903). This contains probably the best available summary of Italian agricultural conditions in comparison with those of other countries, and also an examination of the causes and possible remedies for agricultural distress.

Giglioli's death severs a link between British and Italian agriculturists, and is equally regretted in both countries. It is the hope of all concerned that the close relationship for which he strove may be maintained and strengthened.

E. J. Russell.

Dr. C. A. Sadler.

Dr. Charles A. Sadler was a student at Liverpool in the early days of the University there. After graduating with honours in physics (1905), he joined Prof. Barkla—then lecturer in the University—in his investigations of the secondary rays emitted by substances exposed to Röntgen radiation. Sadler's introduction to the work was made in a detailed investigation of the absorption of the characteristic X-radiations.

The results of these researches were published by Barkla and Sadler in a series of papers in the *Philosophical Magazine* dealing principally with the laws of X-ray absorption, the homogeneity of the characteristic radiations, and the relation between the characteristic radiations and the atomic weights of the chemical elements emitting them. Sadler afterwards (while holding the Oliver Lodge fellowship) continued the investigation of the energy of the characteristic radiations by an accurate and detailed examination of these radiations from several elements. He also applied Townsend's method to a study of the secondary corpuscular radiation, and found that a certain portion of this radiation was associated with the characteristic X-radiation.

In 1911 Sadler was appointed lecturer in physics at University College, Reading. There he became interested in mechanical work, and in 1915 he turned his skill to good account by organising most successfully a training centre for munition workers. Shortly before the armistice he left academic work to undertake research of a technical character with Messrs. Allen and Simmonds, of Reading. This work was, however, cut short by a breakdown in health, followed by his early death on December 5.

Sadler's interest and skill in mechanical methods were exceptional. He was an able experimenter, an accurate observer, an indefatigable worker. These gifts were very highly esteemed by those with whom he collaborated.

Notes.

THE Dyestuffs (Import Regulation) Bill was read for a third time in the House of Lords on December 23 and has been given Royal assent. The measure was referred to in the King's Speech at the close of the session as "the Act regulating the importation of dyestuffs, in order securely to establish the dyestuffs industry in this country."

WE begin this week the publication of a Calendar of Scientific Pioneers, which it is proposed to continue throughout the year. There is inspiration as well as interest in the lives and work of the great men of science thus recalled to memory, and many readers will, we believe, welcome this additional feature in the columns of NATURE. The Calendar has been prepared by Engr.-Comdr. Edgar C. Smith, H.M. Dockyard, Devonport, who has for many years been engaged in compiling biographies of all leading contributors to the advancement of natural knowledge.

A GREAT earthquake on December 16 is reported from the province of Kansu, on the Upper Hoang-Ho, in north-west China. The city of Ping-liang was much damaged, and 2000 persons are said to have perished. Prof. H. H. Turner and Mr. J. J. Shaw, in the *Times* of December 28, give reasons for believing that this earthquake was the origin of the great seismic disturbance registered on December 16. With regard to the suggestion of an Alaskan origin referred to last week (p. 542), it may be of interest to recall the last great earthquakes in that country. They occurred on September 3 and 10, 1899, the latter being the more violent. Though the seismographic evidence implied an origin in or near Alaska, no direct evidence reached this country until September 26, when the *Times* of that date published a short account of the violent earthquakes in Yakutat Bay. The magnitude of the disturbance was not, however, realised until 1905, when Messrs. Tarr and Martin showed, from the evidence of dead barnacles and mussels still adhering to the cliffs, that the uplift of the crust was in one place as much as 47 ft. 4 in.

THE third half-yearly report on the progress of civil aviation has just been issued as a White Paper (Cmd. 1073). It is an interesting document in view of the prevailing conditions in the industry, and holds out hope of a more prosperous future. It is pointed out that regular air services have now been established from London to Paris, Brussels, and Amsterdam, and that passenger, mail, and goods traffic is increasing. The total number of aeroplane miles flown in the half-year ending September 30, 1920, is nearly 700,000, whilst the aggregate since May, 1919, exceeds 1,000,000. The number of passengers by air exceeds 30,000, whilst the goods carried weigh little less than 90 tons. In value the imported goods exceed 500,000*l*., whilst the exports and re-exports are about half that amount. As part of the mail services, about 50,000 letters have passed each way between London-Paris, Brussels, and Amsterdam with a regularity which is notable. Of the three routes the best shows 94 per cent. of deliveries within three hours of schedule time, and the worst 76 per cent. As part of the organisation for further improving these records, it is stated that the wireless direction-finding apparatus installed at Croydon has proved its value, enabling aircraft to correct their course in thick weather. The equipment of aircraft with apparatus for wireless telephony is extending, as it is found to be of considerable assistance to navigation. The fatal accidents are given as in the ratio of 1 per 50,000 miles flown or per 5000 passengers carried. The international character of flying is prominently brought out in a concise statement of activities in other countries than Britain, and shows a breadth of interest which will stimulate efforts to overcome the present difficulties experienced by those engaged in civil aviation.

H.M. STATIONERY OFFICE has published an Interim Report on Glass Bottles and Jars and Scientific Glassware, prepared by a Sub-Committee appointed by the Standing Committee on Trusts and adopted by the Standing Committee (Cmd. 1066, price 2*d*.). The section on scientific glassware is of great interest and importance to all scientific users. After pointing out that prior to the war the whole of the scientific glassware used in this country was imported from enemy countries, principally Germany, the Committee describes the efforts made by certain manufacturers of glass bottles, under inducements by the Government, to develop the scientific glassware industry in Great Britain. The report points out that British manufacturers have to meet to-day foreign competition the nature of which may be gathered from the fact that, "favoured by 'exchange' rates and other conditions, goods of the kind now being made in this country are being supplied by Continental manufacturers at prices less than the actual cost of manufacture here, whereas for goods that are not yet being manufactured here prices are being charged by the Continental makers which mean to the consumer approximately five times the pre-war price of such goods." Finally, after declaring that it is outside its functions to report on the demand of the industry for a prohibition of imports of scientific glassware except under licence, the Committee says: "We cannot refrain from expressing the hope that his Majesty's Government will not find it impossible to implement the verbal assurances said to have been given to manufacturers; for it would appear to be only in that way that this country can be saved from returning to the pre-war position of dependence upon foreign countries for their supplies. We would add that, in our view, at the same time users of such glassware should also be safeguarded as to prices, and that the desired assistance should only be given for a limited period, with powers of withdrawal if it were found that manufacturers were in any way inclined to take advantage of the situation by unduly raising prices."

THE Annual Report of the Chief Medical Officer, 1919–20, Ministry of Health, has recently been issued, being the first annual medical report of the Ministry of Health. The greater part of the volume is occupied with a survey of the general health, of epidemiology and infectious diseases, and of the work of the sections into which the Medical Department of the Ministry of Health is now divided. In the appendix to the volume Dr. Monckton Copeman discusses the relationship of smallpox and alastrim in connection with an outbreak of an anomalous varioloid disease in Norfolk. The disease was introduced from some locality in the Mediterranean area, and, although undoubtedly of the nature of smallpox, would seem more closely to resemble that variety which has been studied in Brazil known as "alastrim." Sir David Semple also gives a brief account of rabies and of the various systems of anti-rabic inoculation.

THE Research Defence Society has published an essay on "Vaccination" by Dr. Mary Scharlieb. A brief history of smallpox inoculation and of Jenner's work on the introduction of vaccination is given, followed by a short account of the symptoms of unmodified smallpox. The "Leicester experiment" is next described and discussed at some length. Finally, the outbreaks of smallpox at Dewsbury, Ravensthorpe, Gloucester, and Glasgow are referred to, and the influence of vaccination on the incidence and mortality of the disease is considered. The essay should be useful to those who desire to have evidence of the value of vaccination. The essay (together with others on the work of the Medical Research Committee, on the value of experiments on animals, and on the prevention of tetanus during the war, already noticed in these columns) may be obtained from the Secretary, 11 Chandos Street, W.1, price 2s. the set.

ANCIENT Oriental chemistry and its allied arts are discussed in the November issue of *Man* by Mr. Masumi Chikashige. The author begins with a review of ancient chemistry in Japan and China, consisting in the latter country of two parts: theories and gold-making, the latter having in its turn two aims, wealth and eternal life. He then passes on to the question of bronze in China and Japan, and supplies a series of analyses of its component elements. Finally, he describes the manner in which iron swords are forged. He concludes by saying: "We may recognise now some resemblance to damascened steel. If the Japanese learned this method of welding from the naturalised Chinese, where had the latter learnt their art? Whether it was their own, which made its way westward to Europe through India and eastward to Japan, or whether, on the contrary, they learned the art from India, is not now to be settled."

THE Asiatic Society of Bengal has published among its Memoirs (vol. vii., No. 3) an important paper by Mr. J. Hornell on "The Origins and Ethnological Significance of Indian Boat Designs." Surveying the shores of the Indian peninsula, Mr. Hornell describes, with good illustrations, the various types of boats now in use and many ceremonies in connection with their launching and employment, with a review of our knowledge of the ancient sea-trade with India. The most interesting part of the paper is an attempt to show how foreign influences have created or modified the types which exist at present. Thus he suggests that compound masts are essentially Mongoloid in origin, being seen to-day among Burmese, Indonesians, and the southern Chinese, and that on the west coast the use of the outrigger for coasting vessels was discarded at a comparatively early period under the influence of seamen from the Persian Gulf and the Red Sea. Also, since the single outrigger and balance-board designs are both Polynesian in affinity, their general diffusion on one or the other of our Indian coasts points to the conclusion either that some of the coast-folk of India are closely allied to the races of Oceania or that it is due to trade relations. Inland boat designs are on a very different footing, the first and larger group having distinctly Egyptian affinities, and the other equally well-marked Babylonian relationship.

THE second volume of the Proceedings of the Lahore Philosophical Society, which forms a record of the papers read before the society during the years 1916–20, has been received. The first volume contained papers read during 1914–16; we gather that lack of funds has prevented the issue of this second volume until the present time, and that publication has now been made possible by a grant of money from the Punjab University. The present volume, of eighty pages, contains records of thirty-two papers, of which eight are printed *in extenso* and the remainder in abstract. The papers are of two kinds: records of original work and summaries of recent researches; the mathematical, physical, and biological sciences are all represented. The membership roll is about fifty, and meetings are held every month during the academical session. A society such as this fulfils an important function in the intellectual life of a comparatively remote and isolated community. While authors of original researches will presumably publish them in other periodicals as well as in these pages, the present volume forms an interesting record of the activities of a society on the successful foundation and continued existence of which the members are to be congratulated.

WE have recently received a small booklet dealing with a proprietary fluid which has been placed on the market under the name of "Solomia." It is claimed to destroy any large insect pest—aphids, bugs, spiders, caterpillars, worms, etc. Further, it is stated to be non-injurious to crops, fruit, or grass, and its efficacy to be unaffected by weather conditions. If "Solomia" can effectively carry out all that its promoters claim for it, there is no doubt that it is a very remarkable mixture.

IN the December issue of the *Entomologist's Monthly Magazine* Mr. F. W. Edwards writes on the British species of Dixinæ. This subfamily includes a small number of gnat-like insects commonly regarded as constituting a family of their own. They are related both to mosquitoes (Culicidæ) and to crane-flies (Tipulidæ), and Mr. Edwards places them in the first-mentioned family. Their larvæ and pupæ are exclusively aquatic, and bear a rather close resemblance to those of Anopheles and its allies. The only genus is Dixa, which enjoys the position of never having had the validity of its name questioned, and, consequently, no synonym exists. Ten British species are recognised, but they have been so little collected that we have only a very vague idea as to their distribution in this country. In the same periodical Mr. J. E. Collin gives useful keys to the British species of the Sylvaticus group of the genus Pipunculus. Since Mr. Verrall dealt with them in his "British Flies" (vol. viii.) further material has accumulated, rendering a revision of the genus necessary.

THE status of the rook in its relation to the farmer, fruit-grower, and forester is briefly reviewed by Dr. W. E. Collinge in the *Journal of the Ministry of Agriculture* for December. Dr. Collinge is of opinion that this bird has become too numerous, and, as a consequence of the stress of competition, it has taken to feeding upon cultivated crops. He contends that if repressive measures were put into force and carefully carried out the rook would soon assume its normal place again, and prove to be one of the most useful birds to the farmer in helping to control the larvæ of such injurious insects as click-beetles and crane-flies. The rook to-day, the author estimates, consumes about 80 tons of cereals, 32 tons of potatoes and roots, 7½ tons of insects beneficial to the farmer, and 65 tons of injurious insects, slugs, snails, etc. This last item is significant, and suggests an extension of this analysis directed to show approximately how many tons of cereals, potatoes, and roots would have been consumed by the 65 tons of injurious insects and their offspring if they had not fallen a prey to the rook.

IN No. 15 of the Economic Proceedings of the Royal Dublin Society (November, 1920) Prof. G. H. Carpenter reports on the injurious insects and other animals observed in Ireland during the years 1916–18. Among the various pests mentioned are larvæ of a species of Bibionid fly which caused much damage in wheat-fields by feeding on the roots, and those of *Bibio Marci*, L., found attacking potatoes stored in a pit. The flax flea-beetle (*Longitarsus parvulus*, F.) caused serious injury to the flax crop during the three years under review, and it was found necessary to re-sow the crop in several localities, no method of control being referred to. Storehouse beetles (*Ptinus fur*, L., and *P. tectus*, Boield.) are recorded as devouring very varied substances. Those of the first-mentioned species are believed to have been introduced from Tasmania, and were noted in 1908 in a consignment of almonds, and in 1911 from stuffed birds. Early in 1918 *P. fur* was received from Dublin localities among seeds of henbane intended for sowing, while *P. tectus* was discovered in a chemist's store of casein. The report is adequately illustrated, but shorter than many of its predecessors, which is possibly accounted for by the war and by conditions in Ireland generally.

THE first Report of the National Institute of Agricultural Botany, recently issued, shows that encouraging progress is being made with the new scheme. The aim and policy of the institute are to develop new and reselected varieties of all kinds of farm crops and to "grow on" promising types until sufficient stocks are available for distribution through the seed trade to the farmer. Liberal financial assistance has been forthcoming, not only from private benefactors, but also from the seed trade and farming industry. As the official seed-testing station is to be incorporated with the institute, a building grant and loan were obtained from the Development Commission. It is now hoped to gain new subscribers to build an adequate maintenance fund. The headquarters of the institute, now rapidly approaching completion, are being erected at Cambridge, and include housing accommodation for a portion of the staff. The rest of the 36 acres of this site is available for trial grounds. In addition, the Hiam Farm at St. Ives (Huntingdonshire) (354 acres) will be used as a seed multiplication farm, and 39 acres of rich market-garden land at Ormskirk, Lancashire, are being developed as the potato testing station. Mr. Wilfred H. Parker has been appointed director of the National Institute, but the Seed Testing Station will retain its independence under its own director, and will be equipped to test all kinds of agricultural, garden, or forest seeds. It is hoped that the buildings will be ready for occupation by August, 1921, and arrangements are being made whereby the work of the institute will be carried on with the least possible delay.

THE possibility of a general world-wide sinking of sea-level to the extent of nearly 20 ft. during post-Glacial times is discussed by Prof. R. A. Daly in the Proceedings of the National Academy of Sciences (Washington) (vol. vi., No. 5), and at greater length in the *Geological Magazine* (vol. lvii., No. 672). Observations on coast-lines in many parts of the world show approximately this degree of emergence, and the facts appear to warrant belief in synchrony in the age of the strands. Prof. Daly, however, points out that the suggestion is published, not to express a fixed conclusion, but to invite criticism and to test the idea in different parts of the world. If this emergence is established throughout the world, its explanation cannot be found in a change in the earth's centre of gravity or in a change in its speed of rotation. Prof. Daly suggests an increase in the past in the volume of existing ice-caps as a possible explanation. He calculates that a thickening of the Antarctic ice-cap to the average amount of 700 ft. would lower the sea-level by about 20 ft. by the abstraction of water from the ocean basins.

A REPORT on two pilot-balloon ascents made at Shoeburyness by Mr. N. K. Johnson is published by the Meteorological Office as Professional Notes No. 13. Both ascents were made on February 18 last. It is claimed that the results indicate the limitations and uncertainty of the single-theodolite method of observation, while they show the accuracy obtainable in determining upper-wind velocities and directions by the double-theodolite method. The first ascent was observed for 74 minutes, and in 48 minutes had attained 26,400 ft. The balloon then apparently developed a leak, and sank continuously to 12,800 ft., when it was lost in a light bank of haze. The second ascent was started at 11.50 a.m., 85 minutes after the first ascent, and was followed for 116 minutes. The balloon rose to 32,000 ft. in 64 minutes, which is said to be in excellent agreement with the rate of ascent given by Dines's formula. It afterwards maintained a practically uniform height until the 93rd minute, and afterwards fell slowly to 27,000 ft., when it was lost to view. Both balloons were followed by two theodolites 4290 ft. apart, and also by a range-finder. The results obtained from the range-finder are said to be very much less accurate than those given by the two theodolites, both the heights and the distances by the range-finder being consistently low by about 10 per cent.

MR. N. A. ALLEN read an interesting paper on the current density in the crater of the carbon arc to the Physical Society on December 10. By using an arc between a positive carbon and two negative carbons in the same plane, but inclined to the positive at 100°, he found that the crater was a circular plane which could be easily focussed on the screen and accurately measured. The distance between the carbons corresponded to the largest "silent" current. Ten minutes were allowed to elapse before a reading was taken, so that the crater had time to assume its normal size. Under these conditions Mr. Allen found that with a maximum inaccuracy of about 1 per cent. the area of the crater in millimetres was equal to the current in amperes multiplied by 1·34. The experiments were made with currents varying between 2·5 and 10 amperes.

A THIRTY-PAGE pamphlet on "Optical Methods in Control and Research Laboratories," just published by Messrs. A. Hilger, Ltd., will prove of great use to works physicists and chemists concerned in the determination of the refractive indices, absorptions, or optical rotatory powers of materials. As a rule, such determinations must be made on direct-reading instruments, but it is desirable that the observer should understand the principles of the instrument which he uses, and be able to tell at once when it has gone wrong and to set it right. The pamphlet contains tables of the ranges and sensibilities of the different types of instruments and gives numerous references to books and memoirs in which further information may be found.

THE October quarterly number of the Journal of the Society of Glass Technology contains an article by Dr. W. E. S. Turner on "Some Developments in the Study of Glass Technology in the Year 1919–20." Dr. Turner states that during the war this country produced chemical glass "second to none in the world so far as chemical resistance was concerned"; and that as regards optical glass, glasses superior to those produced at Jena have been made on a commercial scale in this country, and also in very great variety. If it were a question of quality only, Dr. Turner adds, then we could very reasonably hope to maintain our market intact. But the existing rates of exchange in certain foreign countries operate to the disadvantage of the industry in this country. The article reproduces the fourth annual report of the Delegacy for Glass Research, from which it appears that, besides a considerable output of research work, much has been done to resuscitate the educational work of the University of Sheffield in the department of glass technology. An appendix to the report gives a list of the researches either planned or already in progress. Many of these researches are in fields in which other scientific bodies, such as the National Physical Laboratory, the British Scientific Instrument Research Association, and the Glass Research Association, are also working. The journal contains, besides several interesting papers communicated to the society, including one by Dr. George H. Miles on "The Human Factor in Industry," a useful section of abstracts and reviews.

THE report on the heating of buried electric cables which was presented to the Institution of Electrical Engineers on December 17 is of interest to men of science as well as to engineers. The thermal problems in connection with the cables are those principally considered, and important results have been obtained. For instance, it is proved that the thermal conductivity of the paper insulation used in high-tension cables is about three times as great as that of paraffin wax and practically constant. Hence to determine the temperature of the inner cores of the cables carrying given currents all that is necessary is to determine the thermal resistance of the earth in contact with the lead sheath. The thermal conductivity of earth containing 15 per cent. of moisture was found to be five times greater than that of the paper insulation. Hence by elementary calculations it is now possible to calculate the temperature rise of cables carrying given currents when laid in certain soils. A curious result found by one of the experimenters was that a cable when buried 4 ft. under the ground heated more than when it was only buried 1 ft. Hence the cooling by air convection of the heated ground in the latter case must have been appreciable. It is of interest to notice the close connection between the problem discussed in this report and the corresponding problems in connection with the electrostatic capacity and the current-flow in cables. Kelvin pointed this out eighty years ago.

A PAPER read by Engr.-Comdr. C. J. Hawkes at the meeting of the North-East Coast Institution of Engineers and Shipbuilders on November 26 contains a great deal of information derived from experiments on the injection and combustion of fuel-oil in Diesel engines. These experiments were carried out at the Admiralty Engineering Laboratory on both the solid-injection and air-injection systems. The engine experimented upon was a single-cylinder four-stroke engine having a piston of aluminium alloy, 14½ in. diameter by 15 in. stroke, developing 100 brake-horse-power at 380 revolutions per minute. The paper is very long, and it is possible to make reference to one or two points only. One of the later tests with solid injection gave an average fuel consumption of just under 0·4 lb. per brake-horse-power per hour when developing 100 brake-horse-power at 380 revolutions per minute. The sprayer used in this test had five 0·016-in. holes, with flats, and a fuel-valve roller clearance of 0·003 in. In this test the piston had been fitted with an obturator ring, which proved beneficial. In all the tests the best all-round results were obtained from this sprayer. Taking the fuel-oils experimented with in these tests, it has been found that up to about 100 lb. per sq. in. mean indicated pressure the fuel consumption with solid injection is approximately the same as the fuel consumption with air injection at the same power and speed after taking into account the power required to drive the injection compressor. On an i.h.p. basis the consumption is less with air injection, thus indicating that the combustion is better with air injection. Those interested in the dynamics of cam-driven valves will find much of value in the paper.

MR. D. BROWNLIE has made a survey of a large number of boiler plants, and in the *Chemical Trade Journal* for August–September he published the individual figures obtained relating to different industries. The details of the performance of sixty typical steam-boiler plants used in chemical works are tabulated, and he discusses their merits and demerits. Since these tests were not applied after careful preparation of the plants, they may be regarded as representative of normal working conditions. The true average net working efficiency for the whole sixty plants was found to be approximately 58 per cent., but the author's experience leads him to the conclusion that a modern plant run on scientific lines will give on the average 75 per cent. net working efficiency for continuous performance, a variation between 65 per cent. with purely refuse coal and 82½ per cent. with the best quality coal being approximately the limits which should exist. If the average efficiency could be raised from 58 per cent. to 75 per cent., obviously a great saving would result, amounting to 285,000*l.* per annum on the sixty plants tested. The reasons given for the low results obtained are insufficiency of grate length, economiser capacity, use of superheaters, and insulating steam-pipe covering. Other causes are that the feed-water is not properly treated to avoid scale troubles, and that the combustion processes are not chemically controlled by the use of recorders. Brickwork and foundations, too, were found in a bad state of repair, with a consequent leakage of cold air. The author criticises the use of chimney draught and steam jets when mechanical draught would serve the same purpose more economically. His great insistence, however, is on the necessity for supervision of the plant according to modern scientific methods, and he proceeds to summarise the rigid system of record-taking, which he believes to be essential if the best results are to be obtained. A number of instruments useful for control purposes are mentioned by name, but, of course, their relative merits and demerits are not subjects which the author can deal with in a single article.

Our Astronomical Column.

SKJELLERUP'S COMET.—The following observation was secured by Prof. Barnard at the Yerkes Observatory:—G.M.T. December 18d. 21h. 55·6m., R.A. 9h. 22m. 13s., S. decl. 1° 37′ 49″. The following provisional orbit was deduced from the observations of December 13, 17, and 18:

$$T = 1920 \text{ Dec. } 13{\cdot}1743 \text{ G.M.T.}$$
$$\left.\begin{aligned}\omega &= 343^\circ\ 47'\ 9''\\ \Omega &= 107^\circ\ 39'\ 23''\\ i &= 23^\circ\ 53'\ 10''\end{aligned}\right\}1920{\cdot}0$$
$$\log q = 0{\cdot}06439$$

Ephemeris for Greenwich Midnight.

	R.A. h. m. s.	N. Decl. ° ′	log r	log Δ

20	11 17 42	38 24	0·1167	9·6115

The comet will not become conspicuous, but should be readily visible until the moon interferes with observation towards the end of January.

THE JANUARY METEORS.—Mr. Denning writes:—"The shower of Quadrantids (or Boötids, as they are sometimes called) is due to recur on the nights of January 2 and 3, and it is likely to be conspicuously visible this year if the weather is clear, for there will be no interference from moonlight. The most favourable time to observe the shower will be in the few hours preceding sunrise or in the early evening. The strength of the shower apparently varies from year to year, but its visible character is much affected by moonlight and atmospheric conditions. The meteors are often brilliant and traverse long flights. In 1918 the radiant point seemed to be 7° or 8° north of the usual position, and the display appeared to be more abundant than usual."

THE MASSES OF THE STARS.—The growth of our knowledge of stellar masses has been slow; it was for a long time limited to the very few cases of binaries the orbits and parallaxes of which were known. The next extension came through the spectroscope, which demonstrated the binary character of Algol variables and the existence of the class of spectroscopic binaries. Although the individual masses of the latter could not be found without a knowledge of the inclination, the results could be used statistically, assuming a mean inclination. One product of this research was the fact that the B stars have large masses.

The idea occurred independently to Russell and Hertzsprung that double stars showing curvature of motion could be used statistically for mass-determination even when the arc described was so short that the orbit could not be deduced. Russell concluded that B stars and giant A stars had an average mass of eight times the sun's, while the mass of the other pairs was about double the sun's.

This latter result was provisionally adopted by J. Jackson and H. H. Furner in a paper read to the Royal Astronomical Society on December 10. They utilised all available orbits of binaries, and also several hundreds of other pairs the relative motion of which showed curvature. The parallax of each pair was deduced on the assumption that its mass was double the sun's; its linear motion was then deduced from its observed proper motion.

The resulting apex of the solar motion is R.A. 273·0°, decl. +33·8°, and speed 19·13 km./sec.; the latter is so close to Campbell's spectroscopic value, 19·5 km./sec., that it fully confirms the validity of the assumption.

H. v. Zeipel, in the course of an article on stellar evolution in the December issue of *Scientia*, states that an attempt is being made at Upsala Observatory to obtain the relative masses of the giant stars of the different spectral types by a study of the grouping of these types in the globular clusters. He says: "One can demonstrate . . . that the massive stars congregate in relatively greater numbers than the light ones towards the middle of the group. By careful study of the distribution of the different types, one can deduce the mass of each." The detailed results are not given.

Education at the British Association.

FOLLOWING the presidential address (see Nature, November 4), the Education Section opened its proceedings by receiving an interim report of the Committee on Training in Citizenship. The report should prove valuable to all who are interested in the welfare and future of their country. *Five hundred extra copies were ordered, and are obtainable by application to the Assistant Secretary, British Association, Burlington House, W.1.* It includes:—(1) A comprehensive syllabus of instruction in civics; (2) an analysis of the Scout scheme of training towards citizenship by Lt.-Gen. Sir R. Baden-Powell; (3) schemes of school management and self-government; and (4) suggestions for organising regional study, and notes of lessons in regional survey.

Bishop Welldon, who presented the report, said that training in citizenship was the chief educational interest of the day, and that he hoped a book would be issued on the lines of the syllabus with the authoritative sanction of the British Association itself.

Sir Napier Shaw, in seconding the adoption of the report, discussed the conditions that make for good citizenship, and suggested that, in the establishment of good government, only experience could guide the peoples in this matter, and that it is the business of education to enable the rising generation to profit by the experience of the past.

Mr. J. J. Clarke, of Liverpool, presented a comprehensive survey of teaching civics to adults. He defined civics as a true conception and a recognition of the incumbent duties which necessarily accompany the association of men passing beyond all question of legal contract, and forming the unseen and unforged links which bind the citizen of this vast Empire to the State. He emphasised the necessity of having teachers practically acquainted with details of their work, and inspired by high ideals and a love of the subject.

Mr. A. Patterson, of Cavendish House, contended that civics should be treated not as a special subject, not as an additional subject for the curriculum, but incidentally as part of, and as one of the chief objects in, other subjects. He urged that the teacher should be the student of civics, and hand it on transformed to the child, adapted to his range of experience and capacity. He thought that various forms of school government, and societies in which the children take an active part, are better than lessons, the children thus learning through their own experience.

The papers read before the section dealt mainly with three important aspects of educational work, viz.:—(1) The relation of schools to life; (2) methods of teaching, and the appraisement of ability in a joint meeting with the Sub-section Psychology; and (3) the place in a national system of education of universities, public schools, training colleges, and higher technical schools.

Mr. A. Linecar read a paper advocating the adoption of a general governing principle guiding all school work, such as the power of concentration of mind. All subjects become then a means to an end, and not an end in themselves—the broader the curriculum, the broader the culture; it becomes possible then to cultivate capacity, to appreciate art, literature, beauty, Nature, and nobility without struggling to attain sectional high efficiency, to give power to be happy, and the possibility of a broad, tolerant, healthy, and full mental life.

Mr. F. M. McTavish dealt with the importance of education for the adolescent, and claimed that it was through secondary education our schools are most closely related to life, for it deals with the link between childhood and manhood, and therefore on the grounds of social expediency secondary schools should be free. They only can adequately meet the need of a well-marked stage in human growth and development, the adolescent stage. Each and all must pass through it, whether their parents live in palaces or in slums, and therefore the kind of education best suited to it ought to be available for all.

In a paper on the industrial aspects of life in its relation to schools, Mr. Bray, Assistant Controller of the Training Department in the Ministry of Labour, directed attention to the importance of awakening both employers and trade unions to their responsibilities towards the youthful worker, claiming that up to the age of eighteen these young people should be treated as workers in course of training, and not as workers only. Statistics show that industry as a whole does not yet recognise the new status of the boy under the Education Act of 1918; no adequate provision has been made for trade teaching, for physical welfare, or for general training. The question is a vital one: to members of trade unions it affects the well-being of their sons; to the employers the efficiency of their future workmen. The schools have a double duty: first to educate industry itself by securing a change of attitude towards the juvenile worker through industrial problems in the upper classes of secondary schools, and secondly to assist industry in the selection and training of its entrants.

An excellent paper by Miss Strudwick reviewed in a very happy form the present position of schools in their relation to life. In it she indicated some of the many causes which prevent them from being as effective as they might be, and some of the reforms which are necessary, emphasising the need for cultivating independence of judgment, an appreciation of good literature, and a profitable use of leisure. Miss Strudwick urged the value of corporate life in schools as a means of developing a sense of responsibility, unselfishness, self-discipline, and freedom of criticism. She suggested that co-education was a more natural and wholesome way of beginning life, although there were many difficulties in the way of its being adopted universally. Her plea for a fuller recognition by the nation of the importance of a teacher's work will be endorsed by all sections of the profession—"that right relation between school and life can be attained only when two conditions are fulfilled, when to those who teach their profession is a vocation and the love and confidence of their pupils a reward beyond price, and when those who do not teach are ready to accept in their midst those who do, and to make them feel that, in the best and truest sense, they belong to the world."

In the discussions that followed the Maharaj Rana of Jhalawar and Prof. Kilpatrick, of Columbia University, took part.

A joint meeting with Section E followed to hear a paper by Prof. J. L. Myres on "The Place of Geography in a Reformed Classical Course." Prof. Myres said that the recent decisions respecting "compulsory Greek" compelled a drastic revision of classical teaching. In place of language teaching he advocated a closer co-ordination between history, literature, and geography, and suggested that the Mediterranean region was exceptionally suited to supplement, by contrast, homeland notions of geography; the ancient narrative and description in translations of man's behaviour under these conditions, and his solutions of social and moral problems in ancient times compared with ours, would admirably serve as a foundation for a reformed classical education.

A joint meeting with the Sub-section Psychology was well supported. Prof. T. P. Nunn reviewed the present trend of thought respecting methods of teaching. He said it was generally recognised now that true learning requires the pupil to be at least an active partner in his own education, and that we have travelled far in this direction of recent years Fixed classes and fixed time-tables could not remain as they are if the individual pupil, with his distinctive powers and needs, was to be the centre of the business. Inspired by Dr. Montessori's success, courageous pioneers here and abroad are following up this revolutionary suggestion with pupils of secondary-school age.

Prof. G. H. Thompson read a paper in which he discussed the question: Do Binet-Simon tests measure general ability? He combated the conclusion based on the results obtained that the general ability evaluated by the tests was in the nature of a general common factor present in all performances.

Dr. Kimmins attracted a large audience to hear his paper on dreams of abnormal children—the deaf, blind, and crippled.

A large gathering assembled on the last morning to hear an address by the Right Hon. H. A. L. Fisher on the place of the universities in a national system of education. In Mr. Fisher's unavoidable absence the address was read by Sir Robert Blair. Mr. Fisher referred to the "general influence which universities exercise in promoting a spirit of liberal inquiry as opposed to that rigid and exclusive system of dogma which centuries ago was the product of intolerant clericalism, and is now, in modern democratic societies, preached by revolutionary or class-conscious sects." "If it be the cardinal requirement of our modern civilisation that a career should be open to talent, then it follows that universities should play a much larger part in the life of the people than historical accidents have hitherto assigned to them." He described how this enlargement was going on even before the war, and how greatly it had been increased as a result of it. In his own opinion the Government scheme of grants, whereby more than 25,000 ex-Service men are now undergoing some form of higher education in our universities and colleges, is destined to exert a permanent influence over the history of university development in these islands. In addition, our universities will be swollen by a further influx of students who otherwise before the war would have gone to Berlin or Vienna. The Education Acts of 1902 and 1918 are providing another source of recruitment through grants for secondary and continuation schools. Mr. Fisher pointed out how the work at the universities was held up for lack of funds, and hoped that private munificence will help to supplement and increase the comparatively moderate grant which the State is able to provide. A great addition to the teaching body of this country is imperatively demanded by the circumstances of the time, and he urged that the quality of the education which is to be given to the rising generations will depend upon the extent to which the universities are enabled to leave their impress upon the teachers of our schools.

Mr. Frank Fletcher, headmaster of Charterhouse, followed with a paper on "The Public Schools in a National System of Education." Public schools at the present time could scarcely be said to form a part of a national system, but Mr. Fletcher argued that the question of this relationship has been raised by the Teachers (Superannuation) Act of 1918. A considerable number of public schools were unable, out of their own resources, to provide a satisfactory pension scheme; they would therefore be compelled to seek Government assistance, which would entail conditions linking them up with the national system. He claimed that no reflections of a derogatory character should apply to those who did ask for State assistance, and that those schools standing out should not be excluded from opportunities of rendering services to the State in direct connection with the national system. The form which this service might take (he said) was tentatively put forward by Mr. Fisher:—(1) That the public school should receive boys from county secondary schools the numbers of which were too small to allow of more than one type of education being given, and yet in which might be one or two boys of promise whose bent did not coincide with that of the school; (2) co-operation in the training of teachers and in the inspection of secondary schools. Mr. Fletcher urged the big public schools to accept inspection by the Board of Education rather than that of the universities, so that inspectors of the smaller secondary schools should have experience of the organisations of the larger type. Such service could be rendered without losing that individuality which was the essence of their existence. The inspectorate would then act as a clearing-house of ideas between all types of schools, and each would learn from the other and the Board from both.

Mr. J. C. Maxwell Garnett described by means of a colour diagram sixteen different types of education, showing their interrelationship, and especially the position of the higher technical schools, in what he hoped would be a national system established in the course of the next ten years.

Miss Wodehurst (Bristol University) submitted a paper on training colleges in a national system of education, and argued that there was still a need for the two-year-trained teachers as against the three- or four-year university student. She urged the desirability of keeping the entrance to the teaching profession sufficiently wide to admit those who were unable to obtain full-time courses of study, and showed that there were many sound and valuable reasons why the training colleges were better able to provide for the two-year student than the universities, especially for those who would have charge of children under twelve years of age. It is well known that capacity to profit by a training college experience extends far beyond those who can reach matriculation standard. The universities of the future could meet this need only by lowering their standards of entrance, not only for attainment, but also for ability; hence the use of the non-university college, with a staff of university-trained specialists and a governing body containing university representatives.

One afternoon was devoted to the question of the supply of teachers. An interesting discussion followed an admirable paper by Mr. Spurley Hey on the present shortage of teachers in elementary schools. The reasons for the shortage Mr. Hey attributed to three causes:—(1) The failure of the Board of Education's policy in throwing over the pupil teachers centres and depending on the secondary school to supply recruits; (2) the failure of the Local Education Authority generally to realise the importance of taking steps to maintain an adequate supply of teachers; (3) the hostile and unsympathetic attitude of the teaching staff towards the L.E.A. in creating a supply. Mr. Hey pointed out how the Board had already taken steps to remedy this serious state of affairs by (1) its pension scheme; (2) additional grants for the payment of better salaries; (3) the establishment of the Burnham Committee; (4) providing avenues of approach to the teaching profession other than through the secondary school; (5) impressing upon the L.E.A. the need for immediate action towards creating an adequate supply; and he urged the Board to further action by providing more generously towards the preliminary education and training of teachers by exacting severe financial penalties on the defaulting L.E.A., and by amending the Teachers (Superannuation) Act so as to allow teachers to accept important educational administrative posts without loss of pensionable service. He suggested that recruits are more likely to come forward when the L.E.A. is prepared to regard existing teachers less as paid employees and more as colleagues in carrying on the educational service, and to give teachers a place in consultative and administrative work through the medium of advisory or Whitley committees, or through membership of education committees. He finally pleaded that teachers should abandon their unsympathetic attitude, and that the profession should unite in endeavours for its own expansion and improvement in the interests of education generally.

An afternoon was occupied in hearing a paper by Dr. Vincent Naser and discussing the organisation of international intellectual relations. A committee was formed to deal with the proposals brought forward. The report of the committee upon the educational value of museums was taken on the third afternoon, and the last one was spent in a very interesting and enjoyable visit to the summer school at Barry.

Agriculture at the British Association.

The papers read at the Agricultural Section covered a wide field, and included several of special horticultural interest. The section was well supported by the workers attached to the agricultural departments at Bangor and Aberystwyth, who contributed a considerable proportion of the papers. The attendance from other parts of the country was, unfortunately, rather smaller than usual.

Following the presidential address, Mr. H. V. Taylor (Ministry of Agriculture) read an important paper on "The Distribution of Wart Disease in Potatoes." This disease appears to have been recognised by Newstead so far back as 1878, but the present serious outbreak dates from about 1898, when specimens of infected tubers were brought to the notice of Sutton's by Kerr, of Dumfries. For a considerable number of years the areas infected by the disease were comparatively small in extent, and limited practically to Lancashire, Cheshire, Staffordshire, and the south of Scotland. Since then the disease has spread with great rapidity, and is now found in all areas north and west of a line from Newcastle to Bristol. The north-east of Scotland, however, is still quite clear. The disease is most prevalent in industrial areas, where potatoes are repeatedly grown on the same ground and where there is a less frequent change of seed. The use of infected seed is the most probable cause of the spread of the disease, and the difficulties of transport in the last two or three years have led to less frequent changes of seed and to the use of seed from infected areas. The fact that certain of the newer varieties of potatoes are very susceptible to the disease has doubtless not been without influence.

By 1910 it was known that certain varieties were immune to the disease, and in 1914 experiments were begun at Ormskirk to ascertain definitely which varieties were immune. In 1918 the trade was invited to send in varieties to be tested, and the number under inspection greatly increased. The results of these investigations have been to show that certain varieties, such as Great Scott, King George V., Majestic, Kerr's Pink, Tinwald Perfection, Arran Comrade, Golden Wonder, Langworth, etc., were immune to the disease. The distribution of seed from infected areas is now controlled by the Agricultural Departments of England and Scotland, and the planting in infected areas confined to immune varieties. Serious problems were involved in the administration necessary to secure adequate control, but by the energetic action of the Departments of Agriculture the difficulties are being largely overcome. The magnitude of the task involved will be realised when it is stated that some 37,500 acres of potatoes in Scotland and about 10,000 acres in England were inspected this autumn to ascertain their trueness of type.

Mr. F. J. Chittenden contributed a paper on "The Experimental Error in Potato Trials," describing a series of experiments which had been carried out at the Experimental Gardens of the Royal Horticultural Society at Wisley in Surrey. The paper dealt first with the various factors which influenced the yield so far as they are known at present, special attention being directed to the conditions under which the seed is grown and kept and to the treatment which it receives previous to planting. It was shown that in carefully conducted experiments when forty plants were taken the experimental error was not more than ± 5 per cent.

Two very suggestive papers were contributed respectively by Messrs. T. Whitehead and C. L. Walton, of University College, Bangor, on "A Preliminary Report on the Parasitic Fungi of North Wales" and "The Agricultural Zoology of North Wales." Mr. Whitehead has made a survey of the chief fungoid diseases attacking the cereal and root crops of the four northern counties, while Mr. Walton has commenced an investigation into the entomological and parasitological troubles of the farmer and stockbreeder, and in particular into certain diseases affecting sheep. The work in both cases has scarcely got beyond its initial stages, but promises to yield useful results.

Capt. R. Wellington, of the Ministry of Agriculture, gave the results of "An Orchard Survey of the West of England," while Mr. R. G. Hatton described the investigations which had been carried out on fruit-tree stocks at the Experimental Station, East Malling, since 1912. Mr. Hatton pointed out that the trade had long since discarded even the obvious dividing lines of vigour and growth characters, let alone the precise distinctions of species. The first work, therefore, was that of classification, and stocks of far greater uniformity than was available in the past are now at the disposal of future investigators.

Mr. S. P. Wiltshire described the methods of infection of apple-trees by *Nectria ditissima*, Tul., and the various preventive methods of treatment which had been tried.

Prof. T. Wibberley gave an account of his experiments on "Intensive Corn-Growing" in Ireland which he has been carrying on for the past ten years. He advocated the sowing of oats very early, immediately after the ground was cleared of the first crop; at the end of September the crop was cut several times or grazed, and then manured in the spring. In this way it was claimed that heavier crops could be grown without danger of their being laid.

An important paper on "The Artificial Production of Vigorous Trees by Hybridisation" was read by Prof. A. Henry; the full paper has since been published in the *Quarterly Journal of Forestry* (vol. xiv., 1920, p. 253).

The joint discussion with the Botanical Section on "Plant and Soil Survey Work" brought forward an interesting group of papers on both the chemical and botanical sides. Mr. G. W. Robinson (Bangor) described the results of his soil survey work in North Wales, and showed that attempts to classify the soils according to the geological formation from which they were derived had proved unsatisfactory. This was partly due to large areas having been obscured by glacial drifts, and also to the fact that, even in the case of soils derived from the underlying rock, the variety of soil-types is by no means so great as that of rock types.

The soils have been classified into twelve types, four of which are composed of soils mainly derived *in situ* from the underlying rock, while the other types include transported soils such as drifts and alluvia.

Mr. E. A. Fisher dealt with the important question of soil acidity, and suggested doubts as to the trustworthiness of the ordinary methods for determining the "lime requirements" of a soil.

Prof. R. G. Stapledon described his "Surveys of Grassland Districts"; while Miss W. H. Wortham gave a summary of the results of a botanical survey of North Carnarvonshire and Anglesey.

Sir Daniel Hall, Messrs. C. G. T. Morison, T. J. Jenkin, C. T. Gimmingham, and R. Alun Roberts, Miss E. N. Miles-Thomas, and others took part in the discussion which followed. Sir Daniel Hall said that there did not always appear to be a clear conception as to the object of the work. He suggested the simplification of methods, if possible, and a closer attention to the economic side of the question.

From the discussion two points emerged: (1) The soil chemists were quite agreed that the time had come for a revision of the methods of soil sampling and analysis at present in use, and it was felt that it was not desirable to embark on any extensive new work before this was done. (2) It was evident that there was need for a much closer co-operation between the soil chemist and the plant ecologist, both in planning survey work and in carrying it out. This is more true of England than of Scotland.

It was resolved to appoint a joint committee representing plant ecologists and soil chemists to consider and report on the whole question.

At the closing meeting Mr. G. S. Robertson described the results of his most recent investigations on manuring with ground rock-phosphates. He referred to the increasing demand for phosphates both at home and abroad and to the difficulty of maintaining the supply of superphosphates and slag. The experiments showed that ground mineral phosphates gave results which compared very favourably with the returns given by the old basic Bessemer slags.

Amongst the other papers read were "Experiments on Green Manuring," by H. J. Page; "The Sugar-Content of Straw," by S. Hoare Collins; and "The Varieties of Oats," by C. B. V. Marquand.

ALEXANDER LAUDER.

Studies of Heredity.

MR. C. C. LITTLE has studied (*Journal of Genetics*, vol. viii., 1919, pp. 279–90) colour inheritance in cats, with special reference to black, yellow, and tortoiseshell, and gives an explanation—not a very easy one—of the rare occurrence of tortoiseshell males which may be either sterile or fertile. The genetic constitution of the normal colour varieties of cats as regards yellow and black pigmentation appears to be as follows: B=a factor producing black pigmentation, Y=a factor which restricts black from the coat, and *y*=a factor allelomorphic to Y and hypostatic to it, allowing black pigment to extend to the coat. Mr. Little also discusses (*Science*, vol. li., 1920, pp. 467–68) a curious case in the Japanese waltzing mouse of hereditary susceptibility to a transplantable tumour. He concludes provisionally that from three to five factors—probably four—are involved in determining susceptibility to the mouse sarcoma; that for susceptibility the simultaneous presence of these factors is necessary; that none of these factors is carried in the sex (x) chromosome; and that these factors Mendelise independently of one another. In another paper (*Amer. Naturalist*, vol. liv., 1920, pp. 267–70) the same investigator criticises Dunn's suggestion that there is a linkage between the genes for yellow and for black in mice, and shows that the facts may be explained by assuming that yellow, when present, hampers the action of a lethal factor in much the same sort of way that it hampers the activity of the black-forming factor in the skin and hair. In a note on "Some Factors Influencing the Human Sex-Ratio" (Proc. Soc. Exper. Biol. and Medicine, vol. xvi., 1919, pp. 127–30) Mr. Little concludes: (1) That a significant excess of males is observed in the progeny of human matings involving racial crosses as compared with matings within the race; (2) that racial crosses between the European races studied (Italian and Spanish) will produce in the first hybrid generation a significant excess of males (which will be economically important to the United States); and (3) that there are significantly fewer stillbirths among the progeny of the hybrid matings studied than among the pure matings. In another paper (*Amer. Naturalist*, vol. liv., 1920, pp. 162–75) Mr. Little deals with exceptional colour-classes in doves and canaries. These have been explained on the hypotheses of "partial sex-linkage" and "non-disjunction," but the author thinks it is more legitimate to suppose a factorial change from one gene to its allelomorph, perhaps as the effect of "intergenic and intra-cellular environment." In a note on the origin of piebald spotting in dogs (*Journal of Heredity*, vol. xi., 1920, pp. 1–4, 3 figs.) Mr. Little deals with two cases in dogs which give direct evidence as to the origin of spotted individuals, and suggests that a spotted race may arise from a self-race, by mutation, without passing through a series of minute gradations directed by selection.

Dr. C. B. Davenport (Proc. Nat. Acad. Science, vol. iv., pp. 213–14) deals with an hereditary tendency to form nerve-tumours (multiple neurofibromatosis). Proliferations of the connective tissue-sheaths of nerves result in numerous sessile or pedunculate swellings. The course of the disease, which is rare, is influenced by metabolic changes in the body. There is sometimes an associated production of pigmented spots in the skin. There is evidence that the disease may occur in successive generations, and that it behaves as if it were a dominant, occurring in about 50 per cent. of each affected fraternity. "The fact that neurofibromata have an inheritable basis strengthens the view that cancers in general have such a basis." In another paper (*Journal of Heredity*, vol. x., 1919, pp. 382–84) Dr. Davenport reports a case of a Cleveland family where a tendency to multiple births has appeared in each of four successive generations. We have also received Dr. Davenport's annual report as director of the department of experimental evolution and of the eugenics record office of the Carnegie Institution of Washington. It gives us a glimpse of a manifold activity. Investigations are in progress on the modifiability of the germ-plasm by alcohol, the control of sex in pigeons, the sex-intergrades in Daphnia, the heredity of colour in dogs, cats, doves, and canaries, heredity in aristogenic families, inbreeding in man, and many other subjects.

The Pan-Pacific Scientific Conference.

THE first meeting of the Pan-Pacific Scientific Conference was held at Honolulu on August 2–20. At the close of the meeting a number of general resolutions were passed which concerned the conference as a whole. It was resolved that similar conferences should be held at intervals of not more than three years, and that the Governor of Hawaii should be invited to take action to make the conference a permanent organisation. Other resolutions dealt with the desirability of establishing an International Research Council, and with the need for the equipment of ships by the Governments concerned for the purpose of carrying out scientific research in the Pacific Ocean. The last general resolution was concerned with the promotion of education and with the need for the better payment of scientific workers; this was dealt with more fully in NATURE of October 21, p. 249.

The sections of the meeting have also published a number of recommendations. The section of anthropology advocates measures which are similar to those urged by Prof. Karl Pearson in his presidential address to Section H (Anthropology) of the British Association at the meeting this year at Cardiff. It recommends that centres for study and research in anthropology should be developed by the expansion of university departments or by the alliance of universities with other research institutions, so that such schools may combine all the features of museums and of research and teaching institutions. Research is particularly necessary into the history and culture of the Polynesians in order to reach a satisfactory solution of the ethnological problems of the Pacific.

The resolutions of the section of biological science can be divided into three groups; the first deals entirely with marine biological survey in the Pacific. It is contended that the work should be undertaken by the Governments of those countries bordering on the Pacific Ocean, and that steps should be taken to avoid the overlapping of work which might otherwise occur. The second group of recommendations deals with the land fauna of the Pacific islands. A survey of the fauna, and particularly of the mollusca, on both the better-known and the comparatively unknown islands in the Pacific is advocated. The last group of recommendations deals with the flora of Polynesia. Surveys are again necessary, and attention is directed to the importance of investigating carefully the flora of new lava-flows.

Surveys are also the burden of the recommendations of the geographical section. Topographical maps of many land areas in the Pacific are incomplete, and surveys of the shore-line and coastal waters are necessary. Continued work is also necessary in order to complete the general magnetic survey of the Pacific Ocean, and to extend this work to coastal waters where the magnetic phenomena are known to be complex. Recommendations dealing with physical oceanography merely emphasise those put forward by the biological section when referring to marine biology; the two ends could be served by the same expedition. Meteorology is also included in the scope of the section on geography. Observation at the place of origin of typhoons, cyclones, etc., and of the motion of these disturbances is necessary, and the establishment of an observatory on the Island of Hawaii and the resumption of observations at Macquarie Island are advocated. In most cases it is urged, on the plea of expense, that the work should be undertaken by the States bordering on the Pacific.

The section dealing with geology passed a number of resolutions advocating extensive geological surveys in the Pacific area. It recommends that three maps on the international scale of 1 : 1,000,000 should be drawn, one showing topographical features, another geological formations, and the third mineral resources. Another important group of recommendations deals with the importance of subaerial and submarine erosion, and asserts the need for research on the geological side of these matters. A plea was also made for the planning of research in such a way as to correlate the efforts of different workers and to promote a uniform mode of publication of results.

Three motives, the need for localised work, for publication and for the education of people in providing safeguards against disaster, and for precise geophysics, were the basis of the resolutions passed by the section on seismology and vulcanology. The section recommends the establishment of more volcano observatories, and also the intensive study of earthquakes in seismic provinces as likely to lead to advances in geophysical knowledge. It also advocates that complete statistics of earthquakes and eruptions for the whole world should be compiled. This project could be furthered by the establishment of a central bureau for the Pacific which could collect and disseminate information of a seismological nature, and later the same scheme could be applied to the world. An important resolution was that dealing with the training of people in proper methods of construction and in behaviour during emergencies in countries liable to seismic disaster.

Polynesia is to be congratulated on having successfully gathered together her men of science in an endeavour to increase our knowledge of the Pacific Ocean and of the conditions existing in the archipelagoes of that side of the world.

Mathematics in Secondary Education.

BULLETIN No. 1 (1920), recently issued by the U.S. Bureau of Education, shows that the authorities at Washington are fully alive to the difficulty of the problems that confront the secondary schools in this era of reconstruction. It contains, under the heading "The Problem of Mathematics in Secondary Schools," a report of a committee which confesses at the outset that it has been unable to come to definitive conclusions. The committee has therefore contented itself with throwing out suggestions based upon an analysis of the existing situation in the hope that the result will be such a series of discussions and experiments as will enable future committees eventually to arrive at definite proposals for reconstruction.

At the outset the present state of affairs is acknowledged to be entirely unsatisfactory. Traditions are to go by the board, and the admission of a subject to the curriculum must be based upon its value in relation to the conditions of social welfare. Not only mathematics, but all subjects, are to be reviewed and revalued. The psychologist has come upon the scene. The uncritical belief of the past in "mental discipline" is challenged. The general recognition of individual differences and the growing practice of differentiation and adaptation afford additional reasons for a close examination of the usual courses, and side by side with this problem is that of the courses best adapted for average mortals and for those who will proceed to an advanced stage of study.

As for the method of presentation, the report emphatically condemns the old divorce from reality. The ideas and the interests of the pupils must be utilised as the environment in which the mathematical conception is to find its natural setting. The existence of the conception within the *milieu* provides the necessary stimulus for its utilisation. The ideas and interests of the pupil provide it with projects and problems to which it desires solutions. The instruments for this purpose are to be found in the concepts. The "instrumentally selected content" must be free of all that will destroy potential interest, and will make an end of the watertight compartments into which our subject has so long been divided. With this instrumental basis of selection and procedure it is possible for all to begin together. But the future specialist will already, as he proceeds, be more attracted than the average student by the mathematical relationships, and find pabulum for thought in the mathematical instrument itself and in the assumptions which in the earlier stages he has taken for granted as natural. The place for the fully developed logical system is not here as yet, nor will it be found in the work of the future engineer, who will be content with the mathematics which is required in the projects and problems of a preliminary engineering course.

Definition is likewise required of the demarcation between the practical and the cultural or "interpretative" use of mathematics, and here must also be defined the groups which require enough to meet their social demands and individual aptitudes. These groups must necessarily overlap. The content of the course in all cases must be decided by a preliminary study of the irreducible minimum, and that is obtained by the rigid exclusion of all material of which the specific value for the definite purpose cannot be fully shown. The proposals do not differ in any very marked degree from the conclusions of, say, the Committee of the Mathematical Association, which some years ago drew up a tentative course for average students and for future specialists. There is in this bulletin much that is worth quoting. Conditions of space limit us to the following passage, which, though it contains nothing new, is nevertheless very true, and its teaching cannot be too strongly impressed upon the minds of teachers, especially upon those of the young and enthusiastic.

"Teachers . . . only too frequently deceive themselves as to the place that the presentation of a rigorously logical proof plays in bringing conviction. The worth of a sense of logical cogency can hardly be overestimated; but we who teach not infrequently overreach ourselves in our zeal for it. The teacher of introductory mathematics can well take lessons from the laboratory, where careful measurement repeated under many different conditions will bring a conviction often otherwise unknown to the pupil who is not gifted in abstract thinking. Probably in most instances an inductively reached conviction is the best provocative of an appetite for a yet more thoroughgoing proof."

There is one further point that should be noticed: the resentment on the part of American secondary schools at the attempts of the colleges to dictate the contents of their courses. Any restriction placed upon the free play of discussion and experiment is strongly deprecated.

University and Educational Intelligence.

LONDON.—A lecture on "Some Considerations on Tonus and Reflexes" will be given at the Royal Society of Medicine (1 Wimpole Street, W.1) by Prof. J. K. A. Wertheim Salomonson, professor of neurology in the University of Amsterdam, at 5 p.m. on Monday, January 17. This lecture has been arranged under a scheme for the exchange of lecturers in medicine between England and Holland. Five other Dutch lecturers will also give one lecture each, particulars of which will be announced later. A course of eight lectures on "The Physiology of the Embryo, Fœtus, and Newly-born" will be given by Prof. M. S. Pembrey in the Physiological Theatre, Guy's Hospital, at 4.30 p.m. on Thursdays, January 13, 20, and 27, February 3, 10, 17, and 24, and March 3. Admission to these lectures is free, without ticket.

SIR LEONARD ROGERS has been appointed Stuart Mill lecturer in tropical medicine at the London (Royal Free Hospital) School of Medicine for Women, and Miss Dorothy Maughan lecturer in pharmacy.

IN connection with Somerville College, Oxford, a Mary Somerville research fellowship of the value of 250*l.* for three years will be offered in March next. Particulars may be obtained from Miss M. F. Moor, Old Headington, Oxford.

APPLICATIONS are invited by the Senate of the University of London for the Graham scholarship in pathology, value 400*l.* per annum for two years, and tenable at University College Hospital, Gower Street, W.C.1. Particulars are obtainable *personally* from the professor of pathology at the college. Applications for the scholarship must be sent to reach the Principal Officer, University of London, South Kensington, S.W.7, by the first post of Monday, January 17, 1921, marked "Graham Scholarship."

ON December 20 Mr. J. H. Gardiner, representing Messrs. James Powell and Sons (Whitefriars), Ltd., in company with Mr. P. Annett, divisional organising officer for the Middlesex Education Committee, made a visit to Greenhill, Drill Hall, and Harrow Weald Council Schools, and addressed the boys who, having reached the age of fourteen, were upon the point of leaving school. The object was to interest the boys in the glass industry and to suggest to them the possibilities of good employment in the glassworks that are now being erected at Wealdstone. The boys, having been told the character of the work and the prospects that it holds out to them to learn one of the most important trades in the country, were invited to attend a series of evening continuation classes during the coming term, when a syllabus has been arranged to give them a thorough grounding in English, arithmetic, the metric system, physical manipulation (woodwork, etc.), freehand drawing, and elementary chemistry and physics. After attending the classes a selection will be made of the most promising boys, who will then pass through a special course of technical lectures in glass, its chemistry and properties. After this they will be drafted into the works, where a special laboratory is being fitted up in which for a certain number of hours a day they will learn the rudiments of the many branches of the industry. During the remaining portion of the day they will be employed in making themselves useful in one or other of the many departments of the firm. The speed at which they will learn their business will depend upon their own efforts, aided by all the assistance that can be given to them in the way of instruction.

AN interesting pamphlet has been published by the Universities Bureau of the British Empire, 50 Russell Square, London, W.C.1, containing lists of the students and teachers from our Colonies and from foreign countries who are studying in or attached to the universities of Great Britain. It is a record of the large-scale hospitality which is extended by our centres of learning to students of all nationalities. India sends us by far the largest number of students; including those from Burma and Ceylon, there are as many as 665 Indian students at present being educated in this country, of whom 292 are at London University and 125 and 67 respectively at Cambridge and Oxford. South Africa sends a large contingent, which is divided among the same universities roughly in equal numbers. Canada and Australia also have students in Great Britain, of whom the greater number are at Oxford; the totals for these Dominions are 123 and 121 respectively. Of foreign countries the United States is the largest contributor; 329 students in all are over here, of which 193 are at Oxford, 68 at London, and the remainder are distributed between Cambridge and the provincial universities. The subjects which have the greatest attraction for both Colonial and foreign students appear to be economics and medicine. It is also interesting to note that there are 56 Serbian and 66 Russian students studying in our universities at the present time.

AT a recent meeting of the trustees of the General Education Board of the Rockefeller Foundation grants amounting to 20,251,000 dollars were made to ninety-eight colleges and universities for general education and for the development of medical schools. Of this sum 12,851,666 dollars will be given as an endowment to provide increases in teachers' salaries, provided that the institutions themselves succeed in raising for the same purpose a sum of 30,613,334 dollars. Medical schools will benefit to the following extent:—1,250,000 dollars for endowment and 70,000 dollars for additional laboratory facilities to Washington University Medical School, St. Louis; 1,000,000 dollars for the endowment funds of Yale Medical School; 300,000 dollars for improving the facilities in obstetrics and 350,000 dollars for the development of the teaching of psychiatry in Harvard Medical School; and 400,000 dollars for the development of a new department of pathology in the Johns Hopkins Medical School. For the furtherance of general medical research 1,000,000 dollars has been alloted to the Medical Research Foundation of Elizabeth, Queen of the Belgians, Brussels. Other grants were made for a number of educational purposes, 287,350 dollars for co-operation between State universities and State Departments of Education in the Southern States of America in the fields of secondary and rural education, and 500,000 dollars for endowment and 443,500 dollars for current expenses and equipment of negro schools. A grant of 15,000 dollars has also been made to the American Conference on Hospital Service for the purpose of establishing a library and a service bureau, and one of 25,000 dollars to the National Committee for Mental Hygiene (U.S.) to enable it to carry out surveys on the care and treatment of mental diseases during the year 1920.

Calendar of Scientific Pioneers.

January 1, 1748. John Bernoulli died.—Born at Basle in 1667, he shares with his brother James the credit of developing the infinitesimal calculus, their mastery of which was acknowledged by Leibniz.

January 1, 1817. Martin Heinrich Klaproth died.—The first chemist in Germany to adopt Lavoisier's views, he became in 1809 the first professor of chemistry in the newly created University of Berlin.

January 1, 1894. Heinrich Rudolf Hertz died.—Hertz, who was born in Hamburg, February 22, 1857, went to Berlin in 1878, and later became an assistant to Helmholtz. At Kiel in 1883 he studied Maxwell's work, and afterwards at Karlsruhe gave the first experimental verification of Maxwell's electromagnetic theory of light. The Hertzian waves used in wireless communication are of the same nature as those of light, but of much greater wave-length and with a wider range. Hertz died at the age of thirty-seven, soon after he had discovered how to produce and detect these waves, but the later development of wireless signalling is based upon his fundamental work.

January 2, 1816. Louis Bernard Guyton de Morveau died.—By profession a lawyer, Morveau devoted his leisure to chemistry, and in 1787, with Fourcroy, Berthollet, and Lavoisier, published the important work "Méthode de Nomenclature Chimique."

January 3, 1640/41. Jeremiah Horrocks died.—While a curate at Hoole, in Lancashire, Horrocks at the age of twenty-two calculated and observed for the first time a transit of Venus. This he saw on November 24, 1639. Within fourteen months of his great achievement he died suddenly at Toxteth. The interest aroused by the transit of 1874 led to a memorial to Horrocks being placed in Westminster Abbey in 1879.

January 3, 1908. Charles Augustus Young died.—One of the most energetic of American astronomers, especially in spectroscopic work.

January 4, 1882. John William Draper died.—Chemist, physiologist, and historical and philosophical writer, Draper obtained in 1839 the first portrait by the daguerreotype process, and in 1840 the first photograph of the moon. Born near Liverpool on May 5, 1811, he emigrated to America, and assisted to found, and served as president of, the New York Medical School. His "History of the Intellectual Development of Europe" appeared in 1862. Henry Draper (1837–82), the astronomer, was his son.

January 4, 1906. Charles Jasper Joly died.—Born at Tullamore in 1864, Joly in 1897 became Astronomer-Royal of Ireland.

January 5, 1904. Karl Alfred von Zittel died.—Educated at Heidelberg, Paris, and Vienna, in 1863, when twenty-four, Zittel became professor of mineralogy at Karlsruhe, and three years later succeeded Oppel at Munich. Widely known for his writings, such as his "Handbook of Palæontology" and his "History of Geology and Palæontology to the End of the Nineteenth Century," he was president of the Royal Bavarian Academy of Sciences and a Wollaston medallist of the Geological Society.

January 5, 1913. Louis Paul Cailletet died.—A student at the Paris School of Mines, Cailletet's first researches related to metallurgy. Later work led him to study gases under pressure, and in 1877 he succeeded in liquefying oxygen. A like result was obtained at about the same time by Pictet at Geneva. Cailletet, who was a member of the Paris Academy of Sciences, was in 1910, at his academic jubilee, referred to as "the father of modern cryogenics."

E. C. S.

Societies and Academies.

PARIS.

Academy of Sciences, December 6.—M. Henri Deslandres in the chair.—G. **Lemoine**: The mutual reaction of oxalic and iodic acids: the influence of heat and dilution. Oxalic acid in aqueous solution is slowly oxidised by iodic acid to carbon dioxide, iodine being set free. The reaction is a slow one and well suited for the study of its velocity. Diagrams of the effects of dilution and temperature are given.—P. **Termier** and W. **Kilian**: The overlapping fragment at Mont Jovet (Tarentaise): the glistening schists to the north of Bourg-Saint-Maurice. This fragment is shown to have come neither from the north-west nor from the west; its probable origin is from the east or the south-east, and appears to have been carried from the Briançon layer.—A. **de Gramont**: Table of lines of high sensibility of the elements, arranged for analytical work. A table of wave-lengths for use in the spectroscopical detection of the elements in analytical work. The most prominent and the most persistent lines are given, both for eye observation and for photography with uviol and with quartz prisms.—M. **Laubeuf**: The application of the Pitot tube to the measurement of the velocity of ships. M. Mesnager has recently commented on a note on this subject by the late M. Yves Delage. A note on the same subject was communicated to the Academy so far back as 1901 by MM. Raverot and Belly, and the apparatus there described has been tested on three French ships. It was found to be impossible to correct on theoretical grounds for the numerous sources of error, and the instrument had to be calibrated by running over measured distances and drawing a curve giving the relations between the readings of the instrument and the actual velocities.—G. **Dumas** and J. **Chuard**: The homologies of Poincaré.—P. **Humbert**: Laplace's equation in hypertoroidal co-ordinates.—A. **Egnell**: Congruences of right lines the mean surface of which is a given surface.—B. **de Fontviolant**: Calculation of the strengths of bridges.—J. **Guillaume**: Observations of the sun made at the Lyons Observatory during the third quarter of 1920. The observations made on eighty-one days during the quarter are classified in three tables, showing the number of spots, the distribution of the spots in latitude, and the distribution of the faculæ in latitude.—A. **Danjon**: A relation between the light of the eclipsed moon and solar activity. The luminosity of the eclipsed moon is known to vary. Adopting a scale of 5° of brightness, this has been plotted against the date of the eclipse. The resulting curve rises from one solar minimum to the next, with a sudden fall at each minimum. The passage through a maximum of solar activity is marked by no peculiarity.—P. **Menard**: A reversible mercury manometer with damped oscillations.—A. **Pérard**: The interference method for the determination of quartz standards of length. A description of the modified Michelson method employed, in which any silvering of the surfaces of the standard is avoided, and a table showing the refractive indices of two standards for wave-lengths between 435·8 $\mu\mu$ and 643·8 $\mu\mu$.—G. **Ribaud**: Wide continuous absorption bands of light.—L. **de Broglie**: The absorption of the Röntgen rays by matter.—F. **Brocq**: A general method of continuous electrical integration.—A. **Damiens**: The subiodide of tellurium, TeI_2. Contribution to the study of the system iodine–tellurium. A curve of the melting points of mixtures of iodine and tellurium is given. The only definite compound appears to be TeI_4; no substance TeI_2 exists, the mixture having that composition being a mixture of the tetraiodide and a solid solution of tellurium and tetra-iodide. Both thermal and metallographic analyses lead to the same conclusion.—M. **Barlot**: A complex combination of thallium and hydrofluoric acid. The double fluoride H_2TlF_3 has been isolated. The thallium can be precipitated by the usual reagents, but the solution gives no precipitate with the usual reagents, such as calcium salts, and does not attack glass, although strongly acid to indicators.—M. **Geloso**: The reduction of permanganate by arsenious acid.—G. **Mignonac**: The catalytic hydrogenation of hydrobenzamide. Method for the preparation of benzylamine. From a study of the reduction of hydrobenzamide in alcoholic solution by hydrogen in presence of nickel, it would appear that the addition product described by O. Fischer is not formed; the products are benzylamine, benzalbenzylamine, and ammonia.—P. **Robin**: The oxidation of arisaldoxim: the peroxide of arisaldoxim.—A. **Mailhe** and F. **de Godon**: The preparation of the methyl derivatives of the xylidines and naphthylamines by catalysis.—L. **Bertrand**: The mode of formation of the Pyrenean strata.—F. **Gomez-Llucea**: The geology of Cabrera, Conejera, and other neighbouring islands.—P. T. **de Chardin**: The succession of the mammalian fauna in the lower European Eocene.—H. **Joly** and N. **Laux**: The fauna of the lower layers of the Aalenian of the Grand Duchy of Luxembourg.—A. **Boutaric**: The variation of nocturnal radiation during clear nights. The intensity of the nocturnal radiation during clear nights passes through a maximum shortly after sunset, and then decreases slowly and regularly until dawn.—H. **Courtonne**: The opposed action of soluble chlorides and sulphates on starchy materials. A saturated solution of magnesium chloride rapidly and completely converts, in the cold, starchy matter into soluble starch. Magnesium sulphate exerts a contrary action and prevents the formation of soluble starch in solutions heated in closed vessels to 115° C.—W. **Kopaczewski**: The mechanism of the Bordet-Wassermann reaction.—A. **Lumière** and H. **Couturier**: The shock produced by the introduction of insoluble substances into the circulation. The injection of barium sulphate suspended in an artificial isotonic serum into the carotid of a dog caused the typical symptoms of anaphylactic shock.—A. **Bach** and B. **Sbarsky**: The estimation of the degradation products of proteid materials in blood serum. The reducing ferment of milk may be utilised for the detection and estimation of small quantities of degradation products of proteids.—MM. **Desgrez**, **Guillemard**, and **Savès**: The purification of air contaminated with certain toxic gases. A solution containing sodium sulphide and soap when used in the form of a fine spray has been found to be capable of removing chloropicrin, chlorine, phosgene, methyl chloroformates, acrolein, bromoacetone, cyanogen chloride, and benzyl iodide, bromide, and chloride. Various mixtures were tried, but none proved to be capable of such general application as the above.—M. **Kohn-Abrest**: General method for the detection and estimation of arsenic.

SYDNEY.

Royal Society of New South Wales, November 3.—Mr. James Nangle, president, in the chair.—J. H. **Maiden**: A new Angophora. A mallee-like species recorded so far from Northbridge on the north, and from Kogarah on the south, of Port Jackson. It has been passed over as a petiolate- and more lanceolate-leaved form of *A. cordifolia*, DC., but it is smaller in all its parts, less hispid, the inflorescence less corymbose, and with the differences between the juvenile and mature leaves more accentuated.—J. H. **Maiden**: Three new species of Eucalyptus. The author has previously expressed the opinion that important results are awaiting those who more thoroughly investigate trees attributed to existing forms instead of giving too much attention to the search for rare and bizarre forms. This paper directly illustrates this point, and the following New South Wales trees are proposed as new. All yield valuable timbers:—(*a*) The Blue Mountains mahogany, attributed without doubt to *Eucalyptus resinifera*, Benth., for so many years, has pale-coloured, fissile timber very sharply different from that species. (*b*) The tall grey gum of the counties of Gloucester and Durham, hitherto named *E. punctata*, var. *grandiflora*, and therefore assumed to have a deep red timber, turns out to have pale-coloured, tough timber allied to that of the spotted gum (*E. maculata*, Hook.). (*c*) Less was known of this tree, the type of which comes from Wyee, north of Gosford. It is a grey gum with a deep red-coloured timber, possessing botanical characters intermediate between *E. longifolia*, Link and Otto (woolly-butt), and *E. punctata*, DC., the best known of our grey gums.—L. A. **Cotton** and Miss M. **Peart**: The calculation of the refractive index in random sections of minerals. The method employed is a graphical one, in which use is made of the stereographic projection. Both refractive indices for any given mineral section can be calculated when the form and position of the indicatrix are known. The principle is simple, and has been applied by Miss Peart to the evaluation of the refractive indices of the plagioclase felspars for cleavage flakes parallel to the (010) and (001) crystallographic forms.

Washington, D.C.

National Academy of Sciences (Proceedings, vol. vi., No. 4), April, 1920.—N. L. **Bowen**: Differentiation by deformation. The deformation of an igneous mass during crystallisation, with consequent separation of liquid from crystals, has frequently been suggested as a cause of variation of igneous rocks, and this suggestion is here discussed in considerable detail under the headings of discontinuous differentiation, monomineralic types as members of composite intrusives, monomineralic types as simple "intrusives," complementary dykes, primary banding, and alkaline rocks. —T. H. **Morgan**, A. H. **Sturtevant**, and C. B. **Bridges**: The evidence for the linear order of the genes.—C. W. **Metz**: The arrangement of genes in *Drosophila virilis*. Two papers in continuation of the discussion of the linear *versus* spatial arrangement of the genes.—G. W. **Stewart**: The functions of intensity and phase in the binaural location of pure tones. With frequencies of 100 to 1200 d.v., phase is the chief factor in localisation with pure tones, the intensity effect being practically *nil*, or at least very small.—L. T. E. **Thompson**, C. N. **Hickman**, and N. **Riffolt**: The measurement of small time-intervals and some applications, principally ballistic. A description of a new apparatus for indicating very small intervals of time with application to the ballistics of small arms.—H. H. **Sheldon**: Charcoal activation. The variations due to heat treatment may be explained by assuming that the structure of the charcoal is modified or that the air was the agent causing the variations. Data are given and interpreted on the basis of the latter assumption.—J. K. **Whittemore**: The starting of a ship. A discussion with simple integral equations of the problem of a particle moving under the action of tangential forces dependent on the velocity alone, with suggested applications to marine engineering and to the study of the laws of liquid resistance.—F. L. **Hitchcock**: A thermodynamic study of electrolytic solutions. The adoption of Gibbs's principle of chemical potential leads to the extension of the ordinary theories of melting point, heat potential, and mass law. These extensions are the result of the presence in the expression of the chemical potential of the solvent for the terms in the second and higher powers of the concentrations.—I. W. **Bailey**: The formation of the cell-plate in the cambium of the higher plants. Continuation of a previous paper indicating that the type of cell-plate formation there described is of frequent occurrence, and promises to be significant in any general discussion concerning the dynamics of cytokinesis and karyokinesis.—I. A. **Barnett**: Functionals invariant under one-parameter continuous groups of transformations in the space of continuous functions. Examples of one-parameter continuous groups are given, with in each case a functional invariant in terms of which each invariant of the group is expressible.—H. **Shapley**: Thermokinetics of *Liometopum apiculatum*, Mayr. A curve is obtained relating the speed of these ants to the temperature. The speed is less erratic at higher temperatures, and increases over a 30° C. range from 0·44 cm. to 6·60 cm. per second.—J. **Loeb**: The influence of ions on the osmotic pressure of solutions. A summary and discussion of an extensive series of experiments. At lower concentrations of the electrolyte the influence of the anion increases more rapidly with increasing concentration of the electrolyte than the depressing effect of the cation, while at higher concentrations the reverse occurs. The turning point lies for a number of electrolytes at a molecular concentration of about $m/256$.—D. H. **Tennent**: Evidence on the nature of nuclear activity. The basophilic bodies are not in the nature of chromidia, but are the result of indirect nuclear activity. The explanation offered for the formation of the basophilic extra-nuclear bodies described is intended to be suggestive rather than conclusive.—A. C. **Hardy**: A study of the persistence of vision. Measurement of the persistence of vision for several colours within a cone the semi-vertical angle of which is about 40°.—R. **Pearl**: A contribution of genetics to the practical breeding of dairy cattle. A summary of investigations extending over many years with respect to the value of 224 Jersey Registry of Merit sires in relation to their transmitting qualities in milk-production. This work gives the breeder information of a sort that he has never had before, and that enables him at once to form a real judgment of the worth of various bulls which appear in the pedigree of Jersey cattle.

(Proceedings, vol. vi., No. 5), May, 1920.—H. H. **Laughlin**: Calculating ancestral influence in man. The problem is that of measuring ancestral influence by tracing chromosomes. By applying principles of combination and chance, the probability that a given complex situation will result from a given set of constituent conditions may be formulated mathematically. The formulæ here given are foundational, and are stated in general terms the validity of which depends upon their presenting correct mathematical pictures of chromosomal processes which work out in the germ-cell cycle.—G. **Medes** and J. F. **McClendon**: The effect of anæsthetics on living cells. An attempt to determine the effect of different anæsthetics on several activities or properties of living cells. Not all anæsthetics had the same effect, and the same anæsthetic affected the same activity of a plant differently from an animal, and different activities of the same cell differently. All the anæsthetics tried increased plant-cell respiration and permeability.—R. A. **Daly**: A general sinking of sea-level in recent times. The facts at hand seem to permit belief in the synchrony of the different strand-markings and emergences here considered, but further investigation is needed.—C. C. **Little**: A note on the human sex ratio. A brief study of data collected at the Sloane Maternity Hospital in New York City.—O. **Blackwood**: The existence of homogeneous groups of large ions. It is found that for ionisation from spray and from hot wires the gradation in the size of the ions is continuous, as the mobility curves do not show sharp, separated peaks. The conclusion favours the hypothesis of Sir J. J. Thomson.—E. J. **Cohn**: The relation between the isoelectric point of a globulin and its solubility and acid-combining capacity in salt solution. A detailed discussion of the effect of sodium chloride upon the solubility of tuberin and the effect upon its acid-combining capacity.—H. P. **Armsby**, J. A. **Fries**, and W. W. **Braman**: The carbon dioxide: heat ratio in cattle. Within a range of 5 to 27 grams of feed per kg. live-weight a simple equation may be used for computing the (CO_2: heat) ratio when the live-weight and the amount of feed consumed are known. Thus the heat production may be computed from the observed CO_2 production.—H. S. **Vandiver**: Kummer's memoir of 1857 concerning Fermat's last theorem. It is shown that the proofs given by Kummer are inaccurate and incomplete in several respects.—D. L. **Webster**: An improved form of high-tension direct-current apparatus. A description of an improvement in apparatus previously described.—R. W. **Glazer**: The effect of the concentration of nitrates on the reducing powers of bacteria. A number of species of micro-organisms were tested in Witte's peptone media containing various molecular concentrations of $NaNO_3$ and KNO_3.

Diary of Societies.

SATURDAY, JANUARY 1.

ANNUAL CONFERENCE OF EDUCATIONAL ASSOCIATIONS (at University College, Gower Street), at 10.30 a.m.—A Joint Conference on The Use of Psycho-analysis in Education.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. J. Arthur Thomson: The Haunts of Life: The Open Sea (Juvenile Lectures).

GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.1), at 3.—Lecture.

MONDAY, JANUARY 3.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 3.30.—F. Kingdon Ward: The Travels of a Plant-Collector on the Borders of China (Christmas Lecture).

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—Discussion: Professional Questions.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street), at 8.—C. A. Richardson: The New Materialism.

SOCIETY OF CHEMICAL INDUSTRY (at Chemical Society), at 8.—G. H. Thurston: The Smith Continuous System of Carbonisation.—Dr. I. Masson and T. L. McEwan: (1) The Recovery of Solvent Vapours from Air. Part I., The Use of Cresol for Ether-Alcohol; Part II., The Use of Sulphuric Acid for Ether-Alcohol. (2) The Analysis of Liquid and Gaseous Mixtures of Ether, Alcohol, and Water.

TUESDAY, JANUARY 4.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. J. Arthur Thomson: The Haunts of Life: The Great Deeps (Juvenile Lectures).

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—N. E. Luboshez: The Results of the Demonstration of Portraiture by Artificial Light of October 5, 1920.

MATHEMATICAL ASSOCIATION (Annual Meeting) (at London Day Training College).—Prof. A. S. Eddington: Relativity.—Dr. S. Brodetsky: Aeroplane Mathematics.—The Rev. S. H. Clarke: The Teaching of Mathematics to Boys whose Chief Interests are Non-Mathematical.—Prof. E. T. Whittaker: Some Unsolved Questions and Topics for Research.—Miss E. M. Read: Results of Visits Paid to Lycées of Paris and other Centres, and the Study of Education there, particularly from the point of view of Mathematics.

THE ASSOCIATION OF SCIENCE TEACHERS (at University College).—Miss M. B. Thomas: Presidential Address.—Dr. J. C. Drummond: Vitamines.

WEDNESDAY, JANUARY 5.

ROYAL SOCIETY OF ARTS, at 3.

PHYSICAL SOCIETY AND OPTICAL SOCIETY'S EXHIBITION (at Imperial College of Science), from 3 to 10. At 4.—Sir W. H. Bragg: Sounds in Nature. At 8.—Prof. A. Barr: The Optophone.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Prof. S. H. Reynolds: The Lithological Succession of the Carboniferous Limestone (Avonian) in the Avon Section at Clifton.—Miss E. Bolton: The Carboniferous Limestone of the Wickwar-Chipping Sodbury Area (Gloucestershire).

THURSDAY, JANUARY 6.

ROYAL SOCIETY OF ARTS, at 3.—Sir Frederick Bridge: The Cries of London which Children heard in Shakespeare's Time (Juvenile Lecture).

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. J. Arthur Thomson: The Haunts of Life: The Freshwaters (Juvenile Lectures).

PHYSICAL SOCIETY AND OPTICAL SOCIETY'S EXHIBITION (at Imperial College of Science), from 3 to 10. At 4.—Prof. A. Barr: The Optophone. At 8.—C. R. Darling: Some Unusual Surface Tension Phenomena.

FRIDAY, JANUARY 7.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 3.30.—Lt.-Col. C. Smith: Life on the Gilgit Frontier (Christmas Lecture).

SATURDAY, JANUARY 8.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. J. Arthur Thomson: The Haunts of Life: The Conquest of the Land (Juvenile Lectures).

The Cost of Education.

THERE has just been issued the Seventh Report of the Select Committee on National Expenditure, a document, including appendices, of twenty-three folio pages, sixteen of which are devoted to the expenditure on public education, a subject which receives caustic criticism. It would appear that the net cost of education for the year 1920–21 for all forms of education from the public elementary school to the university throughout the United Kingdom is estimated at the vast sum of 97,206,548*l.*, of which 60,081,831*l.* is derived from taxes and 37,124,717*l.* from rates. This figure is in striking contrast to that of less than ninety years ago, when the local authorities contributed nothing from the rates and the only grant from the Exchequer was one made for the first time in 1834 of 20,000*l.* in aid of school buildings and not of their maintenance. This was the measure of our indifference to the cause of public education, from which the nation has suffered irremediable loss; it enabled more progressive nations with a finer insight into things of real value to compete with us in all departments of civilised life and its varied activities, to our great disadvantage.

Undoubtedly in these strenuous times all possible economies in national and local expenditure ought sedulously to be promoted, but it would be a foolish, not to say a disastrous, policy to limit unduly the expenditure in the means and encouragement of public education, especially for the mass of the people. It is demonstrable that a large percentage of this mass is susceptible to the greatest advantages which can be offered to it of facilities for the highest available education that the country can give. The Education Act of 1918 and the zeal which prompted and sustained its promoters throughout the lengthy debates in Parliament is the subject of deprecation in the Report, chiefly on the ground of the large expense in which the nation would be involved in carrying out its provisions at the present difficult time. Surely it is forgotten that expenditure upon education, wisely directed, is, with this qualification, a truly productive effort which will repay the nation a hundredfold within a generation.

The strictures in which the Committee indulges indicate a lack of genuine sympathy with the vital claims of the people to the benefit of a longer continued means of education for their children. Their claims go much beyond the demand for the familiar "three R's"; they require that the best fruits of literature and science shall be brought within their reach. The Committee views with something like dismay "an enthusiasm for education" on the part of the Board of Education, to which Mr. Fisher replies that "a Board of Education which was not enthusiastic for the promotion of education would not deserve to exist." It makes suggestions having for their object the serious curtailment of expenditure under the Education Act of 1918; such, for example, as would involve the withholding of the proposed continuation schools, one of the most valuable features of the Act; the prolongation of the vicious half-time system which mainly prevails in the textile districts of East Lancashire and West Yorkshire; the stoppage of new developments in the building of schools, both elementary and secondary, in certain towns and rural areas—this last policy has already been largely adopted by the Board of Education during the last five years, having regard to the high prices of materials and of labour, yet, it must be admitted, to the detriment of educational progress—the limitation of means of medical treatment so vital to the welfare of the elementary-school child; and finally, among other important developments made possible by the Act, the curtailment of the means of higher education so essential to the progress and well-being of the nation—objects which are set forth so ably in the Report of the Adult Education Committee and by the Workers' Educational Association.

It must be acknowledged that since the conclusion of the war there has been a remarkable development in public opinion as to the importance and value of education. The demand for secondary education has increased enormously, and the claims for admission to technical colleges and universities have been almost too great for their resources in teaching staff and equipment. In the year 1913–14 the number of full-time university students in the British Isles was roughly 30,000, or about 6·5 per 10,000 of population. The figures available for the year 1918–19 show that the number of students had almost reached 40,000. The number of students per 10,000 of population had jumped to 8·6; almost one in every thousand was receiving university training.

There has been but slight consideration given in the Report of the Select Committee to the enormous rise in the cost of materials and equipment, especially in reference to the secondary schools and technical institutions, during and since the war, nor has sufficient weight been given to the necessary rise in the salaries of the teaching staff due to the increased cost of living. This item alone accounts for 21,000,000*l.* in the estimated expenditure. If the schools and the higher institutions of learning are to be staffed efficiently with well educated and trained men and women, adequate salaries and prospects, and an assured provision such as the Teachers (Superannuation) Act affords for the time when they are no longer capable of rendering effective service, must be offered.

Mr. Fisher in a recent interview shows conclusively with regard to the Report in question that there are adequate safeguards in respect of extravagant expenditure both on the part of the Board of Education and on that of the public represented by the ratepayer. The nation will be well advised to encourage by all the means in its power the desire which is so plainly manifest for a longer life in the schools and for the advantages of an efficient secondary and university education for those who are qualified, to receive it. Now that the war is over we are entering upon a serious and strenuous time, when all the trained brain power at our command will be needed to meet the competition which we shall assuredly be called upon to face, and after all, as Mr. Fisher truly said in the interview before alluded to, "a nation which can afford to spend 400 millions a year upon drink and 100 millions upon tobacco is not quite at the end of its resources."

Territory and Bird Behaviour.

Territory in Bird Life. By H. Eliot Howard. Pp. xiii + 308. (London: John Murray, 1920.) Price 21*s.* net.

ON the publication of his "British Warblers" (1907–14) Mr. H. Eliot Howard took rank as a naturalist of marked ability, as an observer who could be trusted, and as an interpreter well trained in scientific method, fertile in suggestion, cautious in application, and, above all, insistent on the importance of keeping in close touch with the evidence afforded by patient and systematic field-work. A salient outcome of his monograph was a re-grouping of the phenomena presented by birds in their breeding haunts around a concept of "territory." He has now marshalled the evidence in favour of this hypothesis in a work which neither the biologist nor the comparative psychologist can afford to neglect.

To grasp Mr. Howard's root idea, we must recall the familiar routine of a bird's behaviour—and it is clearly with behaviour that observation must primarily deal. There is an orderly sequence the biological value or utility of which is centred in race-maintenance. Within this we can readily distinguish successive phases which are contributory to the routine as a whole. In the life of the wide-range migrant there is departure from the south, arrival in England, settling down in some part of the country, mating, sexual union, nest-building, incubation, feeding and rearing of offspring, and then departure from the breeding quarters to the south. All this is familiar enough. But closer observation discloses other facts. The males arrive in advance of the females; each male settles down in a restricted area within which some bush or tree is thenceforth his headquarters; the extent of this area is determined by the range of flight in oft-repeated excursions from the headquarters, and constitutes the "territory," which varies in size according to the species; the male bird is intolerant of any intruder into this territory, especially of a male of his species, fights him, and drives him out; he sings with maximum vigour at headquarters before any female is in evidence; this expression in song makes an attractive impression on some hen bird when she arrives in migration from the south; she becomes his mate, lives with him within the territory, and helps to drive out intruders. Mating is consummated, a nest built, and a brood reared within the territory, which affords, in the main, sustenance to the family; and in due season they depart. Now, of course, the sexual act may be regarded as the pivot on which the whole system of behaviour turns. But Mr. Howard contends that, to change the metaphor, the territory is the scene of the drama between arrival and departure; that the territory is secured and defended and the outburst of song in evidence before the females arrive; and that the size of the territory is such as to meet the requirements of the future. He holds, then, that the territory, if not the pivot in which the cycle of behaviour is centred, is the hook of biological utility on which it is hung.

Now, with regard to any routine of behaviour or phase therein, four questions arise: (1) In respect of the behaviour itself, is it unlearnt, or is it acquired in the course of individual experience? (2) Under what conditions of external stimulation does it come? (3) What is the good of it—its biological value? and (4) On what, in the constitution of the bird, does it depend? To the first three questions observational evidence affords the data for a reply. The answer to the last is in large measure a matter of inference.

As to the first, Mr. Howard is quite clear that, on the evidence, much of the behaviour involved in territorial routine is in form unlearnt. In so far as it is unlearnt, it is instinctive. This does not mean that the constituent details, as the matter incorporated in the behaviour as a whole, are purely instinctive. They are obviously in large measure learnt. Skill in their performance has been acquired. It means that the male bird in his first year occupies and protects the territory, and acts therein in specific ways, without having learnt by previous experience this *form* of behaviour-routine as a whole. Secondly, the external stimulation is, in Mr. Howard's opinion, afforded by the territorial situation, and not, in the early stage, by the presence of a female. To drive away an intruder involves, of course, the stimulus of his presence; it is, however, within the territory that the occupant attacks him; elsewhere, beyond its confines, the behaviour is no longer the same. The territory is, therefore, a feature of the situation that counts. Thirdly, it is clear enough, on the evidence, that the procedure has biological value. But—and this is of prime importance—Mr. Howard does not regard the prospective value of instinctive behaviour as implying the presence in mind of an end for the sake of which the bird acts. The biological value of securing a territory is the mating which follows in due course. *We* expect this outcome because we have knowledge of routine based on observation. But if the male in his first year has never mated, he cannot, on the basis of individually won experience, foresee this mating and what follows thereon. It is not for him an end to be attained by his behaviour. This is important—nay, essential—to the interpretation offered. For if there be inherited *knowledge*, the whole matter is easily explained as due to ancestral experience transmitted through "memory" to the bird that behaves under its guidance.

We come, then, to the fourth question: On what, in the constitution of the bird, does the behaviour depend? Mr. Howard refers to physiological changes in the organism which are correlated with tendencies to act in just that way which is open to observation in the unlearnt behaviour. This is what we speak of in a broad and general way as the nature of the bird. But this nature, and the correlated psychical nature, is different on different occasions. It is also attuned to the circumstances at the time, and gives to the behaviour much of its biological value. Such an attunement of the nature Mr. Howard calls a disposition. It is a state of physiological and psychical preparedness to act appropriately when the requisite stimulation is afforded. At the moment of action it is focussed as impulse. Thus at least may be interpreted many of Mr. Howard's statements, though in others there seems to be little difference between disposition and impulse. He often speaks of the disposition or the impulse as being "rendered susceptible to stimulation." For example, the territorial situation renders the impulse to drive away intruders susceptible. Some might prefer to speak of the susceptibility of *the bird* when it is in such a state as to respond to these or those external conditions. We thus avoid the risk of hypostatising a disposition or "an instinct." The essential point, however, is that the disposition that is inferred from the performance of unlearnt acts has factors which are congenital, and do not depend on individually won experience.

Brief illustration may here be given of changes of disposition. During the winter, before the mating season, lapwings live together in flocks. The males are seemingly on the most friendly terms with each other. Just such minor squabbles occur as may give some savour to the life of enjoyment. The females are, for the males, just other birds in the flock, and are not viewed, so to speak, in the light of a disposition to mate. Then in due season come the changes which constitute *ad hoc* physiological and psychical preparedness. Now one male and now another leaves the flock and occupies a territory in the fields; and, once there, he is intolerant of other males, fighting with any intruder for all he is worth. With the physiological change (partly due to specific internal secretions contributed to the blood-stream) there is a complete psychical change in the dispositional attunement of the bird's nature. Substantially the same presentation afforded by another male is now linked with quite different modes of overt behaviour. No longer gregarious, he is a solitary occupant of a restricted domain, driving all other males away. Presently he is joined by a mate, and the normal routine of reproduction runs its course. But if a cold snap should come on, the separated males may reunite in a flock, and the male is then no longer intolerant of other males. The physiological state probably reverts to its winter poise, and with this is correlated a reversion to the previous psychical disposition. But it seems that when a male bird (lapwing or other) has secured a territory and is intolerant therein of all others save a mate, he sometimes returns for a while to the flock which occupies a neutral area. *There* he is no longer intolerant of others, but moves among them on quite friendly terms. Hence in different circumstances, (1) in his territory and (2) in the flock, his disposition is different, so that occupancy of a territory appears to be a determining condition of the behaviour observed therein. If this sort of thing occurred in so marked a form in human life, it would perhaps be attributed to "dissociation," and described as an instance of double personality, two "streams of consciousness" being separated as if by a barrier. In any case, just thus, it seems, does the male bird in his first year behave, though he has never so behaved before, or seen others so behave.

Exigencies of space preclude more than an outline sketch of Mr. Howard's main thesis. The treatment in detail is admirable in its method of raising and meeting difficulties with no attempt to shirk them. The way in which the expression of song may produce a different impression on others at different times and in different circumstances is dealt with suggestively. All may not agree with Mr. Howard's conclusions; but all will admit the transparent candour of a genuine seeker after truth. One would like to comment on his contribution to the solution of the difficult problem of migration—turning upon the alternating interplay between the territorial and the gregarious poise in disposition. But lack of space forbids. The book is well written, well printed, and well illustrated, with photogravures from drawings by Mr. G. E. Lodge and Mr. H. Grönwold.

C. LL. M.

Airscrews in Design and Performance

Airscrews in Theory and Experiment. By A. Fage. Pp. ix+198+7 folding plates. (London: Constable and Co., Ltd., 1920.) Price 34s.

IT is difficult to place this book in the scheme of aeronautical progress, for it does not deal adequately with either the theory or the practice of airscrew design. The author has not succeeded in the idea expressed in the first sentence of his preface, where he says that "an endeavour has been made to present in this work an accurate and comprehensive account of the science of the airscrew from both its theoretical and experimental aspects." It is well known to all those connected with the experimental side of aeronautics that Mr. Fage, as a result of his position at the National Physical Laboratory, has had greater facilities for original work than any other British worker. The number of papers in his name which occur in the bibliography testifies to his activities, and the book cannot fail to have an importance in many directions. One would select chaps. v., vi., and vii.—that is, those dealing with experimental data —as justifying the writing of this book.

What is missed is the presentation of the results of research in a form which stimulates application to the workaday theories of the immediate future. Instead, one finds a very important recent development of theory compressed into one and a half pages of the book in such a way that, without prior knowledge, it conveys nothing to the reader. The basic theorem on which design rests comes from the conception that the several elements of an airscrew blade produce an airflow which is essentially of the same character as the flow round a wing. The application of this theory to aerial propellers is due to Drzewiecki and Lanchester, but after some little use and comparison with experiment it was found to be insufficiently accurate for design purposes. The necessary idea for a next approximation was obtained from a realisation of the fact that a wing is always moving into fresh air, whilst an airscrew blade moves into air disturbed by other blades and by the previous passages of the blade itself. The thrust of an airscrew, being produced by dynamic means, involves the throwing back of a mass of air per second the axial momentum of which is equal to the thrust. Owing to the continuity of the airflow, it might therefore be expected that disturbances due to other blade passages would take the form of an "inflow" of air into the airscrew blade. Experiment provides support for, and can be used to give quantitative values to, a theory based on this idea.

In discussions of marine propellers, Froude developed a theory in which half the final momentum of the slip stream was added in front of the propeller disc. Lanchester applied the idea to aerial screws, but, with his sense of the physical incompleteness of the theory, he did not accept "half" as anything more than an approximation. The Fage-Collins theory referred to on p. 19 is merely a theory which supposes that wing elements modified by the assumption of an inflow velocity can be made to agree with an experimental check by the choice of a certain constant closely related to Froude's half.

It is known that a second approximation so made is important, but it is also realised that every unknown quantity, such as the effect of the ends of the blades, their shape, and the changes in type of flow due to centrifugal action, are attributed to inflow. Wood and Glauert devised a scheme for the experimental determination of "inflow" without the above complications, and described their tests in the report referred to by Mr. Fage. It was pointed out that a logical extension of the aerofoil theory would be obtained by placing a succession of aerofoils behind each other in a wind channel so that some of them were working in the disturbed air of blades further into the wind. The relative positions of the blades to correspond with an airscrew were not found to be inconvenient for experiment, and, finally, after tests in a wind channel, a further approximation was made which brought theory nearer to the truth. The differences from the Fage-Collins theory are too great to be dismissed as unimportant, and show that there still remain further factors to be investigated.

This fundamental step in analysis of airscrew performance is the one dismissed by Mr. Fage in less than two pages of his book, and his closing remarks indicate the rather illogical contention that because other points still remain to be explained, the new experiments are of little use. This should surely not be the attitude of research workers at the National Physical Laboratory. It is to be hoped that it does not represent the views of the late Advisory Committee for Aeronautics, to which most of the items of work at the National Physical Laboratory were presented before publication.

This example has been taken at some length as typical of the book, which, on the theoretical side, is sketchy throughout. Perhaps one is tempted to be too critical of a work which largely records war activity. On the other hand, where are we to look for the progressive development of knowledge in aeronautics if such places as the National Physical Laboratory fail us? Is the new Aeronautical Research Committee still accumulating a great mass of undigested material, of which Mr. Fage's contribution is a part, or is it keeping its activities for advice on the general lines of experiment and research? One is not too hopeful that the incubus of the war is being thrown off any more completely by his employers than by the author of the book under notice.

Nomography.

A First Course in Nomography. By Dr. S. Brodetsky. (Bell's Mathematical Series. Advanced Section.) Pp. xii+135. (London: G. Bell and Sons, Ltd., 1920.) Price 10s. net.

THE subject of nomography may be shortly described as dealing with the graphic representation of formulæ. As developed by M. d'Ocagne, there has been an increasing interest taken in recent years in the application of its methods to facilitating calculation in engineering and scientific work generally.

In this "First Course," nomography is arbitrarily restricted to graphic representation in parallel co-ordinates, the resulting diagram being read by the collineation of points. It is true that there is a growing tendency to use the word "nomogram" for such a representation only; but, apart from nomenclature, there are grave disadvantages in this isolated treatment.

For a clear and intelligent appreciation of the subject it is a matter of great importance to keep in the forefront the *principle of duality*, the connection between graphic representation in Cartesian co-ordinates (the intersection diagram) and that in parallel co-ordinates (the alignment diagram), and the transformation of the one into the other.

Throughout the book the explanations are clear and the diagrams excellent, but the former appear occasionally to be unnecessarily diffuse. Nearly fifty pages out of a total of fewer than one hundred and fifty are mainly occupied with a minute description of nomograms for performing simple addition and subtraction, a purpose for which they are seldom practically used. Some introductory reference to them is certainly advisable, but all that is necessary might quite well have been given in a few pages and a couple of illustrations.

Some of the space so saved could with advantage have been devoted to a description of the direct-reading four-variable nomogram, which is a combination of two parallel scales and a network. To this no reference is made, but it is of great importance in practical work.

Diversity of notations is a continual source of irritation in such subjects, but, of course, is at times unavoidable. In the present case it seems a pity that M. d'Ocagne's later notation has not been accepted as standard and used wherever possible. By later notation is meant the one adopted in that writer's "Calcul Graphique et Nomographie" (1908). It is wonderfully concise, without any sacrifice of clarity or completeness, and is quite simple to grasp. M. d'Ocagne evidently considers it an improvement on the more cumbrous notation of his earlier "Traité de Nomographie" (1899), as he has continued to use it in his latest brochure, "Principes usuels de Nomographie avec application à divers problèmes concernant l'Artillerie et l'Aviation" (1920).

Metallurgy for Dental Surgeons.

A Manual on Dental Metallurgy. By Ernest A. Smith. Fourth edition. Pp. xvi + 285. (London: J. and A. Churchill, 1920.) Price 12*s*. 6*d*. net.

SMITH'S "Dental Metallurgy" is read by so many dental students that the goodness or badness of the text has a considerable influence on the stage of knowledge of the embryo surgeon-dentist. Thus for many years it was impossible, even with the help of photomicrographs showing the two metals in patches like the stripes on a zebra, to convince the dental student that a eutectic was a mixure, because the author of this book had declared that such a patchwork might be a chemical compound! This error has, fortunately, been corrected in the new edition, which shows many useful improvements resulting from the incorporation of the rudiments of modern scientific metallurgy.

In spite of these improvements, the general tone of the book is still unsatisfactory, and carries with it the impression that the dental surgeon is content with a much lower standard of knowledge than are his medical colleagues. Thus, in view of the fact that for many years every candidate for the L.D.S. has had to pass an examination in elementary chemistry before taking the test in dental metallurgy, it is almost incredible that a standard text-book should attempt to teach metallurgy without making use of chemical equations. It is, nevertheless, true that the author has described the extraction of the metals from their ores (for which formulæ are usually given) without in any instance providing a chemical equation to express the action which takes place; it must therefore be taken as a singular compliment to the work on dental amalgams, carried out in the Laboratory of Physical Chemistry at Bristol a short time before the war, that it has provided the author with the only example of a chemical equation which the reviewer has been able to discover in the whole of the volume. This treatment of the subject can, however, scarcely be regarded as a compliment to the dental profession; and, even if it represented a reasonable point of view when the first edition appeared in 1898, the time has surely come when dental text-books should be addressed to readers with some knowledge of elementary science, instead of being lowered to the standard of a trade-class of mechanics or plumbers.

T. M. L.

Our Bookshelf.

Peat Industry Reference Book. By F. T. Gissing. Pp. xxiv + 292. (London: Charles Griffin and Co., Ltd., 1920.) Price 7*s*. 6*d*.

THE author, alone or in conjunction with Bjorling, has already published two books on peat. The present volume deals mainly with those developments in the peat industry which have arisen since the publication of the previous books. It is divided into eight sections, dealing with the formation of peat, its winning as cut peat, machine-formed peat and pressed peat, peat gas and its by-products, power gas, peat-moss litter, peat mull and other products, such as alcohol and paper obtainable from peat. The eighth, and last, section contains miscellaneous information, formulæ, and tables, which will be of much use to persons dealing with peat.

The various processes patented, or worked on an experimental scale, have been faithfully described from the point of view of the inventors or exploiters of these processes, and it is this circumstance which constitutes the chief defect of the book. Claims which are experimentally unjustifiable are occasionally admitted into the book without criticism, and for this reason some of the statements made are quite at variance with the actual facts, and are likely to mislead readers unacquainted with the properties of peat. Everyone knows, for instance, that a peat-pulping machine exerts practically no *cutting* action on peat, yet the claim that one peat-pulping machine *cuts the cells* of the peat fibres is passed without comment.

Again, under another process it is stated that wet raw peat contains 20 per cent. of dry peat, and gives 8 per cent. of charcoal. As a matter of fact, wet raw peat from an undrained bog contains only about 8 per cent. of dry peat, and gives only about 2·8 per cent. of charcoal, and even from a well-drained bog the amount of charcoal got from 100 tons of the raw peat rarely exceeds 3·5 tons. It is evident, too, from this book that some "inventors" are still unable to grasp the elementary fact that in order to obtain 100 tons of dry peat from raw peat by the aid of artificial heating somewhat more than 100 tons of dry peat must be burnt to develop the heat required.

Text-book of Pastoral and Agricultural Botany: For the Study of the Injurious and Useful Plants of Country and Farm. By Prof. J. W. Harshberger. Pp. xiii+294. (Philadelphia: P. Blakiston's Son and Co., 1920.) Price 2 dollars.

A KNOWLEDGE of the useful and poisonous plants on a farm is an essential part of the equipment of the agriculturist, but hitherto the requisite information has been to a large extent scattered and difficult of access. In the present volume the account of the stock-killing and poisonous American plants is thorough and comprehensive, a specially useful feature being the inclusion of methods of treatment where they are known. It is a pity that the photographs of affected animals are not reproduced more clearly, as several of them fail to illustrate their point.

The crop plants are dealt with sufficiently, though briefly, and the bibliography at the end of each chapter assists the student to follow up any requisite line of inquiry. It may be suggested that in future editions an "author index" would greatly enhance the value of the book, as at present it is not always easy to determine if a reference is included. The laboratory exercises which follow each chapter are very practical and well thought out, and render the book serviceable to the private worker, as well as to the class student. The same object is attained by the inclusion of a glossary with the detailed index. Prof. Harshberger is to be congratulated on the production of a much-needed working manual, the value of which lies not only in the well-arranged and clearly written information it contains, but also in the suggestiveness which renders it adaptable for use in countries other than America. W. E. BRENCHLEY.

This Wonderful Universe: A Little Book about Suns and Worlds, Moons and Meteors, Comets and Nebulae. By Agnes Giberne. New illustrated edition, completely re-written. Pp. x+182. (London: S.P.C.K.; New York: The Macmillan Co., 1920.) Price 6*s.* 6*d.* net.

MISS AGNES GIBERNE is well known for her charmingly written books on elementary astronomy. This is a new edition of an earlier work, carefully brought up to date, some excellent photographs of the moon, Mars, eclipses, and nebulæ being reproduced. The celestial phenomena are described in clear and vivid language, the difficulties likely to occur to a beginner being answered in anticipation. The book is made more interesting by the inclusion of a certain amount of legitimate speculation on the development of worlds and systems, and the probable condition of the different planets. The concluding section, "Immensity—and Man," deserves thoughtful study.

A few slips should be corrected. P. 69: One of our athletes would only jump 2·6 times as high on Mars as on Earth. "Over a good-sized house" is misleading. P. 84: The paragraph about TG misses the chief interest of the Trojan group of planets—the equilateral configuration with Sun and Jupiter. P. 108: Neptune's orbital speed should be 200 times that of an express train—not three times. P. 124: Two upright sticks a yard apart are not strictly parallel, since both point towards the earth's centre. P. 134: Sun's density is wrongly stated to be less than Saturn's. P. 138 (plate): Date of Mina Bronces eclipse was 1893—not 1889. A. C. D. CROMMELIN.

Practical Physiological Chemistry. By S. W. Cole. With an introduction by Prof. F. G. Hopkins. Sixth edition. Pp. xvi+405. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin, Marshall, Hamilton, Kent, and Co., Ltd., 1920.) Price 16*s.*

IN spite of the fact that a fifth edition of this valuable book was reviewed in NATURE of August 28, 1919, another edition has rapidly become necessary. The volume has been revised and enlarged, and several new methods have been introduced, of which the most important is a modification of McLean's method for the determination of blood sugar. Other additions include Van Slyke's method for the estimation of blood chlorides, and the soya bean method for the estimation of the urea in blood. Six editions of the book have now appeared in sixteen years; this should be a sufficient guarantee of the worth of the contents.

Coal. By J. H. Ronaldson. (Imperial Institute: Monographs on Mineral Resources, with Special Reference to the British Empire.) Pp. ix+166. (London: John Murray, 1920.) Price 6*s.* net.

MUCH information relating to the coal deposits of the British Empire is recorded in this book. The geology of the deposits is described, and the statistics of production and reserves in various countries of the world are given. Apparently the most important coal resources of the world are in the northern hemisphere, particularly in countries near the Atlantic Ocean. Roughly three-quarters of the world's coal supplies are located in North America, principally in the United States, while the British Empire contains less than one-fifth of the known coal deposits of the world. The monograph concludes with a list of references to publications dealing with the coal resources of the Empire.

Science German Course. By G. W. Paget Moffatt. With a glossary by J. Bithell. Third edition (sixth impression). (Science Text-books.) Pp. xii+270. (London: W. B. Clive: University Tutorial Press, Ltd., 1920.) Price 5*s.*

THE third edition of this book is not very different from the first, which was noticed in NATURE of November 21, 1907. All the extracts in Gothic type have been removed to the end of the book, and in place of the separate vocabularies a complete vocabulary of all the words occurring in the extracts for reading has been inserted.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Heredity and Acquired Characters.

(1) MOST biologists believe that the heritage travels down the germ-tract. (2) All biologists believe that in the germ-cell are none of the characters which the individual afterwards develops, but only potentialities for producing them in response to fitting nurture. (3) It follows necessarily that only potentialities are transmitted. (4) All that is transmitted is not produced (as characters of the individual), for fitting nurture may be lacking. (5) Therefore, inheritance and reproduction are not synonymous terms. (6) The individual can produce nothing but what was potential in the germ-cell, and nothing except in response to fitting nurture. (7) Necessarily, therefore, all characters are innate, acquired, germinal, somatic, and inheritable in exactly the same sense and degree. Given these facts and inferences, I asked biologists why they described some characters as "innate," "germinal," and "inheritable," and others as "acquired," "somatic," and "non-inheritable." I gave the example of the head and the scar, both ancient products of evolution. Why, when the child is like his parent both by nature and by nurture, is he said to inherit the head but not the scar? Why is the word "inherit" used as synonymous with "vary," its direct opposite, in the case of the scar? Really, I was asking for such definitions of biological terms as would accord with the current usage of them. As yet I have got none. I think I shall get none.

I may be wrong in thinking that biological terminology is vague, and sometimes even unmeaning, or I may be right. If I am wrong, surely some biologist can give the definitions I ask for. If I am right, the matter is of importance even as a mere question of words. A science cannot progress unless its workers have means of expressing themselves precisely and clearly. Other interpretative sciences—*e.g.* mathematics, physics, astronomy, and chemistry—have such means. It is noteworthy that they all possess in addition a body of established truth—truth which no one who knows the facts disputes. But biology can boast of scarcely an important interpretation (not even the theory of natural selection) which is accepted by everyone. As in religion and politics, its workers are divided into more or less hostile sects and sub-sects—Lamarckians, Darwinians, Neo-Darwinians, Mendelians, mutationists, Mendelo-mutationists, biometricians, and the like. I submit that much of this extreme, and apparently irreconcilable, divergency of opinion is due to confusion of thought consequent on confusion of language.

But beyond words, the matter is important. Biologists classify characters as "innate" and "acquired." Physiologists ignore this classification, and, assuming that all characters develop in response to nurture, endeavour to ascertain what forms of nurture evoke them. In other words, they classify characters according to the nurtures which cause them to develop—use, injury, this or that hormone, and the like. This classification is not merely different from the biological one; it is actually antagonistic; for, of course, if all characters equally arise in response to nurture, they must all equally take origin in germinal potentiality—must be equally innate and acquired. If biologists cannot justify their use of terms (supply valid definitions), it appears to me that they have no alternative but to accept the physiological classification. If that be done, I conceive that some such simple formula as "The sole antecedent of non-inheritance is variation. Apart from variations, like exactly begets like when parent and child develop under like conditions," will almost cover the field of discussion.

In reply to Dr. Ruggles Gates's letter in NATURE of December 2, p. 440, if we believe with Darwin in his theory of pangenesis that the parts of the child are derived from the similar parts of the parent (the child's head from the parent's head, etc.), the distinction between variations and modifications vanishes. Every modification is then a variation. We can distinguish only between germinal and somatic variations. If we believe that modifications in the germ's environment (the soma) may so impress the germ as to cause variations, then I think we are accepting what nobody questions, though I believe the importance of variations so caused has been greatly exaggerated. If we believe that changes in the soma tend to impress the germ-plasm in such a remarkable and unlikely way that the child reproduces in response to a different stimulus the character which the parent produced in response to the stimulus that Nature had fitted his race to respond to, then undoubtedly that child has varied from the parent. He is of a different nature; he has not inherited. I confess I do not see how Mendelians and mutationists *as such* are concerned in this discussion. They think that fluctuations are modifications, and that only mutations are true variations, and, therefore, that only the latter are inheritable—all of which is at least intelligible.

Prof. MacBride and Sir Ray Lankester (NATURE, December 16, pp. 500–1) may conveniently be answered together. But if, after reading what follows, Prof. MacBride will precisely indicate the "quibble" he writes of, I shall be much obliged. In reference to his last paragraph, if the child of a parent with an extra digit lacks that extra digit, or if he is relatively fair, then he has varied from the parent, has he not? Yet he has not departed from what is normal in the species. Prof. MacBride tortures a word which has now an established and perfectly clear meaning.

In 1911–12 I instanced a scar as a so-called "acquired character." Then, as now, Sir Ray Lankester quoted Lamarck in the original French. Lamarck wrote about the effects of use and disuse (not about the effects of injury). Therefore, *pace* Sir Ray Lankester, a scar is not an acquired character. Therefore, "if you, without any warrant, alter the established signification given by the Neo-Darwinian to the chief term in his statement, you can, of course, convert it into nonsense, and your proceeding is merely farcical." It is as if I had asked why kippers were called whales and Sir Ray Lankester had insisted that the term was restricted to red herrings. Fortunately, I am in good company. Did not Weismann himself cut off the tails of rats by way of demonstrating that acquired characters were not transmissible? If in my letter Sir Ray Lankester substitutes any use-acquirements he likes for "scar," his requirements will be met. In 1911–12 Sir Ray Lankester declared I was "doing harm." Influenced, doubtless, by the opinion of so great an authority, the Editor closed the correspondence. Thus was I crushed. The odd thing is that at the time I believed—as I do now—that I was fighting my critic's—or shall I say my contemner's—battles. We had travelled by different roads, but had reached, as far as I could judge, the same goal, and I was seeking to clear the ground. But more of this anon.

If the writings of Lamarck (notably the laws quoted by Sir Ray Lankester) and of those of his successors (*e.g.* Spencer, Romanes, Wallace, Weismann, and even Darwin) be examined, two assumptions will be found—never formally expressed, perhaps, but always apparent. On one hand, it is assumed that all characters develop in response to use. On the other, it is assumed that this development is never considerable. Both assumptions are monstrously wrong. Even in human beings many characters (*e.g.* hair, teeth, external ears, and external organs of generation) do not develop in the least in response to functional activity; on the other hand, in the higher animals, and especially in man, most characters develop from the infantile standard wholly, or almost wholly, in response to that stimulus. Physically and mentally man is the educable animal. He is immensely responsive to both use and disuse.

Low in the animal scale we find little or no evidence of development in response to functional activity. Apparently, even in an animal so high in the scale as a butterfly, use does not cause development nor disuse atrophy. In the egg use plays no part. We have no grounds for supposing that any structures grow during the caterpillar stage *because* they are used. In lack of functional activity the butterfly's structures develop vastly in the chrysalis. Afterwards functional activity does not cause them to grow. The evidence as regards mind is even clearer. In all its conscious phases this animal seems purely instinctive. It does not profit from experience, it does not learn, it is not educable. At any rate, if it develops at all in response to mental functional activity, it does so to a very small extent. Higher in the scale animals are born more and more helpless, but more and more capable of developing in response to use. Nature substitutes "acquired" for "innate" characters. That substitution marks the higher animal. Presently we find animals so capable of learning that mates are able to recognise one another, and also to recognise offspring. Thus family life arises, whereby offspring are afforded opportunity to develop in response to use. At last we reach man, who is born particularly helpless and immature, but enormously capable of growing through use, both in mind and in body. To this potentiality he owes all his adaptability, all his morality, religions, intelligence, knowledge, his whole intellectuality.

Now consider whether the problem of the "transmission of acquired characters" furnishes materials "for a legitimate inquiry." (1) The evolution of the power of developing in response to use is *the* feature of the rise of the higher animals. Steadily this potentiality increases at the expense of other potentialities. It may be argued, therefore, with some appearance of plausibility, that "innate characters" tend to be "transmitted" as "acquirements"; but the supposition that "acquirements" tend to become "innate" is, in the face of enormously massive evidence, ridiculous. (2) For thousands of generations the muscles of the boy have developed into those of the ordinary man in response to use, but no one has suggested that these "acquirements" tend to be "inherited"—to develop in the lack of use. But let one man (*e.g.* a blacksmith) display his human adaptability by developing his muscles by a little more use, and the Lamarckian immediately begins to wonder whether this last scrap of development is "transmissible." (3) Acquirements consequent on use and injury (made as Nature designed them to be made) are all useful. Transmitted, they would be less useful, or useless, or, more often, burdensome. For example, of what utility would scars be to an unwounded man, or the muscles of a blacksmith to his descendant the clerk? Lamarckians gravely argue, in effect, that after Nature has expended millions of generations in evolving a useful trait, this trait, directly it appears, tends to be converted into a useless trait. Here we have the oddest view of evolution conceivable.

To us as rational beings the evolution of the power of developing in response to use is immensely the most important phase of evolution. Of course, everyone is more or less aware of it. Thus parents know that it is necessary to train children, and even schoolboys know that men are more educable than dogs, dogs than cats, and so on. But it is remarkable how this tremendous truth has been ignored in scientific literature. If Lamarck and his supporters had realised it, would they have argued for the transmission of acquired characters? If Weismann and his followers had realised it, would they have condescended to argue against such transmission? Would any men have asked whether nature or nurture is the stronger? Would they have concluded that "nature is certainly five, and perhaps ten, times stronger than nurture"? What caused all this blindness to exceedingly obvious truth? Plainly, it was caused by the classification of characters as "innate" and "acquired." This led to the assumption that use-acquirements are of trivial magnitude, and so threw a veil over reality.

Men of science who study organic Nature—zoologists, botanists, palæontologists, anatomists, physiologists, bacteriologists, psychologists, and the like—are necessarily specialists and, unless they pass the boundaries of their particular studies, very narrow specialists. Biology supplies the connecting links. Every science is at first purely descriptive. Later, as the woof to the warp, interpretation is added. As Newton interpreted facts of astronomy, so Darwin accounted for the structures which zoologists, botanists, and palæontologists describe. Physiology is accounting for the facts of anatomy. It tells, among other things, of the influences in response to which structures develop. Pathology and bacteriology are accounting for the facts, that medical men have described, in terms of causation (nurture). But psychology is as yet, in very great measure, purely descriptive, and, even so, in a very limited field. Perception, conception, association, and the like have been described, but there are other and, for people who seek practical results, even more important characters—*e.g.* courage, cowardice, chivalry, meanness, energy, prejudice, and, above all, intelligence and stupidity. How do these traits, which in their sum constitute individual and national "character," develop? Do they arise in response to training (functional activity), or in response to influences (hormones and the like) largely beyond our present control?

Only biologists are able to settle these problems, for they alone are in a position to combine knowledge sufficiently deep and wide with relative freedom from blinding prejudice, religious and other. Presently, when, drawing on the vast stores of verifiable evidence which are available, they account indisputably for the various items of human character, science will come into its own. It will then have an indisputable title to control education and make it scientific in the sense that right means are adapted to achieve desired ends. It will raise issues far more burning and vital than even Darwin and Huxley raised. It will give a new reading to history. This is what I meant when I said I believed I was fighting Sir Ray Lankester's battle. But, obviously, the first step must be to achieve a right terminology, and so a valid classification of fundamental data. How, then, shall we classify characters—as "innate" and "acquired," or as responses to this or that form of nurture? This is what I meant by "clearing the field."

Of one thing I am very sure: that so long as the present classification is maintained biology will never be other than a tumbling-ground for whimsies—Lamarckian suppositions, questions as to whether nature or nurture is the stronger, and the like. When Darwin, the greatest figure that biology has produced, worked on lines of Lamarck's classification he went hopelessly wrong—as in his theory of pangenesis. His whole success was achieved when he studied, not differences between characters, but differences between individuals.

Prof. Poulton's letter in NATURE of December 23, p. 532, which I have seen since writing the above, is valuable for its line of thought and for its definitions. He begins by comparing *individuals*, and finds that their likenesses and differences are separable into those which are inherent (blastogenic) and those which are acquired (somatogenic). This is the firm ground which Darwin occupied in all his valid thinking. No one doubts the existence of these likenesses and differences, and most biologists believe that only those which are blastogenic tend to be inherited (perpetuated) by offspring. Thus chicks resemble each other innately in that they have heads and differ by acquirement as regards scars. Next, Prof. Poulton transfers the terms "inherent" and "acquired" from the likenesses and differences between individuals to the *characters* wherein they are alike or different. The head is called "inherent" and the scar "acquired." He is now comparing the characters of the same individual. This change, subtle yet vital, is precisely the cause of the chaos which prevails in biology. We are now in the morass in which Lamarck and Weismann floundered. We have departed altogether from Darwin's point of view. We have transferred the argument from the chestnut horse to the horse-chestnut. In what particular is the head more inherent and less acquired than the scar? Prof. Poulton writes: "Whenever change in the environment regularly produces appreciable change in an organism, such difference may be called an acquired character." Suppose I decide to work harder and so develop my muscles beyond the ordinary standard which they have already attained through use. In what respect is the addition more "acquired" than the ordinary development (which is usually termed "innate")? What would be the change in the environment?

I think I can give Prof. Poulton better definitions. Whenever the influence in response to which a character (*e.g.* a blacksmith's muscles, scars) develops is *glaringly* obvious, biologists call that character "acquired" and "somatogenic"; but whenever the influence is *not glaringly* obvious (*e.g.* ordinary muscles, head) that character is called "inherent" and "blastogenic." Whenever a biologist considers a character innate he reasons as if the soma and nurture had nothing to do with it. Whenever he considers it "acquired" he reasons as if the germ-plasm and nature had nothing to do with it. In all this he adheres strictly to ancient popular usage, and is not troubled by such recently discovered, recondite things as germ-plasms and germ-cells. He may talk about the latter unendingly, but they do not influence his thinking. Situated at the hub, whence radiate all sciences connected with life, biology, because of its unique classification of characters, has rendered not only itself, but also all these other studies relatively impotent—intellectually, socially, politically. It can use their data only to a minimal degree; and is not used by them at all.

G. ARCHDALL REID.

9 Victoria Road South, Southsea, Hants.

The British Committee for Aiding Men of Letters and Science in Russia.

WE have recently been able to get some direct communication from men of science and men of letters in North Russia. Their condition is one of great privation and limitation. They share in the consequences of the almost complete economic exhaustion of Russia; like most people in that country, they are ill-clad, underfed, and short of such physical essentials as make life tolerable.

Nevertheless, a certain amount of scientific research and some literary work still go on. The Bolsheviks were at first regardless, and even in some cases hostile, to these intellectual workers, but the Bolshevik Government has apparently come to realise something of the importance of scientific and literary work to the community, and the remnant—for deaths among them have been very numerous—of these people, the flower of the mental life of Russia, has now been gathered together into special rationing organisations which ensure at least the bare necessaries of life for them.

These organisations have their headquarters in two buildings known as the House of Science and the House of Literature and Art. Under the former we note such great names as those of Pavlov the physiologist and Nobel prizeman, Karpinsky the geologist, Borodin the botanist, Belopolsky the astronomer, Tagantzev the criminologist, Oldenburg the Orientalist and permanent secretary of the Petersburg Academy of Science, Koni, Bechterev, Latishev, Morozov, and many others familiar to the scientific world.

Several of these scientific men have been interviewed and affairs discussed with them, particularly as to whether anything could be done to help them. There were many matters in which it would be possible to assist them, but upon one in particular they laid stress. Their thought and work are greatly impeded by the fact that they have seen practically no European books or publications since the Revolution. This is an inconvenience amounting to real intellectual distress. In the hope that this condition may be relieved by an appeal to British scientific workers, Prof. Oldenburg formed a small committee and made a comprehensive list of books and publications needed by the intellectual community in Russia if it is to keep alive and abreast of the rest of the world.

It is, of course, necessary to be assured that any aid of this kind provided for literary and scientific men in Russia would reach its destination. The Bolshevik Government in Moscow, the Russian trade delegations in Reval and London, and our own authorities have therefore been consulted, and it would appear that there will be no obstacles to the transmission of this needed material to the House of Science and the House of Literature and Art. It can be got through by special facilities even under present conditions. Many of the publications named in Prof. Oldenburg's list will have to be bought, the costs of transmission will be considerable, and accordingly the undersigned have formed themselves into a small committee for the collection and administration of a fund for the supply of scientific and literary publications, and possibly, if the amount subscribed permits of it, of other necessities, to these Russian *savants* and men of letters.

We hope to work in close association with the Royal

Society and other leading learned societies in this matter. The British Science Guild has kindly granted the committee permission to use its address.

We appeal for subscriptions, and ask that cheques should be made out to the Treasurer, C. Hagberg Wright, LL.D., and sent to the British Committee for Aiding Men of Letters and Science in Russia, British Science Guild Offices, 6 John Street, Adelphi, London, W.C.2.

The Pea-Crab (*Pinnotheres pisum*).

THERE is an apparent discrepancy between Dr. J. H. Orton's interesting description of the pea-crab in NATURE of December 23, p. 533, and that given by Dr. W. T. Calman, whom he quotes. Dr. Orton attributes the impunity with which the male crab and the male-like female sustain the nip of a bivalve to their "extraordinarily strong carapace" (p. 534). On the other hand, Dr. Calman, discussing whether the Pinnotherid crabs should be reckoned commensals or parasites, observes that they "show one of the characteristics of parasites in being to some extent degenerate in their structure. The carapace and the rest of the exo-skeleton, no longer needed for protection, have become soft and membranous" ("Life of the Crustacea," p. 217).

Does not Dr. Calman's suggestion tend to confound racial degeneracy (such as environment has imposed upon Crustacea and fishes inhabiting subterranean waters, or such as has been induced by habit of life on certain parasitic species of Hemiptera) with modification of growth and adaptation of functional activity in individuals approaching parturition? If the female crab does not, after moulting within the bivalve, renew the hard carapace which protected her in obtaining entrance, the diversion of nutriment to her swelling spermothecæ can scarcely be accounted degeneracy. Rather it suggests analogy to the extreme case of *Termes bellicosus*, the so-called white ant, which is neither parasitic nor, presumably, racially degenerate, but the queen-mother of which is perennially and unintermittently parturient, with the result that, according to Smeatham, her abdomen "grows to such an enormous size that an old queen will have it increased so as to be fifteen hundred or two thousand times the bulk of the rest of her body," and twenty or thirty times the bulk of one of her worker offspring.

Dr. Orton having carried research into the pea-crab's life-history a stage further than Dr. Calman, it is to be hoped that he will soon be able to announce a complete solution. HERBERT MAXWELL.

Monreith.

The Mechanics of Solidity.

IN connection with the correspondence on this subject in NATURE, attention may be directed to the attempts made by C. Benedicks (*Zeit. f. anorg. Chem.*, vol. xlvii., p. 455, 1905; *Ann. d. Physik*, vol. xlii., p. 153, 1913) to relate the hardness (H) to the other physical properties of the substance. He suggested that H is inversely proportional to the atomic volume (V) and to the coefficient of expansion (α), and therefore $HV\alpha$ is constant for different elements. This result includes the relation given by Mr. J. Innes (NATURE, November 18). Benedicks also proposed a new formula for the characteristic frequency (ν) of an element of atomic weight A in the solid state. He assumed that the frequency is proportional to $\sqrt{(H/A)}$, and hence to $\sqrt{(1/V\alpha A)}$. If the further assumption be made that the frequency so determined is identical with the frequency given by one or other of the formulæ summarised by Mr. N. T. Saunders (NATURE, December 23), other relations between the physical constants may be obtained. For example, according to the Sutherland-Lindemann formula ν is proportional to $\sqrt{(T_s/AVl)}$, where T_s is the melting point on the Absolute scale. Combining this with the previous result, we find αVlT_s=a constant, a relation given by Pictet in 1879.

I cannot altogether agree with Mr. Saunders (NATURE, December 23, p. 534) in his omission to consider the hardness in relation to other physical constants mentioned on the ground that it is a surface effect and not a bulk effect. Although the conditions at the surface differ from those in the interior of the solid, those conditions are determined by forces of the same general character in each case. In the case of a liquid a large number of relations between surface tension or intrinsic pressure and other physical and chemical constants have been given, and Laplace's theory points the way towards the co-ordination of these results. Reference may be made to the book by Willows and Hatschek on "Surface Tension and Surface Energy" (Churchill), in which this matter is discussed, and the conclusion that *solids* ought to possess surface tension and intrinsic pressure is emphasised. Mr. Saunders, if he is to be consistent, should omit reference to the melting point as well as to the hardness value, since a pure crystalline solid melts on the surface only, and the melting point is the temperature at which the solid can exist in equilibrium in contact with its own liquid under a specified pressure.

Mr. Saunders is no doubt correct in maintaining that further attempts to relate mechanical and other physical constants of solids must be based on modern theories of the structure of the atom.

The Meteorology of the Antarctic.

IN the preface to my book on Antarctic meteorology I wrote, "I was recalled to my work in India when the *Terra Nova* returned to the Antarctic in January, 1912," and the reviewer in NATURE of December 23 (p. 528) has very naturally concluded that this meant that I was recalled officially by the Government of India. It is, therefore, only fair that I should state the facts. I was granted three years' leave by the Government of India, which would have been sufficient if Capt. Scott's original plan of staying only one year in the Antarctic had been carried out. When, however, it was clear that the expedition would remain two years, I told Capt. Scott that I would stay the second year and write to India asking for my leave to be prolonged. When the *Terra Nova* arrived in January, 1912, she brought me a letter from Mr. Field telling me that Dr. Walker had gone to England seriously ill, and that he himself was so unwell that he did not see how he could carry on. In these circumstances I felt it was my duty to my colleagues in India to return at once.

I think most people will understand how in such circumstances I came to write that I was "recalled" to India, but it was an unfortunate expression, and would not have been used if I had realised the inference which would be drawn from it.

The Mammals of South Africa.[1]

THE first two volumes of the work before us were noticed in NATURE of January 8, 1920, p. 469. We recommended them as containing a store of valuable information on the habits of the wild beasts. A vivid and often fascinating description of the species, with many excellent illustrations, made the perusal of these volumes a particular pleasure.

A study of the two volumes now before us justifies our recommendation. The illustrations are mostly good, while the text is clear and attractive. Technical terms have been avoided as much as possible, and in many cases the author gives us the origin and description of the Dutch terms by which the animals are generally known in South Africa.

No wonder South African farmers often lack that sympathy for the preservation of wild animals, and sometimes ruthlessly destroy everything that they fancy is harmful to agriculture. A number of species have already been exterminated, and are known only from old records and from a few specimens still scattered about in various museums. Of the interesting bluebuck, all that is left are five mounted examples, and, sadly enough, these are in foreign museums. Of the quagga there are, fortunately, a few representatives in our great collections. Yet an enlightened Government now protects species that seem to need protection. The bontebok, blesbok and springbuck, the noble kudu and eland, the African buffalo, and even the white rhinoceros and elephant, are carefully preserved in specially reserved areas.

FIG. 1.—Blesbok. From "The Natural History of South Africa."

The prospective emigrant to that part of the world who may seek some enlightenment from these volumes will be struck by the extraordinary wealth and profusion of the fauna. What a paradise for the sportsman! From the farmer's point of view, however, the truly distressing prospect has to be faced of dealing not only with almost innumerable kinds of antelopes and other large game, but also with twenty-four different kinds of rats, including a giant rat attaining a length of 2 ft. without the tail; with wild pigs and hares; with many species of moles and other underground creatures; and with a voracious porcupine, all eager to obtain their share of the fruits of agriculture.

Reckless and indiscriminate slaughter in the past is no doubt partly responsible for the rarity and extinction of some of the larger game; but at times it became necessary for the farmer to take energetic measures for the protection of his crops. The stories of the vast herds of such antelopes as the springbuck remind us of the description of the American bison in the United States. At certain times the springbuck used to migrate in countless numbers into the fertile districts of South Africa. So prodigious were the numbers that the springbuck even choked the streets of the smaller villages. As late as 1892 a special issue of rifles was made to the Boers by the magistrate of the northern border of Cape Colony for the purpose of turning aside a threat-

[1] "The Natural History of South Africa." By F. W. Fitzsimons. "Mammals." In 4 vols. Vol. iii., pp. xiii+278; Vol. iv., pp. xix+271. London: Longmans, Green, and Co., 1920.) Price 12s. 6d. each vol.

ened invasion of migrating springbuck which would otherwise have utterly ruined the crops in the district (vol. iii., p. 92).

Man, however, is not altogether to blame for the scarcity of some of the larger animals of South Africa. Rinderpest undoubtedly played havoc among them, and large numbers of kudu, African buffalo, and others are known to have been decimated by this dread disease.

The smallest of the South African antelopes, about the size and weight of a large hare, is the blue duiker. It is wonderfully alert, and possesses the senses of sight, hearing, and scent in a high degree of perfection; so much so, indeed, that the bushbuck is believed to have made some sort of compact with it for their mutual protection (vol. iii., p. 42).

The fourth volume deals with the insectivores, rodents, whales and their kindred, and the edentates. One of the most interesting features of the South African fauna is the presence of the golden moles. Though very similar in habit to their European relations, the golden moles differ from them in structure and colour, and have been placed in a distinct family. It is worthy of note that an extinct relation of this isolated group (Necrolestes) has been discovered in the Santa Cruz deposits of Patagonia. The several curious burrowing rodents—viz. the blesmol, mole rat, and sand mole—are sometimes mistaken for true moles. They belong to quite a different order, and feed on roots, whereas the golden moles are insectivorous. The author's statement (vol. iv., p. 170) that two species of the octodont tribe of rodents inhabit South Africa requires some modification, for probably neither of these should be included in the family Octodontidæ. Right at the end of the fourth volume, instead of at the beginning of the work, the author explains what is meant by the term "mammals."

We have already commented on the author's charm of style, and throughout his work he makes one feel that he has acquired his extensive knowledge in the open field and has a personal and intimate acquaintance with most of the species he describes.

Science of Ventilation and Open-air Treatment.

DURING the war it was found that the physical condition of many of our young men was far from satisfactory, and there can be but little doubt that one of the contributory causes to this state of affairs was the ill-ventilated dwellings and factories in which such men frequently had to live and work, combined with a lack of opportunity or disinclination to take exercise. For example, in one region of England, of 200 youths of eighteen to twenty years of age examined and rejected, no fewer than eighty-five failed to pass on account of poor physique and other physical defects.

One important cause of defects of physique and of degeneration is the effect of occupation on workers. "One of the most striking features of the report of grading in the industrial districts is the rapid fall of the numbers of the young men who could be placed in Grade I. at the age of eighteen years compared to the numbers who could be placed in the same grade on being examined four or five years later" (Sir J. Galloway, *British Medical Journal,* September 11, 1920).

A second great cause of rejection was tuberculosis, much of which was unsuspected. Careful statistics from one city revealed the striking fact that of 277 cases proved to be tuberculous, 218, or 78 per cent., were previously unknown to the health authorities.

Such being the state of affairs, the publication of the second part of Dr. Leonard Hill's monograph[1] on the science of ventilation and open-air treatment is particularly to be welcomed. Containing much new work, the volume really comprises a series of essays reviewing the subject from various points of view, both theoretical and practical. The opening essay, in which Miss D. Hargood-Ash collaborated, is devoted to the physics of radiation, and presents the recent knowledge in regard to radio-active elements and the electrotonic theory. The final chapter deals with modern methods of ventilation and heating.

For several years past Dr. Hill, in conjunction with various colleagues, has been devoting his attention to this question. According to the popular notion, "stuffiness" and "closeness" of the air are due to an excess of carbon dioxide in the air, or to organic poisons from the breath. All recent work goes to prove the falsity of these old views. In regard to the latter hypothesis, all the positive results so far recorded as to the poisonous effects of the condensed moisture of the breath can be explained on the assumption that either the amount of condensed fluid injected into an animal was in itself sufficient to kill the animal by virtue of its comparatively great volume, or that the impurity arose from the protein of condensed saliva.

In regard to the carbon dioxide content of the air, much money has been spent in keeping the percentage of this gas down to the requirements of the authorities, yet up to 3 per cent. of carbon dioxide in the air breathed produces no unpleasant effects; with each breath it is a natural act to inspire the dead space air into the lungs, air which in itself contains about 3 to 4 per cent. of carbon dioxide. Indeed, the partial pressure of carbon dioxide in the alveolar air is the normal regulator of the respiratory act. Again, the ill-effects of "stuffiness" have nothing to do with smell; frequently those enduring the smell have no idea of its presence or potency.

It is now abundantly proved that the enervating effects of close and confined atmospheres are due to "heat stagnation" within the body. This is particularly liable to occur when the wet-bulb temperature is high, and efficient evaporation from the skin through sweating prevented. The discomfort under such conditions is alleviated by the use of fans which stir up the air. One of the most illustrative experiments in this direction is that in which a number of persons were confined in a hermetically sealed chamber in which a high wet-bulb temperature was induced by means of trays of water placed above electric heaters. At the height of discomfort to those inside, people outside the chamber could breathe the air without ill-effects. Circulation of the air by fans in the roof brought great relief to the occupants of the chamber.

The chemical purity of the air is important in so far as it may give an indication of infective bacterial content, and in certain trades in which the atmosphere becomes laden with dust particles, particularly silica dust. It is also important from the public point of view as regards the pollution of the air by excessive coal consumption. Coal consumption fouls the air with soot and smoke, producing fogs which diminish sunlight, thereby making cities dismal, and bringing loss of health and happiness to the town dweller. Herein the dweller in the country is at an advantage. Vital statistics show that, despite all the sanitary advances of recent years, the town dweller is still at a disadvantage as compared with the countryman, who frequently lives in any but hygienic surroundings. The country dweller owes his relatively robust health to many of the factors which make for success in open-air treatment.

The success of this treatment in tuberculosis depends upon its judicious application. Exposure to moving air induces efficient respiration, exalts the metabolism, and lowers the fever. It must be so employed that the bodily functions are not depressed and the heat-regulating capacity of the individual exceeded. The patient must always be happy and comfortable. As Dr. Hill puts it: "The ideal conditions out of doors are seen to promote the feeling of comfort and happiness, a gentle cooling breeze to promote adequate cooling of the skin and stimulate the metabolism of the body, coolness and low-vapour tension of the air to promote the evaporation of water from, and blood-flow through, the respiratory membrane."

The clothing of the body, in both health and disease, should always be directed to the prevention of heat stagnation. Many people greatly overclothe. Clothes should be as light as possible, permeable to air, allow free evaporation, and not become wet with water vapour in such a way that they cling to the skin and cause undue heat loss and a feeling of "chilliness." Permeability is essentially a matter of the method of weaving. The cellular type of weaving is to be recommended on this account for underclothing; for outer clothing close-meshed fabric is also to be avoided. Wool owes its advantage in underclothing to the fact that the elasticity of the hair keeps the garment off the skin, thereby securing an air layer beneath which facilitates evaporation and prevents clinging wetness. The less the adherence, the greater the volume of entangled air, and the greater the heat-

retaining power, even of the wet material. In tropical climates there is particularly a great disadvantage in clothes which lessen evaporation. Heat-stroke is due to excessive heat stagnation.

In regard to indoor conditions, these should approximate as near as possible to the outdoor conditions of an ideal day.

Successful ventilation not only prevents heat stagnation of the body, but also keeps the temperature such that it stimulates the worker without producing uncomfortable cooling of the body.

In the British climate, of mist and cloud, radiant heat is always preferable to convected heat, hence the superiority of the open fire and the modern gas-stove. Radiant heat makes up for the absence of sunlight. Buildings should always, so far as possible, be warmed in such a manner as to keep the feet warm and the head cool. The judicious employment of fans to impart air movement will frequently make all the difference between good and bad ventilation. Dr. Hill's kata-thermometers prove of the greatest service in investigating the ventilation conditions of any building, and it is certain that they must be extensively employed in future to ensure satisfactory conditions, particularly in large buildings.

The question of the bodily heat regulation in the tropics is one of vital importance to the colonising white man. For years past there has been discussion as to whether it is possible for the white man to adapt himself efficiently to tropical climates, or whether this can be done only by pigmented races. Many authorities have inclined to the latter view.

The effect of the tropics is largely due to the action of the sun's visual rays, particularly those of the blue end, which, if sufficiently powerful and prolonged in action, have a lethal effect upon protoplasm. The ultra-violet rays are filtered out by the horny layer of the epidermis. The scales of the skin reflect diffusively many of the visual rays, particularly when the skin is wet with sweat. The function of pigment is to absorb the visual rays, thereby protecting the blood and living tissues from dangerous effects. The pigmented man can, therefore, have a thinner horny layer to his skin, and lose heat well through flushed blood-vessels, without risks of injurious effects from ground glare and sky shine. The view which attributes a higher heat-emissive power to the skin of the negro is erroneous. Despite the above advantages, however, pigment puts an extra tax on the heat-regulating mechanism of the body, since it has to get rid of the heat into which light rays are converted.

The great value of pigment is that it protects man from sunburn, and enables him to go naked and secure the full cooling power of the environment by losing heat by radiation, convection, and evaporation. The white man wears clothes to protect himself from sunburn, and the ill-effects of tropical climates are largely due to the wearing of unsuitable clothing, frequently from custom or from an idea of caste distinction. The white man also usually indulges in an unsuitable diet, which sets his heat production at too high a level. For this reason it is imperative that the white man in the tropics shall be suitably clothed and adjust his diet to the climate, resting during the hot hours, and taking exercise freely during the cool of the day.

The efficiency of the yellow races in hot climates shows that climatic adaptation to the tropics does not depend solely on pigmentation of the skin. As shown above, such adaptation seems to depend upon the correct correlation between the metabolism and the heat-losing mechanism of the body. Given proper sanitary measures against infectious disease, much can be done to promote the efficiency of the white race in hot climates by getting rid of the stagnant moist environment produced by clothes and houses. These in particular tell at present against the health of white women.

M. F.

The Discovery of Fossil Remains of Man in Java, Australia, and South Africa.

By PROF. A. KEITH, F.R.S.

PROF. EUGENE DUBOIS, the discoverer of Pithecanthropus, has recently published[1] an account of fossil remains of man found in a deposit in Java, which he regards as of Pleistocene age. In 1890, the year before he made his first find of the remains of Pithecanthropus at Trinil, Prof. Dubois was led to search for traces of ancient man in the district of Wadjak, which lies some sixty miles to the south-east of the site where his more famous discovery was made. His attention had been directed to the Wadjak district by the discovery there of a fossilised human skull in 1889. Further excavations of the terrace-like deposit in which the first skull had been found placed Prof. Dubois in possession of fragments of the jaws and cranium of a second individual, which were in the same state of mineralisation as the skull which first came to light.

Prof. Dubois has only now published a full account of these discoveries, made thirty years ago. He finds that the remains unearthed at Wadjak indicate that Java was at one time inhabited by a people very like the blacks of Australia, but in some respects even more primitive than they. The publication of an account of a fossil human skull found at Talgai, Queensland, by Dr. Stewart A. Smith[2] in 1918 has apparently induced Prof. Dubois to reinvestigate the fossil remains from Wadjak, and to compare them with the ancient Talgai skull. Thus for the first time it is possible for anthropologists to compare

[1] "De Proto-Australische fossiele Mensch van Wadjak (Java)," *Kon. Akad. van Wetensch. te Amsterdam Afdeeling*, May 29, 1920.

[2] Phil. Trans., 1918, ser. B, vol. ccviii., p. 351

the ancient inhabitants of Java and Queensland. The discovery in 1913 of fossilised human remains at Boskop, in the Potchefstroom district of the Transvaal, throws a welcome light on the ancient inhabitants of South Africa, and gives the means of comparing the early inhabitants of remote continents. An account of the Boskop find was contributed to NATURE for August 5, 1915, vol. xcv., p. 615, by Mr. F. W. FitzSimons, of Port Elizabeth Museum, and a detailed description of the remains has since been published by Mr. S. H. Haughton.[3] In none of these discoveries, in Java, in Queensland, or in South Africa, has it been possible to give a definite geological age to the deposits in which the human remains occurred, yet in each case a Pleistocene date has been assigned to the remains by their describers—an inference which is justified, not only by their condition and surroundings, but also by the primitive structural features which are stamped on them.

The more complete fossil skull described by Prof. Dubois is that of a woman showing features which characterise Australoid races, save that the dimensions of the skull are excessive. The length of this ancient woman's skull is 200 mm. and its width 145 mm., measurements which are rarely met with even in the most robust Australian male aborigines. Prof. Dubois, allowing for the great thickness of the cranial wall—10 mm. on the vault—estimates that its cranial capacity or brain space was 1550 c.c.—more than 200 c.c. above that of the average modern Englishwoman. The jaws of the second individual found are much larger and more robustly framed than those of the woman, and are inferred by Prof. Dubois to represent the opposite sex. The upper jaw and palate of this ancient man of Java are such as have never been seen before in either ancient or modern man. In anthropoid apes the molar teeth are set in two approximately parallel rows on each side of the palate; this arrangement is more exactly preserved in the extinct natives of Tasmania, and to a less degree in the native tribes of Australia, than amongst any other existing race of mankind. But in the Java or Wadjak skulls, although Australoid in all their cranial and facial features, the teeth are set on the palate in a horseshoe form, much as is the case in the Pleistocene European—*Homo neanderthalensis*. The teeth, however, show none of the dental characteristics of that race. The width of the palatal area of the Wadjak fossil man, measured between the outer borders of the second molar teeth, is 81 mm., 7 mm. more than has yet been observed in any human palate. The length of the palate—measured from the crowns of the incisors to a line joining the hinder borders of the last molar teeth—must have been well above 60 mm.—a measurement occasionally exceeded in the palates of modern Australian natives. The palatal area, enclosed within the outer border of the dental arch, is enormous, being, according to Prof. Dubois' estimate, 41·4 sq. cm., to which some 4 sq. cm. must be added on account of the missing incisor crowns. The corresponding area of the average modern Englishman is 26 sq. cm.; the largest measurement in living native races is 36·7 sq. cm. These figures give some indication of the remarkable jaw and face development of the fossil Wadjak race.

The Talgai skull from Queensland, described by Dr. S. A. Smith, of Sydney University, is that of a lad of about fifteen or sixteen years of age. Its cranial walls had been severely crushed by earth-pressure, but fortunately the palate and face are in good condition—a most fortunate circumstance, for it becomes more and more evident that we must trust to facial rather than to cranial features for the recognition and discrimination of human races. So far as the cranial features and dimensions of the Talgai lad are preserved, they show Australoid characteristics—the cranial capacity being certainly above that of Australian aboriginal youths of the present day. Here, again, the outstanding character of the fossil type is to be found in the palate, which has been very fully investigated and described by Dr. S. A. Smith. In the form of its dental arcade the Talgai skull possesses the most anthropoid palate yet discovered. Very probably, were the palate of Piltdown man to be found, it would show these anthropoid features to an even greater degree. The two canine teeth in the Talgai boy are set very widely apart, almost as widely as the molar teeth. The width of the palatal area is 66·5 mm.; allowing for the unerupted wisdom teeth, its length amounts to about 70 mm.; the total area, although less than on the Javanese fossil Australoid skull, is still very large, amounting to about 40 sq. cm.

Thus we have evidence which seems to justify us in supposing that at a certain period of the Pleistocene age men fashioned in a primitive Australoid mould, with large brains and massive palates, lived in Java and Australia; but so far as the palate is concerned the fossil stock of Java had differentiated in one direction, the Australian in another. It is amongst the extinct race, which inhabited Tasmania down to modern times, that we find the nearest approach to the anthropoidal palate and the massive teeth of the Talgai boy. On a consideration of all his features we must place the Talgai boy in the ancestral stock of the Tasmanian type of Australoids. Dr. S. A. Smith cites the discovery of the fossil bones of the dingo in Australian deposits of Pleistocene date as evidence of the early arrival of man in the continent of Australia, for it is difficult to believe that the native dog arrived save in the company of man. The discoveries made at Talgai, in Queensland, and at Wadjak, in Java, lend strong support to this early arrival of man in Australia. Whether the Talgai lad represents the first invaders, and whether these early comers were the primitive ancestors of the aborigines of Tasmania, are doubts which must be settled by future discoveries.

[3] Trans. Roy. Soc. South Africa, 1917, vol. vi., p. 1.

In strange contrast to these ancient inhabitants of Java and Queensland is the ancient type of South Africa represented by the Boskop man. The characters of his skull are so peculiar that we must regard him as a separate and hitherto unknown type. As to his facial characters we know little; his eyebrow ridges and forehead show certain features which give grounds for the belief that the face was flattened—much as in living representatives of the Hottentot and Bushman stocks. From the fragmentary lower jaw one infers that the teeth and palate were of very moderate dimensions—not much larger, if any, than in modern Europeans. The dimensions of the cranial cavity, on the other hand, are enormous: the length of the cranium is 205 mm.; its width 154 mm.; and its capacity or brain space is estimated by Mr. Haughton to be 1832 c.c.—about 350 c.c. above the average for Englishmen. The vault of the skull is thick and flat, two great parietal bosses of bone rising up on each side of its median suture and marking the sites of the parietal eminences. There are also peculiar features in the region of the mastoid process behind the ear and in the zygomatic-temporal region in front of it. The only fossil skull which shows any marked degree of resemblance to the Boskop specimen is the Olmo skull found in a Pleistocene deposit in the north of Italy in 1863. It, too, is a very wide and long skull, with flat roof and projecting upper forehead, but showing none of the peculiar features of the Boskop skull. Mr. Haughton has rightly recognised that certain traits which are found in the Hottentot and Bushman skulls, as well as in the Boskop cranium, can best be explained by supposing the Boskop man to stand in the Pleistocene ancestry of those puzzling Mongolian negroids of South Africa—the Hottentots and Bushmen. Further, on the strength of the evidence referred to in the foregoing, we find, at a remote period in South Africa and in Australia, primitive representatives of the native races now occupying these countries; differentiation from the primitive to the modern type seems to have taken place *in situ* in each case.

Obituary.

THE death occurred on Thursday, December 23, of MR. FRANK PULLINGER, C.B., Chief Inspector of the Technological Branch of the Board of Education. Mr. Pullinger, who was born in 1866, was educated at Manchester Grammar School, Owens College, Manchester, and Corpus Christi College, Oxford. He took a First Class in the Final Honours School of Natural Science in 1887, and in 1889 was elected Burdett Coutts scholar of the University. After spending a year in research work at Oxford and another year as a University extension lecturer, he was in 1891 appointed Secretary for Education to the Devonshire County Council. This post he relinquished in 1894 in order to take up an appointment as an Inspector of Schools under the Science and Art Department. In 1900 Mr. Pullinger was appointed Divisional Inspector and in 1908 Chief Inspector of the Technological Branch of the Board of Education, into which the Science and Art Department had been merged. He was a man of great force of character and possessed a very intimate knowledge of the needs of technical education. The years during which he was Chief Inspector witnessed a rapid growth in the responsibilities of the Board towards technical education, and Mr. Pullinger's wide experience and close association with technical problems were in consequence of very great value. In particular it may be said that he organised an inspectorate containing in its ranks men of expert knowledge in engineering, building, chemical, and other industries, and transformed the whole process of inspection. His death at a comparatively early age is greatly regretted by all who have the future of technical education at heart.

THE death is announced on Christmas Day of the REV. HENRY HOYTE WINWOOD, of Bath, at the age of ninety years. Mr. Winwood was for half a century one of the most active amateur geologists in the West of England, and the stimulating friend of many who have made important advances in geological science. In early life he was associated with Prof. (now Sir) W. Boyd Dawkins and the late Mr. W. A. Sanford in several explorations of bone-caves and prehistoric burial places. In 1865 he announced the discovery of flint implements in definite association with the remains of extinct animals in the cave named Hoyle's Mouth, near Tenby. In his own district he diligently observed all temporary excavations, and made notes which were published in the Proceedings of the Bath Natural History Club. When the British Association visited Bath in 1888 he wrote the section on geology for the local handbook. He also took much interest in the Bath Royal Institution, and collected the fund by which it secured the unique museum of local fossils of the late Charles Moore. He delighted in making this museum accessible for the promotion of research. Mr. Winwood was elected a fellow of the Geological Society in 1864, served for many years on the council, and was a vice-president in 1898–1900 and 1915–17.

THE death of MR. J. G. V. MAIR-RUMLEY on December 20, in his seventy-eighth year, is announced. Mr. Mair-Rumley was a member of the Institutions of Civil Engineers and Mechanical Engineers, and gave much assistance to the research committees inaugurated by the latter institution. His papers contributed to the Institution of Civil Engineers were awarded the Watt medal and a Telford premium in 1881, and a Telford premium in 1885.

Notes.

The New Year Honours Lists which were issued at the end of last week include five barons, five Privy Councillors, twenty-one baronets, sixty-nine knights, and two Companions of Honour. Among the honours we note in particular the following conferred upon men whose names are known in scientific fields:—*Privy Councillor:* The Rev. Dr. Thomas Hamilton, for service to the cause of education in Ireland, first as President of Queen's College, Belfast, and afterwards as President and Vice-Chancellor of the Queen's University of Belfast. *Knights:* Prof. P. R. Scott Lang, for more than forty years Regius professor of mathematics in the University of St. Andrews; Mr. P. J. Michelli, secretary to the London School of Tropical Medicine; Dr. S. S. Sprigge, editor of the *Lancet*; Prof. James Walker, professor of chemistry, University of Edinburgh; and Dr. Dawson Williams, editor of the *British Medical Journal*. *C.M.G.:* Mr. I. B. Pole Evans, chief of the division of botany and plant pathology, Department of Agriculture, Union of South Africa. *C.I.E.:* Lt.-Col. W. F. Harvey, director of the Central Research Institute, Kasauli, Punjab, and Dr. E. J. Butler, formerly Imperial Mycologist, Pusa. *K.C.V.O.:* Dr. F. S. Hewett.

The appeal for help to the scientific and literary community of Russia which we publish elsewhere should meet with a sympathetic response. Since the calamitous political disturbances began in their country many Russian scientific men have taken every opportunity of begging their colleagues and friends in the rest of Europe to help them to emigrate to more congenial surroundings abroad. In very few cases has it been possible to grant their petition. Now that the Bolshevik Government seems to have begun to realise that intellectual life has some value for the nation, it may be best that we should encourage our fellow-workers in Russia to remain at home and give them all possible assistance in promoting learning in the sad circumstances in which they find themselves. We understand that the great libraries, the university laboratories, and the old national collections, at least in Petersburg, are still intact, and that some provision has been made for the small remnant of Russians who are capable of using them. They merely need the stimulus of contact with the centres of intellectual work in other countries and an up-to-date knowledge of the results of research elsewhere. We trust that Britain will take the lead in furnishing this stimulus and supplying the necessary publications to enable Russia again to take a conspicuous place in the world of science, literature, and art.

The Rockefeller Foundation has presented to the State of Louisiana a tract of country comprising some 35,000 acres known as the Grand Chenier Wild Life Refuge (*Science*, December 3). The land was purchased by the Foundation from individual holders in 1914 in order to preserve the wild life of the country, and it is a condition of the gift, which includes laboratories, publications, and equipment connected with the preservation enterprise, that the tract shall remain as a perpetual wild-life preserve.

It is announced that Mr. Llewellyn Treacher has been selected for the Foulerton award of the Geologists' Association.

The Aldred lecture will be delivered at the Royal Society of Arts on Wednesday, January 12, at 8 p.m., by Dr. C. S. Myers, director of the psychological laboratory, and lecturer in experimental psychology, University of Cambridge. The subject will be "Industrial Fatigue." Mr. W. L. Hichens will be in the chair.

Science of December 10 announces that the Elisha Kent Kane gold medal of the American Geographical Society has been conferred on Dr. A. Hamilton Rice in recognition of his pioneer exploratory work in South America; also that the Franklin Institute has awarded the Elliott Cresson gold medal to Dr. W. L. R. Emmet in recognition of his notable contributions to the art of ship propulsion.

Dr. E. O. Teale has been appointed Government Geologist of Tanganyika Colony, formerly German East Africa. Dr. Teale has already had much experience of African geology, having spent several years in Portuguese East Africa, and having been occupied more recently with geological work in Nigeria and Gold Coast Colony. With his former colleague Mr. Wilson he contributed an important paper on Portuguese East Africa to the *Geographical Journal*.

At the exhibition of paintings by the Birmingham Art Circle in the galleries of the Birmingham Royal Society of Artists there will be on view until January 20 two portraits (by Mr. Bernard Munns) which will be of interest to many readers of Nature. One is that of the late Prof. John Henry Poynting, an admirable likeness in which the character of the subject is beautifully expressed. This portrait has been painted for the Trustees of the Poynting Memorial Fund, and will be hung in the guest hall of the University at Edgbaston. The other is a fine portrait of the late Prof. Adrian J. Brown, F.R.S. The University already has portraits by the same artist of the late Prof. Charles Lapworth and Prof. P. F. Frankland.

The results of the balloting in the reorganisation of the International Commission on Zoological Nomenclature have been announced as follows:—*Class of 1922 (elected in 1913):* Dr. J. A. Allen, New York, N.Y.; Dr. F. A. Bather, London; M. Ph. Dautzenberg, Paris; Dr. W. E. Hoyle, Cardiff; Dr. K. Jordan, Tring; and Prof. H. Kolbe, Berlin. *Class of 1925 (newly elected, vice Class of 1916):* Dr. D. S. Jordan, Palo Alto, Cal.; Prof. A. Handlirsch, Vienna; Prof. R. Monticelli, Naples; Dr. E. Simon, Paris; Dr. H. Skinner, Phil., Pa.; and Dr. L. Stejneger, Washington, D.C. *Class of 1928 (newly elected, vice Class of 1919):* Prof. C. Apstein, Berlin; Dr. E. J. O. Hartert, Tring; Dr. Geza Horvath, Budapest; Prof. Louis Roule, Paris; and Dr. C. W. Stiles, Washington, D.C. No majority was obtained for the vacancies caused by the death of Prof. Blanchard and by the resignation of Prof. Roule; accordingly a new vote is being taken. Each class consists of six Commissioners elected to serve nine years, and selected from the zoological profession of the world at large.

AT the annual general meeting of the Faraday Society held on December 13, the following officers and council were elected to serve for the coming year:—*President:* Prof. A. W. Porter. *Past-Presidents:* J. Swinburne, Sir Richard Glazebrook, and Sir Robert Hadfield, Bart. *Vice-Presidents:* W. R. Cooper, Prof. C. H. Desch, Dr. J. A. Harker, Emil Hatschek, Prof. T. M. Lowry, Dr. E. H. Rayner, and Dr. G. Senter. *Treasurer:* Robert L. Mond. *Council:* Dr. A. J. Allmand, Dr. H. Borns, Prof. W. C. McC. Lewis, Harold Moore, Prof. J. R. Partington, C. C. Paterson, Prof. A. O. Rankine, Sir Robert Robertson, Sir T. Kirke Rose, and Dr. W. Rosenhain. Prof. Porter, in proposing a vote of thanks to the retiring president, Sir Robert Hadfield, who had guided the society during the whole critical period of the war, referred to the growth that had taken place in the society's work and in its prestige during that period. He remarked that of the twenty-six general discussions that had been organised by the society, many of them in co-operation with other societies the collaboration of which was greatly appreciated, as many as nineteen had been held during Sir Robert Hadfield's presidency.

THE Report of the Watchers' Committee of the Royal Society for the Protection of Birds for the years 1919–20 is a record of excellent results obtained, but it also reveals how much remains to be accomplished, and could be accomplished if the necessary funds for the purpose were forthcoming. Those at its disposal are wholly inadequate to meet even the expenses already incurred. The society employs twenty-three watchers who are located at seventeen breeding stations annually resorted to by some of the rarer, and hence much persecuted, British birds. Thanks to the loyalty and devotion of these excellent men—they are offered bribes and subjected to threats—it is gratifying to learn that nests of the bittern, Kentish plover, red-necked phalarope, chough, whimbrel, and many other species, including in the south of England the raven and the peregrine, were successfully protected. On the other hand, owing to lack of funds to provide for adequate watching, a lamentable state of affairs is revealed. Thus roseate and Sandwich terns were robbed of all their eggs, and divers, the numbers of which are annually growing fewer, were sadly raided, so that in one case of thirteen nests only three young birds were hatched, while in another out of fifteen nests eight were destroyed. The craze for egg-collecting at the present time is, unfortunately, at its zenith, the excuse being that the specimens are taken for scientific purposes. If scientific results may be derived from the study of the eggs of British birds, it may be safely averred that there is already a plethora of material available for the purpose. It is greatly to be hoped that bird-lovers who are not subscribers to the Watchers' Committee will respond to the society's earnest appeal and help to carry on this highly desirable, patriotic work. The society's address is 23 Queen Anne's Gate, S.W.1.

IN a study of variation in the mealworm, *Tenebrio molitor*, Mr. S. A. Arendsen Hein finds two common colour varieties of the larvæ, chestnut-brown and orange-red, and a rare melanic type with black instead of reddish-brown abdomen, antennæ, and legs. Red and yellow eye-colours are inherited, and the latter is sex-linked. Reduction in the number of tarsal and antennal segments is also based on hereditary factors. The duration of the larval stage is largely controlled by temperature. Females usually produce no eggs without previous mating, and egg-production normally continues for two months.

WE have received vol. vii., part 4 (Series C, Zoology and Botany), of the Scientific Reports of the Australasian Antarctic Expedition, 1911–14, containing the bacteriological and other researches dealing with physiology, dietetics, psychology, etc., by Dr. A. L. McLean. Cultivations from the intestinal tract of some of the mammals and birds (*e.g.* Ross seal and penguins) contain no, or very few, bacteria. Similar results have been obtained in the case of Arctic forms by Levin and others. In other mammals and birds (*e.g.* Weddell seal, sea-leopard, and skua gull) the bacterial content of the intestine was high, containing coliform organisms and sporing bacilli. Cultures of bacteria were obtained from ice, snow, soils, and marine mud. Suppuration was observed in the wounds of Weddell seals, inflicted by the sea-leopard and killer whales, with a bacterial flora of streptococci and staphylococci. Observations on the hæmoglobin values of the blood and on blood-pressure showed little of interest. It was noticeable that the hair of the head and the nails grew very slowly.

VOL. XLIII., article 6, of the Bulletin of the American Museum of Natural History (issued on December 4) consists of an extensive paper on the Lepidoptera of the Congo by Dr. W. J. Holland. It takes the form of a systematic list of the species of that order of insects collected during the expedition sent out by the museum to the Congo region. Although the collection is one of the largest made in recent years in that part of the world, it is very poor in moths, most attention being devoted to the showier Nymphaline and other butterflies. As Dr. Holland points out, the primary aim was to secure vertebrates, and the making of insect collections was a subsidiary object. From among about 9000 specimens there are more than 725 species and varieties. It has only been found necessary to erect two new genera, and the new species and varieties amount to fewer than 80. The largest number of specimens was secured at Medje, near the Nepoko River, in the heart of the forest, from April to September, 1910, and the collection as a whole exhibits a distinct affinity with the West African fauna. The paper is evidently an important contribution to our knowledge of the distribution of Lepidoptera in Africa, and is illustrated by nine three-colour-process plates and a similar number of text figures.

AMONG the creatures that live harmoniously with termites in their nests is a Staphylinid beetle, which, like the familiar "devil's coach-horse," turns its abdomen over its back, but in this case the abdomen is greatly swollen, stretches far forward, and is extended backwards only with difficulty. This beetle, previously referred by Dr. E. Warren to the South American genus Corotoca, has now been more closely investigated by him, and is redescribed as *Paracorotoca akermani* (Ann. Natal Mus., vol. iv., pp. 297–366, pls. xvi–xxi, November, 1920). Dr. Warren finds that, structurally, it is closer to the Malayan Termitoptochus, and infers that the resemblances to Corotoca and other termitophilous beetles are due to the similarity of their environment. Paracorotoca has been found only in nests of the common Eutermes (*E. trinerviformis*) of Natal, and is very rare. The inflated abdomen is almost filled with the greatly overgrown sexual organs. The ova are relatively huge, and this is probably connected with the viviparous production of large larvæ. No similar need exists for the large size of the male organs, and it may be supposed that the stimulus for their growth has been transmitted to the male from the female. How far the termites feed the beetles and in what way the beetles repay the hospitality are questions not yet settled. One curious observation has been made: when termites are alarmed they vibrate their bodies in a characteristic manner, and the beetle does the same. Dr. Warren compares the habit in the termites to the trembling with rage or fear in mammals, and suggests that the intimate association of the beetle with the termites has produced in it a similar nerve-tone.

THE *Journal of the Ministry of Agriculture* for October and November, 1920, contains an interesting account of the work of the new Plant Breeding Institution at Aberystwyth by the director, Prof. R. G. Stapledon. In addition to the laboratories, which are now completed, there is a drying-room and a gardeners' room designed for the threshing and cleaning of small lots of seeds. The land attached to the station includes 4 acres of garden-ground, a 13-acre field of arable land for larger trials, and an adjoining farm of 92 acres. One of the chief problems taken up is that of the improvement of herbage plants for the grassland areas of Wales and the West of England. Of the numerous grasses and legumes being tried the following already show promise: *Phalaris nodosa*, a rich pasture grass from South Africa; *Danthonia pilosa*, from New Zealand; *Eragrostis abyssinica*, which produces hay in portions of Natal and the Transvaal; *Trifolium subterraneum*; and the hairy vetch, *Vicia villosa*. Local indigenous grasses are also being brought into cultivation with the view of improving strains which are already adapted to the conditions. Cocksfoot grass from various countries was grown, and the indigenous plants were found to show greater development and to have the advantage of being later. Experiments are also being taken up with cereals, particularly oats, for high elevations and high rainfall.

THE possibility of recognising shoals and channels from a photographic print and of determining in some measure the shape of submerged land-forms opens a new avenue of approach to the study of submarine geography by the use of aerial photography. The subject is discussed by Dr. W. T. Lee in an article in the *Geographical Review* for November (vol. x., No. 5). A number of finely reproduced photographs by the Air Service of the United States Army illustrate the extent to which the camera succeeds in recording submarine features. Experience seems to show that the best results are likely to be obtained early in the morning or late in the afternoon under an evenly illuminated sky. Either an entirely overcast or a uniformly clear sky is more favourable than a partly clouded sky. Waves appear to have little effect on the visibility of submarine relief, but by the diffusion of reflected light they can at times destroy the effect of the detail on the photographic plate. More research, however, is necessary in order to decide the best conditions for determining clear detail.

THE recurrent subject of the growth of flint is revived by Mr. C. Carus-Wilson in a letter to the *Geological Magazine* for October, where a case is quoted of the inclusion in flint of wood bored by Teredo. The problems that this specimen justly raise in Mr. Carus-Wilson's mind could probably be set at rest, as in other cases referred to, by thin sections cut from the encasing flint, and it is to be hoped that the matter will be pursued further.

MR. S. S. BUCKMAN's work on "Type Ammonites," finely illustrated by photographs of actual specimens, has reached its twenty-third part, and is already a monument to the painstaking devotion of its author. We fear that questions from other workers as to generic subtleties must make serious inroads on Mr. Buckman's time, since we cannot now think of British ammonites without him. The work is published for the author by Messrs. W. Wesley and Son, Essex Street, London, W.C.2.

TABLES of frequencies of surface-wind directions and cloud amounts at Metz, Mulhausen, Karlsruhe, and Fránkfort by Capt. D. Brunt have been published by the Meteorological Office as Professional Notes No. 14. The tables are similar to those given previously for Richmond and Greenwich. They are based on the observations from the German Daily Weather Reports for ten years, 1900–10, excluding 1906. The results are said to differ widely from those for Richmond, where the number of clear skies in the summer is much greater in the evening than in the morning, but the tables in the present publication show only a very slight clearing in the evening in the summer, and in July the evenings are cloudier than the mornings. For the towns dealt with, the most frequent wind directions are north-east and south-west. North-east winds divide into two groups, with clear and overcast skies respectively, and in the summer they give more clear skies in the evening than in the morning, the cloudiness of the weather being apparently controlled by the different weather types. South-west and west winds are said usually to be associated with the passage of depressions across the British Isles, tending to give overcast skies, especially during the morning. They are associated with a greater frequency of clear skies in the evening during the months of September and October. Pilot-balloon results show that at Aix-la-Chapelle

(Aachen) and Frankfort the direction of the wind at the surface is practically the same as at an elevation of 1000 metres, while at Strasbourg the wind at the surface is usually backed two points from the wind at 1000 metres.

WHEN the interpretation of crystal structure on the basis of close-packed spheres was put forward by Barlow and Pope in 1906 it was suggested that the sphere of influence of each atom in a given crystal was approximately proportional to its valency, but that these spheres of influence varied in size in a series of isomorphous crystals in such a way as to preserve the proportionality of their individual volumes to the valencies, whilst the sum of their volumes varied with the molecular volume of the compound. Prof. W. L. Bragg's study of the structure of crystals by means of X-ray analysis, on the other hand, led to the conclusion that each atom has a constant sphere of influence, the atomic diameters of some of the common elements being, for instance, as follows:

F = 1·35 Å.	O = 1·30 Å.	Li = 1·50 Å.	Be = 1·15 Å.
Cl = 2·10	S = 2·05	Na = 1·77	Mg = 1·42
Br = 2·38	Se = 2·35	K = 2·07	Ca = 1·70
I = 2·80	Te = 2·66	Rb = 2·25	Sr = 1·95
		Cs = 2·37	Ba = 2·10

A crucial test of these alternative views can be made most readily by carrying out an X-ray examination of an isomorphous series, and this has now been done in the case of calcite and the isomorphous carbonates of manganese and iron, the Laue patterns from which have been analysed by a novel geometric method by R. W. G. Wyckoff (*American Journal of Science* [iv], vol. l., pp. 317–60, November, 1920). The following results were obtained:

	$CaCO_3$	$MnCO_3$ (and $FeCO_3$)
Distance from carbon to oxygen	1·21 (1·42)	1·22 (1·42)
,, ,, ,, metal	3·04 (2·47)	2·83 (2·24 and 2·17)
,, ,, oxygen ,,	2·30 (2·35)	1·96 (2·12 ,, 2·05)

In this table the distances from carbon to oxygen are constant, whilst the distances from carbon to metal and from oxygen to metal are about 0·26 Å. and 0·34 Å. greater for calcium than for manganese and iron. It should, however, be noted that most of these data differ considerably from those given by Bragg (which are shown in brackets in the table), the deviations rising to 0·6 Å. in the distance from carbon to metal, *i.e.* nearly three times as much as the variation on passing from calcium to manganese or iron.

IN *Science* for October 15 Mr. J. J. Willaman, of the University of Minnesota, directs attention to the possibility of utilising artichoke and dahlia tubers as sources of fructose, which could be used, in place of ordinary sugar (sucrose), as a sweetening agent. These tubers contain the carbohydrate inulin, which on hydrolysis by acids is converted into fructose (lævulose), just as starch is similarly convertible into glucose (dextrose). Taking an average crop of artichoke tubers at 40,000 lb. per acre, and assuming a recovery of 10 per cent. of inulin, Mr. Willaman states that it should be possible to obtain about 4000 lb. of fructose per acre, which is nearly equal to the yield of sucrose from a good crop of sugar-cane and about twice the yield of glucose syrup from an average crop of maize; fructose, moreover, is sweeter than either sucrose or glucose, so that artichokes would appear to have a distinct advantage over either sugar-cane or maize as a source of sweetening material. The author realises that the matter may not be quite so simple as it looks, and he appeals for the inauguration of research by some official or industrial organisation to ascertain whether a presentable fructose can be made from artichokes. These tubers have been used in Germany as a source of alcohol, but that is a simpler proposition than the manufacture from them of a serious competitor with cane-sugar. Artichokes grow well in England, as hundreds of allotment-holders discovered during the war; there are plenty of British chemists familiar with the chemistry of carbohydrates, and our large consumption of sugar is met almost entirely by imports. In view of this, the Department of Scientific and Industrial Research might do worse than take Mr. Willaman's suggestion into serious consideration, if it has not already done so, and, if there is anything in it, arrange to have the necessary research work done in this country.

WE have received a Physical Department Paper issued by the Egyptian Ministry of Public Works on "The Effect of Turbulence on River-discharge Measurements," forming an addendum to a Report on Nile Gauge Readings and Discharges published in March last. Mr. Hurst, Controller of the Physical Department, has prepared this note to prevent any misconception which might arise on the statement of certain views attributed to Mr. Craig, of the Egyptian Survey, in the earlier publication. The Survey of Egypt carried out a long series of river-discharge measurements at Sarras, in the Sudan, the results of which, after making all necessary allowances, showed a considerable divergence from the readings at the Aswân Dam, amounting to about 15 per cent. In 1912 Mr. Craig put forward the suggestion that the variation might be due to the effect of turbulence in the flow, and showed mathematically that reductions in apparent volume might have to be made amounting to as much as 20 per cent. during flood and to 10 or 15 per cent. when the river was low. Experimental investigation, however, has demonstrated that the correction for turbulence at the low stage of the river is negligible. After alluding to some further experiments now being carried on, the paper concludes:—"The effect of turbulence at the low stage is now settled, and the probability is that the amount of turbulence present in the Nile in flood at well-chosen sites will not necessitate any corrections of practical importance. The cause of the difference between the discharges at Sarras and Aswân still remains to be found."

WE have received from Messrs. J. Woolley, Sons and Co., Ltd., of Manchester, a copy of their "Scientists' Reference Book and Diary," price 3*s*. 6*d*. The book contains much interesting and useful information in addition to that usually found in diaries. The first section deals with the physical sciences, and contains a short article on recent advances in physics; another portion is devoted to chemical tables, and includes convenient data relating to specific gravities, solubilities, strengths of solutions for analysis, etc. A section is also devoted to scientific societies and departments, in which a brief account is given showing the address and the officials of each. The diary is well bound, and makes a convenient pocket-book for ready reference and notes.

MESSRS. H. F. AND G. WITHERBY are about to publish vol. i. of "A Manual of the Birds of Australia," edited by G. M. Mathews and T. Iredale, illustrated by coloured and monochrome plates.

A NEW edition of Sir Edward Thorpe's "A Dictionary of Applied Chemistry" is announced by Messrs. Longmans and Co. Vol. i., A to Calcium, is promised for January, and vol. ii. for early in the coming summer. The work, which has been carefully revised, will be in six, and possibly seven, volumes.

Our Astronomical Column.

COMETS.—Mr. Woods has communicated by cable the following elements of Skjellerup's comet. Elements deduced by M. Ebell from observations on December 13, 17, and 18 last are also given. Both are for the equinox of 1920·0:

	Woods	Ebell
T in G.M.T.	Dec. 11·11	Dec. 13·46512
ω	341° 10′	344° 9′ 47″
☊	107 47	107 38 7
i	22 12	24 4 7
log q	0·06047	0·06476

Mr. Woods's elements make the position at midnight on January 20: R.A. 11h. 7m. 17s., N. decl. 36° 22′. The position given last week was: R.A. 11h. 17m. 42s., N. decl. 38° 24′.

Herr Hoffmeister observed the comet at Sonneberg on December 18. He described it as a circular nebulosity 8·0′ in diameter, total light 9th magnitude, nucleus 11th magnitude.

An observation by Mr. R. L. Waterfield on December 31 indicates that Mr. Woods's ephemeris is very near the truth.

The two longest-known comets of short period (those of Encke and Pons-Winnecke) are both due at perihelion in 1921. There is a simple method of predicting the date of perihelion of the former comet within a day or so. Eighteen revolutions of the comet occupy $59\frac{1}{2}$ years, equal approximately to five revolutions of Jupiter and two of Saturn, so that the perturbations nearly repeat themselves after this period. The following have been the duration of eighteen revolutions at recent returns:

	Interval (days)		Interval (days)
1845 to 1905	21704·28	1855 to 1914	21705·75
1848 to 1908	21704·08	1858 to 1918	21705·92
1852 to 1911	21705·33	1862 to 1921	21706·1 about

Perihelion should occur about July 13·4.

Winnecke's comet is subject to large perturbations by Jupiter, and no simple cycle is available in this case. The best estimate that can be made of the date of perihelion is the end of June, but this may be a month in error. The period of this comet has increased by four months in the last century, and the perihelion distance has increased from 0·77 to unity. This has resulted in introducing it into a new shower of meteors, first seen on June 28, 1916, the connection of which with Winnecke's comet was quickly detected by Mr. Denning. These meteors should be in evidence next June. The radiant is about 240°+50°.

Another periodic comet may return this year, 1846 IV (de Vico). The most probable period is 75·7 years, which would make the next perihelion November, 1921, but the uncertainty is fully three years. The comet will first become visible to southern observers, but it will move northward very rapidly, its inclination to the ecliptic being 85°.

DISAPPEARANCE OF SATURN'S RINGS.—The earth passed through the plane of the rings on November 7, and a joint paper on the phenomena presented about that date, by Messrs. Hepburn, Ainslie, Steavenson, and Waterfield, was read at the R.A.S. meeting on December 10. They observed with the 28-in. equatorial at Greenwich, by kind permission of the Astronomer-Royal. On November 6 the ring was easily visible, but on the following night no trace whatever was visible outside the ball. This was confirmed by Prof. Barnard, observing with the 40-in. at Yerkes Observatory, who estimated that the thickness of the rings could scarcely exceed 40 miles. A few days later, in spite of the dark side of the rings being turned towards us, the observers at Greenwich could clearly see a number of luminous patches outside the ball, which they were able to identify with the brighter regions of the ring; they noticed that these regions continued visible when twilight was far advanced and long after the inner satellites had disappeared. This would appear to indicate that an appreciable amount of sunlight is able to penetrate the ring, illuminating the particles on its remote side. It will be remembered that a star was recently seen through the ring, so it is not surprising that sunshine should penetrate it.

The ring will again be edgewise to the earth on February 21 and August 2, and to the sun on April 10.

KODAIKANAL OBSERVATORY.—Bulletin lxiii. of this observatory deals with the direction and aspect of the dark filaments which are such a conspicuous feature of spectroheliograms in Hα light, and are known to be prominences projected on the solar disc. Their azimuth is first studied, and shown to be a function of latitude. Near the equator they lie along a meridian; as we recede from the equator the polar end of the filament swings eastward. The mean inclination to the equator is 40° in latitude 30°, and 0° in latitude 60°.

The explanation suggested is the easterly drift produced by the excess of easterly motion at the equator. It was inferred from this that the high-latitude filaments are older than the equatorial ones. However, a study of the history of particular filaments from the photographic records did not give clear evidence of this difference of age with latitude.

Two interesting features of the prominences are discussed: (1) Those on the disc are flanked by a bright strip, which is easiest to see near the limb. It is interpreted as showing that the prominences rest on a bright base which is hotter than the ordinary chromosphere. (2) The lower portion of prominences seen in profile outside the disc is frequently obscured by a dark strip. It is suggested that the central region of a prominence is the hottest, and that the lower portions of the cooler outer envelope may be dense enough to absorb light.

Birth and Growth of Science in Medicine.[1]

By Sir Frederick Andrewes, F.R.S.

The aim of science is to discover the "laws of Nature," and in its truest, though narrowest, sense it is the pursuit of this knowledge for its own sake, irrespective of any practical use to which it may be put. The primary aim of medicine is the practical one of healing the sick or of preventing disease, and therefore, in the narrower sense, medicine is not a science, but an art. Physiology, pathology, and pharmacology are sciences in the strictest sense; medicine is the art of applying the laws established by these sciences to the prevention or cure of disease. More than this, it is the very human art of treating the patient as well as his disease. But in a broader, and surely more natural, sense we may regard medicine as a science. Pathology may, it is true, be pursued as an abstract subject, but in real life it is inseparable from medicine. Treatment and prevention are so intimately based upon a right understanding of the nature of disease and of the laws which govern its course that I refuse to separate pathology and medicine. It has too long been the fashion to limit the sphere of pathology to the dead-house and the laboratory; its field is equally at the bedside, and, indeed, I would assert that there is no method of studying the natural history of disease which pathology may not claim as its proper province. By Harvey's injunction I am to admonish you to seek out the truths of Nature by observation and by experiment. These are two different ways of pursuing a subject, and, indeed, the concrete sciences have been divided into the "observational" and the "experimental"; anatomy is an observational science, physiology an experimental one. The observational sciences long preceded the experimental, and in pathology and medicine, which partake of the nature of both, the experimental method is of late growth.

My aim is to trace, so far as I may in the allotted span of time, the influences which have governed the growth of our knowledge of disease; to pursue them to their beginnings rather than to record their final results. I cannot, indeed, hope to say anything new; I can only endeavour to place before you the facts to be gathered from literature in the way in which they group themselves in my own mind.

In his suggestive little book entitled "The Revolutions of Civilization" Prof. Flinders Petrie has pointed out that culture is an intermittent phenomenon. No civilisation in the past has proved permanent, and he estimates the average duration of any given period of culture at about 1500 years; in Egypt he traces eight such periods. In Europe we are aware of three great periods of civilisation during the past five thousand years—the Mediterranean or Minoan, with its headquarters in Crete, from 3000 to 1200 B.C.; the Classical, of which Greece was the intellectual fountain-head; and the Modern or Western, in which we are still living.

So far as we are aware, the earliest attempts at science began in Ionia some six centuries before Christ, and the name which I would first commemorate as a spiritual benefactor of this college is that of Thales of Miletus. I might have chosen Empedocles or Pythagoras, but we may let Thales, as the first of the succession of early Greek thinkers, stand as the prototype of the group of men who laid the foundations upon which science was to be built by future generations. Doubtless they had acquired what they might of the lore of older civilisations, but they seem to have been the first to pursue abstract knowledge. Until their day men had been content to accept any foolish myth about the nature of the world and of the things they saw around them. The service which Thales and his successors rendered to mankind was that they rejected all fabulous tales and began to think for themselves how things had become such as they saw, definitely reaching out after the laws which they felt sure must govern Nature. Their great contribution to science was to establish that atmosphere of intellectual liberty which rendered science possible. It says much for the liberal spirit of that age that these men, who broke with all the cherished traditions of the past, were not, as a rule, reviled for impiety, but received universal honour. Thales was accounted one of the Seven Wise Men of Greece.

But let me now consider what the earlier Greeks did for medical science. Medicine of a sort and rude surgery must have been transmitted even through the dark ages, handed down, it is said, by special families, the Asklepiadæ, just as the epic tradition was passed along by the Homeridæ. Certain rules of surgery and the practices of blood-letting and purgation are known to be of immemorial antiquity, but for the most part the medical practice of those times seems to have been bound up with fetish worship and superstition. There is no evidence that Egypt had any true medical science to impart, and our knowledge of Minoan medicine is limited to the single fact that in the great palace at Cnossus there existed a system of sanitation so good that it was never equalled until the reign of Queen Victoria. We may be quite sure that the inquisitive and receptive Greek mind was quick to pick up what it could from the older civilisations, and then, in accordance with its peculiar genius, it proceeded to develop it out of all recognition.

Medicine entered upon its first scientific stage with the Greeks; it became an observational science. More than this; just as in other matters the philosophers had put away the myths and fairy tales of their ancestors, so, too, in medicine they rejected the magic and fetish worship which had hitherto formed so large a part of practice. This was one of the greatest services rendered by the Greeks to medical science. Æsculapius was worshipped at numerous temples, and thither the sick were brought to receive such benefit as they might from the rites of the god. But at such health resorts they were also subjected to other influences—careful diet, pure water, rest, and cheerful associations—and when improvement occurred the physicians had the acuteness to perceive that this simple treatment had probably more to do with the result than the religious rites.

This brings me to the second name which I naturally commemorate to-day—that of Hippocrates of Cos—the first great clinician of whom we have any knowledge, and one whose name will always be associated with the phase which Greek medicine had now reached.

When Hippocrates was born, about 460 B.C., observational medicine had attained a considerable pitch of excellence. He doubtless imbibed the teachings of other good physicians who had gone before him, but the veneration in which Hippocrates was held by the Greeks themselves assures us that he was a man of outstanding character and attainments. We can,

[1] From the Harveian oration delivered before the Royal College of Physicians of London on October 18, 1920.

however, judge of him more directly. It is certain that only a small part of the Hippocratic treatises which have come down to us are from the pen of the master himself, but we may reasonably take them, as a whole, to represent his teaching, and they give us a fair idea of the stage at which the best Greek medical science had arrived in the fifth century B.C. It was a simple and rational medicine based on careful clinical observation and on a watchful study of the results which followed hygienic treatment. The healing powers of Nature formed a leading tenet of the Coan school; we may almost regard Hippocrates as the founder of sanatorium treatment. Perusal of those of the Books of Epidemics which are most certainly by Hippocrates himself shows that he was an admirable case-taker; in the light of our present knowledge we can readily make a diagnosis from many of his descriptions. His medicine shows, of course, the natural limits of a purely observational science; it knows little of anatomy and less of physiology; its crude pathology is based on the doctrine of "opposites"; the idea of experiment as a means of investigation has not yet arisen. Yet in spite of this, the school of Cos is a landmark in the history of rational medicine.

The centre of interest now shifts elsewhere, and especially to Alexandria, but it remains Greek. Alexandrian culture represents a sort of continuation of that of Athens, though, perhaps, in comparison smacking somewhat of Wardour Street. The great creative age in art and poetry had gone by; it was a period of imitation in art, and in literature largely a time of scholiasts and commentators on the better work that had been done before. But here we have an excellent illustration of Prof. Flinders Petrie's dictum that in each period of culture science reaches its prime long after art and literature have begun to decline. For all the branches of science then extant continued to advance in Alexandria. I need scarcely recall how mathematics and astronomy flourished under the Ptolemies, and in medical science the Alexandrian school maintained its premiership for many hundred years.

Anatomy and physiology form a necessary basis for medical science, and much as the earlier Greeks had done for medicine, they had lacked any adequate knowledge of these subjects. The later Greeks proceeded to remedy this defect. The practice of dissection became established, and anatomists must look back to the Alexandrian school for the foundation of their science. I must pass over Herophilus and Erasistratus and commemorate the later Greek school in the person of its most distinguished alumnus, Galen. Roman medicine, like its art, was wholly Greek in origin; its great physicians received their training in Greek schools, and Celsus, the best-known writer on medical subjects, was not himself a practitioner of medicine. Thus, though we associate Galen with Rome, I must commemorate him as a Greek—the last and, in many ways, the greatest of the Greek physicians.

Nearly six hundred years had passed between Hippocrates and Galen, and when we compare the two it must be remembered that Galen had the advantage of that six hundred years of medical experience. It gave him a wider outlook, and thus made him a better physician, though I conceive Hippocrates, considering his times, to have been the bigger man. I do not propose to dwell on Galen's eminence as a physician, though he stood far above all others of his age. His real claim to immortality may be put into a few words: he was the first to make systematic use of the experimental method in medicine, and he founded the science of physiology. His experimental discoveries in physiology, and particularly in the domain of the nervous system, entitle him to be called the father of that science. Galen must also be credited with a great advance in pathology. The earlier Greeks had regarded internal medicine from a purely humoral aspect; the later Greeks began to recognise affections of certain definite organs, but Galen developed this conception beyond any of his predecessors.

With Galen we come to the end of the great age of classical civilisation, and it will be fitting, before leaving it, to summarise what Greek genius had accomplished in medical science. An atmosphere of intellectual liberty essential to the birth and growth of science had been established by the Greeks; they had developed the love of knowledge for its own sake. Their shrewd observation had transformed medicine from a medley of traditional empiricism and superstition into a natural science; they freed it from magic and laid the foundations of a rational treatment of disease. Towards the close of their epoch they devised the experimental method, and used it to found the science of physiology. Indirectly we owe to them the laws of clear thinking in medicine and in the other sciences, and the development of mathematics and mechanics.

When the Minoan civilisation passed away the Greeks had been compelled to begin again almost from the beginning. There was no such complete break between the classical period and our modern civilisation; much was handed on by direct tradition, and vastly more by written manuscript. Nevertheless, after the fall of the Roman Empire, Europe had to be remade, and to pass through its dark ages before the dawn of a new culture. The new mixture of races seems to have been incapable of intellectual achievement until the ordained incubation period was over, and that period was at its darkest from the fifth to the tenth centuries A.D. Medicine shared the fate of the other sciences, and what was not forgotten became debased by admixture with Eastern magic and superstition.

The dominant power in Europe during this period was the Church, and, although its conservatism had a wholly deadening influence as regards the advance of science, it did much to preserve the culture of classical times. In the seventh century occurred the last of the four known Arab migrations which have overwhelmed neighbouring peoples; it spread not only over Western Asia, but also round the Mediterranean. Whatever may have been the primitive culture of these Arab invaders, they presently acquired a high degree of civilisation. They were a keen-witted race, quick to assimilate the culture with which they came in contact, and this was largely Greek in origin. For some hundreds of years the Moorish Empire in Spain was far in advance of the rest of Europe in literature, in science, and in medicine. The best medical works of classical antiquity were translated into Arabic, and it is by this strange route that much has come down to us which would otherwise have been irretrievably lost. Their chief share in medicine was to absorb and transmit the knowledge of the Greeks. Medicine reflects the spirit of the Dark Ages in Europe; the traditions of the past were still supreme, and Galen was the god of the medical world. Men felt him to have been a better man than themselves, as in truth he was, and it was enough that Galen said this or that, or that his writings could be interpreted in such and such a sense, and there the matter ended.

Then, in the fullness of time, after more than a thousand years of intellectual slumber, men again began to think for themselves, just as the Ionian Greeks had done twenty centuries before. The Renaissance was at first literally a revival of learning, due to the renewed study of the Greek language and the discovery of much of the classical literature which had been hidden away in the libraries of the East. The first effect of the revival was to strengthen the position of Galen. With the revival of Greek in the fifteenth century his original writings became accessible, and manuscripts hitherto unknown came to light. It became the aim of the scholars of the time to translate these works into polished Latin for the benefit of those unacquainted with Greek. Amongst the medical humanists, as they are termed, was the founder and first president of this college. There is no more honoured name in scholarship than that of Linacre, but it is instructive to note the difference between his mental attitude and that of Harvey, little more than a hundred years later. Linacre stands for the revival of learning, Harvey for the intellectual quickening that revival was to engender. The avowed aim of the medical humanists was not the advance of medical science, but a return to the uncorrupted knowledge of the Greeks; the thought and science of antiquity were still held so immeasurably superior to anything that modern times could produce that no advance was contemplated. But the seed was sown. Greek literature was the product of an original creative activity and a mental freedom to which Europe had been long unaccustomed. Men could not study it without at the same time drinking in something of the spirit in which it had been conceived and which animates it for all time. This was our true heritage in the Renaissance, and once again imbued with this spirit men felt at liberty to ask whether the ancients were always right and to criticise and test their statements. The reign of mere authority came to an end, and science recommenced that advance which has continued to the present day.

The first science to bear new fruit was anatomy. It was in Italy that the resurrection began, and the book written by Vesalius on "The Structure of the Human Body," published in 1543, set the seal upon the new method—the appeal to fact instead of to dogma. We all know that the truth as to the pulmonary circulation was first ascertained, while it was reserved for Harvey to demonstrate the systemic circuit. The method of experiment as an adjunct to observation, instead of being delayed for hundreds of years, as it had been amongst the Greeks, was now, thanks to Galen, an instrument ready to hand. And thus it came about that when a man arose deeply imbued with the true spirit of science and capable of using this instrument with intelligence and an open mind, his study of the circulation was at once rewarded by a discovery of capital importance.

William Harvey stands as one of the landmarks in the history of medical science. His was the first scientific discovery of absolutely first-rate importance to be made by the application of the methods and spirit now revived from ancient times; he possessed the vision, the power of imagination, as well as the needful industry and patience in gathering his facts and in devising his experiments.

Harvey has left us two treatises of unequal greatness. The "De Motu Cordis" has no need of any introductory disquisition on scientific method, for it itself is the method incarnate. It is the mature work of a master who is sure of his ground; it sweeps us along from one short chapter to another, each filled with accurate observation and close reasoning, so that no doubt or hesitation is possible to the reader.

But he also essayed to solve other biological problems, for which his means were not adequate, and the "De Generatione," which he was reluctant to publish, is reading of a different kind. The most instructive part of this treatise is perhaps the introduction on scientific method, "Of the Manner and Order of Acquiring Knowledge." Here Harvey in his later age sets forth the principles which had guided him, with Aristotle as his leader, in his life's work, and we realise how truly scientific were his methods.

With Harvey, we feel that medical science has fairly entered the right path. The conditions essential to scientific progress—freedom of thought, accuracy of observation, imagination, experimental verification, and logical reasoning—all are exemplified in Harvey's work.

There is room for difference of opinion as to the impulses from external sources which have had the most far-reaching effects upon medicine since Harvey's day, but I would name four as of exceptional importance. They are the invention of the compound microscope, the development of chemistry, the acceptance of the doctrine of evolution, and the discovery of the relation of micro-organisms to disease. The microscope was invented in Holland late in the sixteenth century, but its possibilities as an aid to anatomy were not at first grasped, and it was not until after Harvey's death that Malpighi actually saw the capillaries and the contrary direction of the blood-flow in arteries and veins. The rise of histology from that time forward has transformed our ideas of the structure of the body, and with each improvement in the microscope our horizon has widened. We have passed from the organ to the units of which it is built up, and Virchow's "Cellular Pathology" marks an epoch in medicine. To-day we are a stage further, for the inquiry is being pushed into the more intimate structure of the cell itself, in the hope of revealing the nature of the processes by which it carries on its work.

The rise of physics and chemistry has been even more fruitful for medicine. We cannot nowadays consider them separately, so closely merged have they become. We recognise the fundamental importance of these sciences for the right understanding of physiology and pathology by placing them at the root of medical education.

Chemistry has influenced medicine from the days of alchemy onwards; Paracelsus and Van Helmont stand out as picturesque figures in its history. In England the rise of physics and chemistry began in Harvey's lifetime with those meetings of scientific men which later gave birth to the Royal Society. It must not be forgotten that the work of such men as Boyle, Hooke, Lower, and Mayow practically solved the problem of respiration not long after Harvey's death—a problem second only in importance to that of the circulation—though a century was to elapse for its full meaning to become clear with the discovery of oxygen. Every advance in physics and chemistry has borne fruit for us in its turn; to-day we can almost affirm that the chief issues in physiology and pathology are to be sought in the chemical activities of the human body. These, again, are bound up with physical conditions, and there is one recent branch of chemistry the possibilities of which are only beginning to be appreciated in medicine. If we reflect that the body, from a chemical point of view, consists almost entirely of colloids, the behaviour of which is still imperfectly understood, it will be realised that advances in colloidal chemistry are destined to throw a flood of light upon the processes of vital activity.

The doctrine of evolution has scarcely received the attention it merits as a factor in modifying the opinions of medical science. So long as it was believed that the body, with all its natural functions, had been created from the first in its present condition, there was little room for inquiry into the origin of those functions, and still less into that of morbid processes. Darwin has changed all this, as a single instance will suffice to show. Metchnikoff's studies on the comparative pathology of inflammation have taught us that this is not a diseased state, but a purposeful reaction against injury, gradually perfected in passing up from the lower to the higher animals. Almost without our being conscious of it, the idea of evolution has gradually effected a great change in the point of view from which we regard a large number of diseases, the symptoms and morbid changes in which we now understand as efforts of the body to maintain its integrity in face of the injurious agencies which threaten it. One might almost rewrite pathology from the evolutionary point of view

Last, but not least, of the great changes which have swept over medical science is that which was due in the first place to Pasteur, carried on by Koch, and brought to triumphant practical application by Lister. The discovery of the true nature of infection has of necessity transformed the outlook of medicine and surgery, but bacteriology and its daughter science immunology would demand a Harveian oration to themselves.

We loosely speak of such fundamental discoveries as those I have just mentioned as producing a revolution in medical science. It is not revolution, but upward growth. With the establishment of each great principle we gain a fresh height from which the field of science takes on a new and wider aspect, and we may be confident that we shall reach yet greater heights to reward us with an even ampler range of vision. There is no sign that the vitality of science in our civilisation is in any way spent; on the contrary, its fertility is unchecked. During the late war we saw for the first time the scientific forces of this country fully mobilised, and no previous five years have seen so many scientific problems brought to a successful issue. So forcible has been the lesson that science has gained mightily in public estimation, and research is on the lips of everyone. New facts are being gathered in, old facts are coming to be seen in a new light; we are almost bewildered by our own progress. The workers in the field of medical science are many, and it may not be given to any one of us to make an immortal discovery, such as that of the circulation of the blood. But the humblest of us can work in Harvey's spirit and bring his contribution to the building up of knowledge in the full assurance that even a single stone, if honestly and truly squared, will in due time find its proper place in the fabric.

Wheat from Seed-bed to Breakfast-table.

"THE History of a Grain of Wheat from the Seed-bed to the Breakfast-table" formed the subject of the concluding evening discourse given by Sir Daniel Hall at the Cardiff meeting of the British Association, and an account of it appeared in the October issue of the *Journal of the Ministry of Agriculture*. Of all industries there is not one which is older, more universal, or more essential than the growing, grinding, and baking of wheat and its kindred food-grains. Yet, in spite of the extreme age of the industry, the various processes involved in the passage of the wheat-grain from its seed-bed to the breakfast-table still demand the close attention of the best obtainable research men of the day; for it is only by research and by the utilisation of the results so obtained that the increased food production necessary for supplying the needs of the world's growing population can be attained.

Many experiments have been made to try to bring about an increase in yield by treating the seed either by electricity or by soaking it in some nutrient fluid. The results of these experiments are very doubtful, and it is improbable that such treatment can affect the ultimate yield. Attention has also been paid to the influence on the wheat yield of the rate of sowing. Ordinarily, wheat sown at the rate of 2½ bushels per acre gives a thirteenfold yield, but isolated wheat-plants are capable of giving more than a hundredfold yield. It is hoped that by using a suitable machine a perfectly effective seeding can be attained with 1 bushel per acre, and such a reduction in the amount of seed sown would mean a considerable gain to the country. Improvement in the quality of wheat grown has been brought about by careful breeding work. Prof. Biffen, working on Mendelian principles, has obtained a variety of wheat, "Little Joss," which produces very good crops on certain soils because of its resistance to rust attacks, the rust-resistance power having been introduced into the grain by careful selection and breeding. Another wheat, "Yeoman," has been bred for the high milling quality of the grain, and on soils to which it is suited the "Yeoman" wheat yields a very heavy crop, while the quality of the flour is almost equal to that obtained from the best Canadian grain. At the present time millers are compelled to mix strong foreign wheat with our home-grown wheat in order to produce bread of the spongy type desired by the public, but it is hoped that extension of Prof. Biffen's work will ultimately supply strong wheats of the "Yeoman" type suited to the varying conditions of all our different wheat-growing districts, and in this way the millers may be rendered independent of foreign wheats.

Although wheat is *the* crop for breaking in virgin land, yet it will not stand competition; at Rothamsted a wheat crop left unharvested to sow itself without further cultivation entirely disappeared in a grassy wilderness in three years. Wheat, though thus dependent on cultivation, possesses a remarkable power of yielding a good crop upon all sorts of soil. One of the Rothamsted plots has carried wheat for seventy-seven successive years without any manure, and the yield is still about 12 bushels per acre—approximately the average crop for the wheat-lands of the world. The manurial requirements of a wheat crop have long since been decided, and the problem now is to prevent the lodging which occurs with big crops on good soils. It may be possible to breed varieties with stiffer and shorter straw, or it may be that manurial treatment, time of sowing, width of rows, and spacing of the seed have some effect on the lodging, or, again, there may be some actual disease factor involved. All these points are being investigated.

The growth of the wheat-plant, so far as gathering material from the air and from the soil is concerned, is practically completed about five weeks before the grain is harvested. This latter period is occupied by the transference of stored-up food from the leaves and stem to the seed. The transference, however, is never complete, and the straw still retains about half of the valuable material manufactured by the plant. Since the amount of such material depends largely on conditions of soil and water-supply, which are outside our control, one line of development must be to increase the migration into the seed. This is especially urgent in drier countries where insufficient water-supply sets a definite limit to the amount of growth. With regard to the flour, considerable differences in milling operations have been brought about under the stress of war. The miller's object is to crack the wheat "berry" with the least possible breaking up of the husk, so that the endosperm falls out in a clean condition. The endosperm is the most digestible part of the grain and yields the best white flour. Before the war only about 68 per cent. of the weight of grain was recovered as white flour, while the remainder passed into various offals. During the war the extraction of flour from wheat rose to more than 90 per cent.; this brought into use certain valuable food elements which, however, are not suited to all constitutions.

Prior to the war only one-fifth of the wheat we consumed was home-grown; the rest came from North and South America, Russia, India, and Australia. Some of these supplies are now cut off, and although America has considerably increased her wheat acreage, the world's supply is still perilously short. For the next year the supplies are safe enough, but the permanent position is by no means assured. Unless more land is put under wheat a bad crop in one or two of the exporting countries would create a serious world shortage, so that as a national insurance we must grow more wheat. We can extend our acreage, and we can increase our production on the existing wheat-land, but in both cases better skill and more knowledge are required. The country, then, must be ready to encourage the attainment of knowledge, for "on knowledge hangs our assurance of a progressive food-supply in the future."

The Origin of Primary Ore Deposits.[1]

THE author commences at the period when the outer silicate shell of the earth was molten. The primeval magma is regarded as having been practically homogeneous and containing about 60 per cent. of combined silicates. All water was then in the atmosphere, giving a pressure more than 300 times as great as at present. As temperature fell, water and oxygen were absorbed; crust-formation, foundering, and resorption went on for a long period, producing a flat temperature gradient in the liquid. Viscosity eventually rendered further foundering impossible; the crust became permanent, granite developed, and below it the segregated basaltic magma long remained liquid. At this stage the isostatic balance was adjusted. Ore-minerals in large quantity were given off at the surface of the granite; these were denuded and dispersed in sediments and solution. This, with later absorption by intruded basic magma, is assumed to have been instrumental in causing the present erratic distribution of primary ores. All so-called water in magmas is held to exist in combination as hydroxyl with silica not in solution as a gas.

Magmatic differentiation is regarded as having been caused by the agency of silicic acid—silicon combined with hydroxyl—which extracts potash alumino-silicate producing a solution lighter than, and immiscible with, a melt of basic felspars and ferro-magnesian minerals. It is believed that in this way the first great split of primary magma into the world-wide granitic and basaltic types was brought about. Evidence regarding the existence of silicic acid in magmatic liquids and elsewhere in Nature is adduced. The ultimate result of the action of water on rock magmas is that silicates are completely removed and a residue of ore-minerals such as magnetite, ilmenite, and chromite left.

Vein-fissuring was brought about in and above batholiths by the expansive force due to the increase in solid specific volume of various elements. This increase is very considerable, exceeding in amount the contraction on solidification of the granite, and continues throughout the whole of the crystallisation period. The effect of this force appears in waves as fissures in successive series. These developed very rapidly, were instantly filled with magmatic mother-liquor, and were quickly sealed by the deposit of solids therefrom.

Quartz is almost always present in veins along with ore-minerals, and silica often occurs in solution in thermal springs, especially such as carry gold, arsenic, antimony, and mercury. For these and other reasons it is regarded as probable that primary ore-minerals passing up from magmas to veins do so in silicic acid solution, and possibly in combination. The deposition of these ores is usually caused by loss of heat and reduction of pressure. It is believed that there are definite, but narrow, limits of temperature between which each ore-mineral develops. These correspond to the temperatures in the strata at the bottom and the top of the ore at the time of deposition. Ore persisting for a vertical depth of 2000 ft. would, therefore, indicate normally a temperature range of 20° C.

The pneumatolytic theory of the origin of the high-temperature ores is rejected because the phenomena of their occurrence are quite inconsistent with what would result if these metals had been given off as gases by magmas. The boiling points of tungsten fluoride (19° C.) and tin fluoride (705° C.) are so far apart that it would be impossible for wolfram and cassiterite to have developed in contact with one another, as they frequently do. Accessory minerals such as fluorite and tourmaline lose the genetic significance usually attached to them owing to the fact that they are not invariably present with tin and tungsten ores, and are frequently associated with a variety of other ores which are admittedly of hydrothermal origin.

In introducing the paper the author directed attention to the probable importance of variations of pressure in ore solution and deposition. Separation from simple solution would involve deposition of ore along the whole upward course of the solvent. This does not take place, the end being usually abrupt in an upward direction. The phenomena in Nature seem to indicate that reduced pressure causes dissociation and, at some point, the total removal of ore from solution. High temperatures and pressures are not entirely correlative, and, since they usually accompany one another in Nature, it is possible that as regards ore-deposition we may in the past have been confusing the two.

[1] Abstract of a paper by J. Morrow Campbell read before the Institution of Mining and Metallurgy on October 21, 1920.

University and Educational Intelligence.

BIRMINGHAM.—The Tebbutt lectures on administration will be given during the coming term as follows: "The Central Departments of Government and their Relation to Local Administration," by Prof. W. G. S. Adams; "Municipal Administration," by Mr. Arthur Collins (treasurer of the City of Birmingham); "Educational Administration," by Sir Graham Balfour; and "Business Administration," by Mr. Gilbert C. Vyle (managing director of Avery's, Ltd.). The lectures will be open to the public.

SIR WILLIAM BRUNYATE has been appointed Vice-Chancellor of the University of Hong Kong in succession to Sir Charles Eliot.

IT is stated in *Science* of December 3 that an anonymous gift of 200,000 dollars has been made to the fund which is being raised by the American Engineering Foundation for the promotion of research in science and engineering.

A COURSE of ten lectures will be given at the Horniman Museum by Mr. F. Balfour-Browne on "Insects in Relation to Agriculture and Disease," beginning on Saturday, January 15. The course is primarily for teachers, but other persons will be admitted so far as accommodation permits; admission will be by ticket, which can be obtained from the curator at the museum. There will also be a series of ten free lectures on Saturday afternoons, starting on January 15, which will be of a simple, popular nature; two lectures each will be given by Mr. F. Balfour-Browne, Mr. E. Lovett, Dr. W. A. Cunnington, and Miss M. A. Murray, and two further lectures by Mr. H. N. Milligan and Mr. A. R. Wright.

AN election to a research studentship will take place at Trinity College, Cambridge, during July next and in each following year. The studentship will be open to graduates of universities other than Cambridge or to men who can show evidence of exceptional qualifications for research who are not members of the University of Cambridge. A candidate must obtain permission from the Board of Research Studies to enter the University as a research student, and will be expected to proceed to the new research degree of Ph.D. which has been established. The value of the studentship will vary according to the student's pecuniary circumstances, but will not exceed 200*l*. per annum, and the studentship will be tenable until the student is of standing to proceed to the degree of Ph.D. Applications should reach the Senior Tutor, Trinity College, Cambridge, not later than July 25.

THE British Lampblown Scientific Glassware Manufacturers' Association, Ltd., has arranged a series of lectures on glass in connection with the lampblown glass industry. Prof. W. E. S. Turner will deal with the manufacture and the properties of glass tubing and rods (three lectures); Mr. English will deliver three lectures on the manipulation of glass and the graduation of apparatus; Mr. Higgins will give three on thermometry and thermometer testing; Mr. Stott will deal with volumetric glassware (two lectures); and Mr. Davis will give the concluding lecture on technical points in the manufacture of bench-blown chemical glassware. The lectures will be delivered at the Northampton Polytechnic Institute, one every week; they commenced on Wednesday, January 5. Members of the association can attend the course free; others will be charged 2*s*. 6*d*. per lecture, or 10*s*. 6*d*. for the whole course. Further information can be obtained from Mr. W. H. Ashfield, British Lampblown Scientific Glassware Manufacturers' Association, Ltd., 2–3 Duke Street, St. James, S.W.1.

SOME interesting figures showing the salaries during 1920 of university and college officials in the United States are published in Bulletin No. 20 (1920) of the Bureau of Education. Data from 401 institutions have been collected, and, so far as possible, only salaries which recompense full-time service are given. Names are omitted, but the institutions dealt with are numbered and grouped in geographical divisions. In the detailed statements the president's salary is given, and succeeding columns show the number and salaries of the various deans, professors, associate and assistant professors, instructors, and assistants who are employed by the various institutions. Summaries are also provided of the various salaries which are allotted to the different posts, and these again are drawn together in two tables which show the maximum, minimum, average, and most frequent salaries attached to different offices in public and private institutions. The average salary for every post is higher in the former than in the latter type of establishment, due in part, no doubt, to the large number of small schools included in this class.

AFTER a break corresponding to two academic years, statistics are again available showing the number of doctorates in science which have been conferred in American universities (*Science*, November 19). In the year 1919–20, 328 such degrees were conferred by 31 institutions, as compared with 332 doctorates of 28 institutions for the year 1915–16, showing that normal conditions have been practically regained. As in previous years, the Eastern universities have conferred the greater number of degrees; Chicago University continues to head the list with 59, and this year Cornell University follows with 35 doctorates. Interesting figures are also given which show the distribution of the degrees among the various departments of science schools for the years 1912–16 and 1919–20. Chemistry continues to claim the greatest number; last year 96 doctorates were conferred in that subject—a total which is 19 short of the number given in 1916. Comparing the numbers for degrees in other sciences for the same two years, it is noteworthy that those conferred for physics and mathematics have decreased by 14 and 15 respectively, while the numbers for botany, zoology, and psychology have increased, the latter from 19 to 40. The increase is interesting because from the numbers given in previous years attention to that subject appeared to be declining steadily. No doctorates were conferred specifically for palæontology, mineralogy, metallurgy, or meteorology. The article concludes with the first instalment of a list giving the names of the recipients of the doctorates during 1919–20, together with the titles of their theses.

THE second term at University College, London, begins on Tuesday, January 11. During the term a number of public and other courses of lectures will be given, full particulars of which can be obtained from the Secretary, University College, London, W.C.1. The attention of readers of NATURE may be directed to the following:—Public Lectures: "The Navigation of Aircraft by Astronomical Observations," by Prof. L. N. G. Filon, on Friday, January 14; "Greek Medicine," by Dr. Charles Singer, on Friday, January 28; "Basque Customs," by Prof. J. E. G. de Montmorency, on Thursday, February 24; "The History of Plant Delineation," by Dr. Charles Singer and Dr. Agnes Arber, a course of four weekly lectures commencing on March 2; and "The British Museum in War-time," by Sir Frederic Kenyon, on Friday, March 4. The following courses of lectures will also commence on the dates indicated:—"Fine Art Anatomy," by Prof. G. Elliot Smith, on Monday, January 10; "History of Mathematics up to the Eighteenth Century," by Mr. T. L. Wren, on Tuesday, January 11; "General History and Development of Science," by Dr. A. Wolf (continued from 1st term), on Wednesday, January 12; "Measurements of Stresses in Materials and Structures," by Prof. E. G. Coker, on Monday, January 17; "Mathematical Theory of Relativity," by Dr. G. B. Jeffery (continued from 1st term), on Monday, January 17; "History of the Biological and Medical Sciences from Early Times to the Eighteenth Century," by Dr. Charles Singer (continued from 1st term), on Tuesday, January 18; "The Present State of our Knowledge of the Science of National Eugenics," by Prof. Karl Pearson, on Wednesday, January 10; "Spectroscopy, General and Applied," by Dr. S. Judd Lewis, on Friday, January 21; and "Development of Medicine in Modern Times," by Dr. Charles Singer, on Tuesday, March 8.

Calendar of Scientific Pioneers.

January 7, 1786. Jean Etienne Guettard died.—The discoverer in 1752 of the extinct volcanoes of Auvergne and the compiler with Lavoisier of a mineralogical map of France, Guettard has been called "the father of all the national Geological Surveys."

January 7, 1893. Joseph Stefan died.—Professor of physics at Vienna and director of the Physical Institute, the law of cooling which bears Stefan's name was enunciated by him in 1879.

January 8, 1642. Galileo Galilei died.—The founder of the science of dynamics and one of the greatest of the early experimentalists, Galileo, wrote J. D. Forbes, "was beyond all comparison the glory of his age." Some years older than Kepler, Galileo was born in 1571 at Pisa, where he studied and lectured and made his experiments on falling bodies. The leaning Tower of Pisa now bears the inscription:

GALILEUS GALILEJUS
Experimentis E Summa Hac Turri Super Gravium
Corporum
Lapsu Institutis
Legibus Motis Detectis
Mechanicen Condidit
Ingentibusque Suis Posteriorumque Sophorum Inventis
Praelusit

The astronomical discoveries of Galileo were made while he held the chair of mathematics at Padua. In 1609 he heard of the invention of a crude telescope. Seizing upon the idea, he made an instrument to magnify thirty times, and within eighteen months he had observed the mountains and craters of the moon, seen the planets as discs, counted forty stars in the Pleiades, discovered four of the satellites of Jupiter, was perplexed by the curious appearance of Saturn due to the ring-system, observed the gibbous, as well as the crescent, phase of Venus, and had closely followed the spots in the sun. He was then at the zenith of his career. The greater part of his later life was passed at Florence, and to this period belong the controversies and persecutions which embittered his last days.

January 9, 1848. Caroline Lucretia Herschel died.—Returning to England with her brother William in 1772, Caroline Herschel for fifty years was his most patient, skilful, and zealous assistant. The minor planet Lucretia was named after her by Palisa in 1889.

January 10, 1778. Linnæus died.—Carl von Linné or Linnæus was born on May 3, 1707, at Roëshult, Sweden. A student at Lund and a lecturer at Upsala, through much poverty he clung to his first love of botany. An expedition to Lapland was followed by travels in Holland, England, and France. In 1741 he became professor of anatomy and physics in the University of Upsala, but the following year was appointed to the chair of botany. His last edition of his "Systema Naturæ" appeared in 1768.

January 10, 1833. Adrien Marie Legendre died.—The contemporary of Laplace and Lagrange, and the instructor of Cauchy and Arago, Legendre was on the Commission for connecting Greenwich and Paris by triangulation, and made notable additions to various branches of higher mathematics.

January 12, 1665. Pierre de Fermat died. Born in the province of Gascony, Fermat was trained as a lawyer, and became a councillor of the local Parliament at Toulouse. He was the correspondent of Descartes, Torricelli, Pascal, Huygens, Wallis, and others, and made additions to geometry, the calculus of probabilities, and the theory of numbers.

Societies and Academies.

LONDON.

Faraday Society, December 13.—Sir Robert Hadfield, Bart., president, in the chair.—Prof. E. D. **Campbell**: A force field dissociation theory of solution applied to some properties of steel. Understanding of the properties of alloys has been obscured by the use of the term "solid solution" and by expressing constitution in terms of percentage weights. There is no essential difference between a liquid and a solid solution, and the constitution of both should be expressed as molecular or atomic concentrations per unit volume. The electrolytic dissociation theory in its usual form is inapplicable to alloys. The force field theory is a modified form of it applicable to liquid and solid solutions alike. The assumption is made that in a molecule the electromagnetic force field associated with the constituent atoms is closed in the combination, but in solution this force field is opened out by the solvent to an extent depending on concentration and composition. The reactivity of ions is due to the open force fields, and not to the presence of electric charges. In the presence of an impressed e.m.f. the resultant of the reactivity is electrical resistance in the case of metallic solutions, and electrical conductance in aqueous solutions.—A. L. **Norbury**: The electrical resistivity of dilute metallic solutions. It is well known that the small quantities of impurities in solid solution cause a large increase in the electrical resistivity of a pure metal. Data are collected showing the relative atomic effects of such impurities, and a certain relationship appears to be brought out by doing so. The author summarises his conclusions as follows:—(1) A comparison with the atomic volumes, intrinsic pressures, electrical resistivities, thermo-electric properties, and decomposition potentials of the elements concerned shows that none of these atomic properties can be directly applied to explain the results. It is suggested that the atomic effects are small when there is little electrical attraction between the atoms of solute and solvent, and large according as the electrical attraction between the two is greater. (2) It seems probable that in the dilute solutions quoted the atoms of solute are not associated. (3) Assuming, for example, the face-centred cube lattice in a dilute solid solution, an atom of solute will be surrounded by twelve equidistant atoms of solvent, and will not be attached to any one of these atoms in particular. It will, therefore, exert attractive forces on the electrons of the surrounding atoms. (4) It is generally assumed that metals conduct the electric current by means of their "free" electrons; the presence, therefore, of forces restraining the "free" electrons in solid solutions will account for their diminished conductivity.

Geological Society, December 15.—Mr. R. D. Oldham, president, in the chair.—Dr. T. O. **Bosworth**: Structure and stratigraphy of the Tertiary deposits in north-western Peru. The westernmost ranges of the Andes in the north of Peru are of pre-Tertiary age. The Tertiary rocks occupy a narrow strip of country between the mountains and the sea, and they consist of 15,000 ft. to 25,000 ft. of clay-shales and sandstones, with thin seams of beach-pebbles and shells. During the Tertiary period a large subsidence was in progress. The stratigraphical succession is:

		Ft.
MIOCENE.	Zorritos Formation	5000+
EOCENE.	Lobitos Formation	5000+
	Negritos Formation.	
	(Clavilithes Series) (Turritella Series)	7000+

The Tertiary accumulation is greatly broken up by intense block-faulting; between the fault-blocks are differential displacements of many thousands of feet. An important movement probably occurred along a great fault-belt parallel with the Andes.—H. **Woods**, Dr. T. W. **Vaughan**, Dr. J. A. **Cushman**, and Prof. H. L. **Hawkins**: Palæontology of the Tertiary deposits in north-western Peru. The fauna of the Negritos formation is of shallow-water gastropods and lamellibranchs, with a small number of teeth of fishes, decapod crustacea, corals, and one Echinoid. Aturia is also present. The number of species is large, and nearly all are new. By the stages reached in the evolution of Venericardia of the Planicosta group correlation is made with the Tejon group of California; but the relation to the Wilcox and Lower Claiborne groups of the Eastern and Gulf States of America is more marked, and is sufficient to indicate the existence of a sea-connection between the Pacific and the Atlantic. The Lobitos formation is distinguished by Foraminifera of the genera Lepidocyclina and Orthophragmina. In the Zorritos formation Miocene age is indicated by the similarity of some of the gastropods and lamellibranchs to those of the Miocene of Panama.—Dr. T. O. **Bosworth**: Geology of the Quaternary period on a part of the Pacific coast of Peru. Throughout the Quaternary period the littoral has undergone a series of vertical oscillations having a hinge-line in the Andes. The ocean-soundings show a steep 2000-ft. submarine cliff at the edge of the continental shelf. This cliff is taken to be a submarine fault-scarp, marking the important fracture (Pacific fault) which was the western boundary of the Quaternary uplifts. The oldest and highest of the raised sea-floors now has an elevation of 1100 ft. It extends 20 miles inland, and, within the territory discussed, covers an area of 700 square miles. The inland boundary of each "tablazo" is a raised sea-cliff. The original western limit of each one of them was probably the edge of the continental shelf. The depth, 27 miles from the present coast, is 12,000 ft. The Quaternary deposits formed upon it are presumably deep-sea oozes. The events on the east side of the Pacific fault are grouped into four similar episodes. Each consists of a subsidence accompanied by marine transgression, followed by an uplift causing emergence of new land. They are: (1) The Mancora, (2) the Talara, (3) the Lobitos, and (4) the Salina episode. Four episodes have left their mark. The most substantial of the deposits formed during these marine transgressions is 250 ft. thick. The material ranges from shell-limestone to beach-pebbles. The shells have been examined by Col. A. J. Peile, who pronounces them (probably all) to be living species. On the land extensive breccia-fans and valley-terraces were produced under desert conditions during these oscillations. It is considered that not one ten-thousandth part of the Quaternary history outlined can have taken place within the last five hundred years.

PARIS.

Academy of Sciences, December 13.—M. Henri Deslandres in the chair.—C. **Guichard**: Networks which comprise a family of geodesics, and such that their reciprocal polar with respect to a linear complex is a network O.—H. **Parenty**: The waves of shock of A. Dévé.—P. **Vuillemin**: The inflorescence of *Fuchsia coccinea*.—A. **Buhl**: Double integrals in which the pseudo-lines at infinity are zero lines.—T. **Varopoulos**: A class of functions with an infinite number of branches.—M. **Takagi**: Bodies resolvable algebraically.—M. **La Porte**: The utilisation of tidal currents on the coasts of France. Instead of holding back the water by a dam, involving costly constructive work, it is proposed to make use of the horizontal current to move a wheel or turbine. A list of suitable channels on the French coast is given, with details of the current velocities.—A. **Danjon**: New determination of the solar period based on the law of luminosity of the eclipses of the moon. By this method the solar period is found to be 10·87 years between 1583 and 1912.—Z. **Klemensiewicz**: Contribution to the theory of thermal radiation.—S. **Posternak**: The hexabasic polymolybdates.—L. **Moret**: The lithological constitution of the Nummulitic and the Upper Cretacean of the Arâche plateau (Platé massif, Haute-Savoie).—L. **Cayeux**: The cause of the high phosphorus content of the Lorraine minerals. Reasons are given for supposing that the high phosphorus content of the Lorraine iron-ore is of organic origin; remains of fishes are exceptionally abundant.—C. **Gorceix**: Traces of man in the Voglans lignites (Savoie). The fall of a roof in the lignite mine exposed a layer of wood-charcoal, considered by the author as caused by human agency.—P. **Glangeaud**: The traces left in the central French massif by the glacial invasions of the Pliocene and Quaternary: the extent and multiplicity of these invasions. To the parts of the central massif on which glacial action has been proved must now be added the mountains Margeride (at the head of the valleys of the Allier and the Truyère) and Lozère, a part of the Hautes Cévennes, and the Velay. Altogether, more than an eighth of the central massif must have disappeared under ice, snow, or névé. The factors which have contributed to the attenuation or effacement of traces of glacial action in this region are discussed.—Mlle. Y. Boisse **de Black** and P. **Marty**: The origin of certain *claux* of Cantal.—C. E. **Brazier**: The measurement of the vertical component of the velocity of the wind with the aid of anemometric vanes. The instrument known as the clino-anemometer has led to the paradoxical conclusion that the air, instead of flowing horizontally, has an average movement at all seasons of the year of a vertical velocity of about 0·5 metre per second. An experimental study of this instrument in the laboratory has shown that the velocity of rotation, instead of being, as previously assumed, proportional to the vertical component of the wind velocity, is proportional to a fraction of this component, which is smaller as the inclination of the wind to the horizon is reduced. The meaning of the older observations is discussed in the light of these new facts.—A. **Piédallu**, P. **Malvezin**, and L. **Grandchamp**: The action of oxygen on the musts of red grapes. The oxygen in these experiments was passed into the liquid in very minute bubbles through the walls of a porous cell. Practically the whole of the red colouring matter was removed by this treatment.—R. **Wurmser** and Mme. J. **Duclaux**: Photosynthesis in the algæ *Chondrus crispus* and *Rhodymenia palmata*.—P. **de Beauchamp**: Biogeographical researches on the zone of tides at the Island of Ré.—M. **Doyon**: The mechanism of the action of morphine on the coagulability of the blood. The effect is not produced *in vitro*. The property of incoagulability is due to the presence of a nucleoprotein secreted by the organism under the action of morphine, and the circulating blood is capable of preventing, *in vitro*, the coagulation of the blood of a normal subject.—S. **Tchahotine**: The method of microscopic radio-puncture: a means of analysis in experimental cytology. The production of a mechanical lesion of a single cell offers great experimental difficulties. In place of this the author acts on the cell with an extremely thin bundle of ultra-violet rays of a diameter not greater than 5μ. Details of the technique are given.—A. **Salimbeni**: The nature of the bacteriophage of d'Herelle.—P. **Séguin**: Culture of the buccal spirochæta favoured by some bacteria.

ROME.

Reale Accademia dei Lincei.—(Communications received during the vacation.)—F. **Bottazzi**: Striated muscles and ligaments of homœothermic animals, xiii. Contraction of striated muscle by cold.—G. **Fano**: Surfaces of the 4th order with infinite discontinuous birational transformation groups, iii.—G. **Fubini**: Contravariant differentials.—M. T. **Ambrosetti**: Projective determination of a congruence W.—U. **Bordoni**: Isentropic transformations of univariant systems.—L. **Stipa**: Projectively applicable surfaces.—A. **Terracini**: Spaces tangential to a given variety, i.—F. **Tricomi**: Expansion of integrals of a differential equation in a series of definite integrals.—W. **Del Regno**: Variations of electric resistance in nickel-steel due to heat, i.—G. **Canneri**: Nitrite of thallium.—R. **Ciusa**: Salts with *o*-, *m*-, and *p*-quinoid structures, ii.—C. **Mazzetti**: Double ternary systems with lacuna of miscibility in liquid and solid states, i.—G. **Rovereto**: Erosive action in continuous, as opposed to cyclic, development.—E. **Carano**: Cyto-embryonic studies in Erigeron.—L. **Beccari**: Action of adrenalin on the heart.—D. **Maestrini**: Studies of enzymes, iv. Emulsin, cytasis, ereptasis, and ureasis of germinating barley.—M. **Boldrini**: Sexual differences in weight of human body and organs, iii.—E. **Federici**: Campaign against Anopheles larvæ by means of aquatic insects, i.—G. **Fano**: Surfaces of the 4th order with birational transformation groups, iv.—G. **Armellini**: Observations on secular comets. The author disagrees with the prevailing opinion that parabolic orbits are necessarily of stellar origin.—A. **Terracini**: Spaces tangential to a given variety, ii.—W. **Del Regno**: Variations of electric resistance in nickel-steel, ii.—C. **Mazzetti**: Double ternary systems, ii.—M. **Padoa**: Specific heats.—P. **Comucci**: Metamorphoses of contact between limestone and granitic porphide in metalliferous deposits of Oroli, in Sardinia.—S. **Sergi**: Intercostal muscles and sexual differences in respiration of the chimpanzee.—G. **Quagliariello**: Proteid and residual nitrogen in serum of blood of vertebrates and invertebrates.—E. **Federici**: Campaign against Anopheles larvæ by aquatic insects, ii. This part deals with the predaceous Coleoptera and Rhynchota. Of these the beetles and water-scorpions appear rarely to select Anopheles larvæ as their prey; on the other hand, water-boatmen are the most voracious destroyers of the mosquito larvæ, and water-measurers also frequently attack them.—L. **Bianchi**: Quadratic character of numbers in a quadratic body.—G. **Fano**: Surfaces of the 4th order with infinite groups, v.—C. **de Stefani**: Siliceous fossil sponges of western Liguria, ii. These sponge remains occur in the Lower Trias at Arenzano in quartzite, in the Middle Trias of Voltaggio, in the Triassic limestone of Spotorno, and in a peculiar Triassic formation at Isoverde.—G. **Armellini**: Determination of latitude of the Capitoline Observatory, i.—E. **Federici**: Campaign against Anopheles larvæ by aquatic insects, iii. After considering the orders Neuroptera and Pseudoneuroptera the author, in summarising, concludes that the method is of very limited efficacy.—M. **Cantone**: Elastic molecular forces and resulting vibrations.—R. **Serini**: Theory of the circular-plate electric condenser, ii.—G. **Armellini**: Latitude of the Capitoline Observatory, ii. The mean values of three series of observations in 1920, viz. 41° 53′ 33·05″, 33·17″, and 33·28″, show the variation of latitude due to shifting of the earth's axis.—U. **Crudeli**: Oscillatory progressive waves of permanent type, second approximation.—I. **Galotti**: "Glandular coupling" in larval stomach of *Rana esculenta*. The organ described under this name by Ruffini in 1899 occurs in the larva of the frog, and was regarded as going to form part of the glandular system of the stomach of the definitive form.—S. **Pastore**: Action of saliva on starch in presence of gastric and pancreatic juices.—O. **Munerati**: Influence of low temperature on germination of freshly gathered corn and other seeds. In confirmation of a result previously found by G. T. Harrington, these experiments showed that at temperatures of about 12° C. more than 90 per cent. of the fresh corn and seeds germinated in a few days, whereas at higher temperatures very few began to grow.—M. **Ascoli** and G. **Izar**: Action of serum of pregnancy on placenta extracts.

Diary of Societies.

THURSDAY, JANUARY 6.

ROYAL SOCIETY OF ARTS, at 3.—Sir Frederick Bridge: The Cries of London which Children heard in Shakespeare's Time (Juvenile Lecture).

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. J. Arthur Thomson: The Haunts of Life: The Freshwaters (Juvenile Lectures).

PHYSICAL SOCIETY AND OPTICAL SOCIETY'S EXHIBITION (at Imperial College of Science), from 3 to 10.—At 4.—Prof. A. Barr: The Optophone.—At 8.—C. R. Darling: Some Unusual Surface Tension Phenomena.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—Dr. Louise McIlroy: The Use of Morphia in Labour.—P. Cole: A Series of 43 Cases of Inoperable Uterine Carcinoma treated by the Cold Cautery Method of Percy.

FRIDAY, JANUARY 7.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 3.30.—Lt.-Col. C. Smith: Life on the Gilgit Frontier (Christmas Lecture).

JUNIOR INSTITUTION OF ENGINEERS (at Caxton Hall), at 8.—H. G. Pusey: The Indicator: Its Use and Application.

SATURDAY, JANUARY 8.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. J. Arthur Thomson: The Haunts of Life: The Conquest of the Land (Juvenile Lectures).

MONDAY, JANUARY 10.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Meeting), at 7.—A. H. Fuller: The Artificial Production of Ice.

SURVEYORS' INSTITUTION, at 8.—W. W. Jenkinson: The Streets of London before the Great Fire.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Capt. J. B. L. Noel: A Reconnaissance in Persia North of the Elburz.

TUESDAY, JANUARY 11.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. J. Arthur Thomson: The Haunts of Life: The Mastery of the Air (Juvenile Lectures).

ROYAL HORTICULTURAL SOCIETY, at 3.

INSTITUTION OF CIVIL ENGINEERS, at 5.30.

INSTITUTE OF INDUSTRIAL ADMINISTRATION (in Central Hall, Westminster), at 7.—W. J. Malden: The Measure of Output in Agriculture.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—J. Rheinberg: Some New Directions for Photographic Research.—F. C. Toy: A Monochromatic Illuminator of Special Design.

QUEKETT MICROSCOPICAL CLUB (at 11 Chandos Street, W.1), at 7.30.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Prof. C. G. Seligman: The Older Palæolithic Age in Egypt.

ROYAL SOCIETY OF MEDICINE (Psychiatry Section), at 8.30.—Dr. Morowoka: The Morbid Conditions of the Choroid Plexus in Mental Disease (Illustrated by Epidiascope).

WEDNESDAY, JANUARY 12.

ROYAL SOCIETY OF ARTS, at 8.—Dr. C. S. Myers: Industrial Fatigue (Aldred Lecture).

INSTITUTION OF AUTOMOBILE ENGINEERS (at Institution of Mechanical Engineers), at 8.—Capt. S. Bramley-Moore: Recent Developments in Transmission.

THURSDAY, JANUARY 13

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—A. C. Dixon: The Theory of a Thin Elastic Plate, Bounded by Two Circular Arcs and Clamped.—A. S. Eddington: Dr. Sheppard's Method of Reduction of Error by Linear Compounding.—M. Kössler: The Zeros of Analytic Functions.—G. A. Miller: Determination of all the Characteristic Sub-groups of an Abelian Group.—E. A. Milne: A Problem concerning the Maxima of Certain Types of Sums and Integrals.—H. J. Priestley: The Linear Differential Equation of the Second Order.—W. F. Sheppard: Conjugate Sets of Quantities.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Sir William Bragg: Electrons (Kelvin Lecture).

OPTICAL SOCIETY (at Imperial College of Science), at 7.45.—Prof. W. Salomonson: A New Ophthalmoscope.—H. Dennis Taylor: An Anastigmatic Flat Field Telescope and its Application to Prismatic Binoculars.—Inst.-Comdr. T. Y. Baker: A Note on Multiple Reflection.

ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Informal Meeting for Free Discussion.

FRIDAY, JANUARY 14.

ROYAL ASTRONOMICAL SOCIETY, at 5.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.

ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30.—Dr. R. Pickard: Variations in the Size of the Physiological Cup, and their Relation to Glaucoma.—B. T. Lang: Scotometry.

The Development of Agriculture.

THE latest annual report of the Development Commissioners[1] takes the form of a review of the work of the Commission since its establishment in 1909. It includes another novel feature in a series of reports on the past work and future outlook of the research institutes supported by the Commission. These reports have been prepared by the directors of the laboratories, and, covering, as they do, a large part of the field of biology, would, if space permitted, repay detailed consideration. They bear witness to a considerable output of original work, not only in applied science, but also in fundamental research. Of the progress made in the latter, the report on the Rothamsted Experimental Station contains the most noteworthy examples. In 1909 the scientific staff there numbered five only; the technical staff now numbers nearly seventy, of whom twenty-five are university graduates, and the annual grant made by the Commission (through the Ministry of Agriculture) has nearly quintupled the original income of the station. The output and quality of original work at this station in the last decade are well known to our readers. As an example of successful technological investigations, the Fruit Experiment Station established at East Malling, in Kent, may be instanced. The success achieved by this station in improving the value of orchard trees is an example of the rapidity with which the application of science to industrial problems can achieve results of economic importance. As the Commissioners point out, owing largely to the lack of trained workers, the advance of knowledge in relation to the problems of agriculture after the great achievements of Lawes and Gilbert *circa* 1860 was inconsiderable. In a large degree this sterility was caused by the need of money—a need which the Development Fund has supplied. In these circumstances it was not surprising that agricultural education, too, was in danger of becoming outworn. Research and education are closely correlated; each is dependent on the stimulation provided by the other.

The scheme of the Development Act was novel in so far as it provided a fund for the economic development of agriculture to be expended under the direction of a quasi-judicial body without executive powers, "not responsible to any Minister and to that extent insusceptible to political pressure." The Commissioners apparently wish to contrast the limitation of their powers with the freedom of other bodies concerned with the State support of research recently established. They also refer to the statutory restriction of their advances to non-profit-making concerns, and seem to suggest that this limitation in some degree diminishes their usefulness; it certainly appears to be a restriction which is not congruent with the subsequent policy of the State in relation to scientific research.

Measures have also been taken to promote research in the economic problems of our fisheries. A scheme has been developed which provides, *inter alia*, for a large measure of control by a committee of men of science and for the separate orientation of free (or fundamental) from "directed" (or technological) research. Free research will, very properly, be regarded as the function of universities and other independent bodies, while "directed" research—that directly concerned with economic developments—will be entrusted to the various State departments connected with fisheries. We commend the dichotomy to the consideration of the Commissioners in the other aspects of their activities.

The report is noticeably silent on one administrative aspect of all research schemes which is the subject of active controversy at the present time. In a recent issue we commented on the admirable scheme fostered by the Commission under which research workers in agriculture have

[1] Tenth Report of the Development Commissioners for the Year ended March 31, 1920. (H.M. Stationery Office.) Price 2s.

been guaranteed a quasi-permanent tenure and adequate salaries. A letter from Prof. Stanley Gardiner, which we publish elsewhere, shows that the Commissioners' attitude to this question in relation to fishery research has not been productive of satisfaction. Our correspondent's letter raises an issue of great importance. No State-aided scheme of research will be productive unless it attracts as well as retains men of the highest academic attainments.

In one chapter of the report the general economic position of agriculture at the present day is contrasted with that which followed the Napoleonic wars. The conclusion is drawn that agriculturists must be up and doing if disaster is to be averted. We hope that if the adequacy of future efforts as tillers of the soil is dependent on our reaching the standard of hard work attained by our ancestors in the period 1816 onwards, we shall be encouraged by what their successors achieved in other fields in the period 1914–18.

In conclusion, we may pay a tribute of respect to those who have formed the varying and co-operative *personnel* of the Commission and of the Ministry of Agriculture during the last ten years. There can be no doubt that as pioneers in the field of the deliberate encouragement of scientific research by the State they have fully justified the prescience of the founders of the Development Fund.

The Critic in Physiology.

Warfare in the Human Body: Essays on Method, Malignity, Repair, and Allied Subjects. By Morley Roberts. With an introduction by Prof. Arthur Keith. Pp. xiii+286. (London: Eveleigh Nash Co., Ltd., 1920.) Price 18*s*. net.

THE author of this book, although well known in the fields of literature and art, astonishes us by the amount and depth of his knowledge of the biological sciences. A great service is done by the subjection to criticism of current views, especially when the critic is one not actually engaged in the investigations on which they are based. Owing to the wide extent of his outlook, he is often able to throw light on questions which those who, by the exigencies of research, are compelled to an intensive study of a narrow field are apt to miss. We may not entirely agree with his criticisms, but they always make us consider what we really mean by the statements we make. It is not to be understood, however, that the book before us consists merely of criticism. There is much in it of constructive and helpful suggestion.

Although in form consisting of apparently separate essays on such problems as cancer, repair, inhibition, immunity, heredity, cannibalism, bathing, consciousness, and so on, there may be said to be a common thread running through them, and this thread is the belief that much assistance may be given in the comprehension of biological problems by bringing them into relation with analogous cases in the sociological sciences. In the first essay, "On Method in Science," a powerful defence is given of the use of analogy. The author is well aware of the caution necessary to avoid pitfalls. Thus a similar result is not always due to a similar cause, while the metaphorical use of words is no real advance. As an illustration the author refers to Adami's "habit of growth" acquired by cancer cells. Moreover, an analogy suggests different things to different people. As to the way in which it may be used with profit, the original must be read.

Owing to the variety of topics discussed, this review is almost of necessity somewhat disconnected. Furthermore, when the reviewer brings forward objections to certain statements, the impression is apt to be given that he is less in sympathy with the work as a whole than is actually the case. The proportion of statements not agreed with to the rest of the book, with which the reviewer is almost entirely in agreement, must be kept in mind.

A consideration suggested by the title needs a few words at this point, and illustrates a remark made above. Owing to the limitations of language, it is probable that the author's meaning has not been quite correctly grasped, and if this be so we may hope for more essays from his pen in order to make things clear. The word "warfare" will almost certainly not be understood by every reader in the same way. If offensive warfare is implied, it is doubtful whether a true impression is given of physiological processes. Indeed, even the conception of defensive warfare is liable to misinterpretation. If we may regard the components of a reversible chemical reaction as being at war with one another, we may let the name pass, and the remarks of the author on p. 30 seem to imply that this is the way in which he looks at the matter. But is it correct to speak of immunisation as "active warfare"? (p. 138). It cannot be denied that the acts of war "tend to develop all the logical and mental faculties of man" (p. 169), but it does not follow that this is the only way to do this, or the most effective way. It might, not unreasonably, be held that certain valuable qualities are not so developed.

When it is stated that the "unfit" are eliminated, we may ask, Unfit for what? Is not the statement on p. 161 that "union is never voluntary" rather too sweeping? Warfare in most minds is associated with the idea of destruction—that is, of waste. This is perhaps not an essential part of its meaning, and the reviewer is aware that his point of view may not be that of other readers of the book.

Turning to the second essay—that on "Malignancy"—we note that the author, after a profound discussion of various views, comes to the conclusion that it is due to the failure of the mutual action of connective-tissue and epithelium on one another, perhaps under the influence of some internal secretion. We may compare the view put forward by Dr. A. Paine in the *Lancet* of October 2, in which the noxious influence of certain irritants, especially of bacterial toxins, is held to be responsible for the degeneration of the specialised functions of the epithelial cell, so that it returns to its embryonic state. If Mr. Morley Roberts's conclusion is correct, we are led to regard much of the cancer research of the present day as beginning at the wrong end, so to speak. We must learn more about the normal dependence of one tissue on the activities of another before we proceed to examine what happens when this dependence is disordered. Too much direct attack is made on disease before an accurate knowledge of what health really is has been obtained. In this connection we may refer to the apt illustration by the author on p. 4, where it is pointed out that it would be absurd to think of learning how to build a ship by examination of wrecks on the shore.

These considerations may be commended to the attention of the Ministry of "Health." In fact, in the investigation of cancer, as in that of immunity, too narrow a point of view is often taken. The author rightly insists (p. 64) on the vital importance of taking account of work in branches of science other than that actually in view. It must often strike even the moderately cultured investigator how sadly lacking in knowledge of general principles so many of the workers in specialised subjects are apt to be. Many industrial "inventors" would save themselves much trouble, as well as loss of money, by learning more about the fundamental principles of science. This lack is perhaps particularly noticeable in those devoted to the subject of immunity, although there are, of course, notable exceptions, and much excuse must be made owing to the unfortunate domination of the Ehrlich phraseology, against which our author justly protests (pp. 127, etc.). As he points out, we cannot explain a bacteriologist by saying that he is bacteriological. One is sometimes inclined to wish that some gifted investigator who knows nothing of previous work on immunity would attack the problem at its foundations.

The third essay is of much interest. Dealing with the problem of repair, it propounds the thesis that the evolution of an organ is frequently a case of the mending of a breakdown. This opinion, although supported with much evidence, will probably evoke some dissent. But all readers will agree that there are gaps in our knowledge of the processes of repair and of hypertrophy resulting from functional activity. The author's views on direct adaptation are also difficult to accept in their entirety. Although the accessibility of the germ plasm to chemical agents, as in Stockard's experiments with the action of alcohol on guinea-pigs, cannot be denied, there is no reason to suppose that a modification would be of such a kind as to be appropriate in combating the change in the environment. One is somewhat surprised to find that the author accepts the statements of Abderhalden with respect to the production of "protective enzymes."

Turning to another interesting question—that of inhibition—it is curious that the author, although making use of the conception in the case of the nervous system, finds difficulties in the action of the vagus nerve on the heart. This may be due to the interpretation he puts on the word "depressant." Inhibition, whatever explanation we may try to give of the way in which it is brought about, means no more than stopping a process or reducing its intensity, no harm being done to the active cells. Neither is it a question of diverting "energy" in another direction. The author has overlooked Sherrington's experiments which show that a reflex can be inhibited without evoking any other reflex. The reviewer must confess, however, that he is at a loss to understand what the difficulty with the cardiac vagus really is. We find also some unnecessary trouble made about "trigger action." The physiologist understands by this expression merely that the work required to set a process in action has no relation to that set free as a result. It may be that a measurable amount of work is needed to move a trigger, but the energy set free in the cartridge is just the same whether the trigger moves stiffly or easily. One would also like to have a little more explanation of what the author means by "shock" as applied to cells.

This list of criticisms may be ended with one of a different kind. On p. 169 it is suggested that there is an advantage in cannibalism owing to the fact that the food has a similar nature to the body of the eater. But we know that all food is completely broken up in digestion into constituents which are the same for all kinds of flesh, unless there be something present in minute quantity not yet discovered. But this is a very unlikely possibility, and has no evidence in its favour. There seems, then, to be no justification for the statement.

The book abounds in illuminating similes. As an example, one might take the comparison of enzymes or catalysts to the tools with which the cell works, and the nucleus to the tool-room; but the latter is more hypothetical.

What has been said will serve to show how great is the variety of subjects discussed; but a meagre impression has been given of the interesting way in which they are treated. Everyone who cares to put his ideas in order is strongly advised to read the book.

The author deserves our gratitude for providing an index. This is not always to be found even in works of a more special nature.

W. M. BAYLISS.

Life in the Misty Islands.

The Land of the Hills and the Glens: Wild Life in Iona and the Inner Hebrides. By Seton Gordon. Pp. xii+223. (London: Cassell and Co., Ltd., 1920.) Price 15s. net.

THIS beautiful book, fine in temper, style, and illustrations, discloses something of the charm of the Inner Hebrides, "the Land of the Hills and the Glens and the Heroes." Mr. Seton Gordon is a keen ornithologist and a master-photographer, but he is much more—a genuine lover of wild Nature. His pictures are at once realistic and sympathetic. In the early morning, on the top of Ben Nevis, he notices the meadow pipit picking little insects off the frozen surface of the snow, but he leaves the main impression salient—a vast sea of mist, changing from cold grey to rose, from amid which the tops of the highest hills stand out clear and sharp, all the rest of the land deeply submerged.

In a small glen "in the keeping of the great hills" a pair of golden eagles make their nest on one of the veteran birch trees. Mr. Seton Gordon had the good fortune to witness the first flight of the two eaglets, and gives us a fine description. He notices that when two are reared, one is always a cock and the other a hen. As the two eggs we have seen have usually been slightly different in colour, we wonder if this is an index of the future sex. Perhaps this is an old speculation. The scene changes to one of the misty islands when there is a first hint (in February) of the approach of spring—ravens somersault, oyster-catchers stand in the sun, companies of turnstones flit restlessly about, and many barnacle-geese rise up from their feeding. It is suggested in passing that the quaint story of the origin of these barnacle-geese from barnacles may have had something to do with the fact that the nesting site—in inaccessible districts of the High North—was until recently quite unknown. About the time the barnacle-geese return to the lone island after summering in the North, the baby grey seals are in possession, and a visit to the wild nursery in the first week in November enabled the author to make some interesting observations and to take some first-class photographs.

Many of us have had experience of the sea that surges round Ardnamurchan—"The Point of the Ocean"—but few have set foot on its weather-beaten surface. Though on the mainland of Scotland, it is scarcely accessible except from the Island of Mull. "On its cliffs the golden eagle has its home, and in former times the erne or sea eagle was wont to nest on its inaccessible ledges. On quiet days of early spring ravens sail and tumble above its rocks, and one may hear the shrill, mournful cry of the buzzard as she leaves her eyrie. Near by is the haunt of the wild cat, now a fast vanishing species in the Highlands, and as early as February she has been known to produce her young in the rocky cairns above the reach of the waves." On one of the low islands far to the west of this the Arctic skuas arrive from the south about the end of May. They are almost unique in their habit of feigning injury in order to deceive the intruder while the eggs are freshly laid. Many birds do this later on. From observations at his "hide" Mr. Seton Gordon satisfied himself that the skua, at any rate, does not count more than one. One of the Gaelic names for the skua means "squeezer" in allusion to the habit of extorting fish from other birds, and it is noted that "even a bird of such command of flight as the tern very rarely indeed succeeds in getting away from a skua—that is to say, with its fish still in its possession."

We are tempted to linger over the fascinating pictures—the "big glen" in Mull, with one stream flowing east and another west, with its ravens and buzzards and deer; the Hill of the Two Winds rising steeply from the Sound, where the sparse ptarmigan have such a keen struggle for existence (because of the hungry eggs of many gulls and crows) that the cock birds are silent during the nesting season, and the hens are very easily frightened from their nests; the snapshots of the densely peopled sea-pool through every month of the year; the deep lochan in a crater-shaped corrie with eagles sailing above its dark water; the glen of the herons, where one can see eight nests on one small tree (it is noted, by the way, that the heron sometimes feasts on frog spawn); the little islet of Erniesgeir, where the puffins have destroyed all the grass; a seal at Skerryvore playing with a large cod in the water as a cat with a mouse; a great company of Bewick's swans swimming restlessly backwards and forwards along a narrow lane on the freezing loch, trying to keep an open waterway; a flock of dozing whooper swans with their snowy plumage lit up by the moon; but we must stop, for the book is full of these delightful things, to read of which is like taking a holiday. We wish to express our admiration of the succession of seasonal word-pictures of the Western Highlands which form the closing chapters of the book. They form a text worthy of the extraordinarily fine photographs.

Many will enjoy the studies of particular birds, such as the fighting blackcock. "Their curious bubbling note never for one moment ceased, and every now and again, as two individuals struck at each other with their feet, they uttered a sharp hissing sound, reminding one somewhat of the crow of a cock partridge. I think that the more one watches blackcock at their fighting the more one must come to the conclusion that much of this is somewhat half-hearted, and appears to be indulged in mainly with the idea of putting in the time and relieving the birds of their high spirits of an early morning. Of course, combats in earnest do take place, and continue until one of the combatants is either killed or else put to flight." We suppose these tournaments vary in temper, for in the case of the only good show we have seen, the jousting was far from half-hearted, and there were numerous grey hens close by. Mr. Seton Gordon, whose experience is great, says: "It is rarely that the grey hens in any numbers frequent the battlefield. One often sees an odd bird there, or even two or three, but personally I do not think I have ever seen so many as even half a dozen watching the fighting of perhaps twenty cocks." Polygamy notwithstanding, he thinks that there are considerably more blackcocks than grey hens. We should like to hear more of this.

The ringed plover, called in Gaelic "the ptarmigan of the waves," arrive in the Western Isles with the first coming of spring. A glimpse of their courtship is given. "The lady on these occasions stands demurely by while the cock bird rises excitedly from the sun-warmed shingle, and, with curious, erratic flight—a flight that is almost bat-like—twists and tumbles, calling the while with soft and plaintive note. All the time his wings move with scarce half their usual speed, and this characteristic of the love-song of the waders—though I have not seen it set down in any book—is well marked also in the oyster-catcher and the golden plover, to mention only two at random." The newly hatched chicks, like the eggs before them, are very difficult to find in their natural surroundings. "When they crouch at the alarm call of their parents they are almost impossible to locate. It is then that the old birds show signs of very great alarm, and often make believe that they are injured, trailing along just ahead of the disturber of their peace, and perhaps waving a wing helplessly in the air, or lying motionless as though dead, in their efforts to decoy him from the vicinity of their young." Who can help envying Mr. Seton Gordon his close acquaintance with the very interesting red-necked phalaropes which nest by the lochans of one of the far western islands? In their solitude they seem to know no fear, for they allowed the naturalist to come within a few yards of them. "When on the water the red-necked phalarope rides with extreme buoyancy, and progresses rapidly. Its neck is long, and is held erect, and when it approaches the observer the russet-red markings on the cheeks and neck are strikingly handsome. Its call, too, is quite distinctive, a high chirruping cry, resembling no other call that I know of." Here, as elsewhere, the author refrains from comment on the biological peculiarities of the bird; we suppose he prefers simply to tell his own story in his own way, and we think his restraint is wise. The record has a sincere naturalness about it, and a very pleasing style. We wish that we had left space to say a little in regard to the author's references to the people of the islands. Here, as in his natural history, he has the insight that is bred of sympathy and scientific patience.

Modern Oil-finding.

Prospecting for Oil and Gas. By L. S. Panyity. Pp. xvii+249. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) Price 18*s*. net.

It is to be hoped that by now, when so much publicity is given in the Press to commercial oil undertakings (and, unfortunately, to many which are the reverse of commercial in the true sense of the word), the more intelligent public will have learned that "chance" is a relatively unimportant factor in modern oil-finding. Much of the present-day success of existing fields, and undoubtedly the prospects of ultimately locating new productive areas, lie in the application to oil prospecting of the more precise methods of geological survey. Such work can be carried out only by competent persons qualified to undertake a survey for oil, and this implies training of a highly specialised character. Those who have had any experience, therefore, in this branch of teaching will readily appreciate the value of a book such as Mr. L. S. Panyity has written, a book which must also make a wide appeal to the student and to the oil geologist of the older school.

Considered purely from the academic point of view, the volume can unhesitatingly be put into a student's hands at the outset of his course without any apprehension as to its suitability as preface to both lecture and practical work. From the composition and origin of oil and gas, their migration and accumulation, through all the intricacies of modern methods of surveying and prospecting, to the sinking of wells and the production of crude oil, the author takes his reader through a thorough course of elementary instruction without burdening him with unnecessary technical detail. The early chapters deal with general geological definitions, conventions, and successions, considered from the point of view of oil technology. From these we pass directly to actual field-work, initiated by a lucid exposition of plane-table survey, including the more exact processes in triangulation. In the succeeding chapters, dealing with actual maps, it is pleasing to note that the construction and reading of isobath and isochore maps receive adequate attention, as both these phases of the subject present difficulties to the novice at first, though we should have preferred that the question of the interpretation of geologic structures had received fuller discussion, even to the exclusion (if necessary) of the long chapter on fossil flora and fauna. Condensed palæontology or palæobotany is seldom a success, and with the great number of useful text-books available for studying these subjects such an omission would need no apology.

The remaining pages of the volume are devoted more to the engineering aspects of oil prospecting, and include chapters on the location, sinking, spacing, and completion of wells, together with some notes on regulating the course of production of the crude oil derived. A somewhat lengthy appendix contains some useful tables of constants for triangulation work, and also for calculating the capacities of gas wells, etc.

As is usual with American publications of this nature, the book is profusely illustrated with maps and diagrams, and the inevitable "Landscape and Topographic Contour Map" (depicted on the inside cover of all the folios of the United States Geological Survey) finds a place here on p. 70. It is undoubtedly an attractive and useful publication, which, by virtue of its clearness of diction, careful arrangement of subject-matter, and freedom from "padding," should make an appeal to a very wide public.

H. B. MILNER.

The Induction Coil of To-day.

Induction Coil Design. By M. A. Codd. Pp. vi+239+14 plates. (London: E. and F. N. Spon, Ltd., 1920.) Price 21*s*. net.

IT is only within the last few years that the induction coil has emerged from the sanctum of the philosophical instrument maker and even approximated to an electrical engineering "job." It cannot yet be said to have shaken itself free of the trammels of empiricism, and it too often serves largely as a medium for the skill of the cabinet-maker and french polisher to impress a susceptible *clientèle*. Moreover, for X-ray work at any rate (and in particular for work with the Coolidge tube), the interrupterless transformer is finding fresh adherents each day, and it was high time that the case for the induction coil should be put by one who is conversant with coil construction and design.

Mr. Codd candidly concedes at the outset that precision measurements of coil phenomena are difficult, if not impossible, and as a consequence present-day design rests mainly on arbitrary standards which have been evolved empirically from practical experience. Holding the view that a knowledge of these standards should not be confined to the coil-maker, Mr. Codd has accordingly collected data from his experience of a number of typical and accepted designs, and set them out comparatively in the present book. To the coil-maker the wealth of practical and diagrammatic detail should be of value; and even the user, primarily concerned with performance, will be interested to learn of the constructional precautions and skill which have to be exercised, and of the relative common-sense values of the several designs on the market, for each of which extravagant claims of super-efficiency have usually been advanced by its author.

Here it may be remarked that the efficiency of even a large coil rarely reaches 50 per cent., and is usually nearer 30 per cent. Nor can the same coil be equally efficient for all purposes. It is in the success with which he reconciles antagonistic factors that the coil-maker's art finds its greatest expression. He knows, as a practical fact, that for a given transformation ratio the secondary winding should be such as to keep the self-induction as low as possible; he has found that for X-ray work the condenser capacity should be as small as is consistent with preventing undue sparking at the interrupter; and he has grown to realise that the design and performance of the interrupter are all-important and may enhance or undo his work on the coil.

There are certain other features which the coil-maker has learnt to incorporate in his design. He allows for each kilo-volt-ampere input about 15 lb. of iron core, of which he makes the length from six to ten times the diameter. He winds the primary so as almost to cover the whole length of the core, but he keeps the length of the secondary down to about three-quarters the length of the core, and finds that the diameter of the secondary should not exceed about 2·5 times its bore. Among many other guiding facts, he estimates to get about 4 kilo-volts from every 1000 turns in the secondary, knowing also that a transformation ratio in the region of 100 to 1 is a practicable figure.

All this and much besides is to be found in Mr. Codd's book. He supports many of his contentions with the help of a large number of oscillograph records. We regret to find no mention of Prof. Taylor Jones's work, but we gather that the book is limited to the author's own experience. There is a useful bibliography, but no index.

Our Bookshelf.

The Romance of the Microscope. By C. A. Ealand. Pp. 314. (London: Seeley, Service, and Co., Ltd., 1921.) Price 7*s.* 6*d.* net.

To the well-known "Library of Romance" Mr. C. A. Ealand contributes a volume on the microscope. He gives a glimpse of the early days of invention, of pioneer microscopists such as Leeuwenhoek and Hooke, and of the principles of the instrument. He then illustrates the use of the microscope in studying the life of ponds and streams (but why call the amœba "a free swimming denizen"?), the structure of plants, the structure of animals (in the course of this investigation, "Having taken our fill of the spiders' feet we may well turn our attention to their heads"), sections of rocks, impurities of food, bacteria, blood, rusts on leaves, small insects and parts of insects, and so on. We are sometimes forced to doubt the author's sincerity, as when he says that if we put the liver-fluke under the microscope "we can plainly see all its internal organs." That has not been our experience, nor anyone's. Similarly, we are not pleasantly impressed by being told that *Demodex folliculorum* (or, as the author has his specific names printed throughout, *Demodex Folliculorum*) is to be found in the sweat-glands. The book ends with more practical matters: the micro-telescope and super-microscope, chemistry and the microscope, the use of the microscope in manufacture, the camera and the microscope in alliance, the glass used in making lenses, and the choice and use of apparatus.

We think the book will help to diffuse an interest in microscopy, which, of course, means the discovery of a new world and of a new joy in life; but we wish the author had shown more microscopic precision in his workmanship. He tells us that, having found our sea-slug or sea-cucumber, especially the species called *Synapta Inhaerens*, we find by touch that its leathery skin is studded with some flinty matter, which we go on to verify under a low magnification. And so *passim.*

Organic Chemistry for Advanced Students. By Prof. Julius B. Cohen. Third edition. Part i., *Reactions.* Pp. viii + 366. Part ii., *Structure.* Pp. vii + 435. Part iii., *Synthesis.* Pp. vii + 378. (London: Edward Arnold, 1920.) Price 18*s.* net each volume.

THAT a reprint of the above work should be called for in just over a year after the publication of the last edition is clear evidence, if such were needed, of the value of the book; it may further be taken as welcome proof that there exists a large circle of serious students who are not content to acquire their knowledge in "tabloid form," but are prepared to work through a three-volume treatise on advanced organic chemistry. The book has an important mission to fulfil in imparting a sound knowledge of the principles underlying the modern developments of organic chemistry to the rising generation of chemists, and, from the rapid exhaustion of the last edition, one may conclude that it is successfully accomplishing this.

The present edition calls for little detailed comment, since no material changes have been made in the text, the author having confined himself to adding a number of references to recent literature, which will enable the student to bring his information up to date.

Leicestershire. By G. N. Pingriff. Pp. xii + 164. (Cambridge: At the University Press, 1920.) Price 4*s.* 6*d.* net.

AN interesting description of the many features of interest in Leicestershire is given in this book by pen and photograph. In the opening chapters the position, general features, rivers, and watersheds of the county are described. Its geology, natural history, and an account of its climatic conditions follow. Four chapters are then devoted to the people of Leicestershire and their industries, stress being laid on the increase of grassland as opposed to arable farming. The remainder of the book deals with the history and antiquities of the county, and the concluding chapter is a useful index to its chief towns and villages. Instructive diagrams, showing graphically the proportions of the acreage of the principal crops, form a brief appendix. The book is throughout well illustrated by interesting photographs and sketch-maps.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Science and Fisheries.

THE two letters from Prof. McIntosh and Mr. H. G. Maurice published in NATURE of December 30 last are of great interest. The second points out that an arrangement is now in operation by which the scientific staffs of the English, Scottish, and Irish Fishery Departments are arranging to meet at regular intervals to frame their scientific programmes; and the first refers to the responsibility of the Departments "in selecting for the task scientific men whose training and ability specially fit them for the complex work."

It may not be generally known that the real controlling authorities so far as fisheries research is concerned are the Development Commission and the Treasury. The Development Commission considers all applications from any of the three Departments for funds to carry out the researches that may be proposed. This consideration is not merely an office matter, for the proposed researches are considered by a special Committee, mainly of scientific men, presided over by Mr. W. B. Hardy. This Committee has already presented several excellent reports, and generally fresh applications for funds are referred to it. While the Development Commission is thus responsible for the work to be undertaken by the different Departments, the Treasury is responsible for the supply of properly trained scientific men to carry out the actual work. The real onus is on the Treasury, for the payment of all men in the service of the State is reviewed by this Department when providing funds for their payment. We have, on one hand, a body expert both as to the nature of the work proposed and as to the supply of men properly trained to carry out this work; and, on the other, a body with no qualifications whatever to review the work and no special knowledge as to the conditions of pay in different branches of science, especially in biological sciences. It appears to me that the present arrangement is not businesslike, and would not be tolerated in any commercial firm.

The Fishery Departments of the three countries certainly have progressed to a very considerable extent, and it is surely a peculiarly favourable time for a further step in progress. It is generally agreed that the research in fisheries of the three kingdoms should be carried out on one scheme; at present the Departments of Scotland and England are without any scientific directors. Surely the time has come when the scientific work of the three countries in respect to fisheries should be placed under one Director of Fishery Investigations and the three separate scientific staffs should be merged into one. The control of this Scientific Fisheries Division could obviously not be placed in any one of the Fishery Departments, and would have to be assumed by the Development Commission. The latter could act through an Advisory Committee on which the three Departments could be represented, if it is deemed advisable to do so. The Committee might also contain representatives of the different branches of the industry. There would be no competition between the three countries for such scientific men as are available or in respect to the mere numbers of their so-called scientific employees. The one body would be responsible for the work and for the human material necessary to carry out that work; the result, I venture to suggest, would be greatly to the interest of the country and would ensure good value for the money spent. The fisheries form an industry and the public are the consumers; the staffs which exist to protect and develop the interests of both should obviously be under one head.

My own experience of the three Fishery Departments of England, Scotland, and Ireland and of the industry has been altogether pleasant and decidedly "happy," and I am under obligations to the Development Commission as well. I resigned from the English Department on November 30 last because the Treasury declined to give us a staff of such a nature as I deemed necessary to carry out the work proposed. The Treasury, in fact, took from me the possibility of recommending to the Fisheries Secretary a staff capable of doing this work; it offered a lower rate of pay than the higher grade of the Civil Service, with a prospect of promotion from the lowest grade to the next at the age of forty-three or thereabouts, whereas the Civil Service has a prospect of similar promotion about ten years younger. The Treasury instituted a scale of pay in all the four grades of the Scientific Division of the Ministry distinctly lower than that of a higher grade of the Civil Service; in fact, it proposed to create a fresh grading of inferior rank, with very indeterminate prospects of promotion. Apparently the Treasury was doing this on general grounds—the inferiority of scientific men to the ordinary Civil Servants employed by the State! It certainly could not have had the advice of any biologist as to the supply of the men available for the work.

What is required in fisheries is the scientific man who is broadly trained in the relationship of fish to the chemical and physical conditions of the water in which they live, to the biological conditions of the organisms with which they are associated, and ultimately to the biological conditions in relation to the floating plant-life upon which all water-living animals to a considerable degree depend. The successful fishery investigator must be, as it were, a "medical man" who has fish as his speciality instead of human beings; he has to consider every factor in respect to the living fish just as the practitioner has to consider every factor in respect to his patients; he must even know something of statistics. The number of such men is small, but they may be "created" if there are openings for them. The training involves many years of hard study, but no amount of training will compensate for an absence of the requisite ability to visualise and correlate all the different factors that are involved in studying the living fish.

The men who give up their time and thought to such a study put themselves outside the branches of science that are recognised in our different universities. By so doing they renounce the beaten tracks of ordinary scientific promotion and their prospects therein. The responsible heads of scientific departments in universities cannot recommend their best men to do this unless they see adequate possibilities for their future. By the creation of a single strong Division for the scientific investigation of British fisheries under the Development Commission, adequately paid and with prospects of promotion at least equal to those in any university of the kingdom, there would be a great inducement to the best men to undertake this work; its very complexity would attract them. As it is, there are three Scientific Divisions of Fisheries under three different Departments the positions and prospects in which are not such that the best men can be recommended to them; these three Divisions at present have, I venture to suggest, sufficient first-class men to fill adequately the higher posts of the proposed single Scientific Fisheries Division, and it can be recruited to full strength as men of the requisite ability become available.

As a professor in a great university I cannot recommend my first-class man—I do not refer merely to a first-class degree—to apply for a post in research in the service of the State which is inferior to that of the higher grade of the Civil Service. The mental qualifications for research posts are far rarer than for the ordinary work of administration. The holders of such posts cannot be transferred from department to department, so that proper recognition must be guaranteed them from the start. All of us must cordially endorse the resolution unanimously passed by the council of the British Association: "That the council considers that no scheme of payment of professional scientific men in the service of the State is satisfactory which places them on a lower level than that of the higher grade of the Civil Service." If science is to work for and with the State the Treasury must cease treating its scientific as inferior to its administrative services. There are difficulties, of course, in blending the two services, for science will be killed if it becomes bureaucratic; at the same time it must not be allowed to become an underling to the present bureaucracy.

In conclusion, it is interesting to note that while the administrative staffs of the fishery departments of most civilised countries are recruited almost solely from men who have been trained in science, that is not so in this country. The tremendous development of Norwegian fisheries is obviously due to one man, who was first and foremost always a scientific man. The great development in Germany before the war was due to scientific men. The employment of fishery officers who have some knowledge of the conditions of life of the living fish is obviously of primary importance. The users of trawlers and the herring drifters are increasingly taking more and more interest in the lives of their prey, and the Fisheries Departments should not merely follow their lead, as they will ultimately have to do, but should also, as in other countries, seek for inspectors who, at any rate, have the fundamental scientific knowledge upon which alone deductions as to the fish with which they have to deal can be made profitably. Every inspector should surely be able to answer from his own knowledge the ordinary points raised in respect to the lives of commercial fish and in respect to the possibilities of deterioration and pollution on their way to market. The training for such is that broad training in science which is provided in all the greater universities of the kingdom, and the Departments need feel no fear as to the lack of competition for their posts if they adopt the right scheme.

January 8.

The Central Meteorological and Geodynamic Institute, Vienna.

THE Central Meteorological and Geodynamic Institute in Vienna is the oldest meteorological institute in the world. It was founded by the Austrian State in 1851, at the request of the Vienna Academy of Science, with the object of developing the study of meteorology and terrestrial magnetism, and for the past seventy years has served both science and practical life.

In consequence of the war and the subsequent peace the future activities of the institute are in jeopardy. The impoverished little Republic of Austria has not the necessary means for carrying on the work of the Central Institute.

The undersigned feel it their duty, as former and present directors of this old institute, to inform the meteorological institutes, societies, and men of science all over the world who have any scientific or practical connection with the Central Institute in Vienna and exchange publications with it, of the pressing need of the Central Institute.

In acting thus they take the point of view that a scientific institute like the Central Institute is, to a certain degree, the public property of all the cultured nations of the earth, and as such these are all interested in its existence. The undersigned therefore plead for financial aid for the Central Institute.

The low value of the Austrian kroner (less than two Swiss centimes) makes it, on the one hand, easy for foreign States to help, but, on the other, the Austrian State endowment, in spite of repeated increases, is ever insufficient.

The Central Institute can now no longer publish its year-books, even for diminished Austria, although the yearly printing expenses would only be 1000 Swiss francs. The year-books, however, as they contain the results of observations—that is, definite facts—represent the basis of the development of our science.

It is, moreover, impossible for the Central Institute to carry on its work. It has become impossible to procure instruments; hydrogen for pilot-balloon ascents is too expensive; and the same applies to rubber balloons for recording ascents. It is impossible to keep the library up to date, as the smallest foreign books or journals cost hundreds of kroner. Consequently, meteorologists cannot follow the trend of work abroad and so keep up with the times.

It will be possible to issue the weather charts for six months more, until the stock of paper is exhausted, then this issue must cease. It will be possible with difficulty to keep up the seismic observatory in Vienna; the stations at Grätz and Innsbruck must, on the other hand, be given up, as the expenses of running them are too heavy. There can be no question of recommencing the registration of terrestrial magnetism which was carried out at the high-altitude station at Obir before the war.

No matter where we turn we find the same cheerless decay.

We refrain from enlarging on the *rôle* which the Austrian school has played in meteorology during the last fifty years. We venture, however, to name a few books which have emanated from the Central Institute of Vienna:—*Meteorologische Zeitschrift* since 1866; J. Hann, "Handbook of Climatology"; J. Hann, "Text-book of Meteorology"; J. M. Pernter, "Meteorological Optics"; W. Trabert, "Text-book of Cosmical Physics"; and F. M. Exner, "Dynamical Meteorology." We beg that foreign States will remember the Central Meteorological Institute in Vienna from the titles of these books, and that help may be forthcoming.

F. M. EXNER,
Present Director.
J. HANN,
Former Director.

Vienna XIX, Hohe Warte 38, December 2.

Tidal Power.

ESTIMATES of the power to be obtained from the rise and fall of the tide are often greatly in excess of practical possibilities. If it is assumed that an estuary or reservoir of area A is enclosed by a dam at the outer face of which the difference of level between high and low water is H, then (w being the weight of the unit cube of water) the work which might conceivably be extracted from tidal action is $w.A\frac{H^2}{2}$. To attain this end the relation between the water levels outside and inside the dam must be that shown in Fig. 1 by the full and dotted lines respectively. The motors or turbines must be designed to work efficiently with any head from 0 to H, and able to do all the work in such a short time that the high and low water levels remain practically constant during that interval, say 20 minutes.

If the interval between high and low water is six hours, the motors must be capable of delivering eighteen times the average power, and of this power 17/18 must be stored. It is, of course, impracticable to fulfil these conditions. The turbines have to work with a nearly constant head, and it would be impossible to arrange for the whole work to be done in the short time available at high and low water.

The most practicable plan is indicated in Fig. 2. The flow through the turbines is adjusted to reduce the rise and fall inside the dam to half that of the

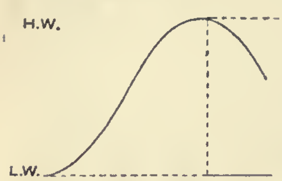

FIG. 1.

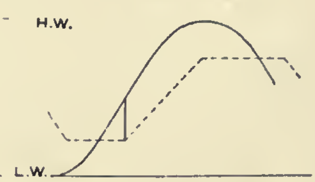

FIG. 2.

tide and the time of working increased to about three hours. The effective head is H/4, and the distance through which it acts (*i.e.* the stroke) is H/2. In this way about one-fourth of the tidal energy $\left(w.A\frac{H^2}{2}\right)$ might be utilised, half of which would have to be stored if the power supply is to be constant. Taking into account the various losses due to turbine, electrical, and storage efficiency, it is improbable that more than one-fifth of the whole tidal power could be delivered as electric current.

If A is 1 square mile and H 30 ft., it will be found that for each square mile of reservoir surface something more than 10,000 h.p. might be expected.

I have no knowledge of the details of the Severn scheme, but if it were possible—which I doubt—to enclose 20 square miles of estuary where the average difference of tidal level was 30 ft., the power available for distribution would be under 250,000 h.p.

It may be remarked that the same power could be obtained from a river having a current of little more than 2 miles per hour and a cross-sectional area of 2000 ft., if in its course there was a fall of 30 ft.

A. MALLOCK.

Heredity and Acquired Characters.

IN NATURE of January 6 there appears a long communication on heredity by Sir Archdall Reid which he conceives to be a reply to criticisms made on a former letter by him on the same subject by Sir Ray Lankester, Prof. Poulton, Dr. Gates, and myself. Leaving these eminent biologists to look after themselves, which they are quite capable of doing, perhaps you will allow me to say a word or two on some points raised in the letter in the current issue.

Sir Archdall Reid accuses me of torturing "a word which has now an established and perfectly clear meaning." The word is "variation." I wished to contribute to clearness by defining it, for, so far from its having a clear meaning, there are at least three senses in which it can be used. Further, let me say that if a five-fingered child were born of a six-fingered parent, I should not describe it as a "variation," but as a "reversion."

Next, Sir Archdall Reid challenges me to define the "quibble" about "acquired character." "Acquired character" is a technical term; by it is meant a quality, *i.e.* the degree of development of an organ, which is produced as a response to function, altered from the normal in response to an alteration of the environment from the normal; but Sir Archdall Reid interprets it as any adult character whatever.

Sir Archdall Reid has, however, understood the point, because he says that "the supposition that 'acquirements' tend to become 'innate' is . . . ridiculous." Such an *ex cathedra* statement contributes nothing useful to the discussion. There are definite experiments on record which, if true, prove this very point, but Sir Archdall Reid apparently knows nothing about them.

Then we are told that "low in the animal scale we find little or no evidence of development in response to functional activity." On reading this the question that instantly occurs to one's mind is: "Where did Sir Archdall Reid learn his zoology?" I have been working with Echinoderm larvæ for many years, and in no animals known to me is structure more sensitive to changes in the environment (Proc. Roy. Soc., B, vol. xc., 1918).

Lastly, Sir Archdall Reid says: "We are now in the morass in which Lamarck and Weismann floundered." I have attended many congresses of biologists, and I have never found evidence of confusion in their minds as to what was meant by an "acquired character." They differed, and continue to differ, as to whether there is evidence that an "acquired character" can be inherited, or, to use Sir Archdall Reid's paraphrase, that "acquirements" can become "innate," and this difference can be settled only by the outcome of experiments which are now in progress, but I have nowhere detected evidence of a condition of thought that could be described as a "morass." I conclude, therefore, that it exists alone in Sir Archdall Reid's mind. E. W. MACBRIDE.

Imperial College of Science and Technology,
South Kensington, S.W.7, January 7.

PROVIDED that biologists understand one another, it is, perhaps, not an insuperable barrier to the progress of biology that Sir Archdall Reid is unable to understand their terminology. I write merely to point out that though he seeks to teach biologists the proper use of terms, Sir Archdall Reid, in his letter in NATURE of January 6, contradicts himself in his own terminology. He states that even in human beings many characters do not develop in the least in response to functional activity, *e.g.* hair and external generative organs. On the other hand, in man most characters develop wholly, or almost wholly, in response to that stimulus. Yet in another paragraph he asserts that all characters are necessarily innate, acquired, germinal, somatic, and inheritable in *exactly the same sense and degree.* If biologists recognise, as Sir Archdall Reid does, a difference between characters that develop in response to functional activity and those which do not, what need is there for him to ask biologists why they describe some characters as "innate," "germinal," and "inheritable," and others as "acquired," "somatic," and "non-inheritable"? J. T. CUNNINGHAM.

University of London Club, 21 Gower
Street, W.C.1, January 7.

Solar Radiation in Relation to the Position of Spots and Faculæ.

ABOUT September 1 last an arrangement was made between the Director of the Argentine Meteorological Service and the Director of the Astronomical Observatory of the University of La Plata for observations of disturbances visible on the surface of the sun, including spots and faculæ to be recorded on a diagram of the sun's surface and transmitted to the Meteorological Office for the purpose of comparing them with the observations of solar radiation received from the Smithsonian Solar Observatory at Calama, Chile.

The observations at first consisted chiefly of a record of sun-spots, and although the time is short the relation seems so apparent as to be worthy of record. The records have been arranged in three series, two of which are practically independent of each other and the third partly so.

The first series was derived from seven groups of sun-spots by taking the day of their first appearance on the east edge of the sun three days before and five days after, and obtaining the average values observed of solar radiation on these days in calories per square centimetre.

The second series was derived from six groups of sun-spots by taking out the mean solar radiation on the last day of visibility and for five days preceding and three days following.

The third series was derived from seven series of spots by taking the mean solar values on the days the spots crossed the solar meridian and for eight days preceding and eight days following.

The results are shown in the following table:

Mean Radiation Values for Different Positions of Sun-spots.

(1)	Days before.		East edge.	First seen.	Days after.				
	2	1	0	1	2	3	4	5	6
Radiation	40	24	45	55	52	48	37	47	39

(2)	Days before.					Last seen.	West edge.	Days after.	
	6	5	4	3	2	1	0	1	2
Radiation	46	45	35	30	48	50	54	40	38

(3) Days before.								Meridian	Days after.							
8	7	6	5	4	3	2	1	0	1	2	3	4	5	6	7	8
42	38	40	49	41	48	33	46	44	45	35	47	40	49	46	40	38

The mean solar radiation value is formed by adding 1·900 to the values given in the table.

As the spots are rarely seen exactly on the edge of the sun, the day on which they are first seen is numbered 1, and the day before is numbered 0; also, when last seen the day is numbered 1, and the day after 0.

The mean solar values during the interval covered by the observations is 1·943, so that on the day when the spots were first seen the radiation averaged 0·012 calorie above normal, and when last seen 0·007 calorie above, or in the mean about ½ per cent. of the solar radiation.

There was one day common to the two series when spots were visible on both edges of the sun at the ends of a diameter passing through the sun's centre, or, in other words, on a great circle about 180° apart. On this day the solar radiation value was 1·969, or more than 1 per cent. above normal.

The grouping around the central passage of the spots does not bring out the relation so distinctly, although higher values are found five days before and five days after the passage across the meridian, the lowest values being found two days before and two days after the central position. If one takes the mean of the five days about the centre, including two days before and two days after the central passage, a value of 1·941 is obtained, which is slightly below the normal value, as if some absorption of heat resulted from the central passage of the spots.

These results have an interest in connection with the fact that Dr. Abbot found a decrease in the contrast of brightness between the edge and centre of the sun coinciding with short-period increase of solar radiation (Smithsonian Miscellaneous Collections, vol. lxvi., No. 5). Both these results can, I think, be explained in the same way. It is well known that solar faculæ and solar eruptions surround regions where spots are numerous.

These eruptions when seen near the edge of the sun tend to decrease solar contrast and to increase the total solar radiation. On the other hand, when they are near the centre of the sun they are seen directly above the hotter gases from which radiation is coming vertically through the sun's atmosphere, and hence is not greatly absorbed.

The cooler gases within the spots may even absorb more of this radiation than is made up for by the increased radiation of the faculæ in the outer atmosphere.

The results, if confirmed by more extended observations, will also have an important meteorological bearing. Numerous investigators like Loomis, Veeder, Arctowski, and Huntington have found evidences of increased solar influences on the earth's atmosphere when the solar spots were near the edge of the sun. E. Huntington especially has made an extensive investigation of the position of the solar spots as related to the storminess in the North Atlantic, and has found that the most marked effects are shown when the spots are near the edge of the sun, and hence when there is probably increased solar radiation (Monthly Weather Review, U.S.A. Weather Bureau, March–June, 1918). H. H. CLAYTON.

Buenos Aires, November 6.

Odours Caused by Attrition.

THE unpleasant odour which attends the attrition of pebbles, etc., appears to have been noticed at a much earlier date than any mentioned by previous correspondents. Robert Boyle ("The Efficacy of Languid Motion," Works, edited by Boulton, 1699, vol. i., p. 234) remarks: "And that it may further appear, that a peculiar Modification of Motion, may contribute to the various Effects produced by it, I shall observe, That those Stones which *Italian* Glassmen make use of [quartz?], afford Sparks of Fire by Collision; but if moderately rubb'd together, they emit *fœtid* Exhalations; from whence probably proceed those offensive Steams, emitted by Glass; and what is more remarkable, and to our purpose is, tho' Glass when Red-hot emits no such *Effluvia*; yet if two pieces be dextrously rubb'd together, they will send forth Steams copious enough and *fœtid*."

It seems to me that there are at least two suggestions not brought forward by previous correspondents in NATURE contained in Boyle's observations, both of which might well be followed up experimentally. The implicit explanation of the cause of smell is also of some interest. J. R. PARTINGTON.

Lostock Gralam, Cheshire.

The Energy of Cyclones.

I SHALL be glad if you will allow me to refer briefly to the objection Mr. W. H. Dines raises to my theory of cyclones (NATURE, December 23, p. 534). Mr. Dines remarks that if "cyclones are caused by an access of warmth in the stratosphere . . . the troposphere ought to bulge upwards over the cyclone, whereas, in fact, it bulges downwards." My view is that where the stratosphere is warmest it must be thickest, and the troposphere must be thin. As the warmest portions of the stratosphere are at cyclonic centres, the lower boundary of the stratosphere must bulge downwards over such areas and the troposphere be correspondingly thin. I assume that the heat of the stratosphere passes downwards so rapidly that the slowly rising air cannot maintain the troposphere at its normal thickness. R. M. DEELEY.

Tintagil, Kew Gardens Road, Kew, Surrey, December 24.

Nature of Vowel Sounds.

By PROF. E. W. SCRIPTURE.

The Analysis of Vowel Curves.

SINCE the time of Wheatstone and Helmholtz the vowels have been almost universally supposed to obtain their tones by acting as resonators to certain overtones of the larynx tone. Helmholtz even constructed an apparatus of a set of harmonic tuning-forks by combinations of which he hoped to produce the vowels. Ever since the invention of the speech-recording machine by Scott and Koenig in Paris the analysis of vowel curves has been expected to solve the problems of the nature of a vowel and of the differences between different vowels.

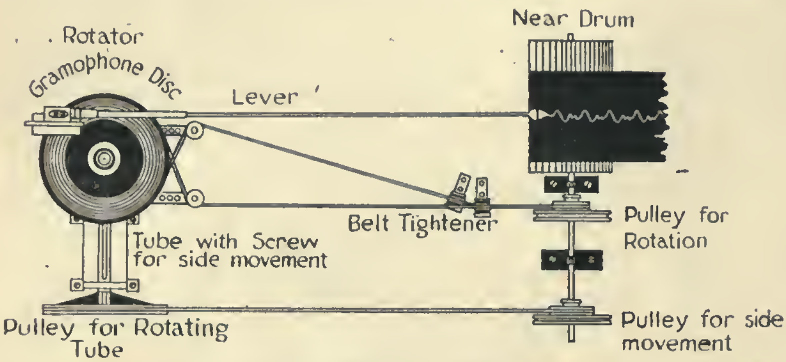

FIG. 1.—Apparatus for tracing gramophone curves. A steel needle near one end of a long lever follows the groove. Its movements are enlarged 500 times and registered on a band of smoked paper.

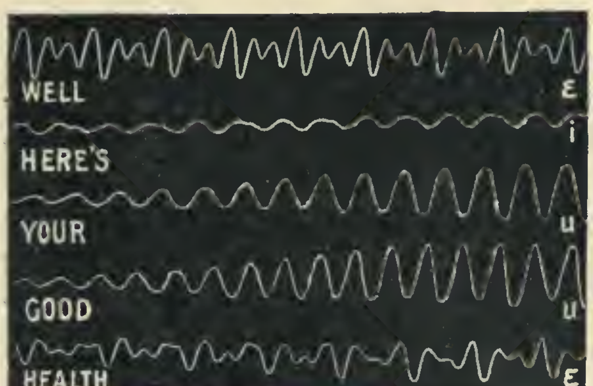

FIG. 2.—Vowel curves. The waves fall into groups; the top line contains eight groups, the next line six, the third seven, the fourth eight, and the last seven. Each group corresponds to one vibration from the larynx. The length of a group gives the pitch of the laryngeal tone; in speech this is always rising or falling. The height of the waves indicates the intensity. This is nearly always small at the beginning of a vowel; there is a steady rise to a maximum and then usually a fall to the end. The small waves within a group give the characteristics of the vowel sound. The top line is a piece out of the middle of the vowel in "well." The second line is from the vowel in "here." The third is near the beginning of "your." The fourth is the first part of the vowel in "good." The last is from the middle of "health." In the second, third, and fourth cases there is evidently present a tone more or less nearly the octave of the laryngeal tone. The other tones and the tones in the other cases can be found only by analysis.

At the present day the vowels can be recorded on talking machines, and their curves can be traced off with an accuracy that leaves nothing to be desired. The work of Hermann on the curves of the vowels and consonants by means of the phonograph is still unsurpassed. For my own investigations the gramophone was chosen as the most available machine.

A disc with the desired record was placed on a very slowly revolving plate (Fig. 1). A long lever of Japanese straw was held in an axle at one end. Near this end a steel point projected downward into the speech groove. At the other end there was a recording point made of a fine glass thread. As the disc revolved, the movements were magnified—up to 500 times—and traced on a moving band of smoked paper.

Pieces of vowel curves cut out of a tracing of a record by Joseph Jefferson are shown in Fig. 2. The curves show that in speech the vowels change constantly in pitch, in intensity, and in character. They also show that the vowels actually used in speaking are often not what the phonetician supposes them to be.

The point of interest on the present occasion, however, is the nature of a single wave of a vowel. At the present day there is only one way of analysing a wave—namely, the harmonic analysis. Any wave can be represented as made up of a series of simple sine waves with the relations of frequency of 1 : 2 : 3 : . . . and with various amplitudes. A harmonic analysis of the wave in the top line of Fig. 3 gives the four curves in the lines below. This means that the four curves, if added together, will give a result like that in the top line.

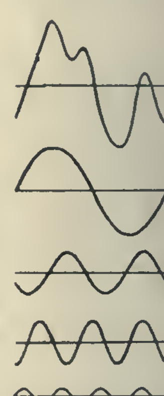

FIG. 3.—A curve composed of four sinusoids.

Suppose, now, that we have a curve that consists of a vibration repeating itself every $3\frac{1}{2}$ times to a wave. The harmonic analysis gives as result a fairly strong fundamental of the frequency 1, a stronger vibration of the frequency 2, a still stronger vibration of the frequency 3, a somewhat less strong vibration of the frequency 4, and ever-lessening vibrations of the frequencies 5, 6, 7, etc. Not one of these vibrations was actually present in the original curve. The strength of the original vibration of $3\frac{1}{2}$ could not be directly given, because there was no place for it in the harmonic series.

The harmonic analysis shows us how a given curve can be represented as made up of a series of harmonic components; it does not say that it was originally so produced. Such a deduction has to be made on other grounds. The familiar experiment with a piano string touched lightly in the middle, then at one-third of its length, etc., shows that it vibrates in harmonic parts; an analysis that gives the harmonic components in various amplitudes can be accepted at once as indicating the strength of the components. An analysis, however, that gives all the harmonics as being present to some degree with a bunch of strong ones at one or more points would indicate at once that one or more inharmonics were present.

A harmonic analysis of the wave in Fig. 4 from the first vowel in "Marshall" gives the harmonic plot shown in Fig. 5. This merely states that the original wave can be reproduced by using harmonics in the relations indicated. The deduction concerning how the wave was originally produced is left for the person who interprets the harmonic plot.

If such a result were obtained for a wave from a musical orchestra, we should have no hesitation

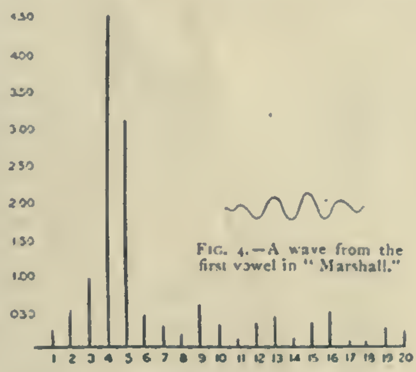

FIG. 4.—A wave from the first vowel in "Marshall."

FIG. 5.—Relative amplitudes of the sinusoids found by harmonic analysis.

in concluding that the wave was produced by a summation of vibrations in the harmonic relation. If the wave originated from a single source, we should certainly not be justified in drawing the same conclusion without further evidence. In seeking for further evidence we find, in the first place, that the waves from musical instruments so far as yet studied—the material is extremely limited—do not give harmonic plots like that in Fig. 5, and do give plots having one, two, or three prominent harmonics with the others lacking. This would agree with the known fact that most musical instruments vibrate in harmonics. If the source of the wave were absolutely unknown, the most plausible deduction would be that it was some body or bodies that might vibrate in either harmonics or inharmonics. We should take the weighted means of the groups of strong harmonics, and should find in this case that the components were the inharmonics

$$1 : 4{\cdot}3 : 9{\cdot}3 : 11{\cdot}5 : 17{\cdot}6 : 19{\cdot}5.$$

The result can be expressed in the inharmonic plot in Fig. 6. This conclusion is of vital importance, because such results are just those that are always obtained from careful vowel analyses. The very harmonic analysis itself leads to the conclusion that the vowel tones may be inharmonic.

In the analyses of vowel waves the fundamental is indicated as weak (as in Fig. 5) or often almost lacking. This fundamental represents the voice tone or the tone from the larynx. We all know that this is the strongest tone of all. We may not be able to hear just what vowel a speaker or singer is producing, but we certainly know whether he is using a high or a low tone of voice. One writer, observing this peculiarity in the analysis of the waves obtained from a phonograph, remarked that this instrument must be deaf to the voice tone. He failed to consider that if it was deaf to this tone it could not reproduce it, and that even the most defective phonograph will produce the voice tone so long as it makes any noise at all. The weakness of the fundamental in Fig. 5, therefore, does not show that

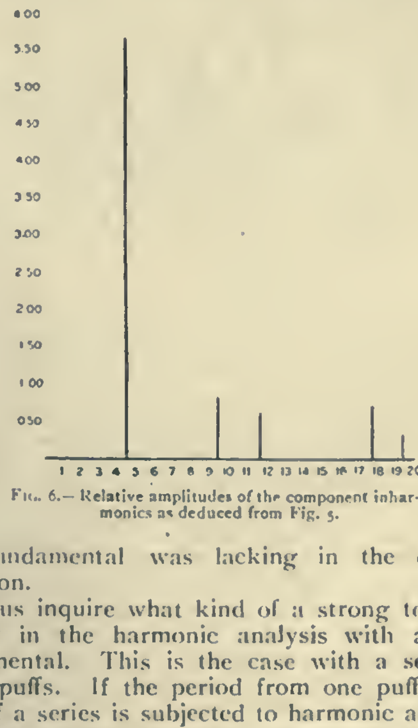

FIG. 6.—Relative amplitudes of the component inharmonics as deduced from Fig. 5.

the fundamental was lacking in the original vibration.

Let us inquire what kind of a strong tone will appear in the harmonic analysis with a weak fundamental. This is the case with a series of sharp puffs. If the period from one puff to the next of a series is subjected to harmonic analysis, the result shows a weak fundamental with all the higher harmonics represented in ever-diminishing amplitudes. The fundamentals in the vowel curves are therefore not of the nature of sine vibrations, but of series of more or less sharp puffs.

This is not a new theory of the vowels. In 1830 Willis published, in the Transactions of the Cambridge Philosophical Society, a paper on the tones of the vowels and reed organ-pipes. He asserted that a vowel was composed of a series of puffs with a set of inharmonic overtones. This was rejected in favour of the harmonic theory by Wheatstone, whose conclusions were accepted and developed by Helmholtz. For nearly a century the harmonic theory has been universally accepted.

In a series of researches beginning in 1889 Hermann found that the analyses of phonograph curves showed the vowels to be constructed of puffs and inharmonics. He thus independently rediscovered the principle of Willis. This theory has been substantiated and developed by thousands of analyses in my work for the Carnegie Institution of Washington, and published in "The Study of Speech Curves" (Carnegie Inst. Publ. No. 44), from which the above results are taken. It should be added that this extensive and somewhat expensive work was made possible by the support of Yale University and the liberality of the Carnegie Institution of Washington.

(To be continued.)

Nitrate Supplies and the Nitrogen Industry.

THE Imperial Mineral Resources Bureau has recently issued a report on the nitrate industry of the British Empire and of foreign countries, containing all available statistics with regard to the production and prices of nitrates during the war period. In conjunction with this report may be considered a paper dealing with the nitrogen industry contributed by H. E. Fischer to the Journal of the Franklin Institute (August, 1920, vol. cxc., No. 2). This paper gives a comprehensive survey of the sources of the world's nitrogen supply, particularly as it affects America. Nitrogenous compounds are absolutely necessary to agriculture, to the manufacture of munitions, to refrigeration, and to the general applications of chemistry, and although nitrogen in its inert gaseous state forms four-fifths of the atmosphere, yet this is of no use for the above objects until it has been combined or "fixed" by some method.

In the combined form, nitrogen is found in Nature as mineral deposits, as organic compounds, and in carboniferous deposits. By far the most important of the mineral deposits are those of Chile. Before the war the greater part of the world's requirements in respect of nitrate and nitric nitrogen was met by the export of nitrate of soda from Chile. The Chilean nitrate industry is one of long standing, and expanded steadily from 100,000 tons per annum in the middle of the nineteenth century to 2,400,000 tons in 1913. It has been stated that the Chilean nitrate deposits are nearly exhausted, but according to the Chilean Nitrate Committee's report "there is no fear of the Chilean nitrate deposits being exhausted for 200 years." The nitrate occurs as scattered deposits in a formation known as caliche, consisting of a conglomerate of rock material cemented with a mixture of soluble salts, in which sodium chloride is the chief constituent as regards quantity, while sodium nitrate is second. It is only in scattered patches that the caliche contains nitrate in quantities large enough to warrant treatment. These patches are sought out and excavated, and the picked ore is hauled to the extraction plant, where the soluble salts are extracted in solution, and the nitrate is separated from the other salts by crystallisation.

A considerable amount of sodium nitrate is also produced in Egypt. For one company in 1913 the output was 4740 metric tons, but the total output is not known definitely. In India potassium nitrate has been produced from very early times, but the trade has always been subject to great fluctuations. It attained its highest values during the American Civil War, for then India had practically a monopoly of the supplies of saltpetre needed for explosives. At that time the average annual exports were 30,000 tons, but the development of the Chilean industry caused the Indian trade to decline, until in the years just before the war the exports were only 13,000 or 14,000 tons per annum. The war period again stimulated the trade, and in 1918 the output was 25,145 metric tons. The potassium nitrate is found in the soils of old villages, mixed with nitrates of calcium and magnesium and with sodium chloride. The process of extraction consists in dissolving out the mixed salts from the surface soil, roughly separating the sodium chloride and the potassium nitrate, and then purifying the nitrate.

Nitrogen compounds are also obtained as by-products in a large number of industries. In dealing with animal, vegetable, and fish products, organic ammoniates are obtained, and these are left as such for use in agriculture, while from sources such as coal distillations, bone carbonisation, oil-shale distillation, and blast-furnace operations, nitrogen is recovered as ammonia and ammonium salts—chiefly ammonium sulphate, which is available in all capacities. The organic nitrogen recovered in these various by-product connections probably constitutes about 40 to 50 per cent. of the total supply, but this nitrogen has to compete for its market against the supplies of nitrates from natural sources and against those of synthetic nitrates, *i.e.* those obtained from combined atmospheric nitrogen.

As early as 1781 Cavendish discovered that a nitric reaction was shown by water obtained by burning hydrogen in excess of air, and since his time very many chemists have studied the problem. In 1900 two Americans erected an experimental plant at Niagara for producing nitric acid from atmospheric nitrogen by means of a very high electric current, but this soon proved unremunerative and was abandoned. The luminous arc process for fixing atmospheric nitrogen was the first to be established commercially. In this process a dilute gaseous mixture of nitric oxides with air is obtained from the oxygen and nitrogen in the air; the nitric oxide is converted into nitric dioxide, and then absorbed in water to form nitric acid. It was started in Norway in 1903, and, owing to the cheap horse-power there available, and to the fact that the raw materials cost nothing and are always at hand, nitric acid can be produced there by the arc process at less cost than by any other commercial process. Efforts to introduce this process outside Norway have been unsatisfactory, partly because of its uneconomical use of power, and partly because of the difficulty in the subsequent handling of the end-product, a 30–35 per cent. acid against a 50–55 per cent. acid obtained by other processes.

The Haber process for ammonia synthesis was brought to a successful commercial stage in Germany in 1913, when the plant capacity was 30,000 tons of ammonium sulphate. In 1918 the output by this process was 1,060,000 tons of ammonium sulphate. The process consists of forming ammonia by the direct combination, under the influence of a catalyser, of nitrogen from the air and hydrogen obtained from water. The production and purification of the hydrogen involve one of the chief items of cost in this process, but in spite of this the Haber is the cheapest process for the production of synthetic ammonia, and has the lowest power requirement of any of the nitrogen fixation methods.

In 1906 the calcium cyanamide process was successfully installed in Italy, and before the war it was also installed in Germany, Norway, France, Switzerland, the United States, Austria, Japan, and Sweden. The method is a complicated one, and involves a large number of stages, but it has developed extensively, because it requires only about one-fifth the horse-power per ton of fixed nitrogen per year that is required by the arc process, though five times that required by the Haber process.

Several other methods for nitrogen fixation are being experimented with, but they are not yet developed commercially. Mr. Fischer, after a full discussion, concludes that the result is that Germany can produce nitrates at one-half the cost in the United States, and, consequently, the German farmer can be supplied with fertilisers at one-half the cost to the American farmer. This is an enormous advantage to Germany, and if Germany succeeds in monopolising this industry —which she is in a position to do, barring internal disorders—she can either export nitrates at a price which will enable her to supply her farmers with fertilisers at a negligible cost, or undercut the price of nitrogenous products so that it will be unprofitable for the Chilean mines to continue working. Germany would thus in time indirectly control the world's production of explosives. Mr. Fischer therefore urges on the American people the importance of constructing plants for producing synthetic nitrates, by which means "our security would be vastly increased, the burden of obligation carried by our fleet would be greatly reduced, and its functional, effective value doubled."

Industrial Research Associations.

VIII.—The British Photographic Research Association.

By Dr. T. Slater Price.

The British Photographic Research Association was the first research association to be formed under the scheme of the Privy Council for the promotion of industrial and scientific research. Early in 1918 the manufacturers of photographic materials and apparatus decided to avail themselves of the scheme, and the research association was incorporated on May 15, 1918. The president of the association is Sir J. J. Thomson, and the chairman Mr. Gerald M. Bishop, of Messrs. Marion and Co., Ltd. The council of the association consists of representatives from the various sections of the industry, together with several well-known men of science, who are also represented on the list of vice-presidents. The first director of research was Dr. R. E. Slade, and laboratory accommodation was obtained in the chemical department of University College, Gower Street, where work was carried on until the end of September, 1920. Owing to the large influx of students in the present session, however, it was necessary to vacate the laboratories at University College, and at the beginning of October the research association was transferred to the Institute of Chemistry, 30 Russell Square, W.C.1, where various rooms have been specially fitted and equipped for research work. In March, 1920, Dr. Slade resigned his position as director of research, and the present writer was appointed his successor, taking up his duties in the middle of September last.

As stated in the programme of research which has been issued, the object of the association is to carry out research in photography, photochemistry, and other related subjects with a view to the general increase of knowledge of the subjects, to improve methods of manufacturing photographic materials, and to discover new photographic processes. It is recognised that manufacturers will always insist on determining for themselves the lines on which their businesses shall develop, and the true aim of the association should be, by the proper application of scientific methods, to obtain knowledge which will be of the widest application to the industry, and which it will be left to each manufacturer to apply in his own way to the development of his business.

It is recognised not only that applied research should be undertaken in connection with the improvement of products now being manufactured and of methods of manufacture, but also that pure research on the scientific basis of photography and on related subjects such as colloidal chemistry and photochemistry should be carried out, although there may not necessarily be any immediate application of the results to manufacturing processes. Pure research of this nature has already been done, as is instanced by the following list of published papers :—

Contrast and Exposure in X-ray Photographs through Metals, by R. E. Slade (Trans. Faraday Soc., 1919, vol. xv., p. 52). A discussion of the effects of various qualities of X-rays on the photographic plate, and the possibilities of using plates to detect very small flaws in the examination of large bodies of metal.

The Fundamental Law for the True Photographic Rendering of Contrast, by A. W. Porter and R. E. Slade (*Phil. Mag.*, 1919, vol. xxxviii., p. 187). A consideration of the conditions which must be fulfilled by photographic materials in order that a true reproduction of the tone-values of an object may be obtained in the final print.

The Emulsion for a Process Plate, by R. E. Slade and G. I. Higson (*Phot. Journ.*, 1919, vol. lix., p. 260). A description of the type of silver halide emulsion most suitable for a process plate giving great contrast.

Photomicrography in Photographic Research, by G. I. Higson (*Phot. Journ.*, 1920, vol. lx., p. 140). A description of a special type of photomicrographic apparatus specially designed for high-power work in the examination of emulsions.

The Photometric Constant, by G. I. Higson (*Phot. Journ.*, 1920, vol. lx., p. 161). A mathematical discussion of the relation between the photometric density and the quantity of silver deposit in a photographic plate.

A New Method of Spectrophotometry in the Visible and Ultra-violet and the Absorption of Light by Silver Bromide, by R. E. Slade and F. C. Toy (Proc. Roy. Soc., 1920, A, vol. xcvii., p. 181). A description of a new method free from certain sources of error, by means of which the extinction curve for silver bromide was determined throughout the visible and ultra-violet regions of the spectrum.

Some Problems in High-power Photomicrography, by R. E. Slade and G. I. Higson (Trans. Faraday Soc., 1920, vol. xvi., p. 101). A contribution to the general discussion on the microscope held by the Faraday Society.

A Simple Non-intermittent Exposure Machine, by G. I. Higson (*Phot. Journ.*, 1920, vol. lx., p. 235). A description of a novel and simple form of exposure machine with which a plate can be exposed to a light of constant intensity for a series of known times.

Photochemical Investigations of the Photographic Plate, by R. E. Slade and G. I. Higson (Proc. Roy. Soc., 1920, A, vol. xcviii., p. 154). An experimental investigation of the photochemical behaviour of the silver bromide grain, from which an expression connecting intensity, time of exposure, and effect on the grains can be deduced.

The Absorption of Light by the Goldberg Wedge, by F. C. Toy and J. G. Ghosh (*Phil. Mag.*, 1920, vol. xl., p. 775). An investigation of the neutrality of the Goldberg wedge, showing that this neutrality is confined to the visible portion of the spectrum.

Before the war the manufacturers of cameras made use of wood which had been stained black right through. It was obtained from Germany, and was not procurable in England after the outbreak of war. The research association undertook the investigation of such a staining process, with successful results, as may be seen by reference to English Patent No. 17,638/19. It now remains for the manufacturers to develop the process on a commercial scale. At the same time, a quick process for staining wood brown right through was devised.

The methods of making sensitive emulsions for coating on plates and papers have been brought to a high standard of excellence by the various English manufacturers. To a large extent, however, the methods used are the result of experience, of trial and error; different manufacturers obtain similar results by widely different methods. An inexhaustible field of work is open for the definite correlation of the physical and chemical properties of the materials used with the methods employed and the sensitiveness and other characteristics of the emulsion obtained. A commencement is being made on this line of work, the technical heads of the various firms putting their experience and knowledge at the disposal of the research association. Any useful results obtained in the research laboratories will then be tested on a large scale in the works, since it is more than usually difficult in emulsion-making to pass successfully from the laboratory to the works scale.

There is also need for improved methods of laboratory testing of the raw materials of the industry so as to establish greater confidence between buyer and seller, particularly in regard to gelatine, bromides, raw and baryta-coated papers, and packing materials.

The literature of photography is very scattered, and, doubtless owing partly to the subtle nature of many photographic phenomena, important details have often been overlooked, with the consequence that the results of different workers often appear very contradictory. One of the objects of the research association is to collect and summarise this literature so that it may be placed at the disposal of the members of the association. Progress is being made in this direction, but it is necessarily slow.

Obituary.

SIR LAZARUS FLETCHER, F.R.S.

BY the death of Sir Lazarus Fletcher, mineralogy loses one who for a long period was recognised as the leading exponent of that branch of science in this country. Born at Salford on March 3, 1854, Sir Lazarus died suddenly from heart failure at Grange-over-Sands on January 6 in the sixty-seventh year of his age. He was educated at the Manchester Grammar School, and afterwards at Balliol College, Oxford, where he held the Brackenbury science scholarship. He obtained first-class honours in mathematical moderations and in the final schools of mathematics and natural science. From 1875–77 he served as demonstrator in physics under Prof. Clifton at the Clarendon Laboratory, and for the next two years he held the Millard lectureship in physics at Trinity College, Oxford. From 1877–80 he was a fellow of University College, Oxford. While at the Clarendon Laboratory he became interested in the study of crystals, and, as the result, when, in 1878, Mr. W. J. Lewis (now professor of mineralogy at Cambridge) retired, owing to ill-health, from the assistantship which he held in the mineral department of the British Museum, Prof. Story-Maskelyne, who was then keeper of minerals, induced Fletcher to apply for the post. He obtained it, and only two years later succeeded to the keepership.

Almost immediately on taking charge of the department Fletcher was called upon to supervise the removal of the mineral collection from Bloomsbury to its present home at South Kensington. What this meant may best be told in his own words[1]: "Some idea of the nature of this task may be formed if it be pointed out that the cabinets of the table-cases at Bloomsbury were to be made use of in the new gallery, but that the glazed table-tops were to be left behind; that the new table-tops were then lying on the gallery floor at South Kensington, and had as yet no supports; that differences of illumination of the old and the new galleries, and differences of construction of the cabinets, made it necessary that the relative positions of the cabinets in the gallery at South Kensington should be completely different from the relative positions in the gallery at Bloomsbury; that every cabinet had for some time to be turned upside down during the process of being fitted to the new floor; that many of them had to be cut in two because of the interference of the structural columns of the gallery, and new mahogany ends had afterwards to be made and fitted to them. Such a series of operations involves great practical difficulties when the specimens to be removed and arranged are numerous, fragile, and require to be cautiously handled, or are small, portable, and of great intrinsic value, and must be kept under lock and key." Once the collections were put in order, Fletcher devoted his attention to selecting and setting out series of specimens to facilitate the study of meteorites, minerals, and rocks respectively, and prepared a corresponding set of elementary hand books which are models of clear and simple exposition of not readily understood subjects. In 1909 he succeeded to the directorship of the Natural History Museum, which had been vacated by Sir E. Ray Lankester two years before. Unfortunately, a severe illness a year or so before his appointment left him with a crippled constitution, and soon he appeared to lose that keenness and energy which had previously characterised him; and by the time, in 1919, he reached the full age for retirement he was a tired man.

Many honours were conferred upon Fletcher by scientific institutions and universities at home and abroad. He was elected a fellow of the Royal Society in 1889, and was a vice-president from 1910–12, and in 1912 he was awarded by the Geological Society the coveted Wollaston medal. In 1894 he was president of the Geological Section of the British Association at its meeting at Oxford. The Mineralogical Society owes him a special debt of thanks, for to him its success and prosperity are largely due; he was its president from 1885–88, and from the latter year until 1909 served as its secretary. To commemorate such long service mineralogists and other friends subscribed and presented him with his portrait. He was knighted in 1916.

Despite the calls of his official duties, Fletcher found time to devote himself to scientific research, mainly to the subject of meteorites, to their history and constitution and the problems presented in the analysis of these bodies, but also to certain isolated, yet exceedingly important, questions in crystallography. Until the publication of his Optical Indicatrix in 1892 the whole theory of the optical characters of biaxial crystals as presented in the text-books was based on faulty and contradictory premises. With characteristic industry he went back to the original source, and read all Fresnel's early papers on this subject, and found that the latter had followed a perfectly logical and convincing course in his approach to his theory, and had departed from it only when desirous of providing a physical basis for his fundamental hypothesis. Fletcher, in his treatise, shows that the wave-surface for a biaxial crystal can in the manner originally put forward by Fresnel be derived from a simple extension of Huyghens's theorem, and his method is followed in all modern text-books on crystallography and the optical characters of crystals. He was gifted with considerable manipulative skill in delicate experimental work, the best example of which was his remarkable investigation of the morphological and chemical properties of the crystallised form of native zirconia, which was first discovered by him, and to which he gave the name "baddeleyite"; he obtained the whole of the requisite information from a study of a single, ill-developed crystal, which was all the material at his disposal, the analysis being made on the tiny fragments that had adhered to the wax of the crystal-holder.

Sir Lazarus Fletcher was twice married, first to Miss Agnes Ward Holme, who died in 1915, leaving a daughter, and afterwards, in 1916, to her sister, Edith; his widow and daughter survive him. A man of studious habit, of quiet geniality, and gifted with a subtle North-country humour, he will be mourned by a large circle of friends.

The death is announced, at the age of seventy-seven, of Mr. Thomas A. O'Donohoe, known by his work in microscopy and bacteriology. Mr. O'Donohoe made investigations on the tubercle bacillus and on the anatomy, habits, and metamorphosis of the house-fly, and at the time of his death was studying the winter stages of this insect. He was an authority on the optics of the microscope and photographic camera, and did much work on the mounting of objects for microscopic research.

[1] "History of the Collections in the Natural History Departments of the British Museum" (1904), vol. i., p. 349.

MANY men of science in this country will learn with great regret that PROF. H. A. BUMSTEAD, professor of physics at Yale University, and president of the National Research Council of the United States, died suddenly at Washington on January 1. Prof. Bumstead was for some time in London during the war, and was the head of the American organisation for keeping touch between the two countries in matters concerning the application of science to war.

Notes.

WE publish in our correspondence columns this week a translation of a letter from Prof. F. M. Exner, director of the Central Meteorological and Geodynamic Institute at Vienna, and Prof. J. Hann, the former director, appealing for financial aid to enable the institute to carry on the valuable work it has done for meteorology for the past seventy years, and to continue its publications. Already, both in Great Britain and in the United States, funds have been provided for meeting the personal needs of meteorologists in Vienna who were without the necessaries of life, but meteorologists are not, as a rule, wealthy men, and they cannot do much more than they have done. Other scientific workers have probably approached much the same limit of their capacity to help. While, therefore, we commend the appeal to our readers, we think it would be difficult for private benefactors to provide the means for carrying on the work of the institute. A much more promising course to urge is that some part of the credits made to Austria by England and France should be ear-marked for the maintenance of essential scientific services. We suggest that the Royal Society or the Royal Meteorological Society should take steps with the object of securing support of this kind for the Meteorological Institute at Vienna.

MR. C. E. FAGAN is expected to retire from the British Museum (Natural History) in the spring of this year. He entered the service of the Trustees in 1873, and became assistant secretary in 1889. He received the title of secretary in 1919, in recognition of the conspicuous value of his services. It is safe to say that Mr. Fagan has done more than any other living man in developing the importance of the museum as a centre of scientific activity. His long experience, his grasp of affairs, and his unfailing capacity for forming a correct judgment have made his co-operation and advice invaluable to the Trustees and to his colleagues. His administrative ability has been of the greatest service to successive directors, whom he has assisted in innumerable ways, while during more than one period of interregnum he has succeeded in maintaining the efficiency of the museum at a high level. Although not himself an investigator, Mr. Fagan has taken a keen interest in many aspects of natural history, and has been quick to appreciate the importance of an opening, whether the chance of securing a valuable collection or the opportunity of encouraging an expedition to some distant country. He has been closely associated with such societies as the British Ornithologists' Union and the Royal Geographical Society, the interests of which are connected with those of the Natural History Museum. Opportunities of making the museum practically useful have a special appeal for him, and he has taken great interest in exhibits of economic importance. From the first he has been a strong supporter of the close connection which happily exists between the museum and the Imperial Bureau of Entomology. Mr. Fagan has rendered exceptional services to science by single-minded devotion to his ideal of increasing and developing the scientific importance of the museum. The fact that he is suffering from a severe illness at the time which he had hoped to devote to putting the finishing touches to his long period of successful service will command the ready sympathy of his many friends.

WE hope that the Victor Horsley Memorial Fund will be well supported. The *Times* publishes a strong appeal for it, signed by the president of the Royal College of Surgeons, the professor of physiology in the University of Edinburgh, and others. "If only each patient whose life he saved," they say, "were to contribute to our fund according to their means, we should have all the money that we require, and more." Contributions may be sent to Sir Frederick Mott, 25 Nottingham Place, W.1, or to Dr. Howard Tooth, 34 Harley Street, W.1. The plan is for a scholarship or a lectureship. We all remember the coming of the news of Horsley's death from heat-stroke in Mesopotamia in July, 1916. Some of us, more fortunate, also remember the wonder of his threefold work in 1884–90: his advancement of the physiology and surgery of the central nervous system, his studies of the thyroid gland and of myxœdema, and his uphill fight, as Pasteur's representative, for the stamping-out of rabies. After 1890 Horsley was for a quarter of a century incessantly teaching, incessantly learning. Alike in hospital practice and in private practice, he set himself to Guy de Chauliac's ideal of a surgeon: "Bold when sure, cautious in danger, kind to the sick, friendly with fellow-workers, constant in duty, not greedy of gain." Moreover, he worked hard, no man harder, for the betterment of his profession, for its greater efficiency in the all-round service of national health, and for the protection of its poorer members against exploitation and the insolence of office. Later he was in the forefront of the fight against drink, the fight for the welfare of children, and the fight for votes for women. He was ever a fighter, and he offended by his vehemence, his intolerance. But those who were altogether opposed to him in politics are none the less thankful for his magnificent work in physiology and surgery; it went over all the civilised world, and we are bound in honour to commemorate his name.

WE refer elsewhere to the annual meeting of the Mathematical Association and the presidential address by Canon J. M. Wilson. The assistance given by

NATURE to the movement for the improvement of geometrical teaching referred to in the address is not without interest to our readers. Prof. Hirst (in his lectures at University College, London, and elsewhere) and a young master at Rugby, the present Canon Wilson (in a paper read before the London Mathematical Society, printed in the *Educational Times* for September, 1868), were among the first to raise the note of dissatisfaction. Mr. R. Tucker, of University College School, was the first to broach the subject in our columns (NATURE, March 24, 1870, vol. i., p. 534), while the next effective contribution was from Mr. Rawdon Levett, of King Edward's School, Birmingham, who (May 26, 1870, vol. ii., p. 64) raised the fiery cross and called for an Anti-Euclid Society. Mr. Wormell then suggested that contributions to the expenses of propaganda should be sent to Mr. Levett. The result was the notice of a forthcoming conference (NATURE, December 29, 1870, vol. iii., p. 169). At the first meeting Messrs. Hirst and Wilson secured the substitution of "improvement" for "reform" in the title of the New Association for the Improvement of Geometrical Teaching, and it was Canon Wilson who suggested that the association would best justify its existence by preparing a syllabus. At the meeting of 1872 he proposed the appointment of a sub-committee to draw up a detailed syllabus of geometry to be submitted to the highest mathematical authorities and examining bodies. The next year he moved that the adopted syllabus should be sent to the British Association for its comments. In 1874 he moved that the five schemes of proportion mentioned in the report of the committee be examined by all the members and their opinions be invited. After that year his attendance became less regular, but it will be seen that he took the foremost place in the actual work of getting out the syllabus. It must be a source of satisfaction to Canon Wilson to find the bantling at the birth of which he was present fifty years ago now in its turn the parent of branches in these islands and the Colonies, and, *post tot annos*, sending forth once more through his lips its message of achievement. Of the venerable canon, who is now eighty-five, it may almost be said that his eye is not dim nor his natural force abated.

THE KING has signified his intention of conferring the honour of knighthood on Dr. Maurice Craig, Consulting Neurologist to the Ministry of Pensions, and Dr. P. Horton-Smith Hartley, senior physician at the Hospital for Consumption and Diseases of the Chest, Brompton.

PROF. E. W. SCRIPTURE, who contributes to this issue the first of two articles on "The Nature of Vowel Sounds," was formerly professor of experimental psychology in Yale University, but is now resident in London, where he has been for some years engaged on studying records of speech in epilepsy, general paralysis, and other nervous diseases. Prof. Scripture has lately returned from Germany, where he has been lecturing on experimental phonetics applied to the study of English. These were the first lectures delivered in Germany since the war by a professor from a former enemy country.

ON Tuesday next, January 18, at 3 o'clock, Sir G. P. Lenox-Conyngham will give the first of two lectures at the Royal Institution on "The Progress of Geodesy in India"; and on Thursday, January 20, Dr. Arthur Harden will begin a course of two lectures on biochemistry (vitamines). The Friday evening discourse on January 28 will be delivered by Sir James Dewar on "Cloudland Studies."

THE council of the Geological Society has this year made the following awards:—Wollaston medal (in duplicate), Dr. John Horne and Dr. B. N. Peach; Murchison medal, Mr. E. S. Cobbold; Lyell medal, Dr. E. de Margerie, director of the Geological Survey of Alsace-Lorraine; Bigsby medal, Dr. L. L. Fermor, Geological Survey of India; Wollaston fund, Dr. T. O. Bosworth; Murchison fund, Dr. Albert Gilligan; and Lyell fund, Prof. H. L. Hawkins, Reading University College, and Mr. C. E. N. Bromehead, H.M. Geological Survey.

THE annual meeting of the Iron and Steel Institute will be held on Thursday and Friday, May 5 and 6, at the Institution of Civil Engineers, Great George Street, London, S.W.1. Dr. J. E. Stead, president, will preside. In March the council will be prepared to consider applications for grants from the Carnegie Fund in aid of research work of such value as may appear expedient, but usually of the value of 100*l.* in any one year. The awards are made irrespective of sex or nationality. Special forms, on which candidates should apply before the end of February, can be obtained from the secretary of the institute. The research work must be on some subject of practical importance relating to the metallurgy of iron and steel and allied subjects. The results of research work must be communicated to the institute in the form of a report.

AT a general meeting of the Royal Meteorological Society to be held in the rooms of the Royal Astronomical Society, Burlington House, at 8 p.m., on January 19, a proposal will be brought forward for the incorporation of the Scottish Meteorological Society with the Royal Meteorological Society. The Scottish society has done useful work in the advancement of meteorology, particularly the meteorology of North Britain, since its foundation in 1855. It was closely connected with the work of the high-level observatory maintained on the summit of Ben Nevis for many years. It is felt that the time has now come when a fusion of the two bodies which represent the science north and south of the Border will be to the interest of meteorology as a whole and advantageous to the fellows of both societies. At 8.30 p.m., after the termination of the business meeting, Mr. R. H. Hooker, president of the Royal Meteorological Society, will deliver an address on "Forecasting the Crops from the Weather." Any workers interested in this subject from either the meteorological or the agricultural side are invited to the lecture.

THE Board of Trade has appointed Sir R. T. Glazebrook to be Chief Gas Examiner under the Gas Regulation Act, 1920, and Mr. C. V. Boys, Dr. J. S. Haldane, and Mr. W. J. A. Butterfield to be Gas

Referees. The Board has also appointed Mr. H. C. Honey to be Director of Gas Administration in the Power Transport and Economic Department, Board of Trade Offices, Great George Street, S.W.1. In pursuance of the provisions of section 2 (4) of the Act, the Board has appointed Sir William Pearce (chairman), Dr. T. Carnwath, Mr. W. D. Gibb, and Dr. T. Gray to be a Committee to inquire whether it is necessary or desirable to prescribe any limitation of the proportion of carbon monoxide which may be supplied in gas used for domestic purposes. It has also appointed Mr. J. H. Gray (chairman), Mr. W. J. A. Butterfield, and Dr. C. H. Lander to be a Committee to inquire whether it is necessary or desirable to prescribe any limitations of the proportions of incombustible constituents which may be supplied in gas. Communications should be addressed to the Secretary to each of these Committees at the Power Transport and Economic Department, Board of Trade, Great George Street, S.W.1.

THE Air Ministry announces that the Cabinet has approved, subject to Parliamentary sanction, the grant of a sum for the direct assistance of civil aviation. During the financial year 1921–22 payments under this grant will be limited to a maximum sum of 60,000*l*., and will be made to British companies operating on approved aerial routes. The routes at present approved are London to Paris, London to Brussels, and London to Amsterdam. Extensions to these routes and additional routes, such as England–Scandinavia, on which the possibilities of a service employing flying boats or amphibian machines or a mixed service of sea and land aircraft can be demonstrated, may be approved from time to time if satisfactory proposals are received by the Air Council. The maximum time allowed for journeys between London and Paris, between London and Brussels, and between London and Amsterdam will be four hours from aerodrome to aerodrome (or such other time limit as may be determined later by the Air Council). Any British company intending to run on the routes and notifying the Air Council of this intention will become an "approved" organisation by fulfilling the conditions laid down. Such notification should be addressed to the Secretary (C.G.C.A.), Air Ministry, Kingsway, W.C.2, to whom requests for further particulars in respect of the grant should be addressed.

THE KING, on the recommendation of the Home Secretary, has approved the appointment of a Royal Commission to inquire into the existing provision for: (1) The avoidance of loss from fire, including the regulations dealing with the construction of buildings, dangerous processes, and fire risks generally, the arrangements for inquiry and research and for furnishing information and advice to public authorities and others on matters relating to fire prevention; and (2) the extinction of outbreaks of fire, including the control, maintenance, organisation, equipment, and training of fire brigades in Great Britain; and to report whether any, and if so what, changes are necessary, whether by statutory provision or otherwise, in order to secure the best possible protection of life and property against risks from fire, due regard being paid to considerations of economy as well as of efficiency. The Commission will be composed as follows:—The Hon. Sir Perceval M. Laurence (chairman), Mr. J. T. Burns, Sir Vincent H. P. Caillard, Mr. A. L. Dixon, Sir Maurice Fitzmaurice, Capt. V. L. Henderson, Sir Joseph E. Petavel, Mr. H. Peters, Lt.-Comdr. Sir Sampson Sladen, Mr. H. Stilgoe, and Lt.-Col. G. Symonds. In addition, there will be representatives of the County Councils' Association, of the Association of Municipal Corporations, and of the Fire Offices' Committee. The names of these representatives will be announced later. The secretary is Mr. J. C. MacIver, of the Home Office. Any communications on the subject should be addressed to him at 5 Old Palace Yard, S.W.1.

UNTIL its work is completed and the materials are collected, published, and exhibited, it is somewhat premature to forecast the results of the Mackie Expedition to Central Africa under the conduct of the Rev. John Roscoe. It is clear from letters received that much success has been achieved among the Bunyoro tribe, which occupies the country to the east of Lake Albert in the Uganda Protectorate. This information has been summarised in an important paper by Sir J. G. Frazer, published in the December issue of *Man*.

MR. W. W. ROUSE BALL has reprinted through Messrs. Heffer and Sons, Cambridge, the interesting lecture which he delivered last spring at the Royal Institution on string figures, which we noticed at the time in these columns. He has added full directions for the construction of several easy typical designs, arranged roughly in order of difficulty, and, for those who wish to go further, lists of additional patterns and references. This fascinating art can be practised with the simple aid of a piece of good string some 7 ft. long.

THE Welsh Department of the Board of Education has issued, under the title of "Scheme for the Collection of Rural Lore in Wales," a pamphlet containing a series of rules and suggestions for secondary schools and colleges. The scheme has been financed by members of the Honourable Society of Cymmrodorion with the object of preparing a kind of Welsh Domesday Book, the material of which is to be collected by teachers and pupils. One part of the scheme is the collection of all Welsh place-names from the ordinary Survey maps and other sources. Rural industries, survivals of old or curious customs and crafts, peculiar words, local proverbs, primitive agricultural implements, marks on sheep or ponies, notice of places where old pottery and the like have been discovered—in fact, all kinds of information on rural and industrial life are solicited. The scheme is well conceived and the instructions are helpful. Educational authorities in other parts of these islands may well consider how far the Welsh scheme can be adapted to local conditions.

THE Gem Dry Plate Co., Cricklewood, N.W., has forwarded to us a pamphlet on photomicrography. A simple account is given of the process, which includes a description of apparatus, illumination, focussing, exposure, the use of light-filters, printing, and development. The pamphlet is illustrated with eight excellent plates showing reproductions of photomicrographs of diatoms, foraminifera, sections of animal and plant tissues, anthers and pollen, etc.

IN *Archives of Radiology and Electrotherapy* for November last (No. 244) Mr. H. A. Colwell continues his sketch of the history of electrotherapy. An account is given of the introduction and use of the galvanocautery, electrolysis, and influence machines, with illustrations of the first apparatus employed. It is interesting to see that an "electrical room" was started at Guy's Hospital in 1836, and various forms of electrical treatment were investigated by Addison, Golding-Bird, and Gull among others.

THE Tidal Investigations and Results of the Canadian Arctic Expedition, 1913–18, are issued as vol. x., part C, of the report of that expedition. Dr. W. B. Dawson notes that observations were made for varying lengths of time at ten stations on the south and east of the Beaufort Sea. The low temperatures and the consequent hardening of the oil in the clockwork of the registering tide-gauges presented a difficulty, which, however, was largely overcome by installing the instruments in snow-houses. The temperature of snow-houses can be kept at 40° to 50° F. by the use of lamps without the walls thawing. The range of the tide on the open shores was usually less than 1 ft., and seldom as much as 1½ ft. At the head of Amundsen Gulf it occasionally exceeded 2 ft. This small range is too slight to have any direct effect on navigation, but sufficient to move grounded ice. From the few data available it appears that the tide enters the Beaufort Sea from the north and moves southward and westward. Dr. Dawson recommends the establishment of some permanent tidal station for reference, and suggests the suitability of Herschel Island, which is one of the few localities in the region with a settled white population.

THE relation of surface visibility of the atmosphere to suspended impurity is dealt with in the *Meteorological Magazine* for December by Dr. J. S. Owens. In commenting on the difficulty of dealing with the whole subject of visibility experimentally, and especially with reference to the visibility of lights, allusion is made to the scattering of light by the small suspended particles in the air. Allusion is also made to the important part that the perception of colour plays in visibility, and it is stated that the sensitiveness of the eye for blue-greens is greater than for reds when the light is fading. Mr. N. K. Johnson contributes a communication on the visibility of pilot-balloons. He gives the results of an attempt made at Shoeburyness to determine which colour is most suitable for pilot-balloons, and especially for long-distance work. When the sun is shining on a balloon its visibility depends on its reflective power; without the sunshine you have to depend on the opacity of the balloon. The results are summarised as follows:—(1) Against a background of continuous dense white cloud either red or blue should be used. (2) If the sky contains slight cirrus or haze red is the correct colour to employ. (3) On occasions on which the sky is cloudless and of a deep blue colour a white balloon should be selected. The magazine shows that the total rainfall in November varied greatly in different parts of the British Isles. The general amounts were:—For England and Wales, 49 per cent. of the average; Scotland, 106 per cent.; and Ireland, 110 per cent.

WE have received from the firm of Messrs. Adam Hilger, Ltd., pamphlets describing their most recent spectrographs. Instruments with quartz prisms and lenses can be supplied ready for photographs to be taken to give the whole spectrum from 210 $\mu\mu$ to 800 $\mu\mu$. In some cases an accurate scale of wave-lengths is mounted internally so that a contact print of the scale can be obtained on the same plate as the photograph of the spectrum. Concave-grating spectrographs with the mounting designed by Mr. A. Eagle are recommended, as this form is found to possess many advantages in comparison with the classical Rowland mounting. The apparatus occupies very little space and possesses great rigidity. For the investigation of the Schumann and Lyman regions of the spectrum, which may yield most important theoretical results, the same type of mounting is used in a vacuum spectrograph. By the use of two slits the whole spectrum from 210 $\mu\mu$ to 50 $\mu\mu$ may be obtained with one setting of the grating. This is the instrument which has been employed by Prof. McLennan and his fellow-workers. Messrs. Hilger also construct an X-ray spectrometer as designed for Sir W. H. Bragg on the principle of Dershem.

THE problem of the high-frequency resistance and inductance of parallel wires is one that has been studied very carefully by many physicists, including Maxwell, Kelvin, Rayleigh, and Heaviside. The problem, however, which they considered was the symmetrical case of a cylindrical conductor when the return current was so far away that its magnetic effects on the distribution of the current in the cylinder could be neglected. A notable advance in the theory has recently been made by Mr. Harvey L. Curtis in a paper published by the Bureau of Standards, Washington (No. 374). Mr. Curtis has developed a new mathematical method by means of which he easily obtains the ordinary solutions applicable to a concentric main, and, in addition, obtains solutions for two parallel cylindrical mains at given distances apart. His solutions have been verified experimentally by the Bureau of Standards. It was found, for instance, that when an alternating current of 3000 frequency was sent through a circuit consisting of two parallel wires 0·651 cm. in diameter and 0·039 cm. apart the ratio of the alternating-current resistance to the direct-current resistance was 2·4. If the ordinary formulæ had been applied the ratio would have only been about 1·5. Similarly, it is shown both by theory and by the experimental results obtained that the irregular distribution of the current over the cross-section of the wire due to the proximity of the high-frequency return current very appreciably diminishes the coefficient of self-induction of the circuit.

THE "Index Medicus: A Classified Record of the Current Medical Literature of the World" (Washington: Carnegie Institution of Washington), which has hitherto been a monthly publication, will in future be issued at quarterly intervals. It will give the full titles of books, pamphlets, theses, original articles in journals, and transactions of medical and scientific societies. In the case of contributions printed in the lesser-known languages, their titles will be rendered into English. Each number will contain a general table of contents, and as soon as possible after the completion of each volume an "Annual Index of Authors" will be issued. Subscriptions to the work should be sent direct to the Carnegie Institution of Washington, Washington, D.C., U.S.A.

A USEFUL catalogue (No. 86) of second-hand books and journals relating to zoological subjects has just been received from Messrs. Dulau and Co., Ltd., 34 Margaret Street, W.1. It contains upwards of 1100 titles. Among the works listed we notice a first edition of "The Origin of Species," "The British Museum Catalogue of Birds" (27 vols.), Dresser's "A History of the Birds of Europe," and Reeve and Sowerby's "Conchologia Iconica"; also complete sets of the *Zoologist* and the *Entomologists' Record and Journal of Variation*. Copies of the catalogue can be obtained from the publishers.

THE latest catalogue (No. 361) of secondhand books and periodicals issued by Messrs. Bernard Quaritch, Ltd., 11 Grafton Street, W.1, is mainly of a general character, but lengthy sections devoted to botany, natural history, and Oriental literature make it worthy of the attention of readers of a scientific journal such as NATURE. As is usual with catalogues circulated by Messrs. Quaritch, many rare volumes are offered for sale.

Our Astronomical Column.

SKJELLERUP'S COMET.—It appears that this comet was first detected by Mr. C. J. Taylor at the Cape on December 8, Mr. Skjellerup finding it independently on December 11. It should, therefore, be called "Taylor-Skjellerup." Mr. R. L. Waterfield observed the comet at Hereford with a 4-in. refractor. His positions are not micrometrical, but eye-estimations from adjacent B.D. stars.:

G.M.T. d. h. m.	R.A. 1920·0 h. m. s.	N. Decl. 1920·0 ° ′
Dec. 31 12 0	10 16 38	16 22
Jan. 4 13 40	10 30 41	21 26

These agree within some 5′ with Mr. Wood's ephemeris, which is continued below (for Greenwich midnight):

	R.A. h. m. s.	N. Decl. ° ′	Log *r*	Log Δ

HISTORY OF THE CHRONOMETER.—Lt.-Comdr. R. T. Gould read a paper on this subject at the meeting of the Royal Geographical Society on December 13 which presents very vividly the tremendous revolution in navigation which this invention implied. He recalls Anson's disastrous voyage in 1741, when a mistake in the longitude caused such delay in making port that half the crew died of scurvy. After describing earlier abortive attempts, he proceeds to the famous prize of 20,000*l.* offered by the British Government in 1713, and won fifty years later by John Harrison, though he had undeniably earned the reward long before—a delay which reflected great discredit on the Government. The paper dwells on the inventive genius and constructive skill which Harrison continued to display; indeed, the performance of his various machines would be creditable at the present day. It is pointed out that his invention of the maintaining spring has never been superseded, and that the "remontoir" device for equalising the force on the escape-wheel, though no longer required on chronometers, has been introduced into the Riefler clock. Several anecdotes are given of Harrison's voyages, in which he frequently corrected the reckoning of the captain and officers; on one occasion he saved the ship from missing the Island of Madeira, to the great relief of the crew, who were short of beer.

Capt. Cook used a duplicate of Harrison's watch made by Kendall, and noted that "our longitudes can never be erroneous while we have so good a guide." The paper goes on to describe the work of Mudge, Le Roy, Berthoud, Arnold, and Earnshaw, and concludes by referring to the recent introduction of wireless telegraphy for time-distribution and direction-finding. The latter have effected a revolution in navigation almost as far-reaching as the invention of the chronometer.

THE PLANETESIMAL HYPOTHESIS.—This hypothesis, enunciated by Profs. Moulton and Chamberlin, has been favourably received by a number of writers, including Dr. Jeans in his recent work on cosmogony. The *Scientific Monthly* for last May contains an interesting *critique* on the theory by Prof. Reginald A. Daly, of Harvard University. Prof. Daly suggests some amendments to Chamberlin's views on the later stages in the earth's development. Chamberlin concluded that the earth's temperature was never very high, that its mass has slowly increased through the impact of planetesimal dust, and that oceans existed when it had only one-third of its present mass. Prof. Daly argues (1) that the matter composing the different planets is likely to be the same in the main, and (2) that the low density of the giant planets, combined with the phenomena observed on their surfaces, gives conclusive evidence of high temperature. He thinks that the earth was molten, if not gaseous, during its early history. An argument is also drawn from the moon; ascribing the numerous pits either to the fall of planetesimals or to volcanic action, there could scarcely fail to be considerable traces of similar formations on the earth unless the surface had been more or less molten. The remaining arguments are geological rather than astronomical, but one may be mentioned. The amount of salt in the ocean has led to an estimate of about 100,000,000 years for the period during which rivers have been flowing into it. This time-estimate would be much too small if we accepted Chamberlin's view of the early stage in the earth's history at which the oceans appeared.

The Physical and Optical Societies' Exhibition.

THE Physical and Optical Societies held their eleventh annual exhibition of scientific apparatus at South Kensington on January 5–6. There was a record attendance. The demonstrations and discourses were unusually attractive, a considerable number of visitors failing in their attempts to attend the discourses because of the overcrowded condition of the large lecture theatre. Sir W. H. Bragg gave an interesting lecture on "Sounds in Nature," and Mr. C. R. Darling showed by means of beautiful experiments some little-known surface-tension phenomena. On behalf of Prof. Archibald Barr, Dr. Morrison gave two addresses on the optophone, the instrument exhibited being the result of much patient research and development work by Messrs. Barr and Stroud. In the optophone a selenium bridge is exposed to successions of sets of light pulsations, which vary according to the forms of letters as these are passed over in traversing a line of printed type, each letter being indicated in a suitably connected telephone by a characteristic succession of single notes and chords. Printed letters are thus translated by the optophone into a sound alphabet which can be readily learned. Miss Mary Jameson, a blind girl, who attended the exhibition, read ordinary type at about ten words per minute, but when undisturbed her normal rate is about twenty-five words per minute. Many blind people were present.

Thermionic tubes and associated appliances were much in evidence. Prof. C. L. Fortescue and Dr. Bryan gave a very instructive demonstration of well-known circuit arrangements having all the parts exposed to view. The "heterodyne" or "beat" method of reception was demonstrated, and surprised many visitors because of the clearness of the beat tone. Another demonstration involving the use of valves was given by Messrs. Creed and Co. The apparatus which was shown received and recorded wireless messages at a working speed of 200 words per minute. The record is a punched slip of paper which by means of a printer is transcribed into Roman characters. The research laboratories of the General Electric Co. exhibited a number of valves with a new type of filament. This filament runs at a much lower temperature than the ordinary tungsten filament in the valves in general use at present. The increased strength resulting from lower temperature permits the use of finer filaments, the watts for heating these being only one-twentieth to one-fortieth of usual values. Thus it is possible to work a six-valve amplifier with a current consumption of half an ampere. Characteristic curves for these valves are very similar to those for existing types in use for wireless telegraphy.

In the optics section, Mr. Aldis exhibited a comparatively cheap but very perfect projector specially suited for projecting pond-life on the screen. With live specimens and a magnification of 300, the alimentary canal and internal organs of many specimens were shown with great clearness. There should be a good future for this projector for educational purposes. Messrs. Adam Hilger demonstrated a little-known application of the Fabry-Perot interferometer. A beam of white light is caused to traverse successively two plates of air, each with silvered faces, a system of fringes being obtained whenever the differences of path occasioned by each of the plates bear to each other a simple relation. If, then, a Fabry-Perot étalon is placed in series with a Fabry-Perot interferometer (the air plate in the étalon having a constant thickness and in the interferometer a variable thickness) a system of white-light bands is produced every time the distance between the silvered surfaces of the interferometer mirrors is either a multiple or sub-multiple of the distance between the plates of the étalon. Messrs. Hilger also demonstrated the Zeeman effect with a wave-length spectrometer and a Lummer-Gehrcke parallel plate. Messrs. R. W. Paul and F. Twyman demonstrated by the use of a Hilger-type interferometer the distribution of temperature around a hot body. The convection currents produced in air by electrically heated wires were beautifully shown.

Cathode-ray workers were interested in a 12,000-volt direct-current generator set shown in operation by Messrs. Evershed and Vignoles. A cathode-ray tube was placed in circuit and some of the possibilities of the method of investigating rapid changes of current were demonstrated.

The general display of all exhibits was particularly good, and great credit is due to the forty-eight instrument-making firms who exhibited for the excellence of their manufactures and for the care taken in arranging and explaining the purposes of their instruments. The finish of electrical instruments was of a very high order—much higher than last year, when many mass-production instruments were shown. In many cases it was gratifying to find that elegance of production was accompanied by a surprising robustness. As an example a simple galvanometer which appeared to be very good for schools was shown by Messrs. Gambrell Bros.; this has a self-locking device when it is not supported on a table, and, in consequence, it withstands extraordinary shocks in transit. The Cambridge and Paul Instrument Co. showed for the first time a modification of the Einthoven string galvanometer having six strings, the deflections of which are recorded on a moving band of photographic paper. This type of galvanometer was first used in sound-ranging in France, and was of great service during the war. An excellent amplifier for cable work (but it should have many other applications) was exhibited by Mr. H. W. Sullivan; the amplifier is a selenium-cell relay which is acted upon by a light beam from a galvanometer; a magnification of 10,000 was obtained. As usual, the Weston Instrument Co. had an excellent display of meters and parts of meters which only required inspection for one to understand why a Weston instrument is always trustworthy.

The optical section of the exhibition attracted increased attention because of the position of the optical trade as a key industry. The exhibits were certainly of a high class, and it is hoped that the efforts of the optical industry to establish itself firmly and to make its products inferior to none will receive support from the large number of visitors who admired the exhibits.

The Headmasters' Association.

THERE was a large muster at the annual meeting of the Association of Headmasters held in the Guildhall of the City of London on January 5. In his presidential address Mr. J. Talbot, headmaster of the Royal Grammar School, Newcastle-upon-Tyne, handled the new psychology in a sensible way. No one can question the results of psycho-analysis when applied to cases of neurosis. Many a soldier owes his recovery from shell-shock to the skill of men like Dr. Rivers, Prof. Elliot Smith, and Prof. Pear. But when a smatterer who has merely "read a book," or perhaps only listened to a lecture, begins to fumble round with the souls of healthy boys and girls it is a different matter, and teachers have no more right to experiment upon them in psychical matters than to make them the vile body for testing the properties of a patent nostrum. It may be true, as Dr. Crichton Miller has pointed out, that in nineteen out of twenty cases examined by the expert analysts the results point to faulty upbringing, either at home or at school, but it must be borne in mind that these twenty cases are not normal or typical in any way. When Dr. Mary Bell says there is no sin in a child helping itself to the contents of the mother's purse in order to buy presents for a teacher, this is simply playing fast and loose with the distinctions between right and wrong. Most homes and most schools will be well advised to stick to the Ten Commandments. If a child gets into serious trouble or is not healthily happy, there is a clear case for psychotherapy. Every schoolmaster of experience knows how helpful it may be in suggesting a hopeful method of treatment, for there were cases of shell-shock among children in the raid areas as well as among soldiers at the Front; and so long as boys are boys there will be cases of practical jokes, such as those which drove the poet Gray out of Peterhouse at Cambridge, and there will be cases of bullying, though these are now, happily, very rare. But for the normal treatment of normal school-life, the best training of the unconscious life, as Mr. Talbot said, is through the school games, school camps, scouting, and everything which enables a child's psychical faculties to function freely in relationship both to his teachers and to his fellows. Inasmuch as every child does not find itself in cricket, football, and hockey, it is well to widen the field of opportunity and to offer as large a variety as possible, so that no child in any school may live such a cowed life as Cowper lived at Westminster.

Prof. Percy Nunn's address on testing intelligence was as full of humour as of practical help and suggestion. Clearly the secondary school needs a certain *quantum suff.* of knowledge as well as of intelligence, and therefore written examination cannot be superseded in the selection of free-place holders. Both these forms of test bring out the child that has the power of rapid mental mobilisation, and the ablest child of all may very likely fail to shine. "Sentimental Tommy" failed to win his place on the list because he spent half the time available in thinking out the exact word which he wanted to fit his thought. Clearly the consummate artist in words is not a successful examinee. There is, in addition, the child who thinks below the surface of things, whom psychologists call the "introvert." He will take the question proposed and look at it in its bearings in relation to other deep thoughts which occupy his mind, and, as likely as not, he will want to reformulate the question altogether before he sets himself to answer it. As Prof. Nunn admitted, our present methods pass over this child; a Newton or a Coleridge would in all probability fail to win a scholarship. This is one point which calls for further work for the psychologists. Profs. Terman and Thorndyke have not yet faced this question, and the American Army had probably no use for a Coleridge or other poetic soul. This is only one of many questions which call for further research. It is important to be able to measure the vital force of the competitor, for a fund of vitality is quite as important for effectiveness in study, and, indeed, in life in general, as intelligence. It would be interesting to know how much deep breathing and cardiac strength have to do with that tenacity of purpose which so often wins through to high achievement, when mere brilliance of intellect fails because it is not backed by strength of perseverance.

The Mathematical Association.

AT a crowded annual meeting on January 4, Prof. A. S. Eddington gave an account of relativity. Those who wish to inform themselves on this subject will naturally go to Prof. Eddington's attractive book, "Space, Time, and Gravitation." No experiments to determine the motion or whereabouts of the æther had ever led to any but a negative result, as if one solving an equation should end up with the disappointing result 0=0 The view had therefore been put forward that there were certain compensating influences concealing the motion of the æther from detection. But Einstein had dared to take up the attitude of Betsey Prig in the matter of Mrs. Harris, "I don't believe there's no sich a person!" The party of Mrs. Harris, however, protested against being called upon actually to produce her.

Two points of pedagogic importance were made. First, there is geometry. In Prof. Eddington's opinion geometry is not the science of space relations in an empty world, but the science of space relations of material objects; its fundamental assumptions are to be ascertained by measurements made on such objects. From this it would follow that the philosophical way to begin the study of geometry is by playing with mathematical instruments and bits of cardboard. This is what teachers have been discovering, beginning at the other side of the problem—beginning, that is, with the boy into whom they have to insert learning. Prof. Eddington reaches the same conclusion by considering the nature of the learning that is to be inserted into the boy. So the two sets of workmen meet in the middle of the tunnel and the line is clear for traffic.

Secondly, there is dynamics. Consider the case of a pendulum. On one side of the equations we have been accustomed to write the forces, including gravity. On the other we write inertia and acceleration, including the acceleration towards the centre. But the last term could algebraically be written on the force side, with sign reversed; it would be identified with what has been known popularly as centrifugal force. Teachers have generally been rather prudish about this term, but Prof. Eddington assures us that centrifugal force and weight are equally real or unreal; it would appear, then, that they should be on the same side of the equation. (But which side?) Similarly, the passenger walking along the aisle of an accelerating tube-carriage is justified in considering himself in equilibrium under a pressure from the floor and a gravitational force equally inclined to the vertical; and gravity is, in practice, not disentangled from the centrifugal force of the earth's rotation.

Dr. Brodetsky followed with a paper proposing to inject fresh blood into dynamics by using the aeroplane. He explained that the problem could be so simplified that, after a year's study of dynamics, the student could work problems on the motion of aeroplanes, including climbing, *vol plané*, and banking. We shall look forward to seeing these suggestions worked out in detail in a forthcoming issue of the *Mathematical Gazette*.

The Rev. S. H. Clarke, of Tonbridge School, pleaded for a more intelligent handling of the older non-mathematical boys, especially those of proved ability in classics. They should not be allowed to drop mathematics, nor should their time be spent in trying to attain an unattainable degree of dexterity in the bits of mathematics that they have already learned to dislike. On the contrary, they should be introduced in a superficial and literary manner to new mathematical regions; here they will find fresh inspiration, and eventually form a public able to view mathematical achievements with sympathy and appreciation. Mr. Durrell recorded that such a scheme has been in operation at Winchester for two years; that it is compatible with success in the school certificate examination; and that examination results on the wider field are bound to be bad. But this does not matter in the least.

Prof. Whittaker, the retiring president, indicated the danger that mathematicians might break up into two non-communicating groups: researchers who do not teach much, and teachers (mainly schoolmasters) who do not research. This was by no means necessary, as the Edinburgh Mathematical Society does useful research work and is composed almost entirely of schoolmasters. There were many problems which might be attacked with fruitful results by schoolmasters whose knowledge does not go beyond an honours course. He described three fields in which oil might be struck near the surface with a very moderate drilling equipment:—(1) A method allied to nomography, at present almost unexplored; (2) the theory of skew determinants and Pfaffians; and (3) the solution of partial differential equations by means of integral equations.

Canon J. M. Wilson, the new president, gave an account of the efforts of mathematical reformers before the foundation of the Association for the Improvement of Geometrical Teaching, now the Mathematical Association (the fiftieth anniversary of this event occurs this year.) He was asked by Dr. Temple, then Headmaster of Rugby, to produce a reformed geometry text-book; this he did after consulting the leading Continental works on the subject. In appreciation of his work he received an address in Edinburgh signed by Members of Parliament, professors, and other leading men. Those on whose shoulders Canon Wilson's mantle has fallen have done little more than to rediscover or develop the ideas put forward by himself and other pioneers more than fifty years ago. Canon Wilson will be pleased to learn that his ideas have now been accepted by all the important examining bodies except London University.

Miss E. B. Read told an interesting story of a recent visit to lycées in Paris and the French provinces—girls' schools, all of them; in boys' schools she never penetrated beyond the director's office. She was impressed by the burden of home-work in these lycées, sometimes occupying the girls up to midnight. This she associated with the predominantly oral method of classwork, little time being spent in working examples in class. C. G.

The Geographical Association.

The annual meetings of the Geographical Association were held in the London Day Training College, Southampton Row, on January 7–8. The session opened with a discussion on historical geography, led by Messrs. Fairgrieve and Jervis. Several historians were present, and they agreed with geographers that each subject demands not only a special and intensive study of its own facts, but also a special and differing attitude of mind. Every geographer must have sufficient knowledge of historical facts and conditions to explain those links of the past which last on into the present, and are thus necessary to the proper understanding of present geographical conditions. Prof. J. L. Myres said that both history and geography were concerned in the effort to help young folk to exploit the general experience of humanity for their own benefit and that of their fellow-citizens, and that it was therefore imperative that the two sets of aspects should be presented harmoniously and instructively.

In the discussion on geography in continuation schools the main point which emerged was that geography was being given a place in the L.C.C. schools because it was felt that it gives a training in good citizenship, in a habit of wide outlook, and in interest in the district in which the pupil lives or works.

Dr. Unstead gave a remarkably able exposition of the difficulties and possibilities which face the teacher of geography in his attempts to deal with such international problems as the altered environmental and psychical conditions in eastern Europe, the racial question on the Pacific fringes, and the atmosphere in India and Egypt. While it would obviously be crude to discuss these things in a political way, even in the upper forms of secondary schools, it is yet essential that these aspects of modern human geography shall be presented, and the only safe way is to show the contrasted *ideals* rather than the detailed claims of each nationality.

Dr. Haddon, whose valuable expedition to the Torres Strait was one of the outstanding scientific events of the last generation, delivered an illustrated lecture on racial and cultural distributions in New Guinea, furnishing thereby a first-rate example of the methods of distributional study.

Prof. Gilbert Murray gave his presidential address on the evening of January 8. He emphasised the fact that in every epoch of history there has been a division of humanity into the select few who understand the world and the barbaric multitude who are without the precinct—the Hellenes and the Barbarians, in mediæval times the world of Christianity, and without the pale the Jews and infidels. The essential mark of the man "without the precinct" is that the motives which underlie his actions are misunderstood, or even not considered at all. Geography should help to remove that spirit of ignorance and misunderstanding from the world. For geographers the present world-situation is of special interest, for not only have the Great Powers been compelled to try to get this spirit of mutual geographic understanding, but also the whole *orbis terrarum* is meeting. China and Peru are members of that League the business of which is the common good of humanity, the securing not merely of *peace*, but also of goodwill between every nation of the world, whatever its status.

The lectures given by Dr. Haddon and Prof. Gilbert Murray will be published in the spring number of the *Geographical Teacher*, which is sent post free to all members of the Geographical Association. The annual subscription is 5s., and the address of the central offices is 1 Marine Terrace, Aberystwyth.

The Origin of Hypergamy.

At a meeting of the Royal Anthropological Institute held on November 9, Mr. S. H. Ray, vice-president, in the chair, Dr. W. H. R. Rivers read a paper on "The Origin of Hypergamy."

Dr. Rivers said that the term "hypergamy" had been used loosely by both Sir Herbert Risley and Dr. W. Crooke to denote marriage between groups which differ in rank, but for the sake of clearness the term should be confined to those instances in which there was a characteristic difference between the marriage rules for the two sexes. Hypergamy thus understood was that form of marriage in which men mate with women of lower rank than their own, but do not give their women in return, the union of these being confined to men of their own or higher grades. Owing to the fact that women of the highest group can only marry men of their own rank, women of high rank either remain unmarried or the inequality is redressed by the practice of polygyny or by female infanticide. On the other hand, since men of the lowest grade may only marry women of their own rank, while such women are taken by men of a higher group, there is a shortage of women of the lowest grade, and the men must remain unmarried or have recourse to polyandry, or they may seek their wives elsewhere. If the neighbouring communities are hypergamous or endogamous, the only unions open to them will be with any aboriginal women who may live in the neighbourhood. The practice of hypergamy is not only peculiar to India, but is there almost entirely confined to the Rajputs, or castes, such as the Kulin Brahmans, which have come under Rajput influence. Where the custom occurs among the castes of Bengal, it would seem to have been derived from the Kulins. It appears probable that the Kulin custom can be traced to Rajput influence, as the Kulins are derived from Brahmans who about A.D. 700 came to Bengal from Kanauj, at one time the centre of Rajput rule. Hypergamy also occurs among the Nayars of Malabar, but in this case its relation to the practice in other parts of India is not so clear. One form arises out of their relation with the Nambutiri Brahmans, among whom the rule is that only the eldest son may marry; the other sons contract unions with Nayar women. A Nambutiri woman would not be allowed to marry a man, Nayar or other, of a lower caste. The status of the children is determined by the Nayar rule of matrilineal descent. There is no evidence to connect the practice among the Nayars and other cases occurring sporadically in the Madras Presidency with Rajput influence, and it is possible that with them it may have a more ancient history and go back to a remote derivation from the warrior caste.

The institution of hypergamy appears to be a special form of interaction between immigrants into India and the indigenous population, and to be an intermediate stage between the complete fusion which has taken place in such cases in other parts of the world and the segregation which has produced the more characteristic forms of the caste system of India. The development of hypergamy may be referred to three special conditions: (1) The especial strength of a sentiment of the immigrants concerning the union of their women with indigenous men; (2) a short distance of migration, so that the immigrants were accompanied by a relatively large number of women; and (3) the military character of the invaders, which allowed them to obtain indigenous women without giving their own women in return.

An interesting discussion followed the reading of the paper, in which emphasis was laid upon the importance of the principles formulated by Dr. Rivers in their bearing upon questions of racial admixture and fusion of language as a result of peaceful penetration or invasion in other parts of the world. Prof. Parsons pointed out that the Saxons had brought a large number of women with them to this country, as was shown by the skeletal remains, whereas the Norsemen who invaded France constituted a male invasion solely, and this probably explained the almost complete substitution of French among them for their own language, the language of the native mothers having prevailed. Mr. Ray pointed out that while the words denoting close family connection in this country were predominantly Saxon, the language of the children contained Celtic elements, as, for example, the word "dad." Prof. C. G. Seligman said that he had found a practice similar to hypergamy among nomad Arab tribes of the Sudan, in which black slaves, the offspring of Arab men and indigenous women, although permitted to hold very high office in the tribe, were not allowed to marry Arab women. Col. Hodgson pointed out that the restriction of marriage to the eldest son also existed among the Kyasths, the reason in this case being that that son was the only true reincarnation of the father, his younger brothers being the "children of sin."

Studies in British Forestry.[1]

The Forestry Commission has made a good start, having acquired during the first year of its operations as many as 65,000 acres of land, of which 1500 acres have been planted with trees. During the present year 5900 acres of new plantations are planned. These figures are well ahead of the schedule of the first two years' work which was laid down in the Reconstruction Forestry Sub-Committee Report. This is satisfactory as regards the part played by the State in national afforestation, but we must not forget the work to be done by landowners in replanting the extensive areas which were felled during the war.

The Forestry Commission can assist private enterprise by money grants for planting, by partnership schemes, and by providing nursery plants at a cheap rate, but it can also stimulate owners to active measures of afforestation by the publication of trustworthy facts and figures concerning all forestry matters. We welcome, then, the three interesting bulletins which have been recently issued. Technical skill in the rearing and planting of trees is not lacking in this country, but much ignorance prevails as to the actual results obtainable by afforestation with different species of trees. Bulletins Nos. 1 and 3 are concerned mainly with this question, and their perusal will enable owners to deal intelligently with some problems of replanting and afforestation.

A survey for the collection of statistics as to the rate of growth and production of timber in the United Kingdom was carried out officially in 1917–19, and

[1] Forestry Commission. Bulletin No. 1: "Collection of Data as to the Rate of Growth of Timber." (To be obtained from the Forestry Commission on sending 4d. and a stamped addressed envelope.) Bulletin No. 2: "Survey of Forest Insect Conditions in the British Isles, 1919." (H.M. Stationery Office.) Price 1s. 6d. net. Bulletin No. 3: "Rate of Growth of Conifers in the British Isles." (H.M. Stationery Office.) Price 3s. net.

Bulletin No. 1 gives an account of the methods which were actually used by the forest officers in charge of the survey. These methods are based on the measurement of well-stocked sample plots of woods of various ages and on all classes of soils. Five working parties were employed, the actual measurements being made by women assistants under the supervision of a skilled officer who inspected the woods and selected the plots. This bulletin is clearly written, and will prove useful to private owners wishing to lay out sample plots by means of which they will be enabled to measure the volume and increment of their own woods by official and scientific methods.

The third bulletin deals with the results of the survey which was restricted to pure woods of conifers. It furnishes us for the first time with accurate yield-tables of larch, Scots pine, and spruce based on accurate measurements of these species in British plantations. Hitherto we were dependent on Continental yield-tables, which apply only very approximately to this country. Provisional tables for Douglas fir, Japanese larch, and Corsican pine are also given in the bulletin. The yield-tables are of the usual kind, giving for various qualities of soils the average height and diameter of the trees and the number of stems and volume of timber per acre, with other figures, corresponding to ages of 10, 15, 20, . . . 100 years. Any wood, provided its age is known, can be allocated to its proper quality class by the average height of the trees, as it is well established that in a fully stocked wood of any species the volume at a given age is in direct relation with the mean height.

A considerable part of Bulletin No. 3 is taken up with a discussion on the factors of climate and soil in relation to the growth of species, like Scots pine, larch, and spruce. This branch of the subject is very important, and deserves much more extended investigation than was possible in this preliminary survey.

Bulletin No. 2, prepared by Dr. J. W. Munro, the entomologist employed by the Forestry Commission, is based on a survey of the insect conditions of coniferous woods in seventeen districts of the United Kingdom in 1919. This survey was rendered necessary by the great increase in harmful insects occasioned by the heavy fellings of timber during the years of the war. Owing to the shortage of labour it was impossible to clear the ground of the branches and débris which, with the stumps of the trees, form the main breeding-grounds of these pests. Dr. Munro investigated the ravages of fifteen species of insects, and reports that coniferous woods generally are in a very unhealthy state. Young plantations on the site of, or near, a felled area suffer most. This bulletin is well illustrated, and Dr. Munro's remarks on measures of prevention should be studied carefully by all foresters engaged in the formation of new plantations.

Greenland in Europe.[1]

By DAVID MACRITCHIE.

AT the present day the name "Greenland" is limited to the great island lying to the east of Arctic America. Formerly, however, it included an undefined territory of Arctic and sub-Arctic Europe, extending eastward, according to some estimates, into north-western Siberia. Sir William Martin Conway has shown (Hakluyt Series, 1904) that during the seventeenth century, in Britain and the neighbouring countries, "Greenland" primarily denoted Spitsbergen. Even in the year 1812 the leading London publishers were selling a school-book which, ignoring the word "Spitsbergen" altogether, applied to that group of islands the sole name of "Greenland."

But so early as the time of the Norman conquest of England a German chronicler, a minor canon of the Cathedral of Bremen, widely known as "Adam of Bremen," had recorded the existence of a Greenland in Northern Europe. There is good reason for assuming that the region he had in view was the Kola Peninsula and a good deal of contiguous territory. He states that those Greenlanders were *caerulei* (blue men), and that they were cruel, "troubling seafarers by predatory attacks"—from which it may be inferred that they were themselves seafarers. In passing, it may be pointed out that at a very much earlier date the Romans had noted the existence of a caste of *caerulei* in the British Isles. In both cases the name probably arose from the custom of painting or tattooing with blue pigments.

The assumption that Adam of Bremen's "Greenland" was the Kola Peninsula and the parts adjoining receives confirmation from a statement made in 1430 by a Danish traveller and writer of the name of Claus Claussön, Latinised Claudius Clavus; for he tells us, from personal knowledge, that at that time "the infidel Karelians daily come to Greenland in great armies." The Karelians, or Karels, a Finnish people, occupied most of the south-western shores of the White Sea in the fourteenth century. In the fifteenth century they ousted the Lapps from their homes on the western shore of the White Sea, driving them north into the Kola Peninsula. The country thus taken possession of by the Karels is now known as Karelia. But the name applied to it by Claudius Clavus was "Greenland."

To make it quite clear that Clavus referred solely to a European country when he spoke of "Greenland," it is necessary to keep in view the fact that in 1430 there was no European intercourse with the Greenland on the other side of the North Atlantic. The situation is definitely explained by Dr. Nansen, who states ("Encyc. Brit.," eleventh edition, vol. xii., pp. 542 and 548) that the last ship known to have visited the Norse colony in trans-Atlantic Greenland returned to Norway in 1410, and that from that date until 1585 the overseas Greenland was unvisited by Europeans and almost forgotten. It is therefore manifest that when any trustworthy writer of the period 1410–1585 makes reference to Greenlanders as people with whom Europeans are then in contact, he has in view a North European race, and not a race living on the other side of the Atlantic.

A further statement by Clavus has a distinct bearing upon this question. He tells us that to the west of the wild Lapps "are little pygmies, whom I have seen after they were taken at sea in a little skin-boat, which is now [about 1430] hanging in the cathedral at Nidaros [*i.e.* Trondhjem]. There is likewise a long vessel of hides, which was also once taken with such pygmies in it." Again, Olaus Magnus relates how in 1505 he saw two of the leather skiffs of "the Greenland pirates" hanging in the cathedral at Oslo (Christiania). And Jacob Ziegler, in his work "Srondia" (1532), speaks of the "light boats of hide" of the Greenlanders. A complaint

[1] Synopsis of a paper read before the British Association (Anthropological Section) at Cardiff on August 27, 1920.

against "the Greenland pirates" in their "small ships without keels" is made in 1551 by Carsten Grip, Mayor of Kiel.

Visits of similar people in skin canoes are recorded in the Orkney Islands by writers of unimpeachable veracity in the seventeenth century. One of these canoes is still preserved in the anthropological museum of Marischal College, Aberdeen. Its framework and implements are made of North European wood. The estimated maximum height of its occupant is 4½ ft.

A vast field of conjecture opens up if we begin to consider the European skin boat in the first thousand years of the Christian era. Von Düben shows that it was the earliest boat used by the Lapps, and Prof. Julius Pokorny interprets the *Fir Bolg* of Gaelic lore as "skin-boat men." "The Greenlandish Attila Lay" is said to date from the eighth or ninth century.

Prize Awards of the Paris Academy of Sciences.

Mathematics.—Grand prize of the mathematical sciences to Ernest Esclangon, for his memoir entitled "New Researches on Quasi-periodic Functions"; the Poncelet prize to Elie Cartan, for the whole of his work; the Francœur prize to René Baire, for his work on the general theory of functions.

Mechanics.—A Montyon prize to Stéphane Drzewiecki, for his book on the general theory of the helix, with reference to marine and aerial propeller-blades; the de Parville prize to Jean Villey, for his work on internal-combustion motors. No memoir was received dealing with the question proposed for the Fourneyron prize, but the arrears accrued are divided between Joseph Auclair and Alfred Boyer-Guillon (1000 francs), for their theoretical and practical studies on the measurement of the acceleration of a point of a body subject to a periodic motion, and Eugène Burlot (1000 francs), for the whole of his work concerning the propagation of waves of shock in air and water.

Astronomy.—The Lalande prize to Léopold Schulhof, for his revision of the catalogue of the proper motions of 2641 stars published by J. Bossert in 1896; the Valz prize to Ernest Maubant, for the whole of his work on the calculation of the perturbations of comets; the Janssen medal to William W. Coblentz, for his work on the infra-red radiation of terrestrial sources and of stars; the Pierre Guzman prize between François Gonnessiat (5000 francs), for his work on the photography of the minor planets, René Jarry-Desloges (5000 francs), for his physical observations on the planets, especially Mars, and Joanny-Ph. Lagrula (4000 francs), for his work on the rapid identification of the minor planets. The Damoiseau prize was not awarded, and the questions proposed for 1917 and 1920 are again proposed for 1923.

Geography.—The Delalande-Guérineau prize to Georges Bruel, for the whole of his explorations and publications relating to French Equatorial Africa; the Tchihatchef prize to Auguste Chevalier, for his explorations in Africa and Indo-China; the Binoux prize to Marcel Augiéras, for his work in the western Sahara. The Gay prize is not awarded.

Navigation.—The prize of 6000 francs between Fernand Gossot (4000 francs), for his treatise on the effects of explosives, Pierre de Vanssay de Blavous (1500 francs), for the whole of his work, and René Risser (500 francs), for his work on ballistics; the Plumey prize between Charles Doyère (2000 francs), for the whole of his work, especially for the services which he rendered during the war, and Edouard Tournier (1000 francs), for his book entitled "Practical Guide for the Use of Mechanics for Calculating the Internal Losses in Machines and Determining their Yield."

Physics.—The L. La Caze prize to Georges Sagnac, for the whole of his work in physics; the Hébert prize to Léon Bouthillon, for his work and publications on wireless telegraphy; the Hughes prize to Frédéric Laporte, for his work on electrical standards and the photometry of electric lamps; the Clément Félix foundation to Amédée Guillet, for his researches on chronometry.

Chemistry.—The Montyon prize (unhealthy trades) to Léonce Barthe, for his work on the hygiene of workshops, a mention (1500 francs) to Paul Goissedet, for his work in relation to poison gas, and a mention (1000 francs) to Henri Guinot, for his chemical work during the war; the Jecker prize (5000 francs) between Henri Gault, for his work in organic chemistry, and Henri Hérissey, for his researches on the glucosides of plants; the L. La Caze prize to Robert de Forcrand, for the whole of his work in inorganic chemistry; the Cahours foundation between Raymond Cornubert, for his work in the *cyclo*hexanone series, and Paul Robin, for his chemical studies in relation to the war and for his work on the oximes; the Houzeau prize to the late Emile Baud, for his researches on the compounds of aluminium and arsenic and his work in the national defence.

Mineralogy and Geology.—The Fontannes prize to Olivier Couffon, for his work entitled "Le Callovien du Chalet (Commune de Montreuil-Bellay)"; the Joseph Labbé prize to Albert Bordeaux, for his applications of geology to the solution of mining problems. The Victor Raulin prize is postponed until 1921.

Botany.—The Desmazières prize to André Maublanc, for his work in mycology and plant diseases, an honourable mention to Pierre Sée, for his book on the diseases of paper; the De Coincy prize to Lucien Hauman-Merck, for the whole of his botanical work. The Montagne prize is not awarded.

Anatomy and Zoology.—The Cuvier prize to Alphonse Malaquin, for the whole of his work in zoology; the Savigny prize to F. Le Cerf, for his "Revision des Ægeriidés algériens"; the Jean Thore prize to A. Cros, for his biological studies of the Coleoptera of northern Africa.

Medicine and Surgery.—Montyon prizes to Pierre Delbet and Noël Fiessinger (2500 francs), for their memoir on the biology of war wounds, Joseph Franchini (2500 francs), for his studies on the pathogenic protozoa, and François Maignon (2500 francs), for his researches on the *rôle* of fats in the utilisation of albuminoids. Honourable mentions (1500 francs) to Henri Alezais and Albert Peyron, for their researches on the histogenesis of certain groups of tumours, to Maurice Heitz-Boyer, for his researches on the physiology and surgery of bone, and to P. Lassablière, for his studies on milk and feeding of new-born infants. A citation to Joseph Rigaut and Antoine Orticoni, for their work entitled "L'évolution de la croissance chez les adénoïdiens"; the Barbier prize to Albert Berthelot, for his chemical work on intoxications of intestinal origin; the Bréant prize between Auguste Marie and Constantin Levaditi (3000 francs), for their work on general paralysis, and Henri Violle (2000 francs), for his memoir on cholera; the Godard prize to Henry Chabanier, for his study of the numerical laws of the renal secretion; the Mège prize is not awarded;

the Dusgate prize, Jules Leclercq receives an encouragement (1000 francs) and Albert Terson an encouragement (500 francs), for work on the signs of death; the Bellion prize to Maurice Courtois-Suffit and René Giroux, for their memoir on cocaine, and an honourable mention is accorded to Jean Bec and André Pérès, for their work entitled "Mémento d'hygiène à l'usage des instituteurs de l'Afrique occidentale française"; the Baron Larrey prize to J. Peyrot, for his study on social medicine in the Bavarian Palatinate, and a very honourable mention is accorded to Flavien Bonnet-Roy and to Pierre Talon.

Physiology.—A Montyon prize to Emile Terroine, for his important work on the evolution of fatty materials in the organism; the Lallemand prize to Paul Sollier, Marius Chartier, Félix Rose, and Ch. Villandre, for their book entitled "Traité clinique de neurologie de guerre," and a very honourable mention is accorded to André Guillaume; the L. La Caze prize to Maurice Arthus, for his physiological work, especially his researches on the coagulation of milk and blood and on sero-anaphylaxy; the Martin-Damourette prize to François Heymans, for his memoir on thermo-physiology; the Philipeaux prize to Charles Dhéré, for his work on hæmocyanine.

Statistics.—A Montyon prize to Eugène Fournier, for his work entitled "Gouffres, Grottes, Cours d'eau souterrains du Départemente du Doubs," and a mention (500 francs) to Fr. M. Messerli, for his contribution to the study of physiological corporal growth between the ages of nineteen and thirty-two.

History and Philosophy of the Sciences.—The Binoux prize between Edouard Doublet (1000 francs), for his various historical publications, and Jean Mascart (1000 francs), for his book on the life and work of Jean Charles de Borda.

Medals.—Berthelot medals to Léonce Barthe, Henri Gault and Henri Hérissey, and Robert de Forcrand de Coiselet.

General Prizes.—The Bordin prize to Jacques de Lapparent, for his studies on sedimentary breccia; the Serres prize equally between Octave Duboscq and Louis Léger, for the whole of their work on protistology and general embryology; Vaillant foundation, a subvention of 4000 francs to Paul Le Rolland, for his researches on the oscillation of the pendulum; the Houllevigue prize between François Gagnepain (3000 francs), for his studies on the flora of the East, and Canon Bourgeat (2000 francs), for the whole of his geological work; the Saintour prize to Paul Bertrand, for the whole of his work on palæophytology; the Lonchampt prize to Eugène Lambling, for his researches in organic and biological chemistry; the Caméré prize to Gaston Pigeaud, for his work in civil engineering; the Gustave Roux prize, for his researches on the gases issuing from thermal springs, petroleum wells, coal-mines, etc., with special reference to determination of the rare gases and radioactivity; the Thorlet prize to Adolphe Richard, for his bibliographical work.

Special Foundations.—The Lannelongue foundation divided between Mmes. Cusco and Ruck; the Laplace prize to Charles René Drouard and Paul Maurice Ferdinand Roy; the L. E. Rivot prize between Charles René Drouard, Paul Maurice Ferdinand Roy (each 750 francs), Edmond Friedel, Léon Migaux (each 500 francs), Raymond Alexandre Auguste Fleury, Jean Lapedie (750 francs), Jean Gérard Rouelle, George Jules Lucien Couprie (500 francs).

Foundations for Scientific Research.—The Trémont foundation to Charles Frémont, for his researches on tools; the Gegner foundation to Paul Hallez, for the whole of his zoological work; the Jérome Ponti foundation to Paul Nicolardot, for his analytical researches and work for the national defence.

The Bonaparte Fund.—Out of fifteen applications eight grants were approved to the following:

2000 francs to R. Anthony, for the publication of the catalogue of the collections of osteology in the comparative anatomy section of the National Museum of Natural History.

2000 francs to Philippe Eberhardt, for his researches on the flora of Indo-China.

2000 francs to Henri Martin, for his La Quina excavations (Charente). Of the material collected the human remains are to be sent to the Natural History Museum, and other objects to the Saint Germain Museum.

4000 francs to Emile Mathias, for his researches (in collaboration with M. Kamerlingh Onnes) of the curve of densities of gases the critical point of which is near the absolute zero (hydrogen, neon).

2000 francs to Jacques Pellegrin, for his researches and publications concerning the fishes of the French Colonies.

2000 francs to Charles Pérez, for his researches and publications on the crustaceans (Epicarideæ) of the Persian Gulf.

2000 francs to René Souèges, for his work on the embryogeny of the higher plants.

2000 francs to P. Wintrebert, for his researches on the automatism of the locomotor movement in the embryos of Selacians.

Charles Bouchard foundation to Charles Vaillant, for his work in radiography.

University and Educational Intelligence.

Cambridge.—Major-Gen. the Right Hon. J. B. Seely has offered to endow a University prize for the best essay on a subject connected with aeronautics. —Mr. F. A. Potts, Trinity Hall, has been appointed demonstrator of comparative anatomy.—Regulations have now been drawn up for the Sir William Dunn professorship of biochemistry, founded under the terms of the benefaction offered to the University last summer.

Mr. A. R. Hinks, the Gresham lecturer on astronomy, will deliver four free public lectures on "The Motions of the 'Fixed' Stars" in Gresham College, Basinghall Street, E.C., at 6 o'clock on January 18 to 21.

The Camborne School of Mines, Cornwall, has issued an appeal for donations towards a memorial in honour of those members of the school who fell during the war. It is proposed to purchase a playing-field and to erect a grand stand on it, on which a memorial tablet will be placed. Communications should be addressed to the Hon. Secretary, Memorial Committee, The School of Mines, Camborne.

We have received the prospectus of the Faculty of Medicine of the University of Paris for the academic year 1920–21. It includes full particulars of the general organisation of the faculty and of the courses of instruction at the schools and clinics of the University. In addition to the regular courses various revision and advanced courses are also given, and practically all the subjects of the medical curriculum are dealt with. The pamphlet is published by Masson et Cie, 120 Boulevard Saint-Germain, Paris, VI., price 1 franc net.

It is announced that Mr. W. Edmonds and Miss S. Edmonds have founded a prize in ophthalmology in memory of their brother, Nicholas Gifford Edmonds, who fell at Magersfontein on December 11, 1899. The prize is 100*l*., and it will be awarded every two years for the best essay on a subject dealing with ophthalmology and involving original work. The competition will be open to all British subjects holding a medical qualification. A committee nominated biennially by the Medical Board of the Royal London Ophthalmic Hospital will have the adjudication of the prize.

Two Theresa Seessel research fellowships, each of the yearly value of 300*l*., are being offered in connection with Yale University for the promotion of original research in biological studies. Preference will be given to candidates who have obtained their doctorate and demonstrated by their work their fitness for carrying out successfully original research work. Applications for the fellowships, with reprints of scientific publications, letters of recommendation, and particulars as to the problems proposed by the candidates, must be sent before May 1 next to the Dean of the Graduate School, New Haven, Conn., U.S.A.

Reference was made in these columns some time ago to the Imperial College War Memorial and Athletic Ground scheme. It now appears from papers issued recently that the enterprise has received a large measure of support from friends and old students of the college and its constituent parts, the City and Guilds Engineering College, the Royal College of Science, and the Royal School of Mines. Up to the middle of November a sum of more than 6300*l*. had been subscribed, and the early response to the appeal has been sufficiently satisfactory to enable the committee not only to proceed with the erection of the memorial tablets in the college buildings, but also to complete the purchase of a sports field at North Wembley, over which an option had been secured. Some of the college clubs are already utilising the ground for the purposes of football and hockey. The further sum immediately required to cover outlay on the memorial tablets, the purchase of the ground, and necessary expenses, including payment of the mortgage, is about 2500*l*., and the committee is appealing to all friends and old students who have not yet contributed to take a hand in bringing the undertaking to a completely successful issue.

A programme of university extension lectures for the coming term has been issued by the University of London. Courses of lectures will be delivered at about seventy local centres in different parts of London and the surrounding district. The subjects treated cover a wide range, and courses in literature, history, art, architecture, and economics are included in the list; in the direction of teaching of a non-vocational character important work is being done by the Board. When, however, we remember that the report of Sir J. J. Thomson's Committee on the position of natural science in our educational system emphasised the value of lectures which bring home to the general public the meaning of science and its importance in the life of the nation, it is astonishing to note that only two courses of the ninety-nine which are advertised—one by Prof. J. Cox on "The Bases and Frontiers of Physical Science" and the other by Mr. L. Tayler on "Human Biology and Welfare Problems"—are in any way related to natural science. Prof. Cox's course of thirteen lectures will be delivered weekly, starting on January 14, at Gresham College, Basinghall Street, E.C.2; Mr. Tayler's course, consisting of twenty-four lectures, will be given on Mondays at the Technical Institute, Adelaide Road, Leyton. Particulars of the courses can be obtained from the Registrar, University Extension Board, University of London, South Kensington, S.W.7.

Calendar of Scientific Pioneers.

January 14, 1742. Edmund Halley died.—The son of a rich London soapmaker, Halley began his astronomical work at Queen's College, Oxford, at the age of seventeen, and continued it until his death at the age of eighty-five. The friend of Newton, he succeeded Wallis as Savilian professor of geometry, Flamsteed as Astronomer-Royal, and Hans Sloane as secretary of the Royal Society. His name is associated with the study of the trade winds, the variation of the compass, Halley's comet, and many fundamental points in astronomy. To his "great zeal, able management, unwearied perseverance, scientific attainments, and disinterested generosity" was largely due the publication of Newton's "Principia." Halley is buried at Lee, near Greenwich, in the same tomb as Pond, Astronomer-Royal from 1811 to 1835.

January 14, 1874. Philipp Reis died.—While teaching at Friedrichsdorf, near Hamburg, Reis in 1861 constructed a telephone which was used with good results by Hughes in 1865, but Reis died when forty years of age, poor and almost unknown.

January 14, 1890. Gustave Adolphe Hirn died.—An engineer and physicist of Alsace, Hirn was a pioneer in the scientific testing of steam-engines.

January 14, 1905. Ernst Abbe died.—Born in 1840, Abbe, while a professor at Jena in 1866, joined Carl Zeiss and devoted himself to the theoretical investigation of optical instruments. His report on the South Kensington Loan Collection of Scientific Apparatus of 1876 led to the co-operation of the glass-maker, Otto Schott, and "Jena" glass became famous the world over.

January 14, 1906. Hermann Johann Philipp Sprengel died.—Trained as a chemist in Germany, Sprengel settled in England. He made notable advances in explosives, and by his invention of the mercurial air-pump rendered possible the Swan and Edison glow-lamps, Crookes's radiometer, and the Röntgen X-ray tube.

January 16, 1806. Nicolas Leblanc died.—The discovery of how to make soda from salt was, by J. B. Dumas, compared in importance with the improvement of the steam-engine by Watt. Leblanc made the discovery in 1787, and his patron, the Duke of Orleans, erected a factory for him. In 1793 the duke was guillotined, the factory confiscated, and Leblanc's patent cancelled. After years of poverty Leblanc's mind gave way and he shot himself. A statue of him now stands in the Conservatoire des Arts et Métiers.

January 17, 1910. Friedrich Kohlrausch died.—The successor in 1895 of Helmholtz at the Physikalisch Technische Reichsanstalt, Kohlrausch was an authority in the field of accurate physical measurement.

January 18, 1878. Antoine César Becquerel died.—Becquerel served in the French Army until the peace of 1815, and then gave himself up to scientific pursuits. A voluminous writer, he was a founder of electro-chemistry, for his work on which he received in 1837 the Copley medal of the Royal Society. His statue stands at his birthplace, Châtillon-sur-Loing.

January 19, 1878. Henri Victor Regnault died.—Distinguished alike as a chemist and physicist, Regnault's great researches on the expansion of gases were made at the Sèvres porcelain factory, of which he was director, but much of his later work was destroyed during the Franco-German War.

E. C. S.

Erratum.—In last week's Calendar the year of Galileo's birth should have been 1564, and not 1571, which was the year Kepler was born.

Societies and Academies.

SYDNEY.

Linnean Society of New South Wales, October 27.—Mr. J. J. Fletcher, president, in the chair.—E. W. **Ferguson** and G. F. **Hill**: Notes on Australian Tabanidæ. The paper deals mainly with synonymy, the results being given of comparison of specimens with the types of Australian Tabanidæ in the British Museum and in the Australian Institute of Tropical Medicine. Seventeen species belonging to five genera are dealt with, one species being described as new.—Dr. A. J. **Turner**: Studies in Australian Lepidoptera: Liparidæ. In Australia the family Liparidæ is represented by sixty species belonging to eighteen genera, of which two genera and ten species are described as new in this paper.—G. A. **Waterhouse**: Descriptions of new forms of butterflies from the South Pacific. One species from Fiji and six subspecies from Fiji (three), Lord Howe Island (two), and the New Hebrides (one) are described as new.—Eleanor E. **Chase**: A new avian trematode. A species of Holostomum is described as new. The specimens described were obtained from a white-fronted heron, *Notophoyx novae-hollandiae*, at Terrigal, N.S.W.—Dr. J. M. **Petrie**: Cyanogenesis in plants. Part iv.: The hydrocyanic acid of Heterodendron, a fodder-plant of New South Wales. The foliage of *Heterodendron oleaefolia* was much used for cattle-feeding during the drought. Chemical examination of the leaves shows them to contain a cyanogenetic glucoside yielding, when hydrolysed, 0·328 per cent. of hydrocyanic acid. The plant is therefore one of the most poisonous cyanogenetic plants known, yielding more than twice as much hydrocyanic acid as bitter almonds. One ounce of the air-dried leaves forms a lethal amount for one sheep. The leaves are invariably found to be deficient in enzyme, and require the addition of emulsin in the estimation to bring about the complete decomposition of the glucoside.—Vera **Irwin-Smith**: Studies in life-histories of Australian Diptera Brachycera. Part i.: Stratiomyiidæ. No. 1: *Metoponia rubriceps*, Macquart. Very little work has been done in any part of the world on the early stages of the Brachycera; many soil-inhabiting, dipterous larvæ, mostly belonging to the Brachycera, have been collected and reared through to the imago or to the pupal stage. The present paper is the first of a series dealing with this work, and gives a detailed account of the life-history of *Metoponia rubriceps*, Macquart. It is also accompanied by a historical review of published accounts of early stages of the Stratiomyiidæ, a list of the species the earlier stages of which have been observed, and a comprehensive bibliography.

HOBART.

Royal Society of Tasmania, October 11.—Dr. A. H. Clarke in the chair.—L. **Rodway**: Additions to the fungus flora of Tasmania. Several new and interesting species of fungi were described. In his introduction the lecturer pointed out that in any community such as Tasmania, where the future largely depends upon agriculture, the study of botany was essential. It was to be regretted that up to the present this study had been absolutely neglected even at the University. Independent of the injury done by some parasitic fungi to our crops and forests, fungi were of the utmost importance to the well-being of the earth. Their principal work consists of decomposing dead vegetable matter and bringing the soil into a fit state to afford food for plant-life.

Books Received.

Survey of India. Professional Paper, No. 15. The Pendulum Operations in India and Burma, 1908 to 1913. By Capt. H. J. Couchman. Pp. 6+vi+190. (Dehra Dun: Trigonometrical Survey.) 2.8 rupees.

Medical Research Council and Department of Scientific and Industrial Research. Reports of the Industrial Fatigue Research Board. No. 5. Fatigue and Efficiency in the Iron and Steel Industry. (Metal Trades Series, No. 4.) Pp. 99+8 plates. (London: H.M. Stationery Office.) 3s. net.

Cocoa. By Edith A. Browne. (Peeps at Industries.) Pp. viii+88. (London: A. and C. Black, Ltd.) 2s. 6d. net.

Kepler. By W. W. Bryant. (Pioneers of Progress: Men of Science.) Pp. 62. (London: S.P.C.K.; New York: The Macmillan Co.) 2s.

John Dalton. By L. J. Neville-Polley. (Pioneers of Progress: Men of Science.) Pp. 63. (London: S.P.C.K.; New York: The Macmillan Co.) 2s.

Union of South Africa. Department of Mines and Industries. Geological Survey. The Geology of the Northern Portions of the Districts of Marico and Rustenburg. By H. Kynaston and Dr. W. A. Humphrey. Pp. 38. 2s. 6d. The Geology of Pondoland and Portions of Alfred and Lower Umzimkulu Counties, Natal. By Dr. A. L. du Toit. Pp. 45. 2s. 6d. Memoir No. 11. The Limestone Resources of the Union. Vol. ii.: The Limestones of Natal, Cape, and Orange Free State Provinces. By W. Wybergh. Pp. 149. 5s. Memoir No. 15. Corundum in the Northern and Eastern Transvaal. By A. L. Hall. Pp. 223+xxiii plates. 7s. 6d. (Pretoria: Geological Survey.)

South African Mammals. A Short Manual for the Use of Field Naturalists, Sportsmen, and Travellers. By A. Haagner. Pp. xx+248. (London: H. F. and G. Witherby; Cape Town: T. Maskew Miller.) 20s. net.

Diary of Societies.

THURSDAY, JANUARY 13.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—A. S. Eddington: Dr. Sheppard's Method of Reduction of Error by Linear Compounding.—W. F. Sheppard: Conjugate Sets of Quantities.—E. A. Milne: A Problem concerning the Maxima of Certain Types of Sums and Integrals.—H. J. Priestley: The Linear Differential Equation of the Second Order.—M. Kössler: The Zeros of Analytic Functions.—A. C. Dixon: The Theory of a Thin Elastic Plate, bounded by Two Circular Arcs, and Clamped.—G. A. Miller: Determination of all the Characteristic Sub-groups of an Abelian Group.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Sir William Bragg: Electrons (Kelvin Lecture).

CONCRETE INSTITUTE, at 7.30.—H. K. Dyson: Tests on High Tensile Steels.

OIL AND COLOUR CHEMISTS' ASSOCIATION (at 2 Furnival Street), at 7.30.—H. G. Clarke: The Evaluation of White Pigments: with Special Reference to White Antimony Oxide.

OPTICAL SOCIETY (at Imperial College of Science), at 7.45.—Prof. W. Salomonson: A New Ophthalmoscope.—H. Dennis Taylor: An Anastigmatic Flat Field Telescope and its Application to Prismatic Binoculars.—Inst.-Comdr. T. Y. Baker: A Note on Multiple Reflection.

HARVEIAN SOCIETY OF LONDON (at Medical Society of London) (Annual Meeting), at 8.30.—Dr. W. Hill: The Great Advances in the Investigation and Treatment of Diseases of the Œsophagus during the Present Century.

ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Informal Meeting for Free Discussion.

FRIDAY, JANUARY 14.

ROYAL ASTRONOMICAL SOCIETY, at 5.—E. E. Barnard: Hind's New Star of 1848 (Nova Ophiuchi No. 2).—W. J. Luyten: Note on the Cluster N.G.C. 6633.—Rev. J. G. Hagen: The Astrophysical Problem of Variable Stars.—C. Easton: The Distance of the Galactic Star-clouds.—J. Hargreaves: Note on the Photography of Meteors.—W. M. Smart and H. E. Green: Photographic Magnitudes and Effective Wave-lengths of Nova Cygni (1920), from Photographs Taken at the Cambridge Observatory.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.
JUNIOR INSTITUTION OF ENGINEERS (at Caxton Hall), at 8.—B. E. D. Kilburn: The Tides: Their Cause, Effect, and Use (Chairman's Address).
ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30.—Dr. R. Pickard: Variations in the Size of the Physiological Cup, and their Relation to Glaucoma.—B. T. Lang: Scotometry.

MONDAY, JANUARY 17.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—Bishop E. G. Ingham: Some Reflections on How Empire Came to Us, and Can Alone be Conserved.
INSTITUTE OF ACTUARIES, at 5.—G. King: A Short Method of Constructing Select Mortality Tables.
ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. Keith: The Principles of Craniology applied to Clinical and Racial Problems.
ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge), at 5.—Lt.-Col. E. F. W. Lees: International Aeronautical Maps.
INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents, Staple Inn Buildings), at 7.—P. Pitt and Others: Discussion on The Mental Equipment of an Engineer.
ARISTOTELIAN SOCIETY (at the University of London Club, 21 Gower Street), at 8.—Prof. G. Dawes Hicks and Others: Discussion on Space, Time, and Deity.
ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—H. C. Bradshaw: The Restoration of Praeneste.
CHEMICAL INDUSTRY CLUB (at 2 Whitehall Court), at 8.—H. E. Coley: Some Chemical and Other Notes on His Tour in Borneo.
ROYAL SOCIETY OF ARTS, at 8.—A. E. L. Chorlton: Aero Engines (Howard Lectures).

TUESDAY, JANUARY 18.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Gerald P. Lenox-Conyngham: The Progress of Geodesy in India.
ROYAL STATISTICAL SOCIETY (at Surveyors' Institution), at 5.15.—A. W. Flux: The Measurement of Price Changes.
MINERALOGICAL SOCIETY (at Geological Society), at 5.30.—A. F. Hallimond: The Olivine Group.—W. A. Richardson: A Method of Rock-Analysis Diagrams Based on Statistics.—L. J. Spencer: Identity of Trechmann's "β-tin" with Stannous Sulphide.—Dr. G. F. H. Smith: Linarite, Caledonite, and Associated Minerals from Cumberland.—Dr. G. T. Prior: The Adare and Ensisheim Meteorites.
INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—S. H. Garner: The Carbonisation of Lubricating Oils.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Capt. C. W. R. Knight: Falconry.
ILLUMINATING ENGINEERING SOCIETY (at Royal Society of Arts), at 8.—J. C. Elvy and Others: Use and Abuse of Light in Studios for Cinema Film Production.

WEDNESDAY, JANUARY 19.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. Keith: The Principles of Craniology applied to Clinical and Racial Problems.
GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. L. J. Wills and B. Smith: The Lower Palæozoic Rocks of the Llangollen District, with Especial Reference to the Tectonics.
ROYAL SOCIETY OF ARTS, at 8.—F. M. Lawson: The Future of Industrial Management.
ENTOMOLOGICAL SOCIETY OF LONDON (at 11 Chandos Street, W.1), at 8 (Annual Meeting).
INSTITUTE OF CHEMISTRY (London Section), at 8.—W. G. Young and Others: Discussion on The Institute of Chemistry: What it Can, Cannot, Should, or Should Not Do.
ROYAL METEOROLOGICAL SOCIETY (Annual General Meeting) (at Royal Astronomical Society), at 8.—R. H. Hooker: Forecasting the Crops from the Weather (Presidential Address).
ROYAL MICROSCOPICAL SOCIETY, at 8 (Annual Meeting).

THURSDAY, JANUARY 20.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. A. Harden: Biochemistry (Vitamines).
ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Sir Robert Hadfield, Bart., S. R. Williams, and I. S. Bowen: The Magnetic Mechanical Analysis of Manganese Steel.—Dr. W. S. Tucker and E. T. Paris: A Selective Hot Wire Microphone.—E. A. Milne and R. H. Fowler: Siren Harmonics and a Pure Tone Siren.—Prof. L. V. King: The Design of Diaphragms capable of Continuous Tuning.
LINNEAN SOCIETY, at 5.
ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.—Lord Montagu of Beaulieu: The Cost of Air Ton-miles compared with Other Forms of Transport.
INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—R. E. Palmer: Some Observations on Mining by the Opencast or Stripping Method.—E. A. Wraight: The Standardisation of Materials Employed in Mining and Milling Plant.—A. M. Pontie: Notes on the High-level Diamond Deposits of Brazil.
INSTITUTION OF AUTOMOBILE ENGINEERS (London Graduates' Meeting), at 8.—W. H. Wardall: Cylinder and Piston Wear.
CHEMICAL SOCIETY, at 8.—J. V. Backes, R. W. West, and M. A. Whiteley: Quantitative Reduction by Hydriodic Acid of Halogenated Malonyl Derivatives. Part I., The Amides of Sym. Dialkyl and Aryl Substituted Amides of Mono- and Di-bromomalonic Acid.—B. M. Gupta: An Investigation on the Influence of Negative Groups of Different Character on the Reactivity of Hydrogen Atoms Carried by the Same Carbon Atom. Part I.—J. Brönsted: The Influence of Salts upon the Chemical Equilibria in Solution.—H. Hepworth: The Action of the Grignard Reagent on Certain Nitric Esters.—G. T. Morgan and H. D. K. Drew: Researches on Residual Affinity and Co-ordination. Part III., Reactions of Selenium and Tellurium Acetylacetones.—G. T. Morgan and D. C. Vining: Dihydroxynaphthaldehydes.—G. T. Morgan: Ortho-chlorodinitrotoluenes. Part II.—C. K. Ingold: The Conditions Underlying the Formation of Unsaturated and of Cyclic Compounds from Halogenated Open-chain Derivatives. Part I., Products Derived from α-Halogenated Glutaric Acids.—A. Findlay and W. Thomas: Influence of Colloids on the Rate of Reactions involving Gases. I., Decomposition of Hydroxylamine in Presence of Colloidal Platinum.—M. Nierenstein: The Constitution of Catechin. Part III., Synthesis of *acacatechin*.—K. G. Naik: The Formation and Properties of Dithioketones ($R_2C{=}S{=}S$) and Dithioethers ($R_2S{=}S$). Part I., The Preparation of Certain Dithioketones and Dithioethers.—W. N. Haworth and E. L. Hirst: The Constitution of the Disaccharides. Part V., Cellobiose (Cellose).—S. H. C. Briggs: The Elements Regarded as Compounds of the First Order.—J. D. Morgan and R. V. Wheeler: Phenomena of the Ignition of Gaseous Mixtures by Induction Coil Sparks.—E. J. Williams: Chloroform Solutions of Hydrogen Chloride.—L. J. Hudleston and H. Bassett: Equilibria of Hydrofluosilicic Acid.—E. Newbery: Chlorine Overvoltages.—P. Rây and P. V. Sarkar: Compounds of Hexamethylenetetramine with Complex Metallic Salts and Acids.
RÖNTGEN SOCIETY (in Physics Laboratory, University College), at 8.15.—M. A. Codd: Increasing the Efficiency of X-ray Tubes by an Improved Design of Coil and Interrupter.

FRIDAY, JANUARY 21.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—Prof. R. S. Troup: Indian Timbers.
ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. Keith: The Principles of Craniology applied to Clinical and Racial Problems.
INSTITUTION OF MECHANICAL ENGINEERS, at 6.—H. J. Smith: The Mechanical Loading of Ships.
INSTITUTION OF ELECTRICAL ENGINEERS (at Faraday House, Southampton Row), at 6.30.—H. J. Howard: Electric Welding.

SATURDAY, JANUARY 22.

PHYSIOLOGICAL SOCIETY (at King's College), at 4.

Scientific Education in the Metropolis.

AMONG the great national problems rendered urgent by the world-war and its consequences not the least important are the highly complex questions affecting the scientific instruction of a large body of students who look to London as their educational Mecca. The matter of adjusting the diverse claims of institutions the interests of which appear to clash is rendered more perplexing and delicate by the circumstance that these establishments embody in varying degrees older policies and ideals of teaching from which it is undesirable and, in point of fact, impossible to separate the educational aims of the immediate future.

The University of London, founded by Royal Charter in November, 1836, when higher education of academic standard was a monopoly enjoyed by the older universities, but refused to many persons on the ground of sex or religious belief, represented an immense increase in the facilities for advanced instruction offered not only in the London colleges, but also in several provincial institutions.

The supplementary Charter of 1858 abolished practically the exclusive connection of the University with these affiliated colleges, and threw open the degrees to all who were prepared to undergo the prescribed examinational tests. This far-sighted development, a practical realisation of the high ideal of "la carrière ouverte aux talents," rendered the University increasingly the *alma mater* of the student whose scanty opportunities for self-improvement compelled him to make use of whatever adventitious aids to education were available within his immediate surroundings.

The University of London Act of 1898, in recognising again the principle of an intimate connection between the University and the principal teaching establishments of the Metropolis, gave a dual aspect to the work of the University, which henceforward had an internal, as well as an external, side to its activities. The dual system is not without difficulties, and at one time it seemed likely that extreme advocates of the internal side would succeed in abolishing the older external side. This step, however, which is less probable now than it was a few years ago, would have extinguished the most characteristic function of the University as an "Imperial institution granting degrees and honours to all comers on condition of examination only."

It is significant of this Imperial aspect of the University's work that in recent years examinational centres have been established in Ireland and Ceylon of which increasing advantage is being taken by the students in those islands. The beneficial effect of this policy is too obvious to need emphasis. The young Irish or Ceylonese graduate, subjected as he probably is to the propaganda of a separatist movement, will view this insidious appeal to his insularity from a somewhat different angle after his affiliation with the metropolitan University; at an impressionable age he will have learnt to think Imperially.

The teaching institutions offering facilities for graduation on the internal side are the three incorporated foundations (University, King's, and the Goldsmiths' Colleges), together with other teaching establishments registered as schools of the University. In addition there are the polytechnics, controlled by the London County Council, which are institutions having recognised teachers, who may arrange their curricula in accordance with the University requirements; students of such courses form an important section of the internal candidates.

The Department of Science and Art, which for many years encouraged the study of science by a national system of examinations and scholarships, provided also higher systematic training and laboratory instruction at the Royal College of Science, with which was incorporated the Royal School of Mines. These two Governmental colleges formed the nucleus of the Imperial College of Science and Technology, which came into being in 1907 by the amalgamation under one governing body of these establishments and the Central Technical College, founded by the liberality of the great Livery Companies acting together through the City and Guilds of London Institute for the Advancement of Technical Education. The Imperial College, which became a school of the University, has since extended the scope of its work by the establishment of several new departments, and, having made good in these varied activities, especially during the war period, now presents itself as a formidable rival of the University in appealing for statutory powers to confer degrees on its *alumni*. In this claim to recognition as a university of technology, the Imperial College points to the established reputation of its staff and the admittedly high standard of its teaching, to the honours gained by its students in the University examinations, and to the scientific interest attaching to the investigations pursued in its research laboratories. From the point of view of the Imperial College, the University examinations are an unnecessary incubus, requiring from their students in November examinational tests precisely similar to those which these candidates passed successfully in the preceding June, sometimes under the inspection of the same examiners.

In order to appreciate the position of the University in the light of this objection, it is desirable to recall the changes which have occurred during the last two or three decades in the regulations relating to degrees in science. Formerly, candidates for the intermediate examination in science were required to qualify not only in mathematics, physics, and chemistry, but also in biology, the requirements in the last-named science being of a generalised but practical character. Moreover, candidates for the B.Sc. with honours were required first to qualify for the pass B.Sc. by examination in any three of the sciences, after which they could present themselves for honours in one or more of the three selected subjects. The effect of these older regulations for the intermediate and pass examinations was to encourage the attainment of a wide knowledge of science and to counteract the evil of premature specialisation.

At present the training in biology has disappeared entirely except for those who wish to specialise in this direction. The broad basis of a knowledge of three sciences is maintained only for those B.Sc. candidates whose natural modesty or lack of self-confidence prevents them from aspiring to the honours standard, where one principal science and one subsidiary subject only are required. The present B.Sc. with honours is in reality a lower measure of comprehensive scientific scholarship than the pass degree; it is largely a degree in physics, chemistry, zoology, or some other single branch of science. The substitution of narrow specialisation for broad scholarship in its science degrees has left the University in this respect with no effective reply to the criticism of the Imperial College. Nevertheless, if the graduate in technology is to be not merely a capable technologist, but also a well-informed member of an enlightened democracy, he will need to learn many things not contained within the purview of a degree in applied science, and it is the proper function of the University to provide him with facilities for acquiring this wider and more liberal education.

On the other hand, the Imperial College cannot hope to establish, and still less can it expect to maintain, a monopoly in applied science. Many teachers of the affiliated schools of the University have in the past made notable contributions to the improvement of industry, and, given adequate facilities for unfettered research, such successes will certainly recur even more frequently in the future. It would be nothing short of a calamity if the tendency towards concentration of educational effort should lead, for example, to the extinction of the Finsbury Technical College, the oldest school of technology in London, which, founded in 1878 by the City and Guilds of London Institute, and developed along original lines by an inspiring band of teachers, including Ayrton, Armstrong, Meldola, Perry, and Silvanus Thompson, has a record of scientific achievement not less meritorious than that of any other college in the metropolitan area. The contemplated closing of this college illustrates one of the risks of over-centralisation; for, while it is vitally important to establish institutions giving the highest specialised instruction and providing the fullest equipment for the most advanced training and research in science, yet due regard must be paid to the claims of the other less pretentious scientific colleges and institutes situated in the various metropolitan boroughs, since these more localised establishments play an important twofold part, first in supplying scientific students sufficiently trained to profit by post-graduate work, and secondly in bringing university teaching within easy reach of the inhabitants of their respective districts.

General Dynamics.

Higher Mechanics. By Prof. H. Lamb. Pp. x+272. (Cambridge: At the University Press, 1920.) Price 25*s.* net.

WE have here, as was to be expected from its author, an excellent statement and explanation of the principal theorems of what may properly be called higher dynamics. Prof. Lamb's title is "Higher Mechanics," which is in accordance with the usage which obtained before the appearance of Thomson and Tait's "Natural Philosophy." In his preface to the "Principia," Newton says: "Mechanicam vero duplicem veteres constituerunt, rationalem, quæ per demonstrationes accurate procedit, et practicam." Thus Newton uses the word "mechanica" qualified by the adjective "rationalis" in the sense of "scientia motuum qui ex viribus quibuscunque resultant," the science of the motions of bodies. The point is not one of great importance, but we prefer with Thomson and Tait the name "dynamics" for the whole science of rational mechanics.

The book begins with chapters on the kinematics of a rigid body, in which degrees of freedom, displacements of a rigid body, and theorems regarding these are very clearly explained and illustrated. Then follows a chapter on statics, in which the usual theorems are set forth, with a short but adequate account of the theory of screws. A treatment of moments of inertia is given which, perhaps, might with advantage have been fuller. Binet's theory of plane quadratic moments is included, while his theorem that the principal axes of inertia at any point P are the normals to the three quadrics which are confocal with the central ellipsoid of gyration, and which intersect at P, is not attributed to its author. The subject of plane quadratic moments does not seem of any but a purely mathematical interest, and one rather grudges the page devoted to it in this brief chapter.

After a chapter on instantaneous motions, we are led on to the equations of motion of a rigid body, with reference to a system of moving axes, which finally, when the body turns about a fixed point, is identified with the principal axes of moment of inertia passing through the fixed point. In connection with the equations of motion for this case—Euler's equations—which are of the form

$$A\dot{p}-(B-C)qr=L,$$

the usual statement is made that the equations may be written:

$$A\dot{p}=L+(B-C)qr,$$

and that then the quantities typified by $(B-C)qr$ are referred to as the components of a "centrifugal couple." This couple is quite rightly designated "fictitious"; but, apart from the lack of reality which afflicts it, its introduction seems undesirable. To speak of these quantities as "centrifugal couples" seems a perfectly artificial, unphysical, and almost unintelligible mode of regarding the matter. Centrifugal couples are worse than centrifugal forces, those unrealities against which Tait used to fulminate vehemently.

What one wants to convince the student here is that $A\dot{p}$ is not the whole rate of growth of angular momentum about the fixed axis, with which the principal axis at the instant coincides, and must be supplemented by the rate of growth $-(B-C)qr$ which exists in consequence of the motion of the axes. The whole rate of growth is $A\dot{p}-(B-C)qr$, and there is no ray of light thrown on the subject by carrying the second part from its proper place to the other side of the equation and calling it a couple. The use of "centrifugal couples" is justifiable only when the action of, or reaction on, an axis is in question.

We hope that we shall not be misunderstood. Of course, Prof. Lamb is perfectly aware of all this; but our point is that, as the question is one of getting correct ideas into the minds of students, this venerable and "Through the Looking-Glass" mode of referring to these terms would be better forgotten. Students, and even some writers, are all too prone to suppose that the component growths of angular momentum are $A\dot{p}$, $B\dot{q}$, $C\dot{r}$, and the equations are naïvely written as $A\dot{p}=L$, etc.

It is, by the way, very important, and very easy, to take the terms $A\dot{p}$, $-Bqr$, Cqr, and show how *each* of them arises.

We miss here what is certainly very instructive: the application of the hodograph to the motion of a rigid body—for example, a top. A sequence of vectors all drawn from a point O is erected in space to represent the successive values of the resultant angular momentum. The curve in space on which lie their extremities is the hodograph for the rigid body motion, and the resultant couple at each instant is represented by the velocity of a point which moves so that it is always at the extremity of the vector which at the instant represents the angular momentum.

In connection with holonomous systems, the only reference is to Hertz, though the fact that there are systems which are not holonomous for which Lagrange's dynamical method "fails," and which require special treatment, was pointed out by Ferrers long before Hertz's treatise appeared.

The paper of Ferrers (*Q.J.M.*, vol. xii., 1873) appeared six years after the publication of Thomson and Tait's "Natural Philosophy," but it is curious that there is not in the second edition (1883) of that treatise any hint of the existence of the peculiar systems of which Ferrers gave examples. In his review of the second edition of the "Natural Philosophy" (NATURE, vol. xx., 1879), Clerk-Maxwell, in his own inimitable way, directed attention to the introduction in that work of the method of Lagrange. "The two northern wizards were the first who, without compunction or dread, uttered in their mother tongue the true and proper names of those dynamical concepts which the magicians of old were wont to invoke only by the aid of muttered symbols or inarticulate equations." The spell of the "northern wizards" was not free from defect, but either their good fortune or their instinct preserved them from the examples in which the use of an incantation insufficiently guarded in its terms might have led to disaster.

This has not been the fate of every wielder of the magic wand of Lagrange. In the first issue, about twenty years ago, of an important treatise on "Rational Mechanics" a discussion of the motion of a coin rolling and spinning on a horizontal table appeared, in which the method of Lagrange was used with erroneous results. The error led the distinguished author to the invention of a new method, in which a set of general dynamical equations, which could be used instead of those of Lagrange, and were applicable in all cases, was set up. The error thus had the fortunate effect of enriching dynamical science. It is not, alas! the fate of all who make mistakes to rise on the stepping-stones of their errors to higher and better things.

In our opinion, recourse is had to the method of Lagrange in far too many cases. The student flies to it on the appearance of the least difficulty. A proper training in dynamics, which should be experimental as well as mathematical, would give students the power of solving problems of all kinds by the direct application of first principles. The use of Lagrange's equations does not develop this—indeed, it has a directly contrary effect. In this power the dynamical students and graduates of our universities are sadly deficient.

A good account of Lagrange's method is followed in Prof. Lamb's book by an exposition of Hamilton's dynamical method, and this in its turn leads to Jacobi's discussion of the integration of Hamilton's canonical equations by means of the complete integral of Hamilton's partial differential equation fulfilled by his so-called principal function S. The corresponding function S' connected with S by the relation $S+S'=\Sigma(pq)$ does not seem to be mentioned. A partial differential equation similar to, and yet curiously different from, that for S also holds for it. S is a function of the qs, t, and as many constants, which depend on the initial co-ordinates of the system, as there are independent co-ordinates; S' is a function of the ps, t, and the same number of constants as before, which, however, depend on the initial motion.

One or two examples of the solution of these partial differential equations—for example, Jacobi's discussion of the elliptic motion of a planet referred to three co-ordinates—would have added to the interest of what is in itself a very interesting chapter of an excedingly interesting book.

A. GRAY.

Maya Civilisation.

The Inscriptions at Copan. By Sylvanus Griswold Morley. (Publication No. 219.) Pp. xii+643+33 plates. (Washington: The Carnegie Institution of Washington, 1920.)

IN this large quarto volume of more than six hundred pages, efficiently illustrated, Dr. S. G. Morley has produced a work which may justly be regarded as of the highest importance. It is necessary to enforce this statement, almost with a feeling of shame, because there are so few individuals in this country who have the faintest idea what enormous strides have been made in the elucidation of Central American archæological problems since our own countryman, Dr. Maudslay, published the results of his explorations in a series of volumes, which Dr. Morley generously, but no less justly, describes as "easily the most important field contribution to Maya archæology." Those volumes might have been expected to give a lead to British archæologists and explorers; as a matter of fact, not only did no one appear in this country to carry on Maudslay's work, but the fine series of moulds of the principal Central American carvings, which he made at the cost of enormous labour and expense, lie buried in the cellars of the Victoria and Albert Museum, and not even an approximately representative series of casts taken from them is available to British students.

It follows that such a work as this is almost the despair of the reviewer. Most people have heard of the Aztec, but the earlier Maya civilisation is familiar to few even by name. Yet the Maya had evolved a remarkably fine art, an elaborate hieroglyphic script, and a very highly developed calendrical system long before the first manifestations of culture made their appearance in the Valley of Mexico. To render a full appreciation and critique of Dr. Morley's book intelligible to the general reader, it would be necessary to write an introduction to Central American archæology; to deal with it from the purely scientific point of view is impracticable within the limits of an ordinary review, so many and important are the problems which the author raises. It is possible, therefore, to give only the merest sketch of the subject-matter, and to add a few remarks on the author's method of handling his material.

The early Maya settlements are found scattered throughout the forested region of Chiapas, eastern Guatemala, western British Honduras, and northern Honduras. It is clear that they had already been abandoned and veiled in thick jungle before the arrival of the Spaniards. The group with which Dr. Morley deals is situated in Honduras, in the valley of the Copan River, and covers a site of 30–35 sq. km. The ruins consist of sculptured monolithic *stelae* and "altars," temples, pyramids, "plazas," and a great complex, known as the "main structure," which exhibits evident signs of growth by accretion through many years. The site, apart from its architectural and artistic importance, is of paramount interest from the fact that it includes by far the greatest number of dated inscriptions, about 40 per cent. of those recorded for the whole of the Maya area, indicating that the "city" was in continuous occupation for about 350 years. It is the inscriptions which constitute the principal theme of the book, and the author has dealt faithfully with every inscribed monument, not only discussing the content of every inscription, but also giving a bibliography of each.

With regard to these inscriptions a word of explanation is necessary. The only portions which can be read with certainty are those connected with the Maya system of reckoning time. As much as 50 per cent. of the entire *corpus* of these inscriptions deals with calculations relative to the calendar; the rest are probably religious, with, perhaps, a small proportion of what may be historical data. But, while dated monuments may thus be arranged in sequence according to Maya chronology, no indisputable method has yet been reached of correlating that chronology with European time. Dr. Morley, in a very scholarly appendix, makes the attempt. His views are of particular interest to the present reviewer, who, some years ago, was rash enough to put forward a scheme on similar lines, producing, however, different results. At the same time, Mr. Bowditch, one of the greatest pioneers in the interpretation of Maya glyphs, working on other evidence, came to the same conclusion. Dr. Morley's theory would make the Copan monuments date from about the close of the second century A.D. to the early part of the sixth century, about 250 years later than the dating of Mr. Bowditch and the reviewer. Dr. Morley's argument does not carry absolute conviction to the reviewer; but discussion is perhaps unnecessary. The author gives good *prima facie* evidence that a certain group of glyphs, which accompanies the so-called "initial dates," relates to eclipses of the sun and moon. With this lead these glyphs should soon be deciphered, and the question will then be capable of proof on astronomical grounds. In this connection it might be mentioned that Dr. Morley has apparently overlooked, in his otherwise excellent bibliography, two papers by Mr. Richard C. E. Long dealing with the correlation of Maya and European time, which were published in *Man* during 1918.

The origin of the Maya civilisation is also closely argued by Dr. Morley in a well-written appendix, but here he lays himself open to criticism. His theory that the Maya came from the region of the Panuco Valley in the north is well argued on general grounds, but he certainly lays too much stress on dates which have been found on two small objects—the Tuxtla statuette and the Leyden plate. Considering the ritual and mythological importance of certain calendrical dates in the Maya religious system, it is impossible to regard specimens of this class as belonging to the same category as monuments which are so obviously commemorative as *stelae*, altars, and the like. The Tuxtla statuette, which bears almost the earliest date known in Maya chronology, he accepts as belonging to the area where it was found—*i.e.* considerably to the north of the "classical" Maya area—in spite of the fact that the glyphs are carved in the same style as the Dresden manuscript, which is recognised as belonging to a later period than the Copan monuments. The Leyden plate, which is carved in the earlier style, and was found in the southern Maya region, he assumes, is a specimen which has "wandered"—a hypothesis which he dismisses in connection with the Tuxtla statuette. This savours of "having it both ways," and his theory would have gained strength had he admitted that portable objects such as these are really *hors concours* as regards local dating.

One mistake—and that really of relative insignificance—may be recorded. Dr. Morley states that the few original monuments brought from

Copan to England by Maudslay, such as Altar R and part of the frieze of Temple II., are in the Victoria and Albert Museum. As a matter of fact, all the original sculptures collected by Maudslay were transferred to the British Museum shortly after their temporary deposition at South Kensington.

In conclusion, Dr. Morley's work is scientific and scholarly. As a scientific man and a scholar he aimed at perfection; he has achieved a landmark. Can higher praise be given?

T. A. JOYCE.

The History of Determinants.

The Theory of Determinants in the Historical Order of Development. By Sir Thomas Muir. Vol. iii., *The Period* 1861 *to* 1880. Pp. xxvi+503. (London: Macmillan and Co., Ltd., 1920.) Price 35*s*. net.

THE period covered by this volume is perhaps the most important in the history of the subject. During that time three important branches of pure mathematics attained vast dimensions—invariant-theory, analytical geometry, and the general theory of algebraic numbers. In each of these, familiarity with determinants and their manipulation is essential, so a great many students mastered the determinant calculus, and applied it to a variety of problems. Incidentally, the properties of determinants aroused interest for their own sake; numerous papers dealing with them were published, and, above all, several treatises on the subject made their appearance, in which a compact notation replaced all the old cumbersome symbols, and practically all the theorems of the determinant calculus proper were expounded in a simple and orderly way.

What we may call the derivative part of the theory consists mainly of classifying determinants of special types. Thus in the present volume we have separate chapters on axisymmetric determinants, symmetric determinants, alternants, recurrents, Wronskians, Jacobians, etc. (sixteen chapters or so). Broadly speaking, these types come from two sources—either as the outcome of a particular research, not primarily concerned with determinants (thus continuants arose from the theory of continued fractions); or else from intrinsic characters belonging to the array from which the determinant is formed, as in the case of symmetric determinants. Of course, any special type of determinant can be specified *per se*; we are thinking rather of the way in which the discussion of particular types actually originated. A remarkable example is Smith's arithmetical determinant (p. 116), of n rows and columns, the value of which is the product $\phi(1).\phi(2) \ldots \phi(n)$, where $\phi(m)$ means the "totient" of m—namely, the number of integers prime to m and not exceeding it.

In a book such as this, one feature is almost sure to present itself. We shall find some excellent work unaccountably neglected, and results of first-rate importance only becoming generally known and appreciated after re-discovery, when their original authors are dead. The cases in this volume which strike the attention are those of Trudi and Reiss. Reiss's work on compound determinants goes back as far as 1867; the analysis of it on pp. 181–90 (in modern notation) shows its importance, and is worth study, because the theory of compound determinants is perhaps the one part of general determinant-calculus not yet fully reduced to its complete and simplest form.

In many applications the rank and elementary divisors of a determinant (or matrix) are of primary importance. The elementary divisors of an array depend upon the arithmetical or algebraical character of the field to which the elements of the array belong. Consequently, the determination of them does not properly belong to determinant-theory; on the other hand, the rank of an array is immediately calculable, on the assumption that we can calculate the "value" of any minor determinant, or, at any rate, decide whether it is or is not zero. It must often have been difficult for the author to decide when a theorem in matrices should or should not be considered one relating to determinants. Rank is referred to several times; apparently theorems about elementary divisors have been omitted. In the case when the elements of an array are ordinary integers it is clear from Smith's paper on linear indeterminate equations and congruences (1861) that he was then perfectly familiar with the existence and properties of elementary divisors; to that extent he anticipated the theory of Weierstrass, Frobenius, and others.

Opinions may differ about Sir T. Muir's choice of a subject on which to bestow his labour; some readers may regret that he did not select a branch of mathematics of a less circumscribed and subsidiary kind than determinant-theory undoubtedly is. But all will agree in admiring the ability and impartiality with which this labour of love has been accomplished, and rejoice to know that the fourth and final volume is nearly complete in manuscript. Histories of other branches of mathematics are badly wanted, and this work is a model of what such histories ought to be.

G. B. M.

Science and Farming.

(1) *The Small Farm and its Management.* By Prof. James Long. Second edition. Pp. 328. (London: John Murray, 1920.) Price 7*s*. 6*d*. net.

(2) *Farm Management.* By J. H. Arnold. Pp. vii+243. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1919.) Price 7*s*. 6*d*. net.

(3) *Types and Breeds of Farm Animals.* By Prof. C. S. Plumb. Revised edition. (Country Life Education Series.) Pp. viii+820. (Boston and London: Ginn and Co., 1920.) Price 16*s*. 6*d*. net.

(1) PROF. LONG is a well-known believer in small farms, and has written much to help the men who embark on such enterprises. In the present volume he brings together in convenient form a great deal of the information which the small farmer ought to possess if he is to make his work a success. At the outset he disclaims any intention of deluding his readers into the belief that fortune awaits the small holder. The 20-acre farm, he says quite frankly, will not bring much money, though it will provide a healthy occupation full of interest to those who really do their best. In the main, the scheme proposed is the production of finished products—milk, pork, poultry, or mutton. Corn scarcely enters into consideration excepting only to provide oats for the farm stock.

The information given is useful so far as it goes, but we should like to have seen some references to other books which would give fuller information on specific points. The idea of rural libraries is growing, and the present deficiency may not always exist. On such points as the feeding of animals an intelligent man might easily like more information; the latest author quoted is Wolff, and no reference is given to Dr. Goodwin's translation of Kellner's book.

Similarly, reference might have been made to the system of advisory officers now established over the country, whose function it is to deal with the questions an intelligent man asks, but which no book ever seems to answer. In spite of these minor defects, however, the smallholder will find this a useful book, both before and after he enters his farm.

(2) Mr. Arnold's is a different type of book; it deals with the principles of farm management so far as they have been enunciated, and though it is only small and printed in large type, it contains much that will interest the farmer as well as the student of agriculture. It is American; we know of no corresponding English book; and the figures quoted all refer to the pre-war period. An inquiry is recorded as to the rate of interest earned on farms in three States of the corn belt: for "landlord's" expenditure (which includes much of our "farmer's" expenditure) the annual return was 3½ per cent., and in an exceptionally good region 5⅛ per cent., after allowing 800 dollars for management salary; this, the author states, "probably represents about what the best general farms are doing." An interesting historical summary traces the development of American agriculture during the last 300 years, and shows that American farm practice is largely derived from English agriculture, modified, however, by the experience of the Indians. Livestock, poultry (excepting turkeys), most of the common grains, vegetables, grasses, and legumes all came from England, as also did the principles underlying the cultivation of the soil and the rotation of crops. It would be interesting to work out the interrelationships of British and American agriculture, for, if American agriculture developed from ours, British agriculture in the last twenty years owes a great deal to America.

(3) Prof. Plumb's book on "Types and Breeds of Farm Animals"—also American—brings out prominently the part played by the British Isles in the evolution of modern types of farm animals; the author draws a map showing the areas in which no fewer than twenty-eight important types were first bred. These have now gone out to all parts of the world, but buyers still come here to replenish their stocks.

The book gives probably the best account published of modern farm animals, and there are good illustrations of many of the best examples to be found to-day. Another very interesting feature is the history of the families which the author has diligently worked out; the leading families in America date back to about 1880, although in England they are much older. Pedigree is more important to a high-class cow than to a human being, and no animal without a clear record can enter the highest bovine circles. The best foreign buyers insist on a pedigree going back a good many years—a great advantage to the English breeder. But the records of the animals described by the author in America show that the American stockman is doing great things, while the book itself proves that the younger generation of American agricultural experts is thoroughly familiar with the characteristics of the breeds and with the uses to which they can be put. It is a book to make the British agricultural lecturer think.

E. J. R.

Our Bookshelf.

Animal Ingenuity of To-day. By C. A. Ealand. Pp. 313. (London: Seeley, Service, and Co., Ltd., 1921.) Price 7*s.* 6*d.* net.

MR. EALAND describes in a lively way the ingenious or apparently ingenious behaviour of a great variety of animals, and we strongly recommend his book of wonders to the young in years and to the young in spirit. It deals with such matters as the humble-bee's nest, the wasp that uses a little pebble for beating down the soil closing the entrance to its burrow, the animated honey-pots of the honey-ants, the aquatic beetle that taps the water-lily's store of air, the male water-bug called Zaitha, which is made to carry the eggs, and the male cuckoo's abetting of his "paramour's" foisting of her egg into another bird's nest, for he takes advantage of his likeness to a sparrowhawk to distract attention from the "nefarious" deed. This case of "mimicry" takes our breath away, and we must rest awhile. But Mr. Ealand's book is extraordinarily interesting, though he is sometimes not critical enough. There is a good account of birds' nests and eggs, though we do not believe in the woodcock's "all-too-conspicuous eggs." With the usual withered leaves around them they do not seem to us to be conspicuous at all. Of courtships, migrations, modes of hunting, engineering triumphs, parental care, and of the whole gamut of animal behaviour, Mr. Ealand has vivid illustrations to give, and we should like it all, both old and new, without reserve, if he were a little more careful. Let us give one example. As he himself says: "Friendship between a crab and a pond-mussel seems to savour of the improbable," and we should think it did, for, friendship apart, the pea-crab in question lives in the sea. We have referred to credulity and inaccuracy, but we must make another criticism of what, after all, we regard as a wholesome book. Is it right and proper to quote long passages within inverted commas without telling us who wrote them? The illustrations of the book are very clever.

Prospector's Field-book and Guide. By H. S. Osborn. Ninth edition, revised and enlarged by M. W. von Bernewitz. Pp. xiii+364. (London: Hodder and Stoughton, Ltd., 1920.) Price 12*s.* 6*d.* net.

A QUANTITY of new material has been added to this handbook since the last edition was published in 1910. Some of it, particularly those portions referring to the description of ore deposits and ore-testing, has been drawn from the bulletins of the United States Geological Survey and the Bureau of Mines, and various publications of schools of mines and the technical Press. Other additions which have been made are lists of outfits suitable for prospecting, fresh field tests, notes on sampling, and a new chapter dealing with alloy minerals. In face of the claim that the new edition is thoroughly up-to-date, it is curious to find "chloride of formyl" given in the appendix as the chemical name for chloroform. A glossary of more than twenty pages gives brief explanations of the technical terms in use, and, in addition, a very full index is provided.

Dictionary of Explosives. By A. Marshall. Pp. xiv+159. (London: J. and A. Churchill, 1920.) Price 15*s.* net.

THIS book is essentially a work of reference for the specialist in explosives, and has little interest for the general reader. It consists of three sections. The main section is descriptive, and arranged alphabetically. This is prefaced by a list of explosives classified according to the uses for which they are intended, and followed by a list of the separate ingredients showing the explosives in which each is used.

In the dictionary the composition and some of the properties of a large number of explosives are given, including many of foreign origin, but only those explosives are dealt with which are, or have been, in practical use in the industries. It is easy to see that the author has been handicapped by the reticence of explosives manufacturers with regard to the composition of their products, only about half the authorised explosives mentioned in the 1914 Annual Report of H.M. Inspectors of Explosives, for instance, being described. For the same reason, many of the descriptions lack the detail desirable in a work of this kind.

A considerable amount of useful and accurate information is, however, presented in a compact and handy form. The book is well printed and free from typographical errors.

W. L. TURNER.

Report on the Quantum Theory of Spectra. By Dr. L. Silberstein. Pp. iv+42. (London: Adam Hilger, Ltd., 1920.) Price 5*s.* net.

THIS small and unpretentious work is one of great value. Many important developments in the application of the quantum theory to spectra, especially to the fine structure of spectrum lines, have taken place during the last few years, and these are almost entirely due to workers in other countries. The literature of the subject is very inaccessible to English readers, who find it difficult to obtain any real idea of the fundamental advances which have been made, or of the logical suppositions on which such advances rest. Dr. Silberstein would have done good service if he had only collected together the original papers, in translation, as they stand. He has, however, done much more. The matter is presented as an orderly scheme, and great discrimination has been shown, so that there is nothing of real importance omitted from the work. At the same time, the author has modified the original treatment in many respects, and apparently always to its advantage. The work is especially noteworthy in that it gives a clear view of the problems which still await solution. We can give nothing but praise to this book, and can recommend it without reserve to those who are anxious to have a simple and not very mathematical account of a subject which is now fundamental in physical theory.

Smithsonian Physical Tables. Seventh revised edition. Prepared by F. E. Fowle. Pp. xlvi+450. (Washington: Smithsonian Institution, 1920.) Price 18*s*. net.
