ABSTRACT

The output from a conventional laser is a spontaneous burst of radiation which lasts about one microsecond. If now the reflectivity of one of the two "mirrors" in the system is controllable, it is possible to develop laser system conditions which permit the generation of high peak-power pulses with a pulse width of about 30 nanoseconds. Such a system utilizes the principle of regeneration modulation and has been successfully applied to the production of single high peak-power pulses. A natural step then is to utilize this method to generate a series of repetitive "giant" pulses.

This report describes the electronics equipment developed to assist in producing such pulses at a 10 kc pulse repetition frequency. The approach used represents a first attempt towards an effective means of obtaining controlled high-powered laser pulses.

r.f.	radio frequency
cm	centimeter

1. Introduction

    Since the first operating laser was introduced by T. H. Maiman in

1960 /5,6/ a great deal of effort has been directed by physicists and

engineers toward understanding and improving the characteristics of

this device. In the past few years it has become readily apparent that

the harnessing of the tremendous potential that the laser unquestionably

possesses will prove to be a great asset to both science and industry.

Already the laser has made an impact comparable to that made by

electron tubes and semiconductor devices, even with its true versa-

tility not yet fully exploited, and perhaps not completely known.

However, in the strides that have been made, a technique for improving

the utility of the laser beam output has resulted. Less than two years

ago an optical switching technique was proposed by McClung and

Hellwarth /1/ of Hughes Aircraft Company, which "compressed" a

great deal of the total energy inherent in a conventional laser pulse

into one "giant" pulse. In this fashion, the characteristic low-energy

sporadic output of uncontrolled "spikes" of the conventional laser, as

shown in Figure 1-a, was modified so that intense and very narrow

pulses of radiation were emitted by the same material. (See Figure 1-b)

To date these giant pulses have been generated by the sudden change

of the regeneration characteristics of a laser cavity whose active

medium is chromium-doped sapphire (ruby). The system which gen-

erates these high peak-power pulses has been called the Giant Pulse Laser or Pulsed Reflector Laser[1] and the principle of operation is based on the fact that materials which laser in the conventional configuration can be caused to emit fast, intense pulses. Figure 2 shows the arrangement used by McClung and Hellwarth in their first experiments. It was similar to the usual laser configuration except that a voltage-controlled Kerr cell /15/ was physically introduced between one end reflector and the ruby. The flash lamp was first fired in order to bathe the ruby in white light. Inversion commenced to a higher energy level (see Figure 3) and when the voltage applied to the Kerr cell was quickly pulsed off, the back reflector was effectively introduced into the optical path thereby permitting the "Q" of the laser cavity to be enhanced and allowing regeneration of the red light beam. Instantly, a single high peak-power pulse was emitted. Characteristically this pulse was about 30 nanoseconds wide and had a peak of about 14 megawatts.

The optical configuration of Giant Pulse Lasers has since been improved by the addition of a Wollaston prism[2] /15/. Figure 4 dis-

---

[1] There exists another technique for generation of high peak-power pulses. It is called the Hair Trigger Mode. See References /2,7/.

[2] The Wollaston prism is not essential but improves the system operation in that regeneration can be achieved on all passes through the ruby and not on just alternate passes as when no prism is in the system.

plays the arrangement of all the essential optical pieces. Each is supported firmly in its specially built holder and mounted on a firm base. After the flash lamp is fired, the Kerr cell is held "on"[3] to permit the ground-level ions to be "pumped" until a high inversion ratio is first achieved. Thus, stimulated emission is restrained until the Kerr cell voltage is removed electronically permitting the Cr^{+3} ions to be then triggered to "fall" together to the ground state. The released energy is emitted as a single narrow pulse of intense radiation of very short duration. The result is known as a "giant" pulse.

A simple calculation can be made of power out which is indicative of the future utility of this system. Assume an output pulse containing one joule of energy--a realistic choice. If this amount of energy is emitted in about 33 nanoseconds, as usually occurs, the power out is 30 megawatts. The state of the art as of the period of the writing of this paper, has exceeded this output. It then becomes apparent that the high peak-power feature offered by the Giant Pulse Laser has a realistic and practical application. The technique described--which is also called regeneration modulation--has an

[3] "On" implies that the quarter-wave voltage is applied to the plates and the polarization characteristics of the entire system is such as to prevent lasering.

obvious extension. With proper electronics circuitry so designed to
pulse the Kerr cell off repetitively it should be possible to develop
a series of such pulses at equally spaced intervals--contingent, of
course, upon how long the flash lamp can continue to bathe the ruby
in white light.

It was proposed that the author attempt to design a pulser (or
modulator) that could force the Kerr cell on and off at a controllable
repetition frequency. The objective of this paper, therefore, is to
present an explanation of the design of the modulator which was
finally used to generate repetitive giant pulses and to disclose the
overall results obtained from both the designed pulser and the ruby
output.

2. Design Of The Kerr Cell Modulator /8,9,11,12,13,14/

As described previously, generation of giant pulses is based upon an important factor, that of suitably switching the Kerr cell from a condition of high voltage to one of essentially less than 1/10 of this level--or, equivalently, a condition of incomplete transmission to one of complete transmission. A 10 kilovolt Kerr cell was used as the criterion in the design of the high voltage modulator. Thus the circuitry required, had to reduce the Kerr cell voltage instantaneously from 10,000 volts to less than 1,000 volts.[4]

The following criteria were used as a basis for the design. They were somewhat arbitrary in that the full requirements and the effect such a design would have on a Giant Pulse Laser had not previously been ascertained.

      (1) 10 kc or higher repetition rate

      (2) ≈ 10 kilovolt pulse height

      (3) Less than 50 nanosecond rise time

      (4) Fall time not critical

      (5) Pulse width from 200- to 400- nanoseconds

      (6) Variable pulse width, if possible

The following pulser waveshape was offered as a suggested goal:

[4] It was found experimentally that the Kerr cell was completely "on" when anything less than 5,000 volts was applied to its plates.
The charge-time back to 10 kilovolts was not critical as long as

the 10 kilovolt level was reached within the stated 100 microseconds.

When the initial specifications were proposed one important fea-

ture was brought to the attention of the author. It was known that an

initial pumping-time interval of about 200- to 500- microseconds was

required during which the chromium ion population was raised to a

high energy level. /3/ It would be necessary to restrain the pulser

from pulsing the Kerr cell during this period. After satisfactory in-

version resulted, lasering could occur. If the Kerr cell was then

triggered "off" the first single giant pulse should result. Preparation

to repeat the cycle would then be a matter of turning the Kerr cell

back "on" while the flash lamp was still emitting light. As long as

the flash lamp was on, any controlled repetitive pulsing of the Kerr

cell should permit well-spaced laser emissions. It became apparent

that, to be really effective in controlling the giant pulse laser output,

the modulator had to commence pulsing only after this relatively

long initial inversion time had passed. This and one other important
feature was kept in mind during the design of the modulator. Other experiments disclosed that immediately after a giant pulse was emitted much less time was required to pump the ruby back above threshold since only a portion of all the excited ions (about 25%) gave up their energy as laser radiation during each successive giant pulse. It was necessary then to excite only this portion of the ions again. (Along with any that gave up their energy in normal flourescence.) The process is depicted below.

A power supply was available which was able to keep the flash lamp "on" a maximum of 1344 microseconds. Therefore, it was hoped that after allowing $\cong$ 350 microseconds initial inversion time, about 1000 microseconds of additional flash lamp on-time would remain. Thereafter, if the modulator could pulse the Kerr cell every 100 micro-seconds, a maximum of 10 giant pulses might be obtained when proper synchronization was used.

The basic problem faced, then, involved the development of a modulator or pulser similar in characteristics to that utilized to pulse a radar magnetron. Consequently, it was natural to investigate radar circuits that could produce a fast, narrow, high-voltage pulse. /16/

Normally two main types of modulators categorize most all elec-tronic circuits that are used to develop or generate high voltage pulses as used in radar. /10/ These are the line-type pulser and the hard-tube type pulser. /17/ Generally such modulators involve the storage of electrical energy by some means and then the discharge of this energy through some load (all or a fraction of it) during a pulse. Usually, the line-type discharges a pulse forming network's stored energy into the load through a "soft-tube" (mercury or hydrogen thyratron) switch. However, in a "hard-tube" pulser the switch is a high-vacuum tube.

Up until the time of the author's experiment, all giant pulse

work involved the production of only single pulses. The modulators used to develop these pulses are composed of a charged line whose characteristic impedance almost match the "on" impedance of the flash-lamp. The line's stored energy is then discharged through a soft-tube switch with the flash lamp as a load. The hydrogen thyratron soft-tube permits developing pulses with exceedingly short rise times--on the order of 30 nanoseconds. Such rise times make it ideal for fast switching use. However, the greatest problem faced in its use results from the very same effect that permits the fast rise time--the ionized hydrogen. After the gas is ionized and the tube fired, it is very difficult to extinguish the discharge. Only after the plate voltage is reduced and the gas is deionized is the tube extinguished. The deionization time is of the order of 10 micro-seconds or more, and is dependent upon the tube used, the degree of ionization and the plate voltage. The hard-tube pulser was there-fore, considered as more appropriate for the use intended since it offered better control features, though the rise-time might not equal that of a soft-tube pulser.

A simplified schematic of the approach considered to solve the modulator problem using hard tube switches follows:

13
Ideally one switch is instantaneously opened as the other is closed.

Thus, when sw#1 is closed and sw#2 is opened, the Kerr cell can be

charged to the full value of the supply voltage. After a fixed incre-

ment of time, sw#1 is opened and sw#2 is closed, thereby discharg-

ing the Kerr cell. (At first it was hoped to use high-vacuum tubes

for both switches. A simpler arrangement was finally evolved by

replacing sw#1 with a suitable resistor.)

Many circuits were tried on paper incorporating the above ap-

proach and three were actually breadboarded. The first circuit

attempted, used an interstage coupling pulse transformer. It gave

a satisfactory output pulse (see Figure 5) but the output stage had

to be operated beyond the rated values of the tubes. It was there-

fore abandoned. The second circuit contained a bootstrap driver but

was also unsatisfactory because of input isolation problems. The

third and last breadboarded circuit was the most suitable, and

although the rise time of the final output pulse was not that originally

OUTPUT WAVEFORMS OF
FIRST MODULATOR CIRCUIT

arbitrarily stipulated, the results obtained proved useful. It was stated previously that the specifications originally offered required a pulse rise time of 30- to 50-nanoseconds. The pulser that was finally assembled developed a pulse with a 90 nanosecond rise time (10% to 90%). While actual testing was being performed on each circuit, it was determined that the final pulse rise time was a function of two principle factors: the pulse transformer used (with its inherent stray capacitance and leakage inductance), and the grid characteristics of the power tetrodes (4PR60B) which were used in the final stage. The last factor proved to be the most difficult to contend with in that the tubes, though listed as possessing sharp cutoff features did not actually function in this fashion. A plot of the change in plate current (ΔI_b) versus change in grid voltage (ΔE_g) was made to verify this point. From Figure 6, which was drawn for a plate voltage of 1,000 volts, it can be seen that unless the grids of these power tubes were driven into the positive region, the operation was essentially in the non-linear region of the curve. Consequently, the g_m was a changing number and relatively low. Thus, the tubes turned on too slowly to obtain the rise time desired, which, perhaps in part, accounts for the slower rise time pulse finally obtained. In the first breadboarded circuit, the last stage tubes were biased off at -500 volts. They were then raised to

0 volts with a +500 volt pulse from the preceding stage. A glance at Figure 6 will disclose that in the range of from -500 volts to zero volts the g_m is varying continuously. Thus, the driving pulse never drove the output power tubes into the truly linear region of operation.

In the approach used for the final design it was considered that one of the better ways of pulsing the output stage was to use a circuit in the preceding stage that was not appreciably loaded when the large output tubes were in the "on" condition. This would then pre-empt loading that might be caused by grid current being drawn. It was decided that either of two alternatives was in order, a pulse transformer for impedance matching or a different and more suitable driving circuit. The second alternative was chosen since parts were readily available. A regenerative driver was assembled to act as the heart of the entire modulator. A pulse amplifier stage preceded a triggered blocking oscillator which drove the final high-voltage output stage (see Figure 7).

An Electro-Pulse, Inc. pulse generator (Model 190215) was used to provide the negative input trigger pulse which initiated the entire pulser action. This pulse when more negative than -10 volts turned-off the normally-on first tube, the 6S4-A, causing its plate voltage to swing from about 40 volts to 300 volts. The resultant positive going pulse was coupled into the next stage, the blocking

19

SCHEMATIC OF 10 KC KERR CELL MODULATOR

FIGURE 7

19
oscillator. The 260-volt pulse out of the first stage triggered the blocking oscillator and started the usual blocking oscillator regenerative action. The resulting plate current developed a positive voltage of 500 volts across an unbypassed 330-ohm cathode resistor. This voltage was then used to pulse "on" two parallel-connected 4PR60B's which made up the last stage. The output of this stage was fed directly to the capacitive energy storage device, the Kerr cell. The 6S4-A (triode) was chosen for the first stage since it could be operated up to 500 volts thereby permitting a large amplitude pulse to be developed in order to trigger the blocking oscillator. It was later determined experimentally that good blocking oscillator action occurred with the 6S4-A plate supply voltage reduced to as low as 300 volts. Below 300 volts, however, the rise time of the pulse triggering the blocking oscillator was increased causing irregular triggering to result and pulse-to-pulse jitter to appear in the output. When triggered hard, the blocking oscillator went into and out of conduction more strongly thereby reducing jitter appreciably, and allowing better control of the last stage output.

The blocking oscillator circuit used was of a standard configuration built around a power triode (the 811-A) capable of developing a large amplitude pulse. A 2:1 (2-winding) pulse transformer (PCA 102-1) was used in the plate and grid circuits. The plate voltage

20

was 1,000 volts and the tube was biased off at -22 volts. Depending
on the amplitude of the trigger pulse into this stage, any variation of
the bias from -20 volts to -30 volts caused a change in the slope of
the leading edge of the output pulse. A bias more positive that -20
volts caused free-running operation of the blocking oscillator. A
diagram of the first two stages is shown in Figure 8.

The final-stage positive driving-pulse was obtained from the un-
bypassed 330-ohm resistor in the cathode of the 811-A. The output
impedance of this cathode follower was determined to be about 90
ohms. Thus, a 93-ohm line (RG62A/U) was used to couple this pulse
to the two 4PR60B tubes used in the last stage. The plate supply
voltage of these tubes was 10 kilovolts and the screen supply was
1250 volts. The grids were biased in the off-condition at -500 volts.
A clamping circuit was also used to assure that the bottom of the
input pulse was held at -500 volts. The chokes used in the grids
of the second and last stages aided in blocking out of the bias
circuits the r.f. components in the pulse. The choice of the
particular tube, the 4PR60B, was based on the following features:
it had (1) low interelectrode capacitance, (2) a plate voltage
capability of 10 kv or greater, (3) the ability to withstand large
current pulses for short lengths of time (a plate dissipation of 60
watts) and (4) a high emission capability. Since relatively large

pulses of current of short duration were handled in the last stage, it was decided to use two of these tubes in parallel. In addition, small resistors were used in the screen and plate leads to suppress parasitic oscillations. An added feature was also incorporated to assure a fast fall time on the output pulse; inductors were tried in the plate circuit of the last stage. First attempts were unsucessful since at the high voltage involved, corona and arcing occured in the "pancake"-type inductors that were available.   The most satisfactory solution during the course of the experiment resulted from the use of inductive wire-wound Sprague high-wattage resistors for the load resistor of the last stage. Though this gave little control over the inductance value, the output pulse was improved. A 2000-ohm wire-wound resistor was used which had a characteristic inductance of 110 mh (bridged at 1 kc). The improved waveform can be seen in Figure 9b, as compared to that of Figure 9c which displays the resulting pulse of the circuit without any inductance in the plate. Care was exercised in the amount of series inductance used since excessive overshoot could have turned the Kerr cell off again at 14 kv. (This is the 140%-of-maximum-voltage point in the sine-squared transmission characteristics of the Kerr cell used. See References /11,12/.) Note that a low value of load resistor was necessary to assure that the Kerr cell charge path (when the 4PR60B's were off)

FIGURE 9

had as low an RC time constant as was practicable in order to give a fast pulse fall time (the time involved in charging the Kerr cell back to 10 kv). A diagram of the output stage is shown in Figure 10.

With no applied pulse and the output tubes "off" the Kerr cell capacitance and stray capacitance ($\cong$ 50 picofarads) was charged by the last stage plate supply through the 2000-ohm load. This gave an R-C charge time constant of 100 nanoseconds which seemed satisfactory for the conditions under which the Kerr cell was to be operated. When the last stage was then turned on the total output capacitance expended its stored energy through the low resistance of the two tubes.

Because of the high cost of Kerr cells it was necessary during the breadboard stage to use a substitute which simulated as closely as possible the Kerr cell's actual characteristics. This required that the author construct a capacitor which presented a capacitive load of about 50 picofarads (includes output, stray, and Kerr cell capacitance) and did not break down with 10,000 volts across its plates. Two plates cut from thin sheet copper were separated by several thin layers of Teflon insulator. Plexiglass outer plates were cut to hold the "sandwich" compactly. It was found that the capacitance was variable from 17 picofarads to 50 picofarads by simply tightening down on the four corner support nuts. The

25
FIGURE 10

arrangement proved quite satisfactory, since results obtained on

the breadboard were not too different from those obtained when the

actual Kerr cell was used.

3. Tests And Results

After it was determined that the circuitry would be capable of

pulsing the Kerr cell, a complete laser system was assembled. An

optical bench 160 cm long was selected as the foundation piece.

A heavy metal base mounting bar was then erected on the optical

bench. Upon this accurately machined bar was mounted the entire

laser cavity with associated optical pieces in their respective special

precision-made holders (see Figure 11). At each end of the bar

(about 15 1/2" apart) was placed a dielectrically coated "flat" of

high grade glass. The back flat had a 98% reflection characteristic

while the front flat had 53%. Adjacent to the back flat and mounted

on the bar was the 10 kv Kerr cell. Next in line toward the front

flat was the Wollaston prism. Between the prism and the front flat

was mounted the ruby's metallic cylindrical cavity containing the

special spiral flash lamp, the trigger lead and the 3" ruby. (See

Figure 12)

In addition to the optical pieces two magnesium oxide diffuse

reflectors were placed on the optical bench--one immediately behind

the back flat as protection from back scatter and the other about 4 feet

forward of the front flat.

The power supply used to operate the flash lamp was specially

designed for Laser operation. It consisted essentially of two
KERR CELL AND HOLDER

FIGURE 11

separate circuits. One was used to charge a pulse-forming network, the other was used to develop triggers to fire the ignitron switch and to ionize the xenon gas in the spiral flash lamp.

To the output of the charged pulse forming network was attached, in series, the flash lamp and the open ignitron switch. After the line was charged, the main switch was depressed. This introduced one trigger to ionize the flash lamp xenon gas and another to ionize the ignitron pool. Upon this action the energy stored on the pulse forming network was released into the series load represented by the "on" condition low impedances offered by the flash lamp and ignitron.

The light pulse width, (or the on-time of the flash lamp) and the rate at which energy could be injected into the flash lamp were controllable. By suitable choice of up to eight independent "L" sections, light pulse widths of from 168 microseconds to 1344 microseconds in eight equal increments could be chosen by inserting capacitance (13.2 microfarad/section) and inductance (530 microhenries/section) to make up the line.[5] The energy stored on the line was also controllable by varying the charging voltage. Except for the distinct upper limit of the light-pulse width resulting from the

[5]Z_o of this line was 6.3 ohms (see Appendix A).

physical limitation of the power supply, all other parameters could be readily controlled.

The first arrangement used for monitoring the ruby light output utilized an RCA 6217 phototube as a photodiode.[6] This tube was housed in a flat-black coated oblong container. A 270-volt battery was used as its power supply and the tube output was fed through a 50-ohm cable (RG 58 C/U) to a capacitive load which totaled .0014 microfarads(20 picofarad, scope; 187 picofarad, line; and .00120 microfarad, fixed) and shunted the input of the Tektronix-555 oscilloscope. The purpose of this capacitive load was to produce integration of the output pulses. During the test the pulse periods used were in the hundreds of microseconds, and since the output giant laser pulse was on the order of 30 nanoseconds, integration would assure that if a pulse existed its amplitude could be detected by the polaroid ASA 3000 film used when the oscilloscope was set on the 100 microsecond/cm time scale.

During this portion of the experiment no major synchronization circuitry was used. The pulser was started and kept on. The flash lamp was then fired while the polaroid camera shutter was kept open. For the initial period of time from about 200 microseconds to

[6]A later arrangement used a more sensitive photomultiplier with Kodak Wratten (gelatin) neutral density filters.

600 microseconds (depending on the pump rate in joules/sec) the ruby was pumped. When the inversion level went above threshold the ruby was ready to laser. If after this point any pulse from the designed modulator opened the Kerr cell optical shutter, the back reflector was switched instantaneously into the optical path thereby increasing the "Q" of the laser cavity to a point which permitted regeneration. A giant pulse resulted as the energy was released. This was accompanied by a reduction in the upper level inverted Cr^{+3} ion population. The Kerr cell was then quickly turned "off" but the flash lamp remained on. Consequently, there was sufficient time for the ruby to be re-pumped. A situation prevailed which was similar to that described on page 11. It appeared possible to continue this process of pumping the ruby, switching the Kerr cell and obtaining a single laser pulse as long as the flash lamp was on and the ruby temperature was not raised excessively. Any rise in temperature was accompanied by an upward shift of the threshold level /4/ and made it more difficult to obtain lasering. As was hoped, when the modulator was operated at 10 kc, about 6 to 8 giant pulses were obtained. (Pictures of the resulting integrated output of laser pulses are shown later in this section.) Since synchronization was not at first attempted only pure chance permitted a large number of laser giant pulses to be emitted. When this occurred,

the pulse sequence of the modulator was such as to allow sufficient time for a large initial inversion above the threshold level to be reached before the Kerr cell was triggered. It was hoped to eventually implement a method of synchronizing all the circuitry in order to assure that the largest number of pulses were emitted during a firing. A schematic of the planned synchronization system is shown in Figure 13. The complete system used to obtain the described experimental results is schematically depicted (without power supplies) in Figure 14, and photographs of the actual equipment are shown in Figure 15. Appendix B also provides pertinent data describing each piece that was used in the system.

During the actual tests of the system the pulser was first started, and the polaroid camera shutter was then held open until the flash lamp was fired. A train of giant pulses, at a controlled repetition rate, was emitted from the air-cooled ruby. The output was monitored by the photodiode whose output was fed to the integrating circuit which paralleled the input of the Tektronix dual-beam (555) oscilloscope. When the flash lamp extinguished, lasering ceased. The camera shutter was then closed. From the photograph taken it was then possible to make a calculation of the energy output in each of the integrated pulses. The energy in these pulses was determined without too much difficulty, since

ACTUAL SYSTEM   FIGURE 15

it was a function of the photodiode sensitivity, the total integration capacitance in the output of the photodiode and into the oscilloscope, the voltage amplitude appearing across the integration capacitance, as read from the photograph, the filters and attenuators used in the optical path, and the general geometry of the readout system. The energy input to the flash lamp was simply a function of the total capacitance in the number of sections of line used and the amount of voltage to which this capacitance was charged. Figure 16 is a group of photographs of the integrated laser output. Time increases from left to right and the leading edge of each step represents a giant laser pulse which resulted when the Kerr cell was pulsed. The giant pulses were so fast that the film responded only to the interpulse decay of the stored energy on the integration capacitance. However, the magnitude of the step-change was a direct representation of the energy that was emitted in each giant pulse. In the following chart, the energy in each pulse is compared as a function of the number of sections used in the pulse forming network that fired the flash lamp. The modulator was operated at a 10 kc rate for these results.

	Energy (mj) in Pulse Number							Total Energy (Joules)	
Sections	1	2	3	4	5	6	7	Output	Input
5	153	204	150	201	153			.86	1200
6	223	121	93	197	147	≈15*		.80	1200
7	115	248	93	188	102	80		.83	1200
8	178	71	233	≈15*	≈16*	259	80	.85	1200

*See photo of Figure 19.

Energy per pulse at a 10 kc pulse repetition frequency.

Similar results were obtained when the modulator was adjusted to pulse at other repetition frequencies. Photographs taken when the modulator pulsed the Kerr cell at a 4 kc rate are shown in Figure 17. All these photographs disclose that for any fixed input energy, an increase in the number of pulse-forming-network sections used (i.e. an increase in the width of the flash lamp light pulse) generally gave an increased number of output pulses emitted from the laser. Also, an increase in the energy input resulted in laser pulses of larger magnitude. It is felt that the pump rate was a significant factor in determining how large the individual pulses were. Time did not permit a thorough investigation of this aspect

of the system. Though not conclusive, it is noticed that the photographs disclose a trend toward larger giant pulses when the pump rate is higher. Eight sections gave a flash lamp light pulse of about 1340 microseconds whereas five sections gave a light pulse of 840 microseconds. Thus, when a fixed energy of 1200 joules was stored on the pulse forming network the pump rates were respectively $\approx .9$ joules per microsecond and ≈ 1.4 joules per microsecond for the light pulses described above. The shorter light pulse injected more joules per microsecond permitting a large inversion condition to result more quickly. This should give larger amplitude laser pulses. It is noted, however, that the wider pulse of white light obtained from the 8-section line gave the ruby a greater opportunity to have its Cr^{+3} ion population inverted more often; consequently, a greater number of pulses resulted even though they were of lower magnitude.

Though the pulser was designed to be operated at a 10 kc rate it was decided to determine if it could be operated at a higher pulse repetition frequency. Figure 18 is a photograph of the pulser output when being operated at a 25 kc rate in comparison with the output when operating at a 10 kc rate. Beyond 25 kc the output tubes began to draw excessive currents to a point where they were operating beyond their ratings. Typical values of voltages and

Toward the end of the experimental period interesting results

were obtained by increasing the width of the input trigger eminating

from the laboratory pulse generator. It seems that when the trigger

pulse was made much greater than 500 nanoseconds wide the

blocking oscillator was able to recycle itself two and even three

times (depending on the width of the input trigger pulse). This

resulted in double- and triple-pulsing of the Kerr cell with subsequent

emission of double and triple giant laser pulses spaced approximately

2.2 microseconds apart. (See Figure 19). The first laser pulse

MULTIPLE – PULSING OF MODULATOR AND LASER

FIGURE   19

was usually quite large; the second and third were much smaller. The short 2.2 microsecond interpulse period did not permit the ruby chromium ions to be inverted sufficiently to provide a significant laser output from the additional pulses. From these results it became apparent then, that a closer investigation was in order, of the integrated output photographs taken during the series of tests where the input trigger pulse had been widened. In the integrated output photograph of Figure 19 what was overlooked before was now obvious. Though barely discernible double-pulsing is apparent in the region of the third and fourth distinct giant pulse step.

A test was carried out to determine what the result would be if the flash lamp was fired with an input energy near its rated maximum of 1500 joules. All 8 sections of the pulse forming network were used in this test in order to obtain the longest light pulse possible with the available equipment. The resulting output is shown in the photograph of Figure 20. This represented the largest total energy output that was obtained in any of the tests performed at a 10 kc repetition frequency.

In order to be sure that each of the laser pulses emitted was truly a giant pulse, a separate test was performed. It was decided to attempt to isolate, at random, one of the pulses that appeared in the train. A slight modification of trigger circuitry was used

46

and the oscilloscope time scale was set to 100 nanoseconds per centimeter. The first pulse out of the laser was used to trigger the Tektronix. By varying the delay time in the oscilloscope any pulse after the first could then be selected for photographing. Figure 21 shows a photograph of a typical giant pulse. Note the very fast rise time (much less than 10 nanoseconds). Another interesting aspect is the pulse width, which is no more than 40 nanoseconds even at the widest portion of the base. For an idea of the power available in such a pulse an average pulse magnitude of 120 millijoules can be selected from the chart shown previously and divided by the pulse width of 40 nanoseconds. The result is 3 megawatts of average power. (From the pulse shape the peak power can be estimated at about 12 megawatts.) Even with the relatively low energy involved, the pulse power is significant and quite comparable to that in some present-day radar pulses. Yet at the time of this writing no radar can give the narrow beam width, spatial directivity, and coherence which is characteristic of the laser output.

4. Conclusions

The major problem faced in attempting to generate a series of repetitive giant laser pulses was that of electronically modulating the Kerr cell. The circuitry used was successful in that it was capable of producing as many as eight successive laser pulses. Except for the rise time of the pulse driving the Kerr cell the more important specifications of those originally stipulated were met satisfactorily. Those specifications that were not actually met in the final circuitry were mainly refinements necessary to assist in controlling the output more effectively. Their omission did not detract from proving the feasibility of the concept. The experimental results proved the possibility of controlling the Giant Pulse Laser output in applications requiring high peak-power pulses.

The following suggestions are offered to assist in improving the entire modulator system that was used in this experiment:

(a) Remove the coupling capacitor that exists between the first stage and the blocking oscillator. In its place insert a variable, or tapped delay line. This will add a means of controlling the output pulse width.

(b) Select an optimum inductance for insertion into the plate circuit of the last stage to improve the pulse fall time.

(c) Introduce external synchronization circuitry so that the modulator pulse can be forced to commence at a desired time after the ruby has had its ion population pumped high above the threshold level.

(d) Use different tubes in the last stage with sharper cutoff features; or drive the tubes used, into the linear region of operation.

(e) Parallel more than two tubes in the last stage so that the Kerr cell discharges through a lower impedance switch, thereby, improving the pulse rise time. More tubes in parallel will also provide the added capability of operating at higher repetition frequencies than 25 kc without the danger of exceeding the individual tube ratings.

(f) Consider using a different modulator design one which takes advantage of the sine-squared transmission characteristic of the Kerr cell. Normally the Kerr cell is operated in a condition of full voltage or zero voltage; however, the sine-squared feature provides another zero of transmission at the 140% full-voltage point. In the Kerr cell used in this experiment it would mean designing the modulator to instantaneously modify the voltage from 10,000 volts to 14,000 volts. This obviously represents a voltage swing of only 4,000 volts in comparison to the $\approx 9,000$ volt swing used in this experiment.

(g) If it is desired to use higher pulse repetition rates without revising the circuit entirely, the last stage plate resistance can be increased in order to reduce the average plate current inherent when using larger duty factors. An increase in plate load resistance, however, will necessarily also increase the Kerr cell charge time.

(h) Finally, a more comprehensive testing program should be carried out in which one system parameter at a time is varied through a wide range of values. Such a program would result in a better understanding of the ultimate capabilities of the modulator.

APPENDIX A

Calculation of the pulse width from, and the characteristic impedance of the pulse forming network used in the large power supply to pulse the flash lamp.

$$\tau/\text{section} = 2\sqrt{LC} = 2\sqrt{(530 \text{ microhenries})(132 \text{ microfarads})}$$

$$\cong 168 \text{ microseconds/section}$$

Maximum light pulse width:

8 sections $(168) \cong 1344$ microseconds

$$Z_o = \sqrt{\frac{L}{C}} = \sqrt{\frac{530}{13.2}} = 6.32 \text{ ohms}$$

APPENDIX B

Pertinent data for some of the other equipment and optical

pieces used in the 10 kc modulator system:

(1) Reflecting Flats: Perkin and Elmer. They were dielectri-

                         cally coated having a 53% and 98%

                         reflectivity at 6943Å.

(2) Laser Cavity: (see Figure B-1) 9.5 cm long by 4.3

                         cm O.D.

(3) Flash Lamp: Kemlite (specially made) (see Figure B-2).

(4) Ruby: Linde and Company

                         .05% doping of Cr^{+3}; 1/4" x 2.5".

                         90° optic axis unpolished; end faces flat

                         to 1/15 of a wavelength and parallel to

                         within 2.5 seconds.

(5) Oscilloscope: Tektronix dual-beam (with power supply

                         and associated fast rise time pre-amplifiers);

                         20 picofarad, 1 megohm input. Photographs

                         of repetitive pulses were taken with a sensi-

                         tivity setting of 10 millivolts/cm.
