THE  
EDINBURGH  
JOURNAL OF NATURAL HISTORY,

AND OF  
THE PHYSICAL SCIENCES.

CONDUCTED BY

WILLIAM MACGILLIVRAY, A. M.,

CONSERVATOR OF THE ROYAL COLLEGE OF SURGEONS, EDINBURGH; FELLOW OF THE ROYAL SOCIETY  
OF EDINBURGH; MEMBER OF THE WERNERIAN NATURAL HISTORY SOCIETY; OF THE  
ACADEMY OF NATURAL SCIENCES OF PHILADELPHIA, &c. &c.

ASSISTED BY SEVERAL SCIENTIFIC AND LITERARY MEN.

VOLUME I.

A. D. 1835—1839.

EDINBURGH:

PUBLISHED FOR THE PROPRIETOR, 13, HILL STREET.

GLASGOW AND THE WEST OF SCOTLAND: JOHN SMITH AND SON, 70, ST VINCENT STREET; AND  
JOHN M'LEOD, 20, ARGYLE STREET. ABERDEEN: A. BROWN AND CO.

MANCHESTER: AINSWORTH AND SONS, 107, GREAT ANCOATS STREET. LEEDS: THOMAS AINSWORTH, JUNIOR,  
50, QUEEN'S PLACE, COBURG STREET.

DUBLIN: GEORGE YOUNG, 9, SUFFOLK STREET.

PARIS: J. B. BALLIÈRE, RUE DE L'ÉCOLE-DE-MÉDECINE, 13, (BIS.)

LONDON: SMITH, ELDER, & CO., 65, CORNHILL.

M.DCCC.XXXIX.

1877  
1878  
1879

THE EDINBURGH  
JOURNAL OF NATURAL HISTORY,  
AND OF  
THE PHYSICAL SCIENCES.

N<sup>o</sup>. 1.

SATURDAY, OCTOBER 24, 1835.

ADDRESS TO THE PUBLIC.

THE taste for Natural History is now universally diffused throughout the empire. Within the last few years, various cheap publications on this subject, illustrated by engravings on wood, have led all classes to observe and to enjoy the ever-varied beauties of the creation. But no description, however correct, or no wood-cut, however well executed, can give that complete idea of a natural object, which is effected by an engraving on steel, when coloured with accuracy. The enormous price at which these illustrations of a higher order are usually sold, has alone prevented them from becoming extensively popular. Hitherto, coloured engravings, executed with beauty and correctness, have been accessible to the wealthier classes alone. It is proposed, in this work, to place elegant engravings of the choicest productions of Nature, within the reach of all classes of the community; and thus, in small towns and in the country, where museums are unknown, and libraries very scarce, the lover of Nature will be enabled to extend his knowledge of the works of the Creator beyond the limited sphere of his own observations.

The plan of this work is twofold.—An attempt is here made for the first time to combine the lighter character of a popular periodical, with the more solid utility of an eminent scientific work. One half-sheet of each Number will contain, "THE EDINBURGH JOURNAL OF NATURAL HISTORY, AND OF THE PHYSICAL SCIENCES;" and the other will be devoted to a new translation of "THE ANIMAL KINGDOM, by BARON CUVIER," with extensive Notes and Additions.

THE EDINBURGH JOURNAL OF NATURAL HISTORY, AND OF THE  
PHYSICAL SCIENCES.

In this portion of the work, interesting articles will be given on every department of Natural History, taken in its most extensive sense. The physical peculiarities of the inhabitants of different countries will be recorded, in so far as they have been ascertained, the habits and instinct of animals will be explained, and such discoveries as may be made from time to time, both relating to Man and to Animals, will be regularly published. The wonders of the Vegetable Kingdom, the culture and management of Plants, and their economical uses, will form subjects of description, as well as the interesting and useful objects of the Mineral Kingdom. The novelties of Geology, and of Physical Geography, will also be embraced; and an account given of every remarkable occurrence in nature, whether proceeding from sudden and violent atmospheric changes, or from causes within the earth's surface. Elementary papers, on the different departments of Natural History, will aid the student in his inquiries. Popular articles will be written on the most interesting phenomena of Astronomy; while Mechanics, Optics, Chemistry, Electricity, and the higher branches of Physical Science, will not be altogether neglected. The novelties of Foreign Science and Literature will hold a prominent place in this Journal; and translations will appear of the more popular parts of important works, which would be otherwise inaccessible to most persons in this country. We shall explain the proceedings of Learned Societies—give Reviews of New Works—and record the demise of all who have been skilled in the Physical Sciences. This part of the work will be written in a style as simple as the subject will admit, avoiding, on all occasions, deep and abstruse reasoning; yet, at the same time, being intelligible and instructive to all classes of readers. A short and popular account of the objects illustrated in each plate will be given in the Number accompanying it, while a more detailed and scientific description will afterwards appear in its proper place.

THE ANIMAL KINGDOM, BY BARON CUVIER.

THE second portion of our publication contains an improved translation of the last edition of this justly celebrated work. It is well known, that the original was chiefly designed by its illustrious author as an outline, being more particularly intended to elucidate the new system of classification, of which he was the inventor. It is proposed, in the present translation, to fill up the masterly outline of Baron Cuvier with interesting and popular accounts of the habits and peculiarities of the whole Animal Kingdom. Care will, however, be taken to distinguish this additional matter from the original text of Baron Cuvier, by printing it in a smaller type; and, wherever it has become necessary, from more recent discoveries, or for other reasons, to supply a few words in the text, these are inclosed in brackets [ ]. The whole will run on in a continuous manner; and the plates are intended to be bound, at the completion of the work, with this Edition of the Animal Kingdom; the whole thus forming the most complete and economical publication on the subject of Natural History ever offered to the Public. It will be accompanied by a Portrait of Baron Cuvier, and by a Memoir of his Life. An historical article will be given on the rise and progress of Zoology; also, a treatise on the Geographical Distribution of Animals, and another

on Fossil remains. The work will conclude with an extensive Synopsis, or Index, of the entire Animal Kingdom.

Occasional wood-cuts illustrate matters of general interest. Throughout the entire work, the utmost caution is observed in excluding all passages which are calculated to offend delicacy; and those details, without which the work would be incomplete, appear in a foreign language. Supplementary plates will be published at intervals, for the convenience of those who may wish to possess figures of the whole Animal Kingdom.

In respect to the execution of the work, although this number is offered as a specimen of its general character and arrangement, yet various improvements will obviously suggest themselves in the course of this extensive undertaking; and unlike many similar works, the later numbers will exceed the first, in the quality and the beauty of their illustrations. The artists employed are all of the most respectable description; the designs are drawn from the objects themselves; or, when this is impracticable, they are copied from the best authorities in our own and in foreign countries; while the engravings are coloured in the most careful manner. The average number of objects upon each plate will be about ten, varying in number according to the dimensions of the animals. We have selected the present size, as being the smallest that can combine economy with accuracy of delineation. It will be seen in the plate of Trogons, accompanying this number, that the Golden Couroucoui, a bird of the size of a small pigeon, has been reduced to about one-third of its natural dimensions; and it will be readily seen, from the great length of its tail, that any smaller work could not possibly have given a correct delineation of an object of this description. Also, by placing many objects on one plate, great facilities are afforded for a comparison of the external forms of allied animals; while room is given for a tasteful approximation and contrast of forms and colours.

It is hoped that the typography and general execution of the work, entitle it to some consideration: the sheets are all carefully pressed, and are not issued in their rough state, as is usual with periodical publications.

In regard to economy this work is unrivalled. The quantity of matter in each number is equal to SIXTY-FIVE ordinary *foolscap octavo* pages; so that a quantity of letter-press, equal to a volume of the Waverley Novels, will be had for ONE SHILLING.

Thus, while the views of the lowest classes will be fully met by the cheapness of this work, it is hoped that its beauty and accuracy will render it worthy of the approbation even of the very highest. By spreading a taste for science, and for intellectual improvement among all classes of the community, we endeavour to promote the moral and intellectual progress of the species. We hope to make it appear, in the words of an illustrious living authority, "that the pleasures of science go hand in hand with the solid benefits derived from it; that they tend, unlike other gratifications, not only to make our lives more agreeable, but better; and that a rational being is bound, by every motive of interest and of duty, to direct his mind towards pursuits, which are found to be the sure path of virtue, as well as of happiness."

No expense or trouble will be spared by the Proprietors of this work to obtain the latest information, and the most correct delineations of natural objects. Naturalists and men of science, in this and in foreign countries, are requested to favor the Editor with an early notice of their observations.

To ensure regularity in the publication of the work, a large portion of the illustrations are already completed. Arrangements have been made at New York, Hamburg, Paris, Brussels, and various parts of the Continent, to render them available to foreigners, as well as to our own countrymen.

ZOOLOGY.

DESCRIPTION OF THE PLATE—THE TROGONS.

THE figures on this plate represent the genus Trogon of Linnaeus, commonly called the Couroucoui. These birds are remarkable for the splendour of their plumage, in which the hue of the emerald is placed in agreeable contrast to those of the topaz and ruby; while their brilliant colours lead us to forget their rather inelegant forms. They are members of that class of birds called *Scansores*, or Climbers, their feet being provided with four toes, two of which are placed before and two behind.

These birds lead a lonely life, frequenting solitary woods. They feed on insects. They fly principally in the morning and evening, and they incubate in the holes of trees. In general, they are very silent birds; but sometimes they cry *Couroucoui*, from which their name is derived, and sometimes *Pio, Pio*. They are noted by naturalists for the plenitude of their plumage.

Fig. 1.—The Golden Couroucoui (*Trogon Pavorinus*), is one of the most beautiful

of its tribe, and remarkable for the great development of its tail, the two centre feathers of which are frequently three feet in length. It inhabits South America and the tropical parts of North America. Our figure is taken from a splendid specimen in the Edinburgh University Royal Museum. The Mexicans celebrated this bird in their mythology; they considered it as sacred to the deity Vitzliputzli, and they adorned the brows of their priests with the elegant feathers of its tail. This idol Vitzliputzli was represented, as in the annexed wood-cut, crowned with a helmet in the form of a Golden Couroucui, composed of feathers of various colours, excepting the beak and crest, which were of gold.

Most nations have some legends regarding the foundation of their capital cities; and the site of Mexico was said to have been fixed by this bird. The Mexican fable was as follows:—

The Navatecas were savages residing in forests and mountains, without laws or government; they worshipped the sun, and sacrificed these birds to his honour. Mexi the great captain and legislator appeared, and conducted by Vitzliputzli, the god of their nation, he led the savages in search of distant lands. Aided by their deity, his arms were irresistible, and his empire soon became extensive. Being in doubt where to establish his capital, a priest announced that it should be built on the spot where a Couroucui was seen perched on a tree, the roots of which were inserted on a solid rock. The spot pointed out was the present site of Mexico. Thus did a barbarous people account, by an idle prodigy, for the situation of a city on an island in the centre of a lake—a spot evidently pointed out by nature as the most secure situation for the capital of a mighty empire.

Fig. 2.—Reinwardt's Couroucui (*T. Reinwardtii*), is a native of Java. The plumage of this species is more compact than that of its American congeners; and also differs from them in having its general form and bill more slender, while the tooth-like edges of the bill is less marked.

Fig. 3.—The Black-necked Couroucui (*T. atricollis*), is a native of Cayenne; and one of the most timid of its kind.

Fig. 4.—The Mexican Couroucui (*T. Mexicanus*), is a recently discovered species, and a bird of great beauty. There are several fine specimens in the Edinburgh University Royal Museum, from one of which we figured our subject, by permission of Professor Jameson.

Fig. 5.—The Flower Couroucui, male (*T. Narini*), and Fig. 6., the female. This species is more nearly allied to the Asiatic bird than to those of South America. It inhabits Southern Africa.

It will be seen that this genus is widely distributed, being found in Asia and Africa, as well as on the continent of America; but it is in the last situation that the species are most numerous.

#### POPULAR ERRORS REGARDING THE TORPIDITY OF SWALLOWS.

It has long been, and continues to be, a popular opinion in this country, and in other parts of Europe, that swallows of a certain species pass the winter at the bottoms of deep lakes and wells. Buffon entertained this idea, and Goldsmith makes the following observations on this theory:—He says, "There is a circumstance attending the migration of swallows, which wraps this subject in great obscurity. It is agreed on all hands, that they are seen migrating into warmer climates, and in amazing numbers, at the approach of the European winter. Their return into Europe is also well attested about the beginning of summer; but, we have another account, which serves to prove, that numbers of them continue torpid here during the winter; and, like bats, make their retreat into old walls, the hollows of trees, or even sink into the deepest lakes, and find security for the winter season by remaining there in clusters at the bottom."

The analogy between birds of passage, and animals which remain in a state of torpidity during the winter, is most inaccurately drawn by Goldsmith; and we offer the following objections to the supposed constitutional connection.

Those quadrupeds, birds, reptiles, and insects, which pass the winter in a state of insensibility, may be recalled to sensation and action at pleasure, by the application of a gentle degree of heat. Naturalists have been induced, from this constitutional singularity of these animals, to conclude, that the return of spring rouses them from their lethargic state to enjoy the pleasures of sensation and locomotion. The animals in question take up their abodes a little below the surface of the soil; some in the crevices of walls, or interstices of rocks; while others, such as frogs, toads, and water-newts, bury themselves in the mud of shallow ponds. In the first of these retreats, they are only covered by a thin layer of earth and moss, or leaves; and in the last, by the addition of a shallow sheet of water; consequently they are re-animated in due season, by the genial rays of the sun, after he has entered the northern half of the ecliptic.

The temperature of places, situate at great depths below the surface of the land and water, is a sufficient objection to the assertion that birds remain in a torpid state, during the winter, in deep and solitary caverns, or at the bottom of deep lakes. Dr Hale has proved, by experimental facts, that the bulb of a thermometer, buried sixteen inches below the earth's surface, stood at 25° of his scale in September, at 16° in October, and at 10° in November, during a severe frost; from which point it ascended again slowly, and reached 23° in the beginning of April. Now the end of September and beginning of October is the season when the hedgehog, shrew, bat, toad, and frog, disappear; and, about the middle of April, these animals re-appear: this agrees very well with the variations of temperature of the preceding theory.

It is a well-established fact, that all places situate eighty feet below the surface of the earth are constantly of the same temperature. Mr Boyle kept a thermometer for a year under a roof of earth, eighty feet in thickness, and found that the fluid in the instrument remained stationary all the time. Dr Withering made a similar experiment on a well eighty-four feet deep, and found that it remained at 49° for the entire year. Surely, then, this invariable temperature is inconsistent with the theory of birds remaining in a state of torpidity in deep lakes, or solitary caverns, where the sun has no influence; for what would call forth their dormant organs into action, the sun having no influence in places so situate? It is but reasonable to conclude, that the cold, which kept them benumbed by its soporific influence, would perpetuate their slumber.

The state of torpor to which hibernating animals are annually subjected, is obviously analogous to sleep, but it differs from sleep in being occasioned solely by temperature. Hibernating animals always assume this torpid condition, whenever the thermometer sinks to a certain point. Man, and almost all animals, seem to be susceptible of this state, at least to a certain extent; for the apparent death produced by cold is probably nothing else but a species of torpor, out of which the animal, in most cases, might be roused if the requisite precautions in applying heat were attended to; for death, in most cases, seems to be produced, not by the cold, but by the incautious and sudden application of heat, which bursts the blood-vessels in some particular part of the body, before the heat has had the power of stimulating the heart, and setting the blood in motion through the whole animal frame; and this bursting of the blood-vessels destroys the texture of the body. It is well known that if any part of the body be frost-bitten, an incautious application of heat infallibly produces mortification, and destroys the part.

In the 28th volume of the Philosophical Transactions, there is a remarkable example recorded of a woman, almost naked, lying buried for six days under the snow, and yet recovering. In this case it is scarcely possible to avoid supposing that the woman must have been in a state of torpor, otherwise she would have endeavoured to find her way home.

That a few stragglers of the swallow tribe do remain in this country long after their fellows have departed, there can be no doubt; and even some have been known to sojourn during the whole winter: but, it is equally true that the uniform habit of these birds is, to quit the north on the approach of winter, and to seek climates more congenial to their mode of existence, which is entirely maintained by insect food.

The Rev. Gilbert White, in his interesting Natural History of Selborne, remarks, "I cannot agree with those persons who assert that the swallow kind disappear some and some, gradually, as they come, for the bulk of them seem to withdraw at once; only some stragglers stay behind a long while, and do never, there is great reason to believe, leave this island. Swallows seem to lay themselves up, and to come forth in a warm day, after they have disappeared for weeks. For a very respectable gentleman assured me, that as he was walking with some friends under Merton-wall, on a remarkably hot noon, either in the last week of December or the first week in January, he espied three or four swallows huddled together on the moulding of one of the windows of that college. I have frequently remarked that swallows are seen later at Oxford than elsewhere. Is it owing to the vast massy buildings of that place, to the many waters round it, or to what else?" He also mentions that a friend of his saw a martin on the 26th November, in a sheltered bottom; the sun shone warm, and the bird was hawking briskly after flies. Mr Sweet mentions the circumstance of a house swallow having taken up its residence, late in the autumn, within St Mary's church at Warwick; it was regularly observed there by the congregation until Christmas-eve; after which, it disappeared and was seen no more.

HEIFER WHICH YIELDED MILK.—Mr Joseph Marshall of Edrington, by Berwick, in June 1830, had a heifer which yielded milk. At that time he possessed two heifers aged two years, one of which he observed for several months to suck the other. On this account he judged it necessary to separate them; and, on milking the nurse, she gave a full English quart of genuine milk, which, on being kept for thirty hours, threw up a good coat of cream. The cream was churned in a bottle, and produced as much and as good butter as any other cream would have done under similar management.

ADDERS.—Two adders, upwards of two feet long, were noticed on the moss of Ashvore, Monedic parish, Methven, on the 3d week of June 1835. This place has long been noted as the haunt of adders.

INSECTS IN INDIA.—During the rainy season in India, the houses are so infected with insects, that it is necessary to have little covers (usually of silver) for tumblers and tea cups. The air is so still and stagnant, that persons are compelled to keep their doors wide open; and, consequently, the tables are thickly covered with a variety of the most disgusting vermin. These, mingling with the blood-thirsty mosquitoes, are tormenting in the extreme. At this season, also, the white ants are extremely numerous and destructive. In one night, they have been known to spread themselves over a large apartment, and to devour the whole matting. They frequently take possession of the beams that support the roofs of the houses, and destroy them in a few weeks. Nothing is secure against the depredations of these mischievous little creatures. Tents, carriages, beds, carpets, and clothes of all descriptions, are subject to their voracious appetites.

**WORMS IN THE EYES OF THE PERCH.**—Dr Nordmann discovered parasitic worms in the eyes of several distinct species of the perch. These eye-worms were sometimes in such numbers as must have interfered with that distinct sight of passing objects, which appears necessary to enable predaceous animals to discover their prey, in time to dart upon and secure it; in a single eye the Doctor detected, in different parts, 360 of these minute animals! When numerous, they often produce cataracts in the eye of the fishes they infest. The little animals which he found appear something related to the *Planaria*, or pseudo-leech; and, to judge from Dr Nordmann's figures, seem able, like it, to change its form. Underneath the body, at the anterior extremity, is the mouth; and in the middle are what he denominates two sucking cups; these are prominent, and, viewed laterally, form a truncated cone; the anterior one is the smallest and least prominent, and more properly a sucker; the other, probably, has other functions, since he could never ascertain that it was used for prehension. A kind of metamorphosis seems to take place in these animals, for our author observed that they appeared under three different forms. These little pests, small as they are, have a parasite of their own to avenge the cause of the perch, for Dr Nordmann observed some very minute brown dots, or capsules, attached to the intestinal canal, which when extracted, by means of a scalpel formed of the thorns of the creeping cereus, and laid upon a piece of talc, the membrane that enclosed them burst, and forth issued living animalcules, belonging to the genus *Monas*, and smaller than *Monas atomus*, which immediately turned round upon their own axes with great velocity, and then jumped a certain distance in a straight line, when they again revolved, and again took a second leap. Looking over our author's list of eye-worms that infest fishes, we find that five out of seven are attached to different species of perch, and one cannot help feeling some commiseration for these poor animals; but, when we recollect that they form the most numerous body of predaceous fishes in our rivers, we may conjecture that thus their organs of vision are rendered less acute, and that thus thousands of roach, dace, carp, and tench, may escape destruction.—*Kirby's Bridgewater Treatise*.

### BOTANY AND HORTICULTURE.

**FOUNTAIN TREE.**—There are few rivulets, and only three springs, in the Island of Ferro, one of the Canaries; and these are on a part of the beach which is nearly inaccessible. To supply the place of fountains, however, Nature bestowed upon this island a species of tree, supposed to be nearly allied to the *Laurus Indica*, possessing properties unknown to trees in all other parts of the world. These fountain trees were of moderate size, and their leaves were straight, long, and evergreen. Around the summit a small cloud perpetually rested, which so drenched the leaves with moisture, that they constantly distilled upon the ground a stream of fine clear water. To these trees, as to perennial springs, the inhabitants of Ferro resorted, and were thus supplied with a sufficient abundance of water for themselves and for their cattle. The last of these remarkable productions received the appellation of the Holy Tree, and it is said to have been destroyed by a dreadful hurricane in 1612. Its real existence has been completely established in the *Viagero Universal* di P. Estala, tome xi.; but by this account the water was merely condensed upon the leaves. Purchas, in his "Book of Pilgrimages, 1639," states that he had been told by Mr Lewis Jackson, of Holborn, London, who visited Ferro in 1618, that the fountain tree he had seen was as large as a middling-sized oak, six or seven yards high, with a white bark, like that of hardbeam; its leaves were like that of the bay, white underneath and green above. Parkinson, in his "Theatrum Botanicum," published at London in 1640, also mentions this tree. He says that the islanders called it *Garoe*, the Spaniards *Arbor sancti*; and that the ancient historians call it *Til*; and adds, "It is thought that Solinus, and Pliny in his Lib. 6, c. 32, meant this island, under the name of *Ombrión* and *Pluvialis*: for he there saith, that in the island *Ombrión* grow trees like unto *Ferula*, from whence water is wrung out; from the black ones cometh bitter water, and from the white that which is sweet and pleasant to drink."

**GREAT PRODUCTIVENESS OF THE ORANGE TREES OF ST MICHAELS.**—The St Michael oranges have long been celebrated for their delicious flavour, and the abundance and sweetness of their juice; when allowed to ripen before being pulled, they are inferior to none in the world. On the other hand, the lemons of that island are less esteemed than those of various other countries, on account of the small quantity of juice in them; and therefore they are not much in demand. The orange and lemon trees blossom in February and March. At this season, nothing can be more gratifying to the sight than the appearance presented by these trees: the glassy green of the old leaves, the light fresh tints of those just shooting forth, the brilliant yellow of the ripe fruit, and the delicate purple and white of the flower, form a delightful contrast. Both orange and lemon trees are from fifteen to twenty feet in height, and their common annual produce is from 6000 to 8000. Dr Webster mentions, that he has known, in a very abundant year, 26,000 oranges to be obtained from one tree, and 29,000 from another. These, however, are the greatest quantities which have ever been known to be gathered from a single tree in a year.

**NEW METHOD OF BLANCHING CELERY.**—In the March number of the *Irish Farmer's and Gardener's Magazine*, a Mr Cogan recommends the following method of cultivating celery, by which he states he has been successful for many years in preserving this favourite vegetable from what is called "rust," occasioned by the attack of grubs. In the month of October he plants the ground, designed for celery the ensuing year, with early York cabbage, which will be cleared away by the first week in June, the most proper season for planting. Previous to forming the drills, he collects the stalks and remaining leaves of the cabbages, and places them in small heaps on the hed. After lying a day or two, they will be found to have collected a great number of slugs and other vermin, which may be easily destroyed. The ground is then prepared and the plants put in; when ready for blanching, the loose leaves of each plant are tied up, and strong wheaten straw laid full length along the side of the drills, and staked down so much that it will completely exclude the light (excepting at the top, which is all that is requisite). By this treatment, he says, in the course of a month he has gathered celery perfectly free from either rust, grub, or insect.

### MINERALOGY.

#### CHEMICAL COMPOSITION OF NATIVE GOLD.

WE principally confine our remarks on the chemical composition of native gold, to that found in the Uralian mountains.

Gold being a simple substance, is of course unsusceptible of decomposition; but, like most other simple bodies, it is never found in the earth in a state of purity, being always more or less combined with silver.

Although the mines of Colombia have long been celebrated for the quantity of gold found in them, yet it has recently been ascertained that the native ore of that country contains a smaller proportion of gold than that of most others. According to the experiments of Bousingauil, who analyzed gold from different places in Colombia, he found it combined with silver in variable quantities, but invariably in definite proportions, namely, one atom of silver with 2, 3, 4, 5, 6, 8, and 12 atoms of gold. We are informed by Fordyce, that he examined gold from Kongsberg in Norway, and found it to consist of 28 parts gold, and 72 of silver, in the 100 parts. Klaproth, in analyzing gold from Selhlangenberg in the Altai, found that it contained 64 parts gold, and 36 of silver; and Lampadius found in gold ore, whose locality was unknown to him, 96.6 parts of gold, and the remainder consisted of silver and iron. Mr G. Rose, who accompanied Baron Humboldt into Siberia, made a collection of gold ores, for the express purpose of testing the position assumed by the French chemists.

Gold ore is found in the Uralian mountains in rocks, and also scattered amongst sand; in which last situation it is now almost entirely sought after, being much less laborious than extracting it from rock veins. Its discovery in this situation occurred in 1819, since which period rock mines have been abandoned.

The gold which is procured in rocks is universally found in quartz. At Beresow, it occurs in a crystallized form; at Newiansk, in plates; but at Czarewo Alexanderowsk, masses are met with which weigh from 18 to 96 lbs. troy.

The proportions of gold and silver from the different localities vary considerably. The following are the extreme limits of this variation:—

	SILVER.	GOLD.
Hiel.....rock.....	87.40.....	12.60.....
Schaitansk.....	95.10.....	4.90.....

The following important consequences were deduced by Rose from his analysis. He remarked that gold and platinum were never found associated.

1. Gold ore does not contain gold and silver in definite proportions.
2. From the above fact, he infers that gold and silver are isomorphous.
3. Native gold always contains silver, copper, or iron. The smallest quantity of silver in combination, was in a specimen from Schabrouski, which only contained 16 per cent. of silver, while 35 per cent. of copper was found.
4. The specific gravity is in the inverse ratio of the proportion of silver contained in the ore. Gold obtained by fusion has a greater density than in a native state; but this may arise from cavities contained in the latter.
5. He found a difference in composition in specimens from the same locality.
6. Gold found in veins varies in different parts of the same mine.
7. Gold from sand contains more silver than that found in veins; that from sand being 89.7 per cent. of silver, and from veins, 79.1.—*Poggendorff, Ann.* xxviii., 566.

**EDIBLE ROCKS.**—Near the Ural mountains in Siberia, a substance called "rock meal"—powdered gypsum—is found, which the natives mix with their bread, and eat. The Tartars likewise eat the lithomarge, or rock marrow; and use rock butter as a remedy for certain disorders.

### GEOLOGY AND PHYSICAL GEOGRAPHY.

**THREATENED ERUPTION OF VESUVIUS.**—According to late accounts from Naples, Vesuvius continued to throw out stones and cinders, and a grand eruption was expected. Some slight shocks of an earthquake were lately felt in the south of Italy.

**WATER OF THE SEINE.**—It was not thought that the basin of the Seine—I mean all that portion of ground in France watered by streams, great or small, which flow into that river—annually received in rain a quantity of water equal to the tribute carried by the Seine to the sea in the same space of time. Perrault and Mariotte were the first who studied the question, supported by experiments, and found, as is common in similar cases, that the vague ideas of their predecessors were the very contrary of the truth. According to Mariotte, the Seine discharges every year into the sea only a sixth of the quantity of water which falls in all the extent of its basin, in rain, snow, and dew. The other five-sixths must either be evaporated to form clouds, absorbed by the superficial earths in which plants find nourishment, or penetrate, by fissures in rocks, into the internal reservoirs from which fountains issue. Mariotte's calculation has been re-made on data more exact, especially as regards the gauging of the Seine. The following are the results, as they were stated in an excellent memoir, hitherto unpublished, by Mr Dausse, civil engineer:—"The basin of the Seine has an area, 4,327,000 hectares. Were the water falling into this basin not to evaporate, nor penetrate into the soil, and were the ground every where horizontal, it would form at the end of the year a liquid sheet of 53 centimetres (20 inches) deep. It is easy to see that such a sheet would contain a volume of 22,933 millions of cubic metres of water. Now, at the Bridge of the Revolution, the mean proportion of the water passing there is at the rate of 255 cubic metres in a second, or 22 millions of cubic metres in a day, or 8042 millions of ditto in a year. This last number is to 22,933 millions of cubic metres, which is the annual amount of the rain received by the basin of the river, as 100 is to 285, or almost as 1 to 3. Thus, the volume of water passing annually under the Paris bridges is scarcely the third of that which falls in rain into the basin of the Seine. Two-thirds of this rain either return to the atmosphere, by means of evaporation, or sustain vegetation and the life of animals, or run into the sea by subterranean communications."—*Literary Gazette, 20th June*.

## METEOROLOGY.

**EAINE.**—On the 11th of April 1832, a remarkable substance fell from the atmosphere, thirteen versts from Wolokolomsk, and covered a considerable space of ground, to the depth of one or two inches. It was examined by Professor Hermann of Moscow. He found it to be transparent and of a wine-yellow colour, soft, and elastic (like gum), and its specific gravity to be 1.1; it smelt like rancid oil, and burnt with a blue flame, without smoke; it was insoluble in cold water, but was soluble in boiling water, upon which it swims; it was also soluble in boiling alcohol; it could be dissolved by the carbonate of soda, and acids separated from the solution a yellow viscid substance, soluble in cold alcohol, and which contained a peculiar acid. When analyzed by oxide of copper, it furnished, of carbon 61.5, hydrogen 7.0, and of oxygen 31.5; total 100. This extraordinary substance has been termed inflammable snow, but Hermann gives it the name of *Eaine*, signifying the *Oil of Heaven*.

**INDIAN DEATH-BLAST.**—At Bandah, in Bundalund (one of the northern provinces of Hindostan), there are numerous rocky hills, which, during the hot winds, become so thoroughly heated as to retain their warmth from sunset to sunrise. The natives, at this sultry season, invariably wear large folds of cloth around their heads and faces, just leaving themselves sufficiently exposed to be able to see and breathe. This precaution is taken in consequence of the terrific blasts which occasionally rush in narrow streams from between the hills. Persons crossed by these scorching winds drop suddenly to the earth, as if shot by a musket ball. When medical assistance, or a supply of cold water, is instantaneously procured, a recovery may generally be expected; but if no immediate remedy be applied, an almost certain death is the result.

## GENERAL SCIENCE.

## COMETS.

THE extraordinary aspect of comets, their rapid and seemingly irregular motions, the unexpected manner in which they often burst upon us, and the imposing magnitudes which they occasionally assume, have in all ages rendered them objects of astonishment, not unmixed with superstitious dread, to the uninstructed, and an enigma to those most conversant with the wonders of creation and the operations of natural causes. Even now, that we have ceased to regard their movements as irregular, or as governed by other laws than those which retain the planets in their orbits, their intimate nature, and the offices they perform in the economy of our system, are as much unknown as ever. No rational or even plausible account has yet been rendered of those immensely voluminous appendages which they bear about with them, and which are known by the name of their tails (though improperly, since they often precede them in their motions), any more than of several other singularities which they present.

The number of comets which have been astronomically observed, or of which notices have been recorded in history, is very great, amounting to several hundreds; and when we consider that in the earlier ages of astronomy, and indeed in more recent times, before the invention of the telescope, only large and conspicuous ones were noticed; and that, since due attention has been paid to the subject, scarcely a year has passed without the observation of one or two of these bodies, and that sometimes two and even three have appeared at once—it will be easily supposed that their actual number must be at least many thousands. Multitudes, indeed, must escape all observation, by reason of their paths traversing only that part of the heavens which is above the horizon in the daytime. Comets so circumstanced can only become visible by the rare coincidence of a total eclipse of the sun—a coincidence which happened, as related by Seneca, 60 years before Christ, when a large comet was actually observed very near the sun. Several, however, stand on record as having been bright enough to be seen in the daytime, even at noon and in bright sunshine. Such were the comets of 1402 and 1532, and that which appeared a little before the assassination of Cæsar, and was (*afterwards*) supposed to have predicted his death.

That feelings of awe and astonishment should be excited by the sudden and unexpected appearance of a great comet, is no way surprising; being, in fact, according to the accounts we have of such events, one of the most brilliant and imposing of all natural phenomena. Comets consist for the most part of a large and splendid, but ill defined, nebulous mass of light, called the head, which is usually much brighter towards its centre, and offers the appearance of a vivid *nucleus*, like a star or planet. From the head, and in a direction *opposite to that in which the sun is situated* from the comet, appear to diverge two streams of light, which grow broader and more diffused at a distance from the head, and which sometimes close in and unite at a little distance behind it, sometimes continue distinct for a great part of their course; producing an effect like that of the trains left by some bright meteors, or like the diverging fire of a sky-rocket (only without sparks or perceptible motion). This is the tail. This magnificent appendage attains occasionally an immense apparent length. Aristotle relates of the tail of the comet of 371 A.C., that it occupied a third of the hemisphere, or 60°; that of A.N. 1618 is stated to have been attended by a train no less than 104° in length. The comet of 1680, the most celebrated of modern times, and on many accounts the most remarkable of all, with a head not exceeding in brightness a star of the second magnitude, covered with its tail an extent of more than 70° of the heavens, or, as some accounts state, 90°.—*Sir J. Herschel's Treatise on Astronomy.*

## MISCELLANEOUS.

**EXTRAORDINARY BALLOON EXCURSION.**—On the 8th of April 1835, Mr Clayton made an ascent in a balloon from Cincinnati, and made the most extraordinary aeronautic excursion, in point of distance, on record. His balloon took a south-easterly direction, and the greatest altitude to which he ascended was two and a half miles, at which height the thermometer stood at 23 degrees. In his progress he descended to nearly the earth's surface; and, on throwing out his anchor, it caught firm hold of the top branch of a tree, in the midst of a dense forest, on a considerable elevation. The wind blowing powerfully, and finding it impossible to extricate himself, he cut away the cable, and soon ascended to an altitude as high as formerly; where he found the temperature intensely cold, but could not ascertain the height of the thermometer. He, however, conceived it to be as low as zero. He put on his gloves, wrapt himself up in two blankets, took some brandy, laid himself down in the bottom of the car, and fell fast asleep. He was awakened by the car striking on the tops of trees, where he

landed in the midst of a forest, at half past two o'clock. The spot where he landed was the top of a mountain 3000 feet, as indicated by the barometer, above the level of the Monroe county, Virginia. The distance travelled was three hundred and fifty miles in a direct line, or more than four hundred by the ordinary route, and this in the short space of nine and a half hours, which is at the rate of thirty-seven miles an hour. But as it was calm for some time after his ascent, the speed during part of the excursion must have been much greater; and this is without taking into account the distance in ascending and descending twice.

## REVIEWS.

*Bridgewater Treatise.*—*On the Wisdom and Goodness of God, as manifested in the Creation of Animals, and in their History, Habits, and Instincts.* By the Rev. W. Kirby, M.A., F.R.S. 2 vols. 8vo. London. 1835.

THOUGH interspersed with much interesting detail, especially regarding the lower classes of living beings, this work more resembles a lecture on divinity than a philosophical treatise. It has evidently the appearance of being *made to order*; and in stead of being delighted with such accounts of the beautiful adaptations in the structure of animals, as are given in the philosophical pages of Cuvier, the reader is fatigued with discussions on the etymology of the Cherubim and Seraphim, and on the fall of Adam. The learned author gravely discusses whether Adam and Eve were troubled before the fall "with certain *personal pests*;" and argues, very plausibly, that parasitic worms were created after the fall, and that their eggs did not exist in the intestines of Adam and Eve before that event. His attack of Laplace and Lamarck seems out of place. We shall return to this work at a future opportunity.

## OBITUARY.

**BARON WILLIAM DE HUMBOLDT** died at Berlin on the 8th April 1835. He was remarkable on account of his extraordinary colloquial knowledge of languages, as well as the philosophy of every tongue of which he could obtain any information. Besides all those of Europe and the East, he was skilled in the languages of North and South America; and he had also an intimate acquaintance with the customs of various countries. He was also eminent as a statesman. The following affectionate account of his last moments, communicated to M. Arago by his brother, the celebrated traveller, Baron Alexander De Humboldt, cannot fail to prove acceptable to our readers:—"While we labour under the burden of severe affliction, we are apt to think of those who are dearest to us, and I feel a solace in writing to you. For ten days we watched his death-bed. His debility had increased for some weeks previously, which was manifested by a ceaseless trembling in all his extremities; yet his mind was unimpaired, and his labours were unabated. He has left two works nearly completed—the one, on those languages of the Indian Archipelago which have sprung from the Sanscrit—and the other, on the origin and philosophy of languages in general. Both will be published. My brother has left the MS. of these works, and his valuable collection of books, to the Public Library. He died of an inflammation on the lungs; and, from its commencement, he traced its progress with an affecting certainty. His mind was of the highest order, and his soul noble and elevated. I continue sorrowfully isolated, but hope for the pleasure of embracing you this year."

## LEARNED SOCIETIES.

**ROYAL INSTITUTION.**—In the course of a lecture on metals, on Saturday the 13th June 1835, Professor Faraday stated the following curious particulars respecting the gold coinage: A small ingot of gold (which he held in his hand, and which measured about ten inches in length by two in breadth), which weighed about 20 pounds troy, was worth L.1000. Last year, 1834, the coinage was somewhat smaller than the average amount; only half sovereigns were coined, and those to the value of L.66,944, or in weight 1433 pounds troy. The quantity of gold that had passed through the Mint since the accession of Queen Elizabeth to the throne, in the year 1558, to the end of last year, was 3,353,568 pounds weight troy. Of this nearly one-half was coined in the reign of George III.—namely, 1,594,078 pounds troy. The value of the gold coined in the reign of that sovereign was L.74,501,586. The total value of the gold coin issued from the Mint since 1558, was L.154,702,385. This gold, if made into a cubic form, would measure on each side thirteen feet thirty-two hundredths. It was extremely difficult to account for the constant loss in the quantity of gold; it continued to be brought in great quantities every year into this country, and yet the value of it did not fall. It was true that population had greatly increased; but that was not alone sufficient to account for the increased consumption of gold. Between the years 1492 and 1823, the estimated value of the gold imported into Europe from the New World was not less than L.1,223,000,000. The average value of gold brought into England for the last few years was L.1,600,000. The far greater portion of this was used in manufactures and articles of jewellery. A considerable quantity was made into gold-leaves, the intrinsic value of each of which was about one halfpenny; and the wages of labour and the profit of the manufacturer were an additional farthing; making altogether a charge of three farthings for each leaf. On the average, nearly two millions of these leaves were manufactured every week in London. Not more than one-half of this was returned in another shape to the goldsmith; scarcely any portion, however, of the gold used in gilding frames was lost, as the Jews carefully looked after the old frames, and burnt the gold off. The ordinary wear and tear of the gold coins probably amounted annually to about one-fiftieth part of their value.

THE EDINBURGH  
JOURNAL OF NATURAL HISTORY,  
AND OF  
THE PHYSICAL SCIENCES.

N<sup>o</sup>. 2.

SATURDAY, NOVEMBER 7, 1835.

ON THE PLEASURES AND ADVANTAGES OF THE STUDY OF  
NATURAL HISTORY.\*

“*Ille*,” says the great Linnæus, “who does not make himself acquainted with God from the consideration of Nature, will scarcely acquire knowledge of him from any other source; for, if we have no faith in the things which are seen, how shall we believe those things which are not seen?”

Natural History, or the study of Nature, may be considered as the parent of natural religion. The history of the world shows, that most nations have had some method of tracing the hand of the Great Author of the universe in his works, and have thence deduced some particular reasons for loving and reverencing him. From the study of Nature we are taught that sublime lesson, inculcated by the religion and morality of every civilized people, and not altogether unfelt even by the untutored savage, namely—to know and acknowledge the divine Author of Nature.

Without considering, at present, that knowledge of the ALL-WISE, derived from revelation, we may remark, that those habits of study and reflection, which arise from seeking after the wonders, of what are termed *natural objects*, directly lead us to acquire a knowledge of the Great Being who formed them. As we advance in pursuit of these inquiries, we are led to admire, at every step, the astonishing skill and contrivance manifested in his works; and we are lost in wonder and admiration of the superhuman power and wisdom displayed in the general system of the world, and in its various details.

For these reasons, the knowledge of the Author of Nature, through his works, may be designated the universal religion; just as the love of rectitude—a regard for justice, for temperance, and for truth—may be termed the universal morality. Neither of these interfere with the religion or morality of any particular people.

This is, then, the first and chief use of the study of Nature. We are taught to look from Nature up to HIM who formed the universe, and who imparts the living principle even to the lowest degrees of animal and vegetable existence.

An extensive acquaintance with natural objects, either in individuals or in a nation, cannot exist without producing great and corresponding improvements in taste, in literature, and in the elegant arts. A correct knowledge of natural objects will elicit greater accuracy in the delineation of them, both in the artist and in the man of letters. It is well known that the public taste is gradually, nay rapidly, improving in respect to painting, sculpture, and architecture; and no inconsiderable portion of the improvement will be found to be attributable to the more correct representation of natural objects. This improvement has also extended itself to our manufactures, more especially to the figures printed on cotton, paper, and earthenware; the great superiority in these is acknowledged chiefly to consist in the more correct imitation of plants, animals, and general scenery.

With what attractive charms this goodly frame  
Of Nature touches the consenting hearts  
Of mortal men! and what the pleasing stores  
Which beauteous imitation thence derives  
To deck the poet's or the painter's toil!

AKENSIDE.

What rational pleasure, or instruction, can a reflecting people derive from the representations of beings, which never had an existence, except in the imaginations of heathen nations? Can there be any really solid taste in admiring a hippogriff, a pegasus, a phoenix, a griffon, a dragon, and fifty more such fictitious animals, which have so long held sway in the ornamental parts of architecture? To the mere student of antiquities, who knows nothing of the beauties of creation, these may call up certain associations, but they are looked at, thrown aside, and treated with contempt by the lover of Nature. As natural history consists in an accumulation of facts, and as it is the province and the delight of the disciples of Nature to trace the *true character* of every object in Nature; so every thing which is detected as departing from the truth, must create disgust rather than pleasure, in those who are accustomed to search after her beauties.

The study of mineral substances is of the greatest importance: for we are led by means of them to the improvement of all the useful arts. What would civilized man be without iron? An acquaintance with the different strata, which compose the crust of the earth, enables us to detect the localities of coal and other useful minerals; and hence the importance of this species of knowledge in working mines and quarries. A knowledge of geology adds greatly to the interest of the traveller in passing through a

country; while we are enabled to learn the past history of the globe from the changes which have evidently taken place on the earth's surface.

Having thus shown the utility of the study of Nature, we now turn to the pleasure to be derived from a pursuit of it. We must in the first place premise, that we consider all knowledge to be pleasure, as well as power; and that in the pursuit of pleasure, the reward obtained will be commensurate with the labour bestowed. These are facts which the reason and experience of ages have incontrovertibly established, and they ought to be treasured up in the mind of every young person, as perpetual incitements to exertion.

From this, however, we would not wish the young student to imagine, that very great mental exertion is required in the study of natural history; for the very reverse is the fact. The principal thing required is a good memory and a correct eye, both of which can be wonderfully improved by practice. It is the want of attention alone which makes the discrimination of objects *appear* a difficult task; for no sooner do we become acquainted with the trivial distinctions, than we are surprised to find how easy it is to recollect them; and things which appeared wrapt in mystery, now become obvious and familiar to us. It is the mere want of knowledge of the plain and simple means pursued by the naturalist, that has all along prevented thousands from following this, one of the most delightful and instructive exercises of the reasoning faculties; and, such are the charms which it carries along with it, that almost all who once enter upon the study become enthusiastically devoted to the subject.

It is our intention to introduce a series of essays, containing elementary instruction in the different departments of the system of Nature, and rendered in language which can be understood by every body. A certain number of technical terms are, however, indispensable; but these can easily be acquired.

We have said, that want of attention alone makes the task of discriminating natural objects difficult, and we shall illustrate this position by a very simple and familiar fact.

There is scarcely a human being who is not acquainted with the general appearance of a sheep. We have looked upon hundreds of them hundreds of times, and yet, strange to tell, we have not acquired an intimate knowledge of their appearance; nor can we discriminate one from another, although they are as unlike each other as are individuals of the human race. Let one be picked out from a flock of five hundred, nay, even of one hundred, and let us examine it for half an hour most attentively, and then set it at liberty again amongst its fellows; the chances are five hundred to one against us, that we shall ever be able again to find out the identical sheep. But let the experiment be tried with a shepherd, and he will, in a few minutes, detect the sheep, although set at liberty amongst thousands. And the shepherd requires no uncommon sagacity to be able to do so; for, on the contrary, there is scarcely a man exercising the calling, who will not readily perform this easy task. So it is with the study of Nature; a little attention and experience will soon render any object familiar and comparatively simple.

The young student, who aspires to become a zoologist, a botanist, or a geologist, need not, therefore, be discouraged from attempting to obtain his share of the superior delight which scientific knowledge can afford, by the obstacles which, only in *appearance*, oppose the acquirement.

Every step in the pursuit produces a reward and gratification in exact proportion to the difficulty; and each advantage, thus gained, produces fresh excitement to proceed in the path of science. Let us draw our illustration from the vegetable kingdom. Every plant, for example, of which we acquire a knowledge by sight and name, so as to be able to recognize it in another locality, not only gives a distinct pleasure at first, but the pleasure is renewed and increased, when we meet it for the second and third time, probably under very different circumstances, either as relate to ourselves, or to the plant. Thus, even the simple knowledge of the name, which enables us to communicate our ideas, although in an indistinct manner, brings with it sensations of a pleasurable kind, and often proves a source of the most interesting associations. But the pleasure we derive from a knowledge of the trivial or popular names of plants, becomes greatly enhanced by more extended views regarding them, which are not strictly botanical. We are astonished when we study their geological relation in any particular district or country; their geographical distribution, relatively to the world itself, or their migration from one country to another; their connection with climate; their being domestic plants, which follow man in his improvement and change of soil, or wanderers seeking to inhabit distant regions, formerly uninhabited by their kinds, or by their being social, and living, like man, in large communities; their abundance or rarity; their mode of propagation; their natural enemies, or more kindly friends; and, lastly, their properties, functions, uses, and culture. It is in acquiring a knowledge of all these that real pleasure is experienced; and, as we acquire this knowledge, our desire to become still farther acquainted with them increases.

\* The principal part of this article was contributed, several years ago, by a writer in this Journal to Chambers's Edinburgh Journal; and it is inserted here by the kind permission of the proprietors of that deservedly popular periodical.

To know any natural object, however, does not merely consist in having seen it, or in recollecting its name. For we cannot be justly said to be acquainted with a plant until we know its rank in the vegetable kingdom, its structure and habit, with all the other circumstances already explained.

There is hardly a child who cannot at once name a ranunculus, or tulip; but how few, even who cultivate these deservedly-admired productions of the garden, are aware that these two plants, however nearly they may be allied as fine flowers, are very different, in point of rank, in the scale of vegetable creation! They belong to separate fundamental divisions of plants, and the organization of the one is much more perfect than that of the other. They display totally different characters of structure and physiological economy, from the seminal embryo, through every stage, to the perfect plant. The ranunculus belongs to a division of plants characterized by a reticulated, or net-like structure, in their parts. It will admit of portions of its leaves being broken, or cut off, without impeding the remainder of the leaf in the performance of its functions; or, in other words, the leaf will continue to grow, and arrive at a state of maturity, although deprived of a portion, or limb. Now, the tulip belongs to a division, the structure of whose fibres are parallel, and will not admit of part of the leaves, more particularly their extremities, being cut off, without impeding their functions, and, consequently, injuring the present health of the plant, and affecting its vigour for the following year. Here, then, we have another example of the utility of natural knowledge; for any one who has paid the slightest attention to the anatomy or physiology of plants, will at once be able to know the distinctive structures of these two divisions; and, if only a part of a leaf be presented to him, the division to which it belongs will immediately be detected by him, and, consequently, the fundamental arrangements, culture, and general management of the plant, as far as regards its most important organs; for leaves are analogous to the lungs of animals. Thus we have the increased pleasure of not only knowing the plant by its name, but also its rank in vegetable physiology, and the manner in which its various functions are exercised.

One of the most extraordinary phenomena in nature is the endless variety of forms in the distinct species of animals, plants, and minerals; and still more wonderful are the infinite modifications of form in the same species. For it is our conviction, that, since the creation of the world down to the present time, there never has been two individuals of the same kind, formed exactly alike in all their parts. This leads us naturally to an expression of our admiration of the works of Providence, in the words of the Psalmist, "O Lord, how manifold are thy works! in wisdom hast thou made them all!"

This idea is sublime; and, however erroneous it may appear to those who have not deeply studied Nature, we firmly believe that it is nevertheless true. Let us illustrate this by another example from the vegetable kingdom. Behold the stately oak of the forest, spreading his branches afar on every side, rearing and shedding his millions of leaves for a series of hundreds of years, but never producing two leaves exactly alike; nay, even consider the leaves of the countless oaks existing at the same moment on the face of the globe, ever varying in appearance; yet a general similarity of form has been, and will be, maintained to the end of time! Let any one who is sceptical on this point repair to the forest, and patiently examine every leaf which has clothed one of its largest oaks, and he will never be able to find two of them perfectly alike in size, shape, and particular structure; nay, he may extend his search to all the oaks of a forest, and he will discover that he has been seeking for that which, like the philosopher's stone, will never be found. So it is with all the works of creation, whether animate or inanimate. One uniform and fundamental plan has been established, alike in its grand leading principles, but exceedingly varied in its detail; and we are thence led to admire the profound wisdom of the Creator and Preserver of the universe. Let us for a moment suppose that all mankind were formed exactly similar. What would be the consequence? Endless monotony, confusion, and crime. The variety of form and intellect in the human species, creates in us those varied sensations of pleasure, which are derived from the admiration and love of one object beyond that of another, for some real or fancied quality. If all were alike, the love of one particular object could not exist, and a disgusting monotony would every where surround us. A man would not know his own wife, nor a child its parent; perpetual scenes of confusion would prevail, and crime could not be traced to its perpetrators. There would be a total want of those varied sentiments which hold their sway over the human heart, and from which emanate every thing that is pleasurable in existence. It has, however, pleased the Dispenser of good to order every thing otherwise; and we now behold the world one vast machine, infinitely varied in its parts, but all of them tending to the furtherance of one mighty design.

The study of Nature teaches us to discover that, in the animal kingdom, there seems to be one great chain of being, from man down to the lowest scale of animated existence; and it is not impossible but that this may prevail even through the vegetable and mineral kingdoms, although man has hitherto been unable to detect the connecting links.

Each shell, each crawling insect holds a rank  
Important in the plan of him who form'd  
This scale of beings; holds a rank, which lost,  
Would break the chain, and leave behind a gap  
Which Nature's self would rue.

STILLINGFLEET.

Natural history is a study calculated in an especial manner for elevating the character of the labouring classes of society. Indeed, it may be said to be a study in which most labourers and mechanics are already engaged. Their implements, and the materials which they manufacture, are all derived from the field of Nature, and are only modified by the experienced hand of man from his knowledge of the several qualities which appertain to each. Besides, it requires less preliminary information than almost any other branch of study; and even the humblest individual has within his reach the means of contemplating Nature in one form or another. It is a much more rational manner of spending time than in dissipation, which debases the mind and undermines the constitution. While other branches of study have the

effect of improving the reasoning powers of the mind, natural history may be said to improve and humanize the whole man. The intimate connexion between moral conduct and the love of animals and plants, will be thought intimate or remote according to the ideas of different individuals; but the more we consider and trace the design and purpose of the works of creation, shall we not sympathize the more with the fitness of man to the ends of human conduct? The deeper we enter into the details of nature, shall we not increase our relish for facts? This is nothing less than laying the foundation for the love of order, of justice, and of honesty.

Even those who have no knowledge of scientific zoology, derive great pleasure from their observations on the manifest variety in the forms, habits, and instincts of animals; and mankind are accustomed from these observations to transfer to some of the higher quadrupeds many of the virtues of humanity. We speak of the courage of the horse, the generosity of the lion, the sagacity of the dog, and the innocence of the lamb; we are delighted with the melody of the songsters of the grove; the industry of the bee holds up to man a useful lesson; the gay attire of the butterfly pleases us; and the noxious and disgusting appearance of various reptiles excite in us varied emotions. But all these are nothing when put in comparison with the pleasure derived by the scientific zoologist. He who can trace the varied degrees of power and intelligence, imparted by the Supreme Being to animals, from intellectual man down to the lowest animalcule,—who can trace the complicated organization of beings down to the minutest conferva or lichen, and who knows scientifically that man is the most perfect of all created beings, enjoys a degree of exalted pleasure which scientific knowledge can alone impart.

## ZOOLOGY.

### DESCRIPTION OF THE PLATE—THE DEER.

THE animals of this active and beautiful tribe belong to the genus *Cervus* of Linnæus; they principally inhabit wild and woody regions. The species of this genus vary much in size. In their contentions, both among themselves and with other animals, they not only use their horns, but also strike furiously with their feet. Some of them are used as beasts of draught. The flesh of the whole tribe is accounted particularly delicious, and well known by the name of venison.

The males only are provided with horns; these are solid—branched; and are shed and renewed annually.

Fig. 1.—The Fallow-Deer (*Cervus dama*.) It is this species which is kept in the deer parks of Britain. It is readily tamed, and feeds upon a variety of vegetables. This animal, like nearly the whole tribe, is gregarious; and in parks where numbers are kept, they frequently divide into two parties, and maintain obstinate battles for some favourite parts of the pasture. There are two varieties of Fallow-Deer in Britain, both of which are said to be of foreign origin: the beautiful spotted kind, which we have figured, is supposed to be a native of Bengal; and that variety without spots, which is now very common in our parks, was introduced from Norway by King James I.

Fig. 2.—The Virginian Fallow-Deer (*Cervus Virginianus*), associate in numerous herds, and supply a most palatable food to the inhabitants of the back settlements of North America, and to other wild tribes. This species can at once be distinguished from the former by its horns being arched forwards.

Fig. 3.—The Long-tailed Deer (*Cervus macrourus*.) This species is larger than the Red-deer, and is distinguished by the size of its tail, which is nearly eighteen inches in length. It inhabits the central and northern parts of North America.

Fig. 4.—The Axis (*Cervus Axis*), is a native of the warmer parts of eastern Asia, and is considered one of the most beautiful of the group of which it is a member. In its general form and markings, it somewhat resembles the Fallow-Deer, but is at once distinguished from it by the structure of its horns.

Fig. 5.—The Malayan Rusa Deer (*Cervus Equinus*.) This animal differs from most of its congeners by its neck and throat being furnished with a thick coating of long bristly hair. It is a native of Bengal.

Fig. 6.—The Guazopuco Deer (*Cervus paludosus*), inhabits South America, and is nearly equal to the European Stag in point of size. Its horns are, however, of comparatively small dimensions. A distinguishing mark of this animal, is the long and flowing hair which ornaments its abdomen, back of the thighs, and under side of the tail.

Fig. 7.—The Nepal Stag (*Cervus Wallichii*), is fully larger than the stag of Europe, and differs from it in having two small antlers at the base of the horns, projecting forwards. Its colour is of a yellowish brown, mixed with gray; it is distinguished by having a very short tail, and a disk of white spreading above the croup.

HUMANITY OF A WREN.—In the end of June 1835, a person was shooting in the neighbourhood of Bandrakehead, in the parish of Colton, Westmoreland: he killed a brace of Blue Titmice (*Parus caruleus*), which some time before had been observed to be constructing a nest, in the end of a house, belonging to a Mr Innes of the same place. In the course of the day, it was ascertained that the Titmice had completed the time of incubation, and that their death had consequently left their offspring in a state of utter destitution. This, however, was not long permitted to continue, for the chirping of the young birds attracted the attention and excited the compassion of a Wren; which, since that period, has adopted the nestlings, and was daily engaged in rearing and feeding them, with the affectionate kindness and unremitting assiduity of a parent bird.

FATAL BITE FROM AN ADDER.—In a moss in the neighbourhood of Buckleyvie, a farm servant, while engaged in cutting peats, a few months ago, was stung by an adder, and died in consequence of the wound in about ten days.

MIGRATION.—By wonderful instinct, birds will follow cultivation, and make themselves denizens of new regions. The crossbill has followed the introduction of the apple to England. Glenco, in the Highlands of Scotland, never knew the partridge till its farmers of late years introduced corn into their lands; nor did the sparrow appear in Siberia, until the Russians had made arable the vast wastes of those parts of their dominions.

BOTANY AND HORTICULTURE.

**AGES OF TREES.**—From examining the layers of wood, it has been satisfactorily ascertained, that olive trees will live in favourable situations for 300, and oaks for 600 years. Greuw, in the year 1400, cut his name on two *Boababs*, and Petiver did the same thing 149 years afterwards. In 1749, Adanson saw these trees, and at that period they had increased seven feet in circumference since the time of Petiver, being an interval of 200 years. These trees are, however, sometimes found to acquire a perimeter of 435 feet; from this it is inferred that they must live many thousand years. The long period required to ascertain the age of trees, renders our knowledge on this subject very imperfect; and it will probably long remain so until records are established by scientific institutions, to ascertain the ages of such trees as are public property.

MINERALOGY.

**PLATINUM IN SIBERIA.**—This valuable metal has been discovered in Siberia; it is found in fine sand. A piece was got at Nischde Tagil, in 1827, which weighed 8 pounds 13 ounces and 4 drachms, avoirdupois. In 1831-32, three pieces were obtained, the two first weighing 17 pounds 11 ounces, and the third 11 pounds 1 ounce and 1 drachm. It is accompanied with gold, osmium, iridium, magnetic iron, chromium, brown oxide of iron, oxide of titanium, epidote, garnet, rock crystal, and sometimes diamonds. The sand in which it occurs is composed of jasper, green stone, and quartz; and also small yellow crystals, of rhomboidal dodecahedrons, resembling chrysoberyl, the precise nature of which is not yet known. Among the class of rocks which accompany platinum in the Uralian chain of mountains, serpentine is the most remarkable. Gold appears generally to exist in the same rock with platinum.—*Records of General Science, April 1835.*

GEOLOGY AND PHYSICAL GEOGRAPHY.

**LARGE FOSSIL OAK TREE.**—In February 1832, in the course of excavating the basin of the harbour at Aberdeen, and within one hundred and fifty yards of the Trades' Hospital, there was found embedded within a few inches of the surface of what was formerly the Green Inches, an oak tree of very large dimensions. It was lying in a horizontal position, in a north-west and south-east direction. The trunk, from the root to where it separated into limbs, was 6 feet 6 inches long, and 20 feet 2 inches in circumference; one of the limbs measured 23 feet 6 inches in length, and 13 feet 10 inches in circumference; the other limb, 8 feet long and 9 feet 7 inches in circumference; and from these two limbs various large branches appear to have struck off, some part of which still remained. The cubical contents of the trunk and two limbs are upwards of 380 feet. As it does not appear that the tree could have grown in the place in which it was embedded, and as the timber had not the marks of decay which are frequently to be seen on very old trees, it could only have been a flood of the river, equal if not greater than that of 1829, which could have brought it from its native soil, while encumbered with its immense branches.

**FLOOD OF THE GARONNE.**—The city of Toulouse has lately been devastated in a manner which has not been surpassed during the last fifty years. In the night of the 29th May 1835, the waters of the Garonne increased so suddenly, that before any measures of security could be taken, several depots of wood in the Port Garau, and the suspension bridge of Mourat, were washed away. The handsome stone bridge at Puisaquel lost two of its arches, and a third received considerable damage. On the 1st June, the waters having partly subsided, the Garonne was confined to its natural bed; but above Toulouse it broke its bank, and the inundation extended far and wide. We learn also, that throughout the whole department, the sudden swelling of unnavigable rivers had occasioned great disasters, and had carried away several mills. In Toulouse, fifty houses were destroyed.

METEOROLOGY.

**EFFECTS OF LIGHTNING.**—At the conclusion of the evening service on Sunday, 21st June 1835, the church of Semur, in the Cote d'Or, in France, was struck by lightning. The electric fluid was divided by the conductor, but entered the windows of the vestry, tore up the floor, and gave a violent shock to a person who was in it. The Abbe Bernard, who was kneeling on a chair, had one of his shoes burnt. The people, who were in the square before the church, received the shock, being all affected in the legs. The river was so much swollen, that the water rose in the houses near the bridge up to the ceilings. A poor woman, while endeavouring to save some of her little property, was crushed by a beam falling upon her.

**FIRE BALL.**—On Wednesday the 24th June 1835, as some fishermen were pursuing their occupation, about six miles off the shore at Stonehaven, they were much alarmed at the sight of a large fire-ball, which spread a brilliant glare all around, and appeared to fall on the bosom of the deep. There had been a considerable thunder storm in that neighbourhood on the previous day.

**REMARKABLE METEOR.**—On the Chinese frontier, near Kiakha, while the weather was very calm and extremely cold, on the 11th of March 1835, there was observed, a few minutes after 9 P.M., at an extraordinary elevation in the north-west, a fiery meteor, in a serpentine form, of a most dazzling brightness. In an instant this meteor was converted into a brilliant cloud, resembling an immense blazing sheaf, which proceeded to precipitate itself obliquely, with extreme rapidity, towards the earth, assuming the form of an enormous sheet of flame, which filled all the visible space of the horizon with a light as clear as day, and, separating into three portions, disappeared. The roar of distant thunder was then heard, and this occasioned a tremulous motion to be felt in the houses. Two other sounds were perceived, but these were reckoned merely the echoes of the first reverberating from the neighbouring mountains. This phenomenon, which lasted but a few seconds, has not occasioned, as far as has yet been ascertained, the least damage.—*Russian paper.*

GENERAL SCIENCE.

MILITARY MORTALITY IN THE BRITISH COLONIES.

MAN possesses a greater power of adapting his frame to different temperatures and climates than any other animal. But this power has its limits; and we find that a person, who has long been inured to the chill blasts of an arctic region, or to the milder airs of Britain, is frequently incapable of resisting the burning heats of a tropical climate. A sudden transition from the one to the other is often attended with fatal consequences. Individuals may escape its immediate effects; but when large bodies of men are considered, a greater mortality is absolutely certain to occur. This fact has been long noticed, in public and private records, by the frequent premature decease of many a gallant officer or near relative; and the popular views on this subject are fully confirmed by the following

OFFICIAL RETURNS

Of the mortality among officers and soldiers in the several British colonies—chiefly for the seven years from 1820 to 1826—showing the annual deaths out of 10,000 men:—

		Excess per cent.

Other climates seem to exercise an opposite influence over the human frame; and longevity is often promoted by exchanging the moist and ungenial air of Britain for the purer climates of the South and West. The following returns, procured from the same source, and for a similar period with the preceding, point out the annual deaths in 10,000 men. For

Great Britain (1824 and 1826),	144
Lower Canada,	138
Cape of Good Hope,	133
Nova Scotia,	115
Upper Canada,	107
Gibraltar,	107
New South Wales,	68

These returns generally include the whole regiments stationed at the several colonies; and it has been thought probable, that if we could distinguish between officers and private soldiers, the mortality of the former would be found much less than that of the latter. Private soldiers are more exposed to severe fatigues, and to night guards; while their general habits are likely to lead them to more frequent excesses, and to neglect the first appearances of disease. For these reasons, it has been considered that the mortality among them should exceed that among officers alone, by about one-third.

How far the above-mentioned difficulties may necessarily attach to the military life in general, we shall not at present attempt to determine. But, we have no hesitation in asserting, that the degree in which the average duration of the life of the officer exceeds that of the private soldier in foreign climates, has been very greatly exaggerated.

It is well known that, unless a statement of the law of mortality, in any place, is founded upon a very wide induction of particulars, it is in an eminent degree calculated to mislead. Surprising and unaccountable differences will be found to prevail in the mortality of small classes of men, in succeeding years, and in comparison to the rest of the community. It is only when the observations are extended over a large commu-

nity, that any fixed *law* is found to exist; and, whenever a small number of individuals are alone included in the inquiry, the results must be received with considerable caution and reserve.

As the number of officers always bears a small proportion to that of the privates of a regiment, it becomes almost impossible to distinguish the one from the other, in framing a table of mortality. Who would think of attempting to ascertain the duration of human life in London or Edinburgh, by recording the deaths among his acquaintances? Yet few persons of any importance can number less than 136, which is the total number of British officers who have resided in the island of Ceylon, for a period of nine years.

A writer in the *United Service Journal* for June 1835, in an article of some interest, gives the first two columns of the following table, as being the observed mortality at the several stations, among officers alone. We have added a third column, which is deduced from the others by calculating the mortality for a radix of 10,000 men, that we may be able to compare it with the tables already given, for officers and private soldiers collectively.

MORTALITY AMONG OFFICERS IN THE BRITISH COLONIES, DURING THE NINE YEARS FROM 1826 TO 1835.

Station.	Officers.	Deaths.	Die annually out of 10,000.
Corps at home . . . . .	936	96	114
Bengal . . . . .	388	138	395
Madras . . . . .	398	158	441
Bombay . . . . .	186	44	263
*Ceylon . . . . .	136	15	123
*Mauritius . . . . .	113	10	98
*Jamaica . . . . .	178	45	281
Windward and Leeward Islands . . . . .	283	45	177
*New South Wales . . . . .	102	11	120
Cape of Good Hope . . . . .	102	12	131
North America and Bermuda . . . . .	351	28	89
Gibraltar . . . . .	219	22	111
Malta . . . . .	140	12	95
Ionian Isles . . . . .	212	22	115

We have marked with an asterisk (\*) those returns which appear particularly liable to suspicion: the first three on the list are probably not very far from the truth.

Upon comparing these results with the tables for officers and private soldiers collectively, we shall find the mortality to be represented exceedingly low—to a degree, in some cases, altogether extravagant.

We particularly notice Ceylon, in which the mortality is stated to be very slightly greater than in Great Britain, being only as 123 to 114—a result completely at variance with all other documents. A good authority on this subject describes the climate as being exceedingly diversified according to situation. In some parts, it is hot and oppressive, and liable to frightful storms of thunder and lightning; in others, it is more temperate and salubrious. But the woody parts prove destructive to strangers, who frequently become victims to the putrid miasmata, which taint the atmosphere. Until lately, the kingdoms of the interior have been guarded from the attacks of Europeans by the insuperable barrier of an unhealthy climate; and those who escaped the hazards of war generally fell victims to the ravages of disease.

How far the healthiness attributed to this island in the returns, may arise from the peculiar facilities afforded by an insular situation to such officers, whose constitutions are broken down, to die in peace on the passage homeward, and thus to escape enumeration in the returns, we cannot at present determine. Ceylon was believed, and is yet considered by many of the Orientals, to have been the paradise where Adam was created. Hammalleel, or Adam's Peak, is still held in great veneration by the natives. But though the notion, that Ceylon was paradise, may be popular, we must protest against documents which would give rise to the belief, that it is so still, at least in respect to the duration of human life.

In conclusion, we earnestly entreat our military friends, who are anxiously looking out for a station congenial to health, to be certain that the data on which they found their calculations are derived from a sufficiently wide induction of particulars, before they trust themselves implicitly to their guidance. We would recommend the seniors of each rank rather to expend their money in purchasing the chance of promotion by death or vacancies in Ceylon, than in negotiating an exchange to this boasted land of promise.

#### MISCELLANEOUS.

THE EUPHRATES EXPEDITION.—(From the *Malta Gazette*, June 3.)—By his Majesty's brig *Columbine*, Commander Henderson, from the *Orontes*, we have received some account of the Euphrates expedition and its first proceedings. Colonel Chesney and the whole of the officers and men were quite well on the 3d of May; they were encamped on a spot near the mouth of that river, to which they have given the name of *Amelia Island*.

The *George Canning* was towed by the *Columbine* almost the whole way from Malta to the bay of the *Orontes*, where the expedition anchored on the 3d of April. On the 6th the landing of the packages and stores was commenced by means of a hawser, which was extended over the bar from the *George Canning* to the shore, a distance of 1,200 yards, by the officers and men of the brig of war. Captain Henderson likewise stationed Lieutenant Thomson and Mr Pritchard, with 25 men, at the camp established on shore; and everything being thus well disposed, nearly two-thirds of the whole of the equipments were landed by the boats of the two ships, eight in number, during the first week. The only accident that happened was the temporary loss of a cask, containing the valves and other parts of the steam-engines, which, by the breaking of the slings, sank to the bottom; but it was soon recovered by part of the apparatus of the diving-bell.

The attention of the officers of the expedition was then directed to other objects. To Captain Estcourt was allotted the repair of the road to the Euphrates; to Lieutenant Murphy and a party the survey of the bay of the *Issus*; to Lieutenant Cleave-

land the landing of the stores and the preparation of the caravans; whilst Colonel Chesney and Lieutenant Lynch, of the Indian Navy (who had been waiting and preparing for the expedition some time in Syria), were employed in soliciting aid from the authorities of the country, and making arrangements with the Arabs near Bir, on the Euphrates, whither Lieutenant Lynch proceeded to receive the first section of light materials, which would have arrived there about the 17th, if it had been possible at once to procure camels.

During the second week the weather was so boisterous as to retard the landing a good deal, and the gig of the *Columbine* was upset on the bar with Captain Henderson and four men in her, who were all happily saved by a boat which immediately pushed off from the *George Canning*. But, notwithstanding the bad weather, by the 21st every thing was disembarked except a few coals.

The estuary of the *Orontes* appears to have been a happy selection for the disembarkation of the expedition; and the success with which it has been effected may be a favourable omen of its future progress. *Amelia Island* is described as presenting a scene of high interest. The people of the surrounding places constantly visited the camp, and viewed with wonder and amazement the operations of our sailors and mechanics. The landing of the boilers and large pieces of the iron steam-beats and engines, as well as the fishing up of the heavy cask from the bottom of the sea, caused the greatest possible surprise. In truth, the various costumes, the mixed nature of the stores, the general activity which connected the ships with the shore, and the beautiful scenery, with the crest of Mount Cassius towering above to the height of 5,618 feet in the back-ground, formed altogether a striking picture on the ancient coast of Syria. Since the above was published, a private letter has been received, which gives us later information. It is dated "*Orontes Camp, Amelia Island, May 23d, 1835.*"—I wrote you on the 2d instant by his Majesty's brig *Columbine*. We have since put the *Tigris* together; we commenced laying her down on the 6th, and had her ready for launching on the 21st, being thirteen working days. Her draft of water, when launched, with the two bed-plates and air-pumps of her engines, was  $6\frac{1}{2}$  inches upon an even keel. The intention of putting her together at present is, that we hope to be able to carry the other boat, heavy weights, &c. up the *Orontes*, as far as Antioch, a distance of about twenty miles, which will enable us to avoid a range of mountains, that we should have to contend with in land carriage, after which we intend to take her to pieces in eight sections, for transportation to Bir. All the men are in excellent health and spirits."

#### OBITUARY.

In the month of May last, at Chamarande, near Paris, died T. R. Underwood, Esq., Fellow of the Geological Society of London. He was born in London, the 24th of February 1772. The disease under which he sank, after long and constant suffering, originated, many years ago, in the *antrum maxillare*. Mr Underwood enjoyed the acquaintance of several of the most distinguished men of the age. He was an excellent artist, and a perfect judge of the arts—of much patient industry and indefatigable research. Geology seems to have been his principal study, but his attention was by no means confined to it; for, as a naturalist, he had accumulated an immense variety of observations, which, if placed in some able hand, would contribute largely to the general stock of knowledge. Mr Underwood was a Protestant; and, on the occasion of his interment, it is gratifying to record an instance of liberality on the part of the Roman Catholic clergyman of the village of Chamarande. In the absence of a Protestant minister, none being within many miles, the rev. gentleman, in a spirit which reflects the highest honour on his feelings and his character, led the mournful procession which followed the remains of the deceased to their last resting-place. Mr Underwood was so great an enthusiast in science, that he wished only to live that he might witness the return of Halley's comet; and would have consented to an excruciatingly painful operation, if his surgical friends could have given him hopes that his life could have been prolonged by it only for a few weeks.

#### LEARNED SOCIETIES.

GEOGRAPHICAL SOCIETY.—The president, Sir John Barrow, in the chair. A letter, addressed to Dr Hancock from Mr Paterson, a gentleman residing on the river Demerara, British Guiana, was read, on the climate and productions of that country. The seasons, it appears, have, within the last twenty years, become far less regular than they formerly were; and it is now somewhat difficult to predict, with precision, when the wet or dry seasons will set in. The wet season used to commence about the middle of April, gradually increasing until June, when it rained incessantly, accompanied with tremendous thunder and lightning; by the middle of August, what was called the long rainy season, had quite terminated. It is now of shorter duration, and much less severe. August, September, October, and November are generally dry; December and January are wet; in February and March it is again dry. There is most thunder in June and July, and the wet season frequently terminates abruptly, after a violent thunder storm. A remarkable change has also taken place within the last fifteen years in the violence of the wind on the coast, which had an important influence on the tides, causing them to rise so high, that the camp-house, stores, &c. were frequently in imminent danger of being washed away; the tide of late years, from the decrease of the wind, does not approach within a considerable distance of the fert; and the water being now left to pursue its natural channel, has increased so much in depth, on the bar of the river, that vessels, drawing eighteen feet of water, pass without difficulty. The average rise and fall of the river at Christianburgh, sixty-five miles up, is about six and a half feet. The country affords an inexhaustible treasure to the mineralogist, ornithologist, and botanist; it abounds with valuable woods and drugs.—*Literary Gazette*, 27th June.

ZOOLOGY.

DESCRIPTION OF THE PLATE.

**THE RHINOCEROS.**—The animals of this genus are nearly equal in size to the Elephant, although they appear less, owing to their legs being much shorter, in proportion to the dimensions of their bodies. They are generally of peaceable dispositions, if unmolested, living upon herbs and branches of trees, and frequenting marshy places. There have been five species of this genus ascertained by naturalists.

Fig. 1.—The Indian Rhinoceros. (*Rhinoceros Indicus*, Cuvier.) This species has been the longest known to mankind, by the name of the one-horned Rhinoceros. It inhabits India beyond the Ganges. In a wild state, it grows to twelve feet in length, its circumference being nearly equal to its length. Its skin is composed externally of numerous horny tubercles, which render the hide impervious to the claws of the Lion and Tiger; and this, together with the formidable horn on its nose, makes it more than a match for either of these desperate animals. It is but seldom the Elephant will dare to give the Rhinoceros battle; when he does, he generally meets death as a reward for his temerity. The hide of this animal is remarkable for the deep folds formed across and behind the shoulders, as well as on the front of the legs, thighs, and flanks. The sight of the Rhinoceros is but dull, but its sense of hearing is said to be extremely acute.

Many of the Indian princes drink out of cups made of the horn of this animal. They have a superstitious belief, that, when these hold any poisonous draught, the liquor will ferment till it runs quite over the top. Martial informs us, that the Roman ladies of fashion used these horns in the baths, to hold their essence-bottles and oils. The Javanese make shields of the Rhinoceros' hide; the flesh is used as an article of food; and the teeth, which are very white and solid, are used by dentists in making false teeth.

Fig. 2.—The lesser two-horned Rhinoceros. (*Rhinoceros Africanus*, Cuvier.) This animal inhabits Africa, and differs from the Indian species in having two horns, and also in the appearance of its skin, which is nearly smooth, having merely slight wrinkles across the shoulders and hinder parts, and a few fainter folds on the sides; he also differs in colour, being usually of a brownish black; while the other species is of a violet-tinged blackish gray.

Bruce says that these Rhinoceroses are very swift when pursued, and even to a degree which is astonishing, when we take into account their unwieldy forms. Le Vaillant informs us that whenever they are at rest, they place themselves in the direction of the wind, with their noses towards it, in order to discover by smell the approach of any enemies. Bruce mentions, that, "besides the trees capable of most resistance, there are in the vast forests, within the tropics, trees of a softer consistence, and of a very succulent quality, which seem to be destined for the principal food of this animal. For the purpose of gaining the highest branches of these, his upper lip is capable of being lengthened out, so as to increase the power of laying hold with it, in the same manner as an elephant does with his trunk." It is not true that the skin of the Rhinoceros is so hard and impenetrable as to resist a musket ball. In his wild state he is slain with javelins thrown from the hand, some of which enter his body to a great depth; and the Shangalla, an Abyssinian tribe, kill him with very clumsy arrows, and afterwards cut him to pieces with the worst of knives.

**PACE OF A LOADED CAMEL.**—I have made many long journeys on camels, and I certainly think that animal, when well taken care of, and not overloaded, fully capable of marching ten or eleven hours per day, at an average rate of two miles and a half an hour, in valleys or over rough roads, and three miles on plains, without being at all distressed. On the banks of rivers, and in districts where water and forage are plentiful, except urged on, the men are always inclined to move more slowly, and make a shorter day's journey, not so much to save their camels, as to lessen the fatigue to themselves; a few days more or less *en route* being generally a matter of indifference to them.—*Travels in Ethiopia*, by G. A. Hoskins, Esq. London, 1835.

**ENRAGED ELEPHANT.**—A very characteristic action of D'Jeck, the famous elephant of M. Huguet, was lately near costing the life of a young man, a native of Bruges. The elephant, it is well known, is very fond of sweetmeats, and this young man amused himself at Madame D'Jeck's expense, baulking her by offering her some, which, whenever she reached out her trunk to take, he immediately withdrew. This trick having been noticed by M. Huguet, he observed to the young man how foolish such conduct was towards an animal at once so susceptible and vindictive. But not taking warning from this remark, the Belgian again invited the elephant to approach, and not only again deceived her, but gave the sweetmeats to Mademoiselle Betsey. Madame D'Jeck now lost her patience, and, regardless of the presence of her master and a numerous assemblage of spectators, lifted her trunk and knocked the young man down, tearing open his cheek, and rending his clothes to tatters. Happily M. Huguet

interposed his authority, and the elephant left her hold, but the imprudent sufferer was long confined to his bed from the effects of his absurdity.

**SOCIAL HABITS OF BIRDS.**—In June last (1835), a singular instance of the domestic and social habits of birds was to be seen at Auchmuty paper-mills, in the parish of Markinch, Fifeshire, where a monthly China rose-bush, trained to the front of the dwelling-house, was fixed upon by three distinct species of birds, even of different genera, to build their nests and rear up their little families. A blackbird, a yellow-hammer, and a sparrow, composed this small community. Delighted with the rich green foliage and expanding roses, amidst which they had placed their downy dwellings, they lived together in the greatest harmony and good fellowship, alternately singing their sweet notes, and watching their progeny.—*Caledonian Mercury*, 13th June 1835.

**CULTURE OF BEES.**—Mr Begbie, gardener to Sir John D. Erskine, Bart., Torry, purchased a hive (a second cast) last year, and which, towards the approach of winter, showed that the "store" was far from "complete," and quite inadequate to their wants during that season. He determined to try a novel expedient; and, in November last, buried the hive in the earth three feet below the surface, covering it carefully with straw, and placing a flag above, and then earth on the top. In April it was dug up and found to be in good condition, contrary to all expectation; and to crown the whole, this hive threw a capital swarm in June last, as a grateful testimony of the snug quarters enjoyed during winter.

**DESCRIPTION OF A NEW BRITISH SHELL.—THE CLOUDEN SCALLOP.—***Pecten Nebulosus*.—Shell almost circular, ears nearly equal in size, with seven broad, unequal, and fattish ribs; external surface of both valves covered with very fine, parallel, longitudinal striae, and also with minute, undulating, transverse striae, which are hardly discernible to the naked eye, but feel rough to the touch. Both valves are somewhat inflated towards their base, with a longitudinal series of densely-set ribs, and the margin finely crenulated, two-thirds the length of the shell. The upper, or convex valve, is of a rich, reddish brown, irregularly clouded with white; under valve, cinereous, and immaculate; inside white, of a pearly lustrous lustre, exhibiting slightly iridescent reflections. Length, one inch and seven-eighths; breadth, the same. The specimen from which the following figure was drawn was found at Largs, mouth of the Clyde, in July 1834.

We are indebted for the discovery of this beautiful species to that zealous naturalist, Mr John Blythe of Glasgow. He first noticed some fragments of this shell about seven years ago, while examining the shores at Millport, and afterwards found a perfect specimen. Mr Blythe informs us that the shell is not uncommon in Lochfine, and that his friend, Mr Drew, writer, Inverary, has procured several live specimens attached to the lines employed in cod fishing. They live in very deep water. We read an account of this shell before the British Association at Edinburgh in 1834, and were then doubtful whether it was an undescribed species. We thought that it might possibly be the *Pecten ospersus* of Lamarck, as it is nearly allied to it in form and markings. We thought that Lamarck's might be the young shell. Since that time, however, Mr Blythe has kindly presented us with two young specimens, in both of which the ribs, or rays, are seven in number; whereas Lamarck says his shell is five-ribbed; and we hardly think so acute an observer would have overlooked the transverse undulating striae.

## BOTANY AND HORTICULTURE.

**AIR VESSELS OF PLANTS.**—M. de Mirbel, in an interesting paper, laid before the Paris Academy of Sciences, divided the vessels which deposit the bark of plants into two sorts; the one which forms cortical layers, and the other a cortical net-work. The former of these are renewed annually, while the net-work is only to be met with in the young branches, or stems.

**ZOSTERA.**—M. M. Pasteur d'Estrellis and Adolphe Dommieu transmitted to the French Academy of Science a memoir on the plant called *Zostera*. This plant grows abundantly on the southern coast of France, and on the south of the Baltic, where it assists in binding the sands of these shores together, and has long been known as an excellent manure. Its leaves have commonly been employed in packing fragile objects, and it has more recently been ascertained that they make a most excellent material for stuffing beds.

**COWDIE TREE.**—The British government having satisfactory information of the fitness of the timber of the Cowdie tree of New Zealand for spars for the navy, sent the Buffalo ship to that country for specimens. That vessel returned in the end of April 1835, and brought a cargo far exceeding all expectations. Before the return of the Buffalo, an enterprising and experienced naval officer, who had formed an establishment of his own in New Zealand, had offered, and, we believe, contracted with the government, to furnish spars of this kind from that island, at a lower price and of better quality than those from the Baltic—a circumstance which, in the not impossible contingency of a war with Russia, may be of essential importance to this country.

**NEW SPECIES OF WHEAT.**—It is said that a new species of wheat, which grows and ripens in seventy days, has been introduced into the department Du Nord.

**FOREST TREES.**—North America has 140 species of forest trees, which reach 30 feet in height; but France has only 30 of this magnitude.

**MANAGEMENT OF FRUIT TREES.**—A valuable discovery in the management of fruit trees (it has been applied to thorn hedges before) has been made by M. Crozier, nurseryman, late of Alnwick, and now of Newcastle-upon-Tyne. The object is to obtain new wood where it may be wanted, and for this purpose he makes a nick above the eye where it is wished to produce new shoots; and after many trials, M. Crozier has found the experiment completely successful. In the garden of Mr Carr, at the Barras Bridge, near Newcastle, there is a pear tree which has sixteen shoots produced by the above means this season. It has been applied with equal success to apple, pear, and plum trees, and to the cherry to a certain extent.

## MINERALOGY.

**DISCOVERY OF COAL IN GREECE.**—A Saxon engineer has just discovered in the isle of Negropont a very rich mine of excellent coal, a discovery which is of great importance at a moment when it is in contemplation to establish steam communication throughout the Levant. The British government have given orders for the immediate construction of six fine steam-vessels, which are to be built on an entirely new principle. It is intended with these to open a direct communication between Great Britain and her Indian possessions, by way of the Mediterranean, the Isthmus of Suez and the Red Sea, through Alexandria in Egypt, by which means the voyage to India will not occupy more than eight or ten weeks, avoiding thereby the tedious route of the Cape of Good Hope, and the contrary winds which are so prevalent in the Indian sea. This grand project was one of the great ideas of the emperor Napoleon, who intended to have had a navigable canal cut from one port to the other, and thus facilitate his design of seizing our Indian possessions.

## GEOLOGY AND PHYSICAL GEOGRAPHY.

**METALLIFEROUS VEINS.**—A new geological work has just appeared, entitled *Etudes sur les dépôts Metallifères*, by M. Fournet. This author conceives veins to have been produced generally by more or less violent local dislocations, by first forming fissures, which have been afterwards filled with metallic, or other matter, either by means of sublimation or dissolution. He particularly refers to the successive modifications effected on mineral substances in veins, which have transformed the primitive matter even into a different species. M. Fournet demonstrates, in a clear manner, the importance of these decompositions, and the great influence possessed by them by their constant action and reaction, and their infinite division into veins, rocks, and strata; and thus throws considerable light on the more obscure parts of geology.

**VESUVIUS.**—A letter from Naples, dated 3d April 1835, says, "Vesuvius, which had for the last fortnight given indications of an approaching eruption, burst forth last evening in all its fury. During the afternoon a storm of hail and rain had detained the crowd of visitors at Resina, who would otherwise have been inevitably sacrificed, as the very ground around the crater, where hundreds of human beings had been walking only the evening before, was carried up into the air at the first explosion."

**DISCOVERY OF BONE CAVES IN NEW HOLLAND.**—Hitherto no quadrupeds of a life-large size have been found to inhabit New Holland; and yet Colonel Lindsay, of the 39th regiment, mentions the discovery of great quantities of fossil bones of animals, embedded in marl and other substances, in caves in New Holland; some of these, the bones of quadrupeds, are of large dimensions, and consequently must have belonged to large animals.

**TIVOLI.**—Near this town there is a celebrated cascade, which has long been the admiration of travellers, who have for past ages flocked from all quarters to gaze on its beauties. This classic ground, together with the Grotto of Neptune, which have given rise to so many poems, and have been the subjects of so many descriptions, both oral and written, will soon disappear. The rock over which the river Arno precipitates itself to form this superb cascade, consists of a soft freestone; and in the lapse of ages, the waters have washed away a great part of the soft rocks, near the Grotto of Neptune, and threatened with destruction a portion of the town, and even the Temple of the Sybil. To prevent the impending danger, the Arno will be led into another channel some hundred paces farther up. The rock opposite to Tivoli is broken

through—a work which will render illustrious the reign of Gregory XVI. The river precipitating itself into the valley, in a north-west direction from the present cascade, will form a new one, equal in elevation and volume to that of Terni. The channel cut in the rock is 400 feet in length, and has been completed for some months; and the preparations for conducting the river into its new bed will be shortly terminated. Perhaps some little delay may take place, as the Pope intends to be present, and will probably wait for the cool season.

**FALLS OF NIAGARA.**—A recent letter from New York announces the fall of the Table Rock, at the Falls of the Niagara. This immense mass of stone was on the Canada side of the river, projecting so as to afford the spectator a front view of the horse-shoe fall. It was considerably undermined, and several fissures on the surface had for some time past indicated the approaching disruption. A large mass was detached two or three years back. By the total fall of the Table Rock, the visitor is now deprived of the most favourable position for viewing the magnificent appearance presented by that stupendous fall of waters.

**EARTHQUAKE.**—Letters from Valparaiso, Chili, to the 1st March 1835, state that a very severe earthquake occurred at Concepcion on the 20th February, and its effects were felt throughout the whole province. It was unusually terrific; and the damage and loss of property must have been very great, particularly at Concepcion, from its being situated on a plain between two rivers, which on convulsions of this nature always rise to a considerable height above their banks. The shock was felt at Valparaiso for about two minutes. The old town of Concepcion, situated about nine miles from the present, was totally destroyed by an earthquake in 1751.

An express was received by the government, mentioning the total destruction, on the 20th February, of the cities of Talca and Carico, with the towns of Conquesnes, Lemaies, and Chillaux. In Concepcion, not a house is standing, and all the workmen who were repairing the cathedral of that city were buried in the ruins.

**THE GULF STREAM.**—We copy the following account of the Gulf Stream, from that ably conducted periodical, *The United Service Journal*, for June 1835.—"THROWN overboard from the packet-ship, *South America*, in March 1833, in the Gulf Stream, off Cape Cod, in latitude 40° 30', longitude 68° W. Any person finding this bottle is earnestly requested to publish the fact in the nearest newspaper, in order to confer a benefit upon science, by determining the currents of the ocean." Of all the experiments upon the currents of the Atlantic, none was ever more important and successful than this. The whole ocean, from America to Europe, a distance of 68 degrees of longitude, has been crossed by this bottle. Estimating the time occupied in traversing the Atlantic to be 500 days, and the distance about 3000 miles, it follows that a current, which averages about six miles per day, flows regularly over all the North Atlantic Ocean, from America to Europe. But, according to the best American charts, and even the Admiralty charts of this country, no current whatever is laid down as extending to the eastward beyond the 35th degree of west longitude, where the current of the Gulf Stream is supposed to end and to be lost. In consequence of this, navigators invariably cease to allow for any influence from currents after passing that longitude, which, from the perseverance of this bottle onwards to the land, is evidently a most serious mistake. For, allowing that a ship bound from the West Indies to Europe should be drifting at the rate of only six miles a day, for a period of twenty days, and this not allowed for in the reckoning, it follows, that the ship in that time would be nearer to the land, by a distance of 120 miles, than would be supposed by the navigator. Thus it is, that so many merchant vessels sail, in the night, dead upon the land upon the western coast of Ireland, because the commanders are wholly unprepared to suppose themselves within several degrees longitude from the shore. But six miles a-day, be it observed, is much too little to allow for the drifting of a ship, since a heavy body will float, by reason of its own impetus, very much faster than a light substance similar to a bottle; nor has it indeed been ever sufficiently dwelt upon, that the heavier the cargo, and the deeper in the water, the greater is the influence of the current on the ship. It is therefore probable, that a current of about ten miles per day should in general be allowed for, from the 35th degree of west longitude onwards to the European coasts. I have myself twice returned from America to England, and upon both occasions with very experienced and careful navigators; yet the commanders of both these ships were so extensively ahead as to be utterly astounded upon speaking vessels which had just left the land. Experience has now completely disproved the position, that the influence of the Gulf Stream is at an end in the midst of the Atlantic.

## METEOROLOGY.

On the 13th November 1834, Mr W. H. White of London arose at half-past one in the morning, for the purpose of making meteorological observations, when a phenomenon presented itself, which, in all probability, was the falling of a meteoric stone. We shall give its description in his own words:—"In a few minutes another meteor, of a paler colour than any I had observed before, glided almost perpendicularly towards the earth; this was succeeded by another, of a more brilliant appearance, which took a westerly direction. This meteor cast a brilliant blue light, and had a short or truncated train, which was of a paler light than the meteor itself, and gradually shaded off into a yellowish red; it appeared, in fact, like a stream of light, which the meteor, in its velocity, left behind. Another remarkable circumstance attended this meteor, which I have never observed before, and that was, the meteor separating itself from its train. The latter immediately vanished, while the former continued its downward course with amazing velocity, gradually losing its bright blue light, and increasing in redness as it approached the earth. As this meteor continued its course till surrounding objects hid it from my view, I inferred that it was the falling of a meteoric stone.

"Had this beautiful meteor taken its course against the wind, which was blowing a strong breeze from the north east, I should have concluded that the train was under atmospheric influence; but, as its direction was nearly with the wind, the train must either have been outstripped in velocity by the meteor, or it must have been the result of Electricity."\*

\* Magazine of Natural History, viii. p. 98.

**METEORIC STONES.**—It has only recently been discovered that copper forms an ingredient of meteoric stones. Hofrath Stromeyer asserts that it exists in all meteoric masses. He has examined specimens from Agram, Lenard, Elbogen, Bilburg, Siberia, Gotha, Louisiana, Buenos Ayres, Brazil, and the Cape of Good Hope, and detected in them all an appreciable quantity of copper, varying from one-tenth to one-fifth per cent. He has come to the conclusion that the presence of copper must be considered as a constant character in these substances, as are the nickel and cobalt, which are found in greater proportions.\*

H. Stromeyer examined a meteoric mass, found at Magdeburg in 1831, the specific gravity of which was 7.39, and which contained 4.32 per cent. of copper. Another mass was found near the Iron Works of Rothchutte, in the Hartz, containing 7.69 per cent. of copper.

The celebrated chemist Berzelius, who analyzed a mass of meteoric stone from Macedonia, did not detect copper as forming part of its substance. Its ingredients were, silica 39.56, protoxide of iron 13.83, and peroxide of iron 5.00, making a total of iron 18.83. Alumina 2.70, oxide of chromium 0.50, lime 1.86, magnesia 26.30, oxide of nickel 0.10, oxide of manganese 2.40, potash 2.08, soda 1.20; making a total of 95.53. Besides the above substances, Stromeyer has detected copper, cobalt, arsenic, phosphorus, sulphur, silicon, and carbon.

**LIGHTNING.**—The *Medical Gazette* of St Petersburg states, that the life of a soldier, struck by lightning, has been saved by copious bleeding.

## GENERAL SCIENCE.

### NO. I.—ON THE COMET OF HALLEY, SOMETIMES CALLED THE COMET OF 1759.

#### HISTORY OF THE COMET TO A.D. 1456.

Hast thou ne'er seen the comet's flaming flight?  
Th' illustrious stranger passing, terror sheds  
On gazing nations, from his fiery train  
Of length enormous; takes his ample round  
Through depths of ether; coasts unnumber'd worlds  
Of more than solar glory; doubles wide  
Heaven's mighty cape, and then revisits earth,  
From the long travel of a thousand years.

YOUNG.

[The following is the first of a series of papers, drawn up chiefly from the works of M. Arago, and of M. de Pontécoulant, upon this interesting heavenly body which has just visited us.]

The first appearances of this comet are unrecorded and unknown. Its origin, like that of the most powerful empires of the earth, or of the greater number of extraordinary men, who have astonished and enlightened the world, is enveloped in profound darkness. Historians, influenced by the universal terror which these bodies formerly inspired, have given an exaggerated tone to their descriptions; and that propensity to assign unusual events to supernatural causes, when the explanation of them surpasses the human understanding, has long induced mankind to consider these stars, and their long train of attendant light, as evident signs of celestial wrath. They have been viewed as the messengers of destruction—the forerunners of the three greatest plagues which can desolate the earth—war, pestilence, and famine. Some comets were even thought to have been appointed on the special mission of presiding at the birth or death of those distinguished mortals, whom we may, without impropriety, style meteors of a moral order. Such was the extraordinary comet that appeared during seven days at the death of Julius Cæsar; and also that equally remarkable one, seen at Constantinople in the year signalized by the birth of Mahomet. We may therefore infer, that historians of those times, being under the influence of popular superstitions, viewed with a partial eye the comets they describe; or, at least, they seem to have greatly exaggerated the circumstances attending their appearances. Indeed, ever since these bodies have been examined without prejudice, and for scientific purposes alone, we no longer see them extending from east to west, covering one entire portion of the celestial sphere. No longer does their fearful hue appear to reflect, by anticipation, the blood-stained field of battle, or the flames of approaching conflagrations. Since, then, we have no other guide than these faithless accounts of cotemporary writers, it becomes very difficult, at the present time, to recognize the more sober visitants of the last two centuries among these denizens of a fairy sphere. An account drawn up with fidelity, wherein the physical appearances of a comet are exactly described, may be sufficient to establish a general probability, that two of these bodies, observed at different periods, are identical; yet, as we shall hereafter show, it is wholly inadequate to prove their identity.

The PERIOD of a comet is that portion of time which elapses between its two consecutive returns. That of Halley, the subject of these papers, reappears at intervals of time, the mean, or average of which, is about seventy-five years and a half. By counting backwards, it has been thought to correspond sufficiently near with that which appeared at the birth of Mithridates (A.C. 130). The comet of Mithridates—the most extraordinary of any that have ever been seen or described—exhibited itself for eighty days: its splendour surpassed that of the sun, its size occupied a fourth part of the heavens, and it took four hours in rising, and as many in setting! An origin so illustrious would not have been unworthy of a comet, occupying a place so important in the history of astronomy. But, after we have made all the necessary deductions for the tone of exaggeration evidently impressed on this account, the identity of the comet of Mithridates with that of Halley is still very doubtful, as it has been assumed, in the calculation, that the comet of 1759 returned periodically at equal intervals of time.

In the year A.D. 323, a comet was observed in the constellation Virgo (the virgin), which appears to have had some resemblance to that of Halley. All the historians of

the Constantinopolitan empire allude to a comet seen at an interval of 76 years after the former, in the year A.D. 399. The coincidence of the period would lead us to consider this body to be identical with the comet of 1759, and to infer that one of the periods of its return to the neighbourhood of the sun is here pointed out. This comet was said to have exhibited some extraordinary characters. Lubienietki (*Theatrum Cometarum*) describes it as being of prodigious size, of frightful aspect, and seeming to dart its hair even to the earth. “Cometa fuit prodigiosa magnitudinis, horribilis aspectu, comam ad terram usque demittere visus.” Again, we hear of a comet in A.D. 550;—and that nothing marvellous might be wanting to its history, the return coincided with the taking of Rome by the Goths, under Totila; and it was, of course, considered by a credulous people as one of the causes of that event. After an interval of 380 years (A.D. 930), historians speak of a star, which we may again suppose to be the same comet, after having performed five revolutions during that time. It reappeared at its following return (A.D. 1005); and after passing over three periods, we find, from the list of 415 comets which Lubienietki has described, that in the year 1230 a comet was observed, which may have been the same with that of Halley. But it is no longer possible to follow the comet through the obscurity and ignorance of the middle ages. In those times of barbarity, the physical appearances of the heavenly bodies were either not observed, or distorted by the delusive medium through which they were viewed. We have already explained, that our only means of establishing the identity of Halley's comet with those recorded in ancient writers, is the constant periodical return of the comet of 1759, at equal periods of time. But the periods of this star are continually, and must essentially vary, as we shall hereafter show, by the interval of about one year or eighteen months. We cannot, therefore, place implicit reliance upon the preceding calculations, deduced from a principle which is not in itself strictly exact. In addition to this, there are some years when a great number of comets are visible. At present, a year does not elapse, without some comet being remarked at the different observatories of Europe. It is therefore absolutely impossible to decide, whether the comet of 1759 is really identical with those, whose appearances are stated to have been so extraordinary in 550 and 399; or whether it did not pass, during these or neighbouring years, without attracting the attention of common observers, who would have been entirely engrossed with other more remarkable phenomena. It is, therefore, only with the utmost reserve that we have ventured to suggest these analogies between the present comet and similar bodies which have appeared before the thirteenth century. We have related these circumstances, more as matters of curious research than of positive truth, upon the faith of those learned men who have sought the annals of antiquity for traces of Halley's comet. Like some historians, who love to surround the cradle of their favourite hero with circles of light and lambent flames, we expose the legends of antiquity. It is, in fact, only about two centuries ago that comets were first observed with care; and, previous to that time, the tales related of them are exceedingly doubtful.

Let us return to the uncertain history of this comet.—In the year 1305, there appeared one of these bodies, which would correspond in character with the comet of Halley. The chroniclers of the times gave a tremendous description of it. “Cometa horrendæ magnitudinis visus est circa ferias Paschatis, quem secuta est pestilentia maxima.” (A comet of dreadful magnitude was seen about the Easter holidays, which was followed by a pestilence of the worst description.) The concluding observation throws a doubt upon the exactness of the whole statement; and, as Lalande has observed, it is very possible that fear of the pestilence may have increased the impressions left by the comet. However, it is but right to state, that from the position which the comet of 1759 occupied in its orbit, it must have passed very near to the earth during the year 1305: this would have given it an appearance of unusual magnitude.

In the catalogues of Alstedius and of Lubienietki, there are two comets mentioned, one in 1379, and another in 1380, separated from the former by an interval of about 75 years; but as no details are given of the time, place, or form of their appearances, nothing satisfactory can be ascertained.

The same comet reappeared in 1456, and was accompanied by several remarkable circumstances. “Cometa inauditæ magnitudinis toto mense Junii apparuit cum prolongâ caudâ, ita ut duo ferè signa cæli comprehenderit.” (A comet of unusual magnitude appeared during the entire month of June, with a tail of so great length that it covered nearly two entire signs of the heavens.) It is possible that the length of this tail may be a little exaggerated, especially as the visible part of the heavens is 180°, and a sign is 30°. Yet we must allow that there was something grand in its appearance; because it had the effect of spreading, at this epoch, as great a terror throughout all Christendom, as the rapid progress of Mahomet II., who had just made himself master of Constantinople. The Pope, Calixtus II., with an economy of labour remarkable for the age, exorcised the comet and the Turks in the same Bull, and ordered public prayers, with a formula, to be made, which might include them both. Notwithstanding these efforts of his Holiness, Mahomet and the comet continued their several courses; the former succeeded in converting the Cathedral of Sancta Sophia into his principle mosque; and the latter vanished peaceably into the infinity of space.

The great length of tail ascribed to the comet of 1456, and the consternation which it diffused throughout benighted Europe, have led scientific men to consider it in another point of view. They have ascertained the position which a comet must occupy, in order that it may appear of the greatest possible brilliancy; and the result is, that this comet, from its near approach to the sun, and from its situation relative to the earth, must have united all the conditions necessary to that appearance of splendour assigned to it by the chroniclers of the times.

Although no precise observations upon this phenomenon have been handed down to us, yet the time when the comet appeared, and the course which it held, are described with sufficient accuracy; so that Dr Halley did not hesitate to assert its identity with the comets of 1531, of 1607, and of 1682. This appearance of 1456 ought, therefore, to be clearly distinguished from all those preceding it, and to be considered as a remarkable epoch in the history of science.

\* Ann. Der Physik., xxvii. p. 699.

## MISCELLANEOUS.

**PROJECTED VOYAGES OF DISCOVERY.**—At the instance of the Geographical Society, government have granted L.1000 towards the expenses of two voyages of discovery; the one into the interior of Africa from Delagoa bay, on the east coast, and the other to explore the high land which forms the boundary between British Guiana and the basin of the Amazon in America.

**THE FRENCH DISCOVERY-SHIP LA LILLOISE.**—No tidings have been received regarding that vessel since the month of August 1834, which, under the command of Lieutenant de Blossville, was sent on a voyage to the coasts of Iceland and Greenland.—The following is the proclamation issued by order of the King, dated June 17, 1835:—1. That a sum of 100,000*l.* (L.4,000) shall be given to any French or foreign mariners who will bring back to their country the whole or part of the officers and crew of La Lilloise.—2. That a pecuniary reward proportioned to the service shall be granted to those who would be the first to bring any positive intelligence respecting the said officers and crew, or procure to France the restitution of any papers and effects soever which had belonged to the above expedition.

Since writing the above, intelligence has been received by the French Government, from M. Gaynard, surgeon and naturalist to the discovery ship commanded by Lieut. de Blossville, that from the information which has been obtained at Iceland, there is but little hopes of the object of the expedition being attained. M. Gaynard has been fortunate in obtaining numerous treasures in Natural History, which he purposes forwarding to the Jardin des Plantes at Paris.

**EXPEDITION OF DISCOVERY—VAN DIEMEN'S LAND.**—Hobart Town papers of the 25th February 1835, have been received, which announce that letters had been transmitted by Mr Frankland, giving a very satisfactory account of the progress of his expedition. He proposes to trace the source of the Heron, the Derwent, and other rivers, to penetrate the east coast between Port Davy and Macquarie Harbour, and to return by the hitherto unexplored country in the neighbourhood of Mount Wellington. The weather had been favourable for him, and there was every prospect of the undertaking proving successful.

## REVIEWS.

*A Selection from the most Remarkable and Interesting Fishes found on the coast of Ceylon, from Drawings made in the southern part of that Island.* By John W. Bennett, Esq., F.L.S., &c. Royal quarto. Longman and Co. London. 1830.

ALTHOUGH this volume has been before the public for some time, we do not think it is so well known as it deserves to be. It contains thirty plates of fishes, all of which are remarkable for the splendour of their colours, or the singularity of their structure; and these are executed with a fidelity which reflects high credit on the author as an artist. We cannot too favourably speak of the beautiful manner in which the engravings have been executed by Mr J. Clark, and also of the careful and sparkling effect of the colouring. The author has introduced into his descriptions not only the scientific, but also the Cingalese names. This elegant book is well fitted to ornament the table of the drawing-room or saloon; and we especially recommend it to the notice of all those who have been resident in the East.

*Excursions illustrative of the Geology and Natural History of the Environs of Edinburgh.* By William Rhind, Member of the Royal College of Surgeons, and of the Medical and Physical Societies, Lecturer on Natural History, &c. Royal 8mo. Maclachlan and Stewart, Edinburgh; and Baldwin and Cradock, London. 1833.

To every person who has the slightest desire to become acquainted with the Natural History of the vicinity of Edinburgh, we can confidently recommend this excellent pocket treatise. Indeed, it ought to be the companion of all our walks; for in whatever direction we may bend our steps, Mr Rhind edifies us with the structure of the rocks, the botany of the meadow or wood, and the animals which we are likely to meet with in our rambles. Our author, in particular, gives a lucid description of the geological structure of Arthur's Seat, Salisbury Crags, Castle Hill, Calton Hill, Craigleith Quarry, Braid, Blackford, Pentland, and Corstorphine Hills; Cramond Island, Isle of May and Bass Rock; the sea beach at Newhaven; all that is interesting in the natural history of Duddingston Loch and Lochend; Roslin, Lasswade, Musselburgh, and Ratho; with a list of the mountain rocks, fishes, and land shells. The work is illustrated with coloured maps of the environs of Edinburgh, with a coloured geological section of the country, from the Calton Hill on the east to the Pentland Hills on the west, and with eleven wood-cuts.

To strangers visiting Edinburgh, this cannot fail to prove a useful companion. It is handsomely printed, and very cheap.

## LEARNED SOCIETIES.

**ROYAL SOCIETY.**—The last meeting of the season was held on the 18th June, Sir John Rennie, V.P. in the chair: on which occasion, the following papers were read, viz.—1. Discussion of Tide Observations made at Liverpool, by J. W. Lubbock, Esq. 2. Experimental Researches in Electricity, by Michael Faraday, Esq., tenth series. 3. On the Distinction between certain Genera of Shells, by S. E. Gray, Esq. 4. On the Ova of Mammiferous Animals, by T. W. Jones, Esq. 5. On the supposed existence of Metamorphoses in the Crustacea, by J. O. Westwood, Esq. 6. On the Star-fish of the Comatula, by T. V. Thompson, Esq. 7. On the influence of Perspiration on the quantity of Blood in the Heart, by James Wardrop, Esq. 8. On Sound, by P. Cooper, Esq. 9. On the Tides, by P. Cooper, Esq. The Society then adjourned till the 19th November next.

**LINNEAN SOCIETY.**—The Duke of Somerset in the chair. The president nominated Robert Brown, Esq., Edward Forster, Esq., Dr Horsfield, and A. B. Lamher, Esq., to be vice-presidents of the society for the present year. There was read an account of the galls found on a species of oak from the shores of the Dead

Sea, which have been mistaken for the fruits of certain plants; and a note on the mustard plant of scripture, by Mr Lambert. Also, descriptions of five new species of the genus *pinus*, discovered by Dr Coulter in California, by Mr Don, Lib. L. S. At a meeting on Tuesday evening, a paper was read, being some observations on the screech-owl, by Mr Knight; and also a memoir on the metamorphosis in the macroura of the class *crustacea*, by J. V. Thompson, deputy-inspector of hospitals. Mr Christy exhibited a flowering specimen of the very rare British plant, *liparis laselii*, from Bottisham Fen, Cambridgeshire.

**ROYAL INSTITUTION.**—On Friday, 12th June 1835, the evening meetings of this institution closed with a lecture on the "History and Manufacture of Gunpowder," by Mr Henry Wilkinson. Mr Wilkinson quoted a variety of authors, ancient and modern, to prove that gunpowder had been known in China and India, beyond all periods of investigation; and observed, that in the Gentoo laws, supposed to be coeval with Moses, there was a prohibition of the use of gunpowder and fire-arms. He then minutely described all the progressive stages of the manufacture of gunpowder, and produced specimens of each ingredient in its various states; and concluded with a variety of interesting experiments, to show the quantity of permanently elastic fluid generated by the ignition of gunpowder. This he effected by firing gunpowder under water, and collecting the gases in the pneumatic trough. The enormous amount of gunpowder consumed in war, he illustrated by stating the quantities used at the sieges of San Sebastian, Badajos, and Ciudad Rodrigo; and he concluded with several curious experiments, showing the effect of fulminating powders on gunpowder. A train of fulminating powder was drawn across another of gunpowder, and the fulminating powder inflamed, which passed with such rapidity over the gunpowder, that it merely separated without igniting it. He then sent the flame of fulminating powder through a box of gunpowder without igniting it; and proved, by other experiments, that the ignition depended on the velocity with which the flame was transmitted. The whole lecture gave very great satisfaction to a numerous auditory. At its conclusion, Mr Faraday addressed the audience on topics of general interest to the institution, and of consequence to the scientific world.

**GEOLOGICAL SOCIETY.**—13th May 1835.—Charles Lyell, Esq. president, in the chair, by whom a paper was read "On cretaceous and tertiary strata of the Danish islands of Iceland and Moën." Afterwards a notice was read "On a peculiarity in the neck of Ichthyosauri, not hitherto noticed;" by Sir Philip De Malpas Grey Egerton.

May 27.—C. Lyell, Esq. in the chair. A paper was read "On certain lines of dislocation of the new red sandstone of North Salop and Staffordshire; with an account of trap-dykes, in that formation, at Acton Reynolds, near Shrewsbury;" by Roderick I. Murchison, Esq. Afterwards a paper was read "On the crag of part of Essex and Suffolk;" by Edward Charlesworth, Esq.

June 10th.—C. Lyell, Esq. in the chair. There were read—1. "Notes on the trappean rocks associated with the new red sandstone of Devonshire;" by Henry T. De la Beche, Esq. 2. "On the range of the carboniferous limestone flanking the primary Cumbrian mountains, and on the coal-fields of the north-west of Cumberland;" by Professor Sedgwick, and Williamson Peile, Esq. 3. "Notice of the occurrence, near Shrewsbury, of marine shells of existing species in transported gravel and sand resting upon peat which contains embedded trees;" by Joshua Trimmer, Esq. 4. "Description of some fossil crustacea and radiata found at Lyme Regis, in Dorsetshire;" by William John Broderip, Esq. 5. A letter from Sir Philip Grey Egerton, Bart., to the president, "On the discovery of fishes in the coal-field of North Staffordshire." 6. Two notices of Gideon Mantell, Esq., "On bones of birds from the strata of Tilgate Forest, and on the coffin-bone of a horse from the shingle bed of the newer pliocene of strata of the cliffs near Brighton." 7. Extract of a letter from Professor Daubeny, "On the saline contents of the mineral spring lately discovered near Oxford."

**EASTERN LITERARY AND SCIENTIFIC INSTITUTION.**—On the 23d June, a lecture was given in the room of this institution, in the Hackney Road, by Mr Taylor. The subject of the lecture was the safety-lamp, and the object was to show, by actual experiment, that the lamp hitherto used in coal-mines, and invented by Sir H. Davy, is liable to some serious objections. Mr Roberts proposed an improvement on Sir H. Davy's lamp, to remedy the practical objections to which it is liable. Mr Taylor commenced his lecture by explaining the nature of combustion. He described carburetted hydrogen, or fire-damp. He then detailed the doctrine of flame and the progress of combustion. He pointed out by experiments the properties of nitrogen, carbonic acid, and oxygen, and showed the manner in which the safety of the invention of Mr Roberts is connected with them. Mr Roberts then displayed his lamp, and described the manner in which it differs from that of Sir H. Davy. He stated the objections to the lamp of Sir H. Davy, being the insecurity it affords to the currents of carburetted hydrogen or fire-damp, and the dangers arising from the ignition of the small particles of coal adhering to the wire gauze by which it is surrounded, from the oil clinging to the sides of the gauze when the lamp is upset or held in a horizontal position. His own lamp he stated to be free from the two last-mentioned defects. It is surrounded by a double tube of wire gauze, and also by a glass chimney, and is so contrived that a current of carbonic acid air, or nitrogen, passes continually between the external atmosphere and the flame of the lamp; the flame alone can burn, and any ignition from external explosive current of fire-damp is repelled by the carbonic acid of nitrogen, by which combustion is immediately destroyed. In the course of the lecture allusion was made to the late deplorable accident by which upwards of a hundred lives have been destroyed by the explosion of fire-damp; and many other instances were given of the loss of life occasioned, either by a too strong reliance on the safety of the lamp hitherto used in the mines, or by the neglect of proper means for ventilation.

ZOOLOGY.

DESCRIPTION OF THE PLATE—BUTTERFLIES.

THE Papilionaceous or Butterfly tribe of insects yields to no other in the Animal Kingdom in point of beauty. Many of the species wear a garb of the most gorgeous colours, exhibiting the tints of the rainbow in all the varied and dazzling brightness of iridescent splendour; and the wonderful changes through which they pass are no less calculated to excite our admiration and even astonishment.

The whole of this tribe undergo four changes in passing from the egg to the perfect insect or butterfly. These metamorphoses seem to have been known to the ancient Greeks, and most probably suggested to them their principles of metempsychosis. Nothing could appear to them more confirmatory of the doctrine than that an inert aërelia should be again transformed into a living body. The only method which they had for explaining this phenomenon was, that it had been tenanted by the soul of some wretch, whose misdeeds on earth had merited such a pilgrimage.

Butterflies are strictly oviparous animals, and the female, by an unerring foresight, uniformly deposits her eggs in the place where food is to be found for the future caterpillar after its exclusion from the egg.

The eggs are usually enveloped in an adhesive cement, by which they are attached to the spot where they are deposited. This wise provision is designed to prevent the eggs from being removed to a situation where the proper food of the species might not be found, and where the caterpillar would consequently die of hunger.

The eggs of butterflies are of many different shapes, and hardly two species produce them alike. The following cut, figure 1, represents one of the eggs of the small tortoise-shell butterfly (*Vanessa Urticæ*); these are of a cylindrical form, with eight prominent ribs; while the eggs of the large tortoise-shell butterfly (*Vanessa Polychloris*) are shaped like a flask, and quite smooth, as in figure 2.

When the eggs have remained their proper time, the caterpillar, or larva, bursts from its confinement. At first it is exceedingly small, but increases daily, until it reaches its full size, as seen in figure 3, which represents the caterpillar of the Purple Emperor Butterfly (*Aptera Iris*).

The great proportional bulk at which many caterpillars arrive, in comparison to their original size when they emerge from the shell, is surprising. The larva of the Goat Moth (*Cossus ligniperda*), on attaining its full magnitude, is seventy-two thousand times heavier than when it first bursts into life; and the maggot of the Blue Fly is, in twenty-four hours, one hundred and fifty-five times heavier than at its birth. Many caterpillars consume more than twice their own bulk of food every twenty-four hours. The cause assigned for this is, that their stomachs have not the power of dissolving vegetable matter, but merely the faculty of extracting their juices. When the larva has attained its full size, it soon afterwards ceases to eat, becomes excessively restless, and searches for a place fitted to its nature, to which it may retire, for the purpose of being transformed from one state of existence to another, and of assuming its pupa condition. Some spin for themselves a covering of silky filaments, while others simply attach themselves to the under side of a leaf or branch, as represented in figure 4, which is the pupa of the Purple Emperor. After remaining for some months in this state, the concealed animal bursts its casement, and emerges as the perfect Butterfly; in which condition it exists only for a very limited period; and, after having provided for the continuance of its race, speedily dies.

The transformation of insects, however, consists rather in a series of developments than in any absolute metamorphosis, being only a transition of changes in organs which lie concealed from human view. The caterpillar is compound in its nature, with the germs of the perfect insect hidden in a succession of cases. The first is the covering of the pupa, which is concealed within three or four mantles, the one over the other: these will, in succession, enrobe the larva; and as it enlarges the parts

become visible, and are alternately thrown off, until the perfect insect bursts from its confinement.

It is certainly wonderful that the simple caterpillar, when it first emerges from the egg, not thicker than a thread of silk, should contain its own covering threefold, and, in some instances, even eightfold, with the mask of a pupa and a butterfly, folded in the most astonishing manner over each other; and besides these, should possess different respiratory and digestive organs, a nervous system, and muscles of motion peculiar to every successive stage of its existence. And, what is truly wonderful, the stomach in its caterpillar state is fitted for the reception of vegetable food, while in the perfect condition of the butterfly, it is incapable of digesting ordinary vegetables, and is only fitted for containing honey, which the animal sips from flowers by means of a proboscis.

The whole of the figures given in the plate are of the natural size.

Fig. 1. Royal Butterfly (*Endymion Regalis*), and, 2. Do. Female, inhabit Brazil.—3, 4. Azure Blue (*Polyommatus Argiolus*), and, 5. Do. Female, inhabit Britain.—6. Mazarine Blue (*Acis*), inhabits Britain.—7. Silver Streak (*Argynnis Paphia*), inhabits Britain.—8. Nicippe (*Pieris Nicippe*), and, 9. Do., inhabits the United States.—10. Imperial Trojan (*Popilio Priamus*), one of the most beautiful of butterflies, inhabits Amboyna.—11. Merry (*Aconthia Lubentina*), and, 12. Do. Female, inhabit Java.—13. Painted Lady (*Cynthia Cardui*), inhabits Britain.—14. Amphinome (*Amphinome*), inhabits Surinam, and, 15. Do.—16. Elin (*Vanessa Polychloris*), inhabits Britain.—17. Oriental Emperor (*Nymphalis Riphæus*), inhabits China.

INSTINCT IN DOGS.—A singular instance of that power, commonly called instinct, possessed so remarkably by pigeons, and exhibited by dogs, lately occurred. The celebrated greyhound, Black-eyed Susan, was brought to Edinburgh from Glasgow in the boot of a coach, on the night of Wednesday the 13th May 1835. On the following Sunday evening she made her escape, and in forty-eight hours reached her kennel, eight miles beyond Glasgow, being fifty-two miles in all. The road between Glasgow and Edinburgh she had never travelled on foot, and from the time taken she cannot have come direct; but, by what route or process this animal made her point good, it is in vain to conjecture.

Another instance, of a similar nature, is recorded in Brown's Biographical Sketches and Anecdotes of Dogs. In the year 1816 a female greyhound was sent from the neighbourhood of Edinburgh by a carrier, *via* Dumfries, to the neighbourhood of Castle Douglas, in the stewartry of Kirkcubright. She brought up a litter of pups there, and, in the following year, was returned by the same route to Edinburgh, from whence she went, by way of Douglas and Muirkirk, to the neighbourhood of Cumnock in Ayrshire. After remaining there five or six months, she found her way across the country to the house near Castle Douglas where she had brought up the pups. The fact of her crossing, and not pursuing her journey by the route she had been taken to Cumnock, was ascertained by shepherds, who saw her, accompanied by a pointer dog. The latter left her almost immediately, and found his way home again. This female greyhound was bred in East Lothian, and had never been previously either in Ayrshire or Dumfries-shire.

THE ELEPHANT'S LOVE OF SWEETMEATS.—The elephant has a natural partiality for sugar, which he finds abundant means to gratify in the plantations of sugar cane. A curious instance is recorded of his liking for sweetmeats, and of a method adopted in his savage state to gratify this propensity. It chanced that a Cooley, laden with jaggery, which is a coarse preparation of sugar, was surprised in a narrow pass in the kingdom of Candy by a wild elephant. The poor fellow, intent upon saving his life, threw down the burthen, which the elephant devoured, and being well pleased with the repast, determined not to allow any person egress or ingress who did not provide him with a similar banquet. The pass formed one of the principal thoroughfares to the capital, and the elephant, taking up a formidable position at the entrance, obliged every passenger to pay tribute. It soon became generally known that a donation of jaggery would ensure a safe conduct through the guarded portal, and no one presumed to attempt the passage without the expected offering.

SAGACITY OF TWO MULES.—About two miles from the town of Ballymahon, in the county of Longford, Ireland, resides a gentleman, who has in his possession two mules of the Spanish breed. They will regularly go to a pump placed in the yard, and while one applies his mouth to the spout, the other works the handle by alternately raising and depressing his shoulder. When one has satisfied his thirst, he exchanges with his companion, and returns the service he has received.

THE ELECTRICAL EEL.—(*Gymnotus electricus*).—This rare fish was caught some time ago near Gravelines. The pilot of the vessel received a severe shock on taking it from the nets, and all the crew, on touching it, experienced a like sensation, which, however, weakened at every touch, and diminished gradually, till the animal expired.

## BOTANY AND HORTICULTURE.

**SUPPOSED FALL OF SULPHUR.**—Captain Hufty communicated to the Academy of Sciences an account of a singular phenomenon which happened at Olerand, in the department of the Basses Pyrenées. On the 28th April 1835, there occurred a heavy fall of snow, which next day was covered with a fine yellow dust, having all the appearance of sulphur. The only probable explanation which can be given of this phenomenon is, that the dust must have been the pollen proceeding from the blossoms of numerous pine trees in the vicinity, and which flower at that season. This pollen is of a highly inflammable nature, and might easily be mistaken for sulphur.

**TULIPS.**—The sum of L.610 has lately been given for the bulb of a new variety of tulip, called the "Citadel of Antwerp." This enormous sum was paid by M. Vander-niek, of Amsterdam, a florist, but formerly a captain in the Dutch navy.

**FOON OF SILKWOORMS.**—There has lately been presented to the Institute of France a memoir on the leaves of the *Machura Aurantiaca*, which, it is conceived, may replace those of the mulberry, for the food of silkworms, in climates wherein mulberry trees do not thrive. They stand the spring frosts, at Geneva, Paris, Turin, and Strasbourg, where they have been successfully cultivated for six years past. This tree is a native of North America, and is abundant on the banks of the Missouri, in the country of the Natchez.

**THE KRUBUT, OR GREAT FLOWER OF SUMATRA.**—This very wonderful vegetable production has been named, in scientific language, the *Rafflesia Arnoldi*. Its generic name is in honour of the late Sir Stamford Raffles, governor of Sumatra, and founder of the Zoological Society, and its specific name in memory of Dr Arnold, who discovered it in 1818.

In writing on this subject, Dr Arnold says, "At Pulo Lebbar, on the Manna River, I rejoice to tell you, I happened to meet with what I consider the greatest prodigy of the vegetable world. I had ventured some way beyond the party, when one of the Malay servants came running to me, with wonder in his eyes, and said, 'Come with me, Sir, come! a flower very large, beautiful, wonderful!' I went with the man about a hundred yards into the jungle, and he pointed to a flower growing close to the ground, under the bushes, which was truly astonishing. My first impulse was to cut it up, and carry it to the hut: I therefore seized the Malay's parang (a sort of instrument like a woodman's chopping-hook); and finding that it sprang from a small root, which ran horizontally (about as large as two fingers or a little more), I soon detached it, and removed it to our hut." The following is a representation of the full blown flower.

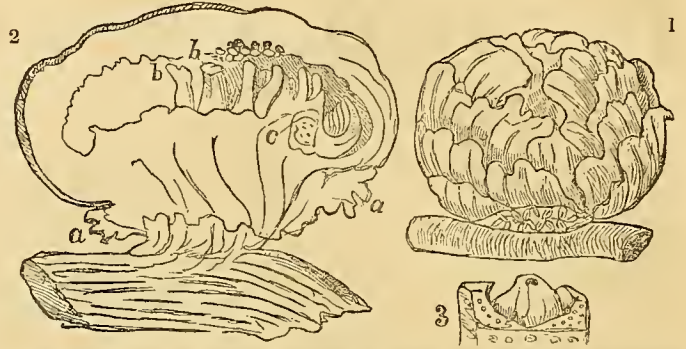

The Krubut is a parasite, growing in the woods, on the roots and stems of those immense climbing plants, generally of the genus *vitis* (or vine), which are attached, like enormous cables, to the largest trees of the forest. The flower constitutes the whole of this plant, there being no leaves, and neither roots nor stems. Thus, the plant forms a complete anomaly in the history of vegetables. It grows out of another plant in the manner of the mistletoe, and not on the decayed surface of plants, as is the case with the common fern on the trunks of old oak pollards. In the latter case, the proper term is not *parasite*, but *epiphyte*.\*

The flowers of this extraordinary plant are of one sex; and the male only has yet been sent to England. The breadth of a full flower exceeds three feet from the margin of the one petal *d* to that of the other *d*; the petals, or leaves of the flower, are roundish, and measure twelve inches from the base to the apex. It is about a foot from the insertion of one petal to the opposite one; and that part which is considered the nectarium, or central cup of the flower, would hold twelve pints of liquid. The pistils, which are abortive, and as large as cows' horns, are represented in fig 2. *b b*.

The weight of the whole flower is calculated at about fifteen pounds. It is of a very thick substance, the petals and nectary being in few places less than a quarter of an inch thick, and in some parts three-quarters of an inch; it is succulent in texture, but of a firm fleshy consistence. The flower, fully blown, was discovered in a jungle of Sumatra, growing close to the ground, under the bushes, with a swarm of flies hovering over the nectary, and apparently laying their eggs in its substance. The colour of the five petals, or flower leaves, of which it is composed, is a brick-red, covered with protuberances of a yellowish white. The inside of the cup is of an intense purple, and more or less densely yellow, with soft flexible spines of the same colour. Towards the mouth, it is marked with numerous depressed spots of the purest white, contrasting strongly with the purple of the surrounding substance, which is considerably elevated on the lower side. The smell is that of tainted beef.

\* From ( $\epsilon\pi\iota$ ) *epi*, upon, and ( $\phi\upsilon\tau\omicron\nu$ ) *phyton*, a plant.

The structure of this plant is too imperfectly known to admit of determining its place in the natural system. That learned botanist, Mr Brown, however, thinks it will be found to approach near to *Asarina*, or to the *passifloreæ*, or passion flowers. Its first appearance is that of a round knob, proceeding from a crack or hollow in the stem or root, as represented in the following cut, Fig. 1.

This knob, when cut through, exhibits the infant flower enveloped in numerous bracteal sheaths. These successively open and wither away as the flower enlarges, until at the time of full expansion, when there are but a very few remaining, presenting somewhat the appearance of a broken calyx, as represented in fig. 2, *a a*. The female flower differs but little in appearance from the male, further than in being without the anthers, fig. 2, *e*. Fig. 3 represents one of the anthers a little larger than the natural size, and shewing a section of the cavity in which it is immersed. It takes three months from the first appearance of the bud to the full expansion of the flower. The blossoms decay not long after their expansion, and the seeds (*sporæ*) are raised with the pulpy mass. The fruit has not yet been seen by botanists, but is said by the natives to be a many-seeded berry.

Mr Brown has made some interesting observations on the *Rafflesia Arnoldi*, wherein he remarks, that it is not common for parasitic plants to fix indiscriminately on the roots or branches of their stocks, as is supposed to be the case with the genus *Rafflesia*; and observes, that "plants parasitic on roots are chiefly distinguishable by the imperfect development of their leaves, and the entire absence of green colour; that their seeds are small, and their embryo not only minute, but apparently imperfectly developed." Mr Loudon says, that "the modes of union between a parasite and its supporter, or stock, vary in different genera and species of this class of vegetables. Some, as the mistletoe and *Rafflesia*, depend on the stock for nourishment during the whole of their existence; others, as the common broom-rape, are originated in the soil; and afterwards, when they have attached themselves to their stock, the original roots die. Other parasites, again, are originated on the stock, and in their more advanced state produce roots of their own. In some cases the nature of the connexion between the parasite and the stock is such, as can only be explained on the supposition that the germinating seed of the parasite excites a specific action in the stock, the result of which is the formation of a structure, either wholly or in part derived from the root, and adapted to the support and protection of the undeveloped parasite; analogous, therefore, to the production of galls by the puncture of insects. On this supposition may be explained the connexion between the flowers of the genus *Rafflesia*, and the root from whence it springs."

In Sumatra, all the vegetable productions seem to be on a gigantic scale. Sir Stamford Raffles, after describing this great flower, says, "There is nothing more striking in the Malayan forests than the grandeur of the vegetation. The magnitude of the flowers, creepers, and trees, contrasts strikingly with the stunted, and I had almost said, pigmy vegetation of England. Compared with our fruit trees, your largest oak is a mere dwarf. Here we have creepers and vines, entwining larger trees, and hanging suspended for more than 100 feet, in girth not less than a man's body, and many much thicker; the trees seldom under 100, and generally approaching 160 to 200 feet in height."

**THE KNOWLE-PARK BEECH.**—This most magnificent tree in Knowle-Park, Kent, is the largest undecayed and entire beech in the kingdom. It was measured in October 1835, and the following are its dimensions:—Circumference of the stem, at six inches from the ground, thirty-nine feet, five inches; at one foot, six inches; thirty feet, nine inches; four feet above, twenty-eight feet, one inch; seven feet above, twenty-five feet; one spiral limb, fourteen feet from the ground, fifteen feet. The mean height of the tree, eighty-nine feet; and the circumference of ground covered by branches, three-hundred and forty-seven feet.

**THE TALLIOT TREE** is a native of the island of Ceylon, in the East Indies. This tree is remarkable on account of its leaves, which are of such a size as to cover ten men, and keep them from the rain; they are very light, and travellers carry them from place to place, and use them for huts.

## MINERALOGY.

**DISCOVERY OF MARBLE.**—In the island of Tiree, on the west coast of Scotland, an engineer has lately discovered some beautiful blocks of white marble, and inexhaustible strata of variegated granite, in undulating streaks, of red, white, and black. At the Ross, in the island of Mull, comparatively pure red and white granite occurs in vast abundance. This is by far the most beautiful variety in this country, or perhaps in the world. One of the many blocks forming the *debris* of an adjoining mountain was found to measure 12 cubic feet to the ton—no less than 104 square tons of workable granite!

**DEPTH OF MINES.**—Kit's-puhl copper mine in the Tyrol mountains, 2764 feet; Samson's mine at Andraesburgh, in the Hartz, 2220 feet; Valenciana mine, Guanaxuato, Mexico, 2170 feet; Pearee's shaft, consolidated mines, Cornwall, 1650 feet; Monkwearmouth colliery, Durham, 1600 feet; Wheel Abraham's mine, 1452 feet; Dulwath mine, Cornwall, 1410; and Erton mine, Staffordshire, 1380 feet.

## GEOLOGY AND PHYSICAL GEOGRAPHY.

## GREAT ERUPTION OF THE VOLCANO OF COSIGÜEINA.

IN America, between the 10th and 15th degrees of north latitude, there are at least twenty-one active volcanoes. All these are situate in the provinces of Guatemala and Nicaragua, which lie between Mexico and the Isthmus of Panama. The following account of the last great eruption of the volcano of Cosigüeina is translated from the official reports published by the government of Guatemala.

On the 20th of January 1835, at half-past 6 o'clock in the morning, the volcano of Cosigüeina broke out, and the vapour which arose was beautiful. At 11 o'clock it covered the whole of the territory around Nacaome, and at noon the obscurity was so intense as to exceed all description. We had then a night of 18 hours' duration, while tremulous movements of the earth, noises, tempests of thunder and lightning, caused by the combustible matter which filled the atmosphere, and an impetuous wind impelling a heavy shower of ashes, rendered that night a period of distress and horror. The morning of the 21st was melancholy, though the light penetrated through the dense vapours, and the sun sometimes showed a pale and saffron-coloured countenance. The 22d resembled the preceding day, and the night was passed rather quietly until 12 o'clock. There then commenced a hollow growling sound, vehement and alarming, which continued without interruption or diminution for at least 13 minutes. This noise was instantaneously followed by some terrific detonations, as loud as reports from artillery of the largest calibre. At a quarter past 12, a violent tremulous movement indicated a fresh eruption, which was soon confirmed by the ascent of a volume of smoke. At half-past 2 there was a sort of twilight, which served to interrupt a night of 36 hours, and the noises continued, being louder than on the 26th. A reflection of red light occasionally broke through the obscurity of the atmosphere; but so constant and terrible were the explosions, and the thunder and lightning, that it appeared to threaten the annihilation of the world itself. The 24th commenced much in the same manner as the 21st.

That a volcano should renew its eruptions, vomit forth lava and ashes, and occasion damage, might be expected to occur. But that the eruption of a hill, not one-eighth so high as Pacaya, should have darkened for several days the half of central America, and covered a space exceeding perhaps 15,000 square leagues with lava and ashes, to the height or thickness, in some places, of half a yard, in others a quarter, and no where less than two inches; that men should fly to the mountains, and wild beasts to the towns, as has happened at Nacaome, in Pesperi, Corpus, Ila del Tigre, Conchagua, or Puerto, &c.; that the fishes should have perished in the rivers, the birds be suffocated by dust, the reptiles and quadrupeds by slime; and that Man should remain unhurt amidst this convulsion of the elements—is a thing truly astonishing, and scarcely to be credited. Cosigüeina continued, like Isaleo, to vomit exhalations until the 5th of February. The atmosphere cleared up slightly about 6 o'clock in the evening and 8 in the morning; but when the wind began to blow, clouds of dust enveloped Nacaome on all sides. Hitherto no bad effects had resulted except inflammation about the head, eyes, mouth and throat, which caused very severe coughing. It is extraordinary that the inhabitants of Nacaome were able to endure the showers of dust without being suffocated, especially as it has been found to be loaded with sulphur, iron, and antimony, and to be very inflammable. Cattle and flocks perished, and an unusual mortality was expected from the deficiency of pasture and from the deterioration of the water.

At San Marcos, from the 23d to the 29th of January, the atmosphere of the city was observed to be impregnated with smoke and ashes; and on the 24th particularly, so great a shower of ashes fell, that the roofs of all the houses were whiteoed with it. Until 9 o'clock in the morning, repeated explosions were heard, by which great alarm was created through the various towns, under the impression that they proceeded from the volcano of Quezaltenango; and the city was presently deserted by many of the merchants, who removed themselves to a distance, for the better security of their families.

On the 20th of January in the morning, the inhabitants of the town of Masaya heard towards the north-east some faint volcanic sounds, whilst those of the town of Viejo observed a sheet of fire rising perpendicularly to a considerable elevation, and afterwards declining towards the north. This was the same appearance which was observed in the department of Segovia, where at the same time some reports were heard, and some slight shocks were experienced.

In Leon, the capital, and in the department of Granada, the catastrophe had not been perceptibly felt until the dawn of the 25th, when the explosion developed itself to such a degree, that from 1 o'clock the sky was darkened with an opacity which continued to deepen till 11 in the morning, when the inhabitants of the capital were enveloped in a most frightful darkness, whilst terrific reports were heard, and showers of ashes were precipitated over all the face of the country.

This natural event produced an impression in the minds of the superstitious inhabitants that it proceeded from the Divine anger; and whilst the people ran in crowds to the temples to implore the mercy of Heaven, the garrison of the town diverted their consternation by discharges of cannon and musketry. This was done by order of the government, who, by the advice of some intelligent chemists, directed discharges of artillery to be fired, rockets to be let off, fires to be lighted, and the bells of all the churches to be rung, in order to dissipate the dense vapours with which the atmosphere was impregnated.

The quickness was astonishing with which, on the 23d, all the atmosphere was filled with volcanic matter, from Nicaragua, as far as the department of that name, towards the south-east. The murky clouds then gradually moved towards Nandayme, where, about 3 o'clock in the afternoon, the darkness reigned over the city, and extended to the town of Rivas. The same thing occurred in the department of Granada, the towns in which suffered nearly to the same extent as in Leon, whilst those of Matagalpa in Segovia experienced a night of 36 hours' duration.

Fortunately not a single life was lost, though in the immediate neighbourhood of the mountain where the eruption occurred some cattle were destroyed. It does not appear that the damage will be so great as was conceived at the time of the catastrophe, because the sand or ashes that have been scattered over the plains will wonder-

fully fertilize them—a fact which has been ascertained in some places watered a few days afterwards by the rain, where the plants showed a most luxuriant appearance, the pasture was rapidly rising, and every thing seemed to promise a forward spring.

The agitation of the air, when winds prevail, usually affects people with disagreeable sensations, and does great injury to cattle, on account of the dust which fills the atmosphere, to such a degree that it is impossible to see even for the distance of a league.

On the 9th of March, a commission went to observe the volcano, and they could not recognise the coast with perfect distinctness, or throughout its entire extent, in consequence of the cloud of smoke which covered the plains. A forest, which appeared to have survived many changes of the earth's surface, had disappeared. Two islands have been formed in the sea—one being 800 yards, and the other 200, in its greatest extent. Their composition consists of pumice-stone and scoriae, with a number of pyrites of a golden colour, and having a strong metallic odour. Some shoals in the sea, from 500 to 600 yards long, were formed. In one of them a large tree was fixed with its branches downwards, and its roots raised up. The river Chiquito, which ran towards the north-west, was completely choked up, and another river, six yards broad, had sprung up in the opposite direction.

A party proceeded from the town of El Viejo to make another observation, by which it was ascertained that the farms of Sapasmapa and Cosigüeina, situate in the immediate neighbourhood of the volcano, had disappeared. From the first not a single head of cattle had escaped. In the latter 300 quadrupeds were found remaining, but in a weak and wretched condition, and they were not expected to survive. The remains of immense numbers of quadrupeds and birds were found lying in the immediate neighbourhood of the volcano. A vessel, which on the 20th of last month was near the coast, having a crew of seven men, was supposed to have been destroyed, since no information respecting it was received.

In the city of Leon the ravages done have been less, for the darkness there was not very great, and the same may be said of the showers of dust. The noise travelled to Costa Rica, where the cause was considered to be very near. The Colombian galley Boladora, which left Acapulco on the 20th ult. for the Realejo, experienced the darkness at 20 leagues from the shore, as well as such a copious shower of dust that the crew were apprehensive of being suffocated; and they were occupied for 48 hours in clearing the vessel with spades. Not being able to make for the Realejo on account of the darkness, they directed their course to Punta Arenas, with the full conviction that the whole state of Nicaragua had disappeared. The volcano continued vomiting fire and smoke, and causing at intervals a trembling of the earth.

Until further information arrives, it is impossible to calculate precisely the distance to which the showers of cinders extended and the noises were heard. The detonations were so loud as to be heard at Ciudad Real de Chiapas, which is 325 leagues from the mountain in one direction, and at El Peten, which is 322 leagues in another; and, as it is probable they could have been heard farther, we may estimate that the eruption affected the district, extending around the mountain 350 leagues in every direction. Even at Dolores, in the district of Peten, showers of ashes, volcanic reports, and earthquake shocks, were experienced.

In the time of the Roman Emperor Titus, in consequence of an eruption of Vesuvius, the ashes are stated to have been thrown into Africa, a story which has been considered incredible by some modern writers. This eruption of Cosigüeina shows the statement of the ancients to be by no means improbable.

FOOTMARKS OF AN EXTINCT ANIMAL IN THE SOLID ROCK.—Baron Alex. Von Humboldt has again arrived in Paris. At a meeting of the Academy of Sciences on the 17th August 1835, he directed the attention of the members to the prints of the footsteps of a quadruped in the variegated sandstone, or *bunte sandstein*, of Hildburghausen. It is an animal of the Plantigrada division, which had traversed the rock in various directions while soft. A stone, from ten to twelve feet long, and three to four wide, containing these impressions, has been sent to the Collection of Geology at Berlin, of which the Baron submitted to the Academy a beautiful drawing. There are four or five impressions of a smaller species, which cross those of the larger quadruped at right angles, and are remarkable for the unequal dimensions of the fore and hind feet; all of them have the impressions of five toes. The rock is covered with them as with a net-work, and here and there sinuous serpular concretions are visible—perhaps the plants on which the animals walked, or probably some accidental defect in the process of drying. The great importance of this discovery consists in the position occupied by this sandstone in the chronological series of rocks.

SHOCK OF AN EARTHQUAKE AT CHICHESTER.—On Monday the 10th August 1835, between eleven and twelve o'clock, many of the inhabitants of Chichester were awakened from their sleep, and much alarmed by two shocks of earthquakes. It is nearly twelve months since the last of these awful phenomena, and people began to hope that they would have entirely ceased. These shocks, however, were considered generally to have been less violent than most of those which had occurred last year.

FLOATING ISLANDS.—From the earliest times, authors have described those singular geological phenomena called floating islands. Pliny tells us of the floating islands of the Lago de Bassanello, near Rome. Near St Omer's, in the province of Artois in France, there is a large lake, in which there are several floating islands, some of which are inhabited; on one of them there was a church, and a religious convent of Bernardines. These islands are moved in different directions by the wind; and sometimes they are moored to the side with ropes. There are floating islands in Loehlomond, Scotland, and in the lake of Derwent-water, Cumberland: such islands appear and disappear. The latter, which had been under water for some time past, reappeared about the 7th September 1835, and attracted the attention of numerous visitors. Mr A. Pittingal, junior, in 1829, described a floating island about a mile southward of Newbury Port, in Massachusetts, Essex county, North America, 140 poles in length, and 120 in breadth. It is covered with trees; and in summer, when dry weather has long continued, it descends to the bottom of the lake.

## METEOROLOGY.

**TEMPERATURE.**—Mr Warden made observations on the remarkable fall of the thermometer during the winter 1834-5, in the United States. It proved to be the most rigorous season known there for the last fifty years.—M. Gaynard, surgeon and naturalist to the discovery-ship sent by the French government to the coasts of Iceland and Greenland, has made daily meteorological observations, and has ascertained that a period of unusually cold weather occurred in Iceland at the time that the United States suffered from a remarkably low temperature.

On the night of midsummer-day 1835, several sheep perished of the cold, on Welland and Little Malvern Common.

**RAIN.**—M. Fleureau de Belle-Vue has addressed a letter to the Academy of Sciences, Paris, giving his opinion that the diminution of the springs of Poitou, for ten years past, has arisen from the decrease of the annual quantity of rain during that period. This fact was doubted by various members of the Academy, but M. Arago assured them that this has been the case, not only in Poitou, but in several other parts of France, where regularly-recorded observations have been made. This is very remarkable in the spring at Arcueil, which now yields very little water, and from the same cause.

## MISCELLANEOUS.

**SUBMARINE VESSEL.**—According to the Paris papers, some curious experiments have lately been made at St Ouen, near Paris, with a submarine vessel, the invention of M. Villerni, the engineer. The vessel is of iron, and of the same shape as an animal of the cetaceous or whale tribe. Its movements and evolutions are performed by three or four men who are inside, and who have no communication with the surface of the water or the external air. With this machine navigation can be effected in spite of currents, any operations may be carried on under water, and it may be brought to the surface at will, and navigated like an ordinary vessel. It was with a machine similar to this that the project was formed, in 1821, for getting away Napoleon from St Helena. The Societ  Generale des Naufrages (Protector, the King of France) appointed Admiral Sir Sidney Smith, Count Godde de Liancourt, the Baron de St Denis, and Dr Daniel St Antoine, to report on the experiments. These took place at St Ouen; when the vessel was repeatedly sunk to the depth of 10 or 12 feet, and reappeared on the surface at different points. M. Godde de Liancourt got into it, and remained there a quarter of an hour, without experiencing the slightest inconvenience, or any difficulty of respiration, during his voyage under water.

**DIVERS, AND THEIR POWERS OF SUSPENDING RESPIRATION.**—Surprising statements have been made by travellers—a privileged race—respecting the powers of pearl-fishers and others, in voluntarily suspending their respiration under water at considerable depths: some have mentioned half-hours, and some even longer periods, as within the bounds of possibility. Dr Lefevre of Rochefort, who was lately stationed at Navarino, had ample opportunities of putting the prowess of the best divers to the test. He witnessed the performance of those who were employed to fish up the relics of the Turkish fleet sunk in Navarino harbour. The depth to which they had to plunge was 100 feet; but though the Greek divers are, and always may have been, famous for their prowess, none of them could sustain submersion for two whole minutes together. Seventy-six seconds was the average period in fourteen instances, accurately noted; and frequently, after reaching the surface, blood issued from the mouth, eyes, and ears of the swimmer. But, in general, these people can repeat their task three or four times in an hour.—*Medical Gazette.*

**LONGEVITY.**—A woman, 110 years old, died lately at Fayence, in the department of the Var (France). She was born at Digne, in 1725, and had lived in service in one house since 1745.

**ZOOLOGICAL GARDENS.**—Such is the interest felt by all classes of the community in Britain, that the number of persons who visited the Zoological Gardens, London, amounted in July 1835, to 44,446, and the income derived therefrom L.1672, 9s., and in the month of August, 26,334, yielding an income of L.992, 16s.

**STATUE OF CUVIER.**—The inauguration of the statue of this eminent naturalist took place with great ceremony, at his native town of Montbelliard, on the 23d August 1835, being the day of his birth. Deputations from several learned bodies were present, and various orations were delivered in honour of the occasion. The house in which Cuvier first saw the light was very tastefully decorated, and the following inscription was placed on it:—*Ici naquit G. Cuvier, le 23, Aout 1769.* The ceremony was succeeded by a banquet, a grand concert, and a ball.

**EUPHRATES EXPEDITION.**—Captain Chesney, with the expeditions under his command, had reached Bir, without encountering any obstacles, on the 11th August last.

**SENSITIVE HAIR.**—In the hospital of the royal guards at Paris was a private soldier who had received a violent kick on the back of the head from a horse. The excitement of the hair produced was extreme, and could only be kept under by almost innumerable bleedings, both local and general. Amongst a series of phenomena produced by this state of preternatural excitation, the sensibility acquired by the hairs of the head was not the least remarkable. The slightest touch was felt instantly, and cutting them gave exquisite pain, so that the patient would seldom allow any one to come near his head. Baron Larrey, on one occasion, to put him to the test, gave a hint to an assistant who was standing behind the patient, to clip one of his hairs without his perceiving it. This was done with great dexterity, but the soldier broke out into a sally of oaths, succeeded by complaints, and it was sometime before he could be appeased.—*Oracle of Health.*

**CAPTURE OF THE LAST NATIVE INHABITANTS OF VAN DIEMEN'S LAND.**—The following is a highly interesting extract of a letter from Launceston, Van Diemen's Land, dated the 31st of January 1835:—"I am just returned from seeing a very interesting but melancholy sight—the last of the unfortunate native inhabitants of this island, the remainder of those few unhappy savages, who so long kept us in terror! They were taken a few days since to the westward, and consist of three women, one man, and some little children, called piccaninies. One of the party, an old woman, spoke pretty good English, having probably learned it some years ago among the stock-keepers. They inform us that they are the last of their tribe, once 500 strong, which

was long dreaded under the name of the Big-river tribe. They say that, by innumerable affrays with the white men, they were at last reduced to three men, exclusive of women and piccaninies, and that, a few months since, they were surprised, and two of the men were killed; that they wandered all over the island for the purpose of joining some other tribe, feeling themselves too weak to exist, and under constant dread that the remaining man would be killed, and the rest, who it appears could not get food themselves, starved. They wandered over the island in every direction, but found no traces of black men; they began to despond, and led a miserable existence, feeling themselves to be the last natives in the whole island, and that the white men had rooted them out. It makes my heart bleed to think of it, but they acknowledge having killed a great many white men, and said they were very glad when they were taken. This was effected by means of some Sydney natives. On a shot being fired they all fell on their faces, and did not attempt to escape. They are now merry and happy, and pointed to the vessel which was to take them off the island with great glee. They are there taught gardening, agriculture, and the arts of civilized life. We had long believed the natives were nearly, if not quite, extinct, and have not the slightest doubt of the truth of their simple story. To look on that fine, tall, and somewhat solemn-looking savage, the last of his tribe, filled me with emotions which it would be in vain to attempt to describe. *Sic vos non vobis.*"

**SHORT'S POPULAR OBSERVATORY.**—We congratulate our countrymen on the opening of this patriotic establishment, on the Calton Hill, Edinburgh, where every man who has a shilling in his pocket can behold the wonders of the solar system, through glasses of the first order. Among the many attractions are, "Short's large Gregorian Equatorial Reflecting Telescope; a Superb Achromatic Telescope, ten feet focal length, six inches aperture (the largest in the kingdom), by Tulley; an improved grand Solar Microscope of prodigious power, by Dollond; an improved grand Compound Microscope, with Achromatic Object Glasses (an exquisitely fine instrument), by Dollond; an elegant Orrery, with Planetarian, Tellurian, and Lunnarian apparatus, by Dollond; a Camera Obscura, Camera Lucida, Phantasmagoria Lantern, Diagonal Mirror, &c. &c.

## LEARNED SOCIETIES.

**ROYAL ASIATIC SOCIETY.**—A general meeting of this association was held on the 4th July 1835, the Right Honourable Sir Alexander Johnston in the chair; when the first part of a paper, by George Earl, Esq. was read, giving an account of a voyage he made in the year 1834, from Singapore to the western coast of the island of Borneo, accompanied by two interpreters, who were masters of the Tartar and Malay languages. The purpose of this voyage was to establish, if possible, a commercial intercourse with the Chinese colonies, who are in possession of rich gold and diamond mines on that island. Mr Earl sailed from Singapore on the 1st March; and on his arrival at Sinkawan, the principal seaport of the Chinese settlers, he proceeded to the court-house, the residence of the Chinese magistrates; but they declined giving Mr Earl permission to trade, lest it might give offence to the Dutch, who have two small settlements on the coast, and who are masters of the sea, and had prohibited all traffic but through the medium of their own ports. Under these circumstances, it became necessary for Mr Earl to sail for one of those ports, called Sambas, in latitude 1° 25' north, situated on a small river, about fourteen miles inland. Here he found the habitations little better than huts, all built of wood, and for the most part erected on floats, and moored to large posts in the river. There is a fort here; and before the Dutch became masters of the place, the inhabitants lived entirely by piracy. This town is now inhabited by Chinese and Malays, the former being the most numerous. The latter are ruled by a kind of Rajah, who, however, is controlled by the Dutch resident. The Rajah derives his revenue principally from a monopoly in the sale of opium, which is here smoked to the greatest excess by all classes. The Dutch monopolize the sale of salt. The principal food of the inhabitants is rice, which they import from Java, in exchange for gold dust. The aboriginal inhabitants are called *Dyaks*: they are a ferocious people, divided into tribes, many of which retain their old-established customs. One of these is, that before a young man can be permitted to enter the marriage state, he must present the female of his choice with the head of a man which he has severed with his own hand! It was observed by Mr Earl that the natives of New Holland had had a similar mode of limiting population. On the death of a male of a tribe, they kill a male belonging to a neighbouring tribe, for the purpose of maintaining a balance of power.

## NEW WORKS ON NATURAL HISTORY, AND THE PHYSICAL SCIENCES.

Reynolds' Voyages Round the World, 8vo, 22s.—The Sea-side Companion, or Marine Natural History, by Mary Roberts, 12mo, 6s. 6d.—Naturalist's Library, vol. 9, Pigeons, 6s.; vol. 10, British Diurnal Butterflies, 6s.—Cuvier's Work on Fishes, vol. 10.—Popular Illustrations of Natural History, &c., fcp., 6s. 6d.; the Language of Flowers. 3d edition.—Observations on certain curious Indentations in the old Red Sandstone, by Jabez Allies, Esq., 8vo, plates, 3s. 6d.—Barrow's Excursions in the North of Europe, 2d edition, 9 engravings, 8vo, 12s.—Lyell's Principles of Geology, 4th edition, 4 vols. 12mo, 24s.—Gleanings in Natural History, 3d Series, by Edward Jesse, post 8vo, 10s. 6d.—Zoological Journal, Part 20, 10s. 6d. coloured, 7s. 6d. plain; Part 5, the Supplementary Plates to ditto, 14s.; Parts 84 and 85, Conchological Illustrations; No. 42, Genera of Shells, by G. B. Sowerby.—The Shrubbery, 32mo, 3s. 6d.—The Earth, by R. Judie, fcp. 5s.—An Account of New Zealand, by the Rev. W. Yates, royal 12mo, 10s. 6d.

ZOOLOGY.

DESCRIPTION OF THE PLATE—PIGEONS.

PIGEONS constitute a numerous family of the Gallinaceous order. Possessing a wider geographical range than almost any other tribe of birds, they are found in every quarter of the globe, from the southern boundary of ice, to the confines of the Arctic Circle. The general structure of the bill and feet being in all exceedingly characteristic, they form a well-marked family; and though modern naturalists have separated them into several sections and sub-genera, yet they all have such an affinity of form, as not easily to be mistaken. Their sizes are exceedingly various. The Goura or Crowned Pigeon (fig 9), the largest of the tribe, measures about twenty-eight inches in length; while the Ground Dove (fig. 7) is not larger than a sparrow, being only six inches and a half from the furthest extremity of the bill to the point of the tail.

The Domestic Pigeon, and Ring Turtle Dove, have been known to mankind from the remotest period of history, and are both frequently alluded to in the Sacred Writings. From the affectionate regard exhibited by the sexes, the ancients considered the dove as an emblem of love, and hence it was frequently depicted as an attendant in their representations of Venus and Cupid.

Many species of this tribe are remarkable for their powers of flight, and the short space of time in which they perform long journeys is almost incredible. To ascertain with some degree of exactness the speed of the Carrier Pigeon, a gentleman, some years ago, sent one from London by the coach to a friend at Bury St Edmunds, desiring that it might be set at liberty two days after its arrival, precisely as the town-clock struck nine in the morning. This request was strictly attended to, and the pigeon arrived at the Bull Inn, in Bishopsgate Street, at half-past eleven o'clock of the same morning, having thus flown seventy-two miles in two hours and a half.

During the breeding season, pigeons associate in pairs, and pay court to each other with their bills. Both the male and female assist in the labour of incubation. The female lays two eggs, and the young ones produced are generally a male and a female; these are attended to by both the parent birds. At first they are fed with a substance resembling curd, secreted within the crop, the coating of which becomes thickened and enlarged. The process is somewhat analogous to the secretion of milk within the mammae of quadrupeds. If the state of the crop be examined during incubation, it will be found to have a glandular and irregular appearance. Upon killing an old pigeon, when the young are just protruding from the egg, it will be observed to have within this cavity small pieces of white curd mixed with its ordinary food of pease, barley, and other grains. It is for a short time that the young are fed with this substance; for, on the third day it is administered along with a mixture of common food, and in eight or nine days the secretion of curd completely fails in the old birds, from which time they are capable of ejecting common food alone. This singular disposition of Nature is very remarkable, and we cannot but admire the final cause by which the pigeon is assigned the power of casting up this curd alone, although other food be in the crop at the same time.

The plumage of nearly the whole species is of a close texture; its tints are various, and its lustre remarkable.

Fig. 1.—The Blue-headed Ground Pigeon (*Columba Cyanocephala*) is a native of Jamaica, Cuba, and the Southern American Islands. It seldom resorts to trees, but is generally found upon the ground, where it forms its nest, and incubates. It runs with astonishing rapidity, and its habits are retired and solitary. Having but limited powers of flight, it seldom rises to a great height above the ground, but usually skims from one place to another, in nearly the same manner as the common Land Rail. Its size nearly approaches to the common Partridge.

Fig. 2.—The Zenaida Pigeon (*Columba Zenaida*.) This beautiful bird has been but recently discovered. It is about ten inches in length, and a native of Florida, in the United States of America. These pigeons also are generally found on the ground, in which situation they amuse themselves in dusting and seeking for gravel, which they swallow to assist in digesting their food.

Fig. 3.—The Purple-crowned Pigeon (*C. Purpurata*) is a native of the South Sea Islands, in many of which it greatly abounds. The first specimens which reached this country were brought from Tonga-Taboo. Their geographical range extends as far south as New Holland. This bird is from nine to ten inches in length, and frequents woods, feeding on different kinds of fruit, such as the Limonia bifoliata, and the Banana.

Fig. 4.—The Passenger Pigeon (*C. Migratoria*.) This elegant species is sixteen inches in length. In symmetry of form, and in the arrangement and contrast of its colours, it is exceeded by none of the genus. It inhabits North America, from the Stony Mountains to Hudson's Bay, and its range extends as far south as the Gulf of Mexico. Unlike most of the species in the genus *Columba*, these birds generally

associate together, both during their incubation and also during their migrations, in such vast numbers as to exceed all belief. They are sometimes seen in feeding parties, covering the country to the extent of two miles in length, and a quarter of a mile in breadth. Their migrations are occasioned by a scarcity of food, which is commonly the beech-mut, and not by temperature, as is the case with some other birds. When they have fixed upon a resting-place, they do not remove from it even after they have exhausted all their food, but will extend their range for a distance of eighty miles to another forest, and return in the evening to their temporary home. When these roosting-places are discovered by the neighbouring inhabitants, they repair to them in the night. Vast numbers are first stupified with pots of burning sulphur, and then killed with poles, guns, and other instruments of destruction.

Fig. 5.—The Blue and Green Pigeon (*C. Cyano-virens*.) Although displaying no great variety in its plumage, it is nevertheless a bird of great beauty. This species is a native of New Guinea, where it frequents the vast forests with which that country abounds. It is about eight inches in length.

Fig. 6.—The African Ground Pigeon (*C. Afra*.) This beautiful little species, as its name denotes, is a native of Africa.

Fig. 7.—The Ground Pigeon (*C. Passerina*.) The birds of this species are natives of North and South Carolina, and Georgia, in the United States. They also frequent several of the West India Islands, where the inhabitants frequently catch and keep them in cages. They congregate in small flocks of about fifteen or twenty, and are usually found on the ground. When disturbed, they rise to a short distance and then alight.

Fig. 8.—The Black-capped Pigeon (*C. Melano-cephala*) inhabits the island of Java, and builds in trees. Its length is nine inches.

Fig. 9.—The Great-crowned Pigeon (*C. Coronata*.) This splendid bird is the largest of its tribe. Many attempts have been made to domesticate it, but they have invariably failed. This is to be regretted, as it would not fail to be an important acquisition for our poultry-yards. It has been found in the forests of Africa, New Guinea, and the Molucca Islands.

FLYING FISH.—The animals of the ocean seem to correspond in their general habits to those of the land—one portion depending upon an erratic mode of life for subsistence, like the wandering Arabs of the desert, and the other upon a sedentary life, like the domesticated ones of the plain. The erratic tribes of the ocean, however, have this advantage over those of the land, that, while the green oases scattered thinly over the deserts of the latter, and the caravans at chance intervals traversing them, afford but an uncertain supply to its roaming hordes, those of the ocean derive always an abundance in the variety of the finned fishes, and the gelatinous Mollusca and spawn which the latter contains; the smaller finned tribes preying upon the Mollusca and spawn, and the larger again upon the smaller, until their eventual decease enables the Mollusca to prey in turn upon them. The animal species has, by an eminent naturalist, been compared to a circle, into which all are progressively united by successive connecting links; and it may be only a high philosophic enthusiasm for practically demonstrating the truth of this circular theory, which induces them to eat each other in a circle also. Of all the smaller erratic fishes, the flying species is the most interesting, in consequence of its being one of the singular links connecting the fish with the bird tribe, its length seldom exceeding a foot, its shape roundish, and tapering from the head to the tail, with a long fin projecting out on each side of its centre of balance, to be applied either to swimming or flying, according as exigencies may require. It is not, however, a universal wanderer; like most of the other deep-sea fishes, its range of feeding-ground is confined to the latitudes of the trade winds, most probably in consequence of its slender filmy wings and delicate form rendering it unfit to encounter the rough buffeting of the stormy winds and waves of the seas beyond. Having so many enemies constantly in quest of them as a prey in their own element, no wonder that the Flying Fish should be by nature a timid race, always taking to the air for protection, when threatened by an enemy in the sea. The approach of the Porpoise, Dolphin, Albicore, and Bonetta, quickly scare them from their watery haunts; but the terror produced by the latter, is nothing in comparison to that excited by a huge ship suddenly plunging in among a shoal of them sunning themselves near the surface of the water, tumbling over and over in their hurried efforts to get up, or knocking each other down again into the sea in their haste to escape the fancied fangs of the nondescript monster that has thus unexpectedly invaded their domain. Strangers, on first seeing them, almost invariably take them for a flock of birds; and, indeed, when viewed at a little distance on the wing, it frequently requires a practised eye to detect the deception, a fresh flock of them being often made to start up at every plunge of the ship, when sailing through a part of the sea where they are rife. Mounting suddenly upwards, with a squattering noise like a flock of

ducks, they now flicker away in a covey together, with astonishing speed, their long, thin, tapering wings quivering in rapid vibrations as they dart through the air, resembling the wings of the sparrow tribe. They appear to have as perfect self-command in the air as the water, the body of the flock always following the motions of the leaders, just as seen in a flock of birds, soaring up and sinking down, or wheeling to either hand, according as the pilots of the band vary their own onward flight. They fly by night as well as by day, although their power of vision in the former must be very defective, as is shown by their frequently dropping on board ship during the night, an accident which never happens to them during the day. Like most other fishes, they are attracted by a glare of light, and it is by taking advantage of this that they are allured in such numbers into the nets constructed for them on the Barbadoes coast, as to constitute no inconsiderable item in the food of the inhabitants of that island. Ships have sometimes followed a similar plan with singular success. H.M.S. Prometheus, in running down the trades, by nailing hammock-cloths along her sides, supported out by handspikes, and illumined by a row of pursers' lanterns between, caught as many nightly as gave a daily meal to all on board. They are sweet, delicate, and juicy eating, contrary to that of most of the other deep-sea fishes, which are harsh, dry, and tasteless. Their manner of cooking them in Barbadoes is by frying with a little lard and flour, dusting until brown and dry, and in this state exposing them for sale, every boat that visits a ship having generally large platters-full of them piled up in cross layers over each other, which always find abundance of eager customers, particularly after a long salt-beef cruise. Nor is the peculiar oratory, playful motions, and merry smirking faces of the jetty belles who vend them, the least interesting part of the scene; dancing nimbly about on some convenient boat plank, wagging their heads laughingly to and fro, and snapping their fingers in cadence to the tune they are humming, until attaining the object they had in view, of attracting the attention of some one to their wares, they now sip out, in their best boarding-school English, some such speech as the following:—"Hye, buckra, do come buy him fine fish fo yam-chah! bady, what fo you no buy him all den off? I pop fo moe like a bottle o' pruce."

**EGGS PRESERVED FOR THREE HUNDRED YEARS.**—Three eggs were found in the wall of a chapel, which was built upwards of 300 years ago, near the Lago Maggiore. These were embedded in the mortar of the wall, and, upon attentive examination, they were found to be quite fresh. It has been long known, that the eggs of birds, brought from India or America, when covered with a thin coating of wax, retain their vital principle, and have been hatched after the wax had been dissolved by alcohol.

**BUTTERFLY FEASTS.**—There is a certain mountain in New Holland, called the Bugong mountain, from multitudes of small moths called Bugong by the natives, which congregate at certain times, upon masses of granite, on this mountain. The months of November, December, and January, are quite a season of festivity amongst the people, who assemble from every quarter to collect these moths. They are stated also to form the principal summer food of those who inhabit to the south of the snow mountains. To collect these moths, or rather butterflies, the natives make smothered fires under the rocks on which they congregate; and suffocating them with smoke, collect them by bushels, and then bake them by placing them on heated ground. Thus they separate from them the down and the wings; they are then pounded and formed into cakes resembling lumps of fat, and often smoked, which preserves them for some time. When accustomed to this diet, they thrive and fatten exceedingly upon it. Millions of these animals were observed also, on the coast of New Holland, both by Captains Cook and King. Thus has a kind Providence provided an abundant supply of food for a race that, subsisting solely by hunting or fishing, must often be reduced to great straits.

## BOTANY AND HORTICULTURE.

### FAIRY RINGS.

THE cause of these singular appearances was long unknown to Natural Philosophers, although many attempted to remove them, by conjecture, from the dominion of "fairy elves," into the soberer domains of Science. As is well known to shepherds and agricultural labourers, fairy rings are spots of grass, more luxuriant and green than any other part in a field. These spots are usually circular, either having within them a spot of grass, very luxuriant throughout its entire surface, or being only a circular zone of very luxuriant grass, inclosing within it a quantity of similarly coloured herbage, but not quite so luxuriant as the zone, although superior to the rest of the grass in the same field. Often the circle is incomplete, and consists only of an arch or segment of a circle, which is frequently bent in an irregular manner.

It is unnecessary at present to speak of the absurdity of the popular opinion on this subject. The belief in Fairies or Genii, as secondary causes of the various phenomena of nature, seems congenial to the human mind, and it has, accordingly, been found in almost every country. The Arabs call them Ginn, and the Persians Peri; and they were supposed to inhabit a fairy-land, which was called Ginnistân. In many districts of our own country, the belief in the existence of Fairies, Benshees, and Bogles, still retains its hold over the minds of the people.

Mr Jessop and Dr Priestley thought that fairy circles were caused by Electricity. "I have been often puzzled," says Mr Jessop in one of the earlier volumes of the Philosophical Transactions, "to give an account of those phenomena which are called Fairy Circles. I have seen many of them, and those of two sorts; one sort bare, of seven or eight yards in diameter, making a round path, something more than a foot broad, with green grass in the middle; the others like them, but of several bignesses, and encompassed with a circumference of grass, about the same breadth, much fresher and greener than that in the middle. But my worthy friend Mr Walker gave me full satisfaction from his own experience. It was his chance one day to walk out among some mowing grass (in which he had been but a little while before) after a great storm of thunder and lightning, which seemed by the noise and flashes to have been very near him; he presently observed a round circle, of about four or five yards diameter, the rim whereof was about a foot broad, newly burnt bare, as the colour and brittleness of the grass roots did plainly testify. He knew not what to ascribe it unto

but to the lightning, which, besides the odd caprices remarkable in that fire in particular, might, without any wonder, like all other fires, move round and burn more in the extremities than the middle. After the grass was mowed, the next year it came up more fresh and green in the place burnt than in the middle, and at mowing time was much taller and ranker."

Dr Priece suggested to Dr Priestley that fairy rings might be of an electric origin, and be produced in the same manner as those circular spots, which are procured by submitting metallic substances covered with water to the influence of an electric battery. "I have examined one of these rings," says Dr Priestley; "it was about a yard in diameter, the ring itself about a quarter of a yard broad, and equally so in the whole circumference; but there was no appearance of any thing to correspond with the central spot," observed in the electrical experiments.

Mr Cavallo, in his Treatise on Electricity, which appeared in 1777, was the first who called in question the electric origin of these circles. "This supposition," he observes, "is not very probable, for the spots in the fields, called *fairy circles*, have no central spot, no concentric circles, neither are they always of a circular figure; and, as I am informed, they seem to be rather beds of mushrooms than the effects of lightning."

Mr White, in the Natural History of Selborne, makes the following observations on the subject:—"The cause, occasion, call it what you will, of fairy rings, subsists in the turf, and is conveyable with it; for the turf of my garden-walks, brought from the Down above, abounds with those appearances, which vary their shape, and shift situation continually, discovering themselves now in circles, now in segments, and sometimes in irregular patches and spots. Wherever they obtain, puff-balls abound, the seeds of which are doubtless brought in the turf." Mr Johnson of Weatherly, in a paper in the fourth volume of the Philosophical Journal, attributes them "to the droppings of Starlings, which, when in large flocks, frequently alight on the ground in circles, and sometimes are known to sit a considerable time in these annular congregations."

The suggestion made to Cavallo, that these circles are occasioned by mushrooms, has, since that time, been completely confirmed by the observations of Drs Withering and Wollaston. The former considered them to be caused by a species of *Agaricus* (*Ag. Orcades*); but the latter showed that many other species of *Agarici*, and the *Lycoperdon hovista*, were capable of producing them.

In a valuable paper in the Philosophical Transactions for the year 1807, Dr Wollaston described the manner in which these circles were formed:—

"That which first attracted my notice," says he, "was the position of certain fungi, which are always to be found growing upon these circles, if examined in a proper season. In the case of mushrooms, I found them to be solely at the exterior margin of the dark ring of grass. The breadth of the ring in that instance, measured from them towards the centre, was about twelve or fourteen inches, while the mushrooms themselves covered an exterior ring about four or five inches broad.

"The position of these mushrooms leads me to conjecture that progressive increase, from a central point, was the probable mode of formation of the ring. I was the more inclined to this hypothesis, when I found that a second species of fungus presented a similar arrangement, with respect to the relative position of the ring and fungi; for I observed, that in all instances the present appearance of fungi was upon the exterior border of a dark ring of grass. I thought it not improbable that the soil, which had once contributed to the support of fungi, might be so exhausted of some peculiar *pabulum* necessary for their production, as to be rendered incapable of producing a second crop of that singular class of vegetables. The second year's crop would consequently appear in a small ring surrounding the original centre of vegetation, and at every succeeding year the defect of nutriment on one side would necessarily cause the new roots to extend themselves solely in the opposite direction, and would occasion the circle of fungi continually to proceed by annual enlargement from the centre outwards. An appearance of luxuriance of the grass would follow as a natural consequence, as the soil of an interior circle would always be enriched by the decayed roots of fungi of the preceding year's growth. During the growth of the fungi, they so entirely absorb all nutriment from the soil beneath, that the herbage is for a while destroyed, and a ring appears, bare of grass, surrounding the dark ring. If a transverse section be made of the soil beneath the ring at this time, the part beneath the fungi appears paler than the soil on either side of it; but that which is beneath the interior circle of dark grass is found, on the contrary, to be considerably darker than the general surrounding soil. But in the course of a few weeks after the fungi have ceased to appear, the soil where they stood grows darker, and the grass soon vegetates again with peculiar vigour; so that I have seen the surface covered with dark grass although the darkened soil has not exceeded half an inch in thickness, while that beneath has continued white with spawn of these mushrooms for about two inches in depth.

"For the purpose of observing the progress of various circles, I marked them three or four years in succession, by incisions of different kinds, by which I could distinguish clearly the successive annual increase, and I found it to vary in different circles from eight inches to as much as two feet. The broadest rings that I have seen were those of the common mushroom (*Agaricus campestris*); the narrowest are the most frequent, and are those of the champignon (*Agaricus Orcades* of Withering.) The mushroom accordingly makes circles of largest diameter, but those of the champignon are most regular. There are, however, as many as three other fungi that exhibit the same mode of extension, and produce the same effect upon the herbage. These are the *Agaricus terreus*, *Agaricus procerus*, and the *Lycoperdon bovista*, the last of which is far more common than the two last mentioned agarici.

"There is one circumstance that may frequently be observed respecting these circles, which can satisfactorily be accounted for, according to the preceding hypothesis of the cause of their increase, and may be considered as a confirmation of its truth. Whenever two adjacent circles are found to interfere, they not only do not cross each other, but both circles are invariably obliterated between the points of contact, at least in more than twenty cases; I have seen no one instance to the contrary. The exhaustion occasioned by each obstructs the progress of the other, and both are starved."

MINERALOGY.

SINGULAR SECTIONS OF A KENTISH FLINT.

THE common flint is found in spherical masses embedded in the chalk formations, and the manner in which it has there been formed has given rise to considerable discussion among geologists. It is certainly a singular circumstance to find in extensive strata of chalk, which is a substance almost entirely composed of pure carbonate of lime, isolated masses of flint, formed of silica, or quartz. Most commonly the nucleus of these flint nodules consists of an animal or vegetable substance, as a shell-fish, coral, or piece of flustra, or sponge; but frequently no such matters are found. The nodules, too, assume various shapes, and seem to be moulded according to the cavities of the chalk in which they are surrounded. From the appearances of these nodules, it is evident that they have been in a fluid state, previous to their assuming such shapes, either from the agency of intense heat or of a liquid menstruum, or perhaps from the combination of both these means. The accurate experiments of modern chemists have shown us that silica may be liquified with the greatest ease in combination with either of the mineral alkalies. Thus, if silica and soda be subjected to the intense heat of a furnace, it liquifies into a glass; and if this glass be taken and again subjected to the agency of water, heated under a highly-condensed pressure, the silica will be dissolved, and will be deposited, on cooling, around the edge of the vessel. When combined with a large proportion of the alkali, and when under very minute mechanical division, silica may also be dissolved in water at the ordinary temperature of the atmosphere, thus forming the substance called liquor of

flints. By one or other of such processes, then, taking place in nature, we may suppose that a quantity of liquified silica has been diffused among a bed of chalk. The singular circumstance however is, how it should have collected into the numerous separate nodules in which it is universally found; and this has been attempted to be explained, by supposing that a chemical attraction has taken place between the vegetable or animal remains strewn profusely among the chalk and the silicious matter, by which the latter has been accumulated around, and incorporated into, the minutest parts of the organized substances, thereby forming the petrifications so generally found in the flint nodules. In those cases where no traces of organization are found, it may be supposed either that the organic structure has been entirely destroyed, or that the silicious matter has been from the first simply deposited in a cavity or fissure of the chalk. Flint nodules, although composed of the same materials, have not generally the compact and dense structure of the pebble or agate. Flint is of a more porous nature, and of an opaque and clouded appearance. If a piece of flint be broken, and immediately examined, minute drops of moisture will be seen to ooze out from its pores, affording a proof that water must have originally assisted at its fluidity. It must be remarked, however, that alkaline matter is not found to exist in any great quantity in its composition. From the opaque and porous nature of flints, it has been conjectured that they may have been formed partly from particles in a state of minute mechanical division, and partly from others in a state of chemical solution.

The fracture of flint nodules usually presents a dark opaque ground, clouded with whitish and dark gray spots and patches. Some of these often assume very fantastic imitations of figures of men and animals. In the British Museum is an agate on which is portrayed a very accurate likeness of the poet Chaucer; and during the French Revolution, immediately after the king was beheaded, a very remarkable portrait of this unfortunate monarch was discovered distinctly marked in a piece of Labrador spar. So accurate was the likeness, and so curious was this coincidence reckoned at the time, that a very large sum of money was obtained for it; and fac-similes were engraved from it, and worn as rings by the loyal inhabitants of Europe. In the annexed engravings we have given a fac-simile of three remarkable portraits found in a flint nodule, which may be seen in the Museum of Mr Robert Frazer, Jeweller, 17, South St Andrew Street, Edinburgh.

This mass of flint, weighing about sixteen ounces, was picked up by mere accident, on the Kent road, near London. On breaking off a small piece of it, the profile, No. 1, was discovered on the surface of the fracture, and immediately recognised as bearing a very striking resemblance to the

general contour of the features of the first warrior and general of the age. The portrait has somewhat the appearance of an enamel painting; the figure being of a whitish-gray substance, surrounded by a dark brown ground. As it was conjectured that, in all probability, the impression of the figure might penetrate deep into the stone, it was slit up nearly through the centre, when the figures No. 2 and 3 were displayed on each side of the exposed surfaces; and it will not require a very active fancy to discover in these the face and lineaments of a monarch endeared to the British nation. These two likenesses have actually been recognized and pointed out by different individuals, who had no previous knowledge that such a similarity had before been discovered; thus affording a test of the truth of the general resemblance. At the time that these likenesses were first discovered—about five years ago—it was looked on as a curious coincidence that the monarch and his prime minister should both be found depicted on one stone by the hand of nature, and by a process which, even with all the aids of modern chemistry, we fear we have but imperfectly conjectured, and endeavoured to explain to our readers.

Flint is not the only substance which is found to contain animal and vegetable matter within its nodules. Small portions of moss plants, and other cryptogamia, are frequently found, beautifully preserved, in the rock crystal, topaz, and agate, with all the minute lineaments of their original structure. This affords another proof of the fact that such crystals must have been in a fluid state, without any great increase of temperature, at the period when they assumed their solid form. Many of these stones as well as jaspers contain various figures assuming the forms of vegetation; being, in reality, merely accidental admixtures of various metallic substances, which, in crystal-

lizing, thus assume the appearance of leaves and stems of plants. Of this kind are the mocha stone, arborescent jasper, landscape marble, &c. Drops of water, however, and portions of air, are occasionally found in such crystals, under circumstances which led Dr Davy to suppose that these have been enveloped in the crystal while under great expansion by heat. On carefully opening the cavities, he found that the water and air diminished in volume, when exposed to the ordinary pressure of the atmosphere, in some instances to the extent of six to eight times their bulk—in the chalcedony to the extent of sixty times their volume.

## MISCELLANEOUS.

## NO. I.—ANIMAL MAGNETISM.

THE extraordinary influence of the imagination over the human body is strikingly illustrated in the History of Animal Magnetism, as well as the astonishing delusions by which an ignorant and credulous mind is liable to be influenced, when in the hands of a cunning and designing impostor. We shall, accordingly, give a few articles on this interesting and comparatively little-known subject.

In consequence of the extent to which the practice of Animal Magnetism, as it was called by its inventor, M. Mesmer, was carried in Paris, the French king appointed a committee, consisting of four physicians and five members of the Royal Academy of Sciences, to investigate the matter, in the year 1784. Among the latter were M. M. Bailly, Lavoisier, and Dr Franklin, who was at that time the American minister at Paris. This agent, which Mesmer pretended to have discovered, he affirmed, was "a fluid universally diffused, and filling all space, being the medium of a reciprocal influence between the celestial bodies, the earth, and living beings—it insinuated itself into the substance of the nerves; upon which, therefore, it had a direct operation. It was capable of being communicated from one body to other bodies, both animated and inanimate, and that at a considerable distance, without the assistance of any intermediate substance; and it exhibited in the human body some properties analogous to those of the loadstone, especially its two poles. This Animal Magnetism," he added, "was capable of curing directly all the disorders of the nervous system, and indirectly other maladies; it rendered perfect the operation of medicines, and excited and directed the salutary crises of diseases, so that it placed these crises in the power of the physician. Moreover, it enabled him to ascertain the state of health of each individual, and to form a correct judgment as to the origin, nature, and progress of the most complicated diseases," &c. In short, he said, "La nature offre dans le magnétisme un moyen universel de guerir et de préserver les hommes." (Nature supplies in Magnetism one universal cure for the maladies of the human race.)\* Mons. Deslon, a pupil of Mesmer, also practised Animal Magnetism at Paris, and undertook to demonstrate its existence and properties to the commissioners. He commenced his instructions by reading a memoir, in which he maintained, that "there is but one nature, one disease, and one remedy, and that remedy is Animal Magnetism."

The first step of the commissioners was to examine the mode and instruments of operation, and the effects of the agent. It was observed that M. Deslon operated upon many individuals at the same time. In the middle of a large room was placed a circular chest of oak, raised about a foot from the floor, which was called the *Baquet*; the lid of this chest was pierced with a number of holes, through which there issued moveable and curved branches of iron. The patients were ranged in several circles round the chest, each at an iron branch, which, by means of its curvature, could be applied directly to the diseased part. A cord, which was passed round their bodies, connected them with one another, and sometimes a second chain of communication was formed by means of the hands, the thumb of each one's left hand being received and pressed between the forefingers and thumb of the right hand of his neighbour. Moreover, a piano-forte was placed in a corner of the room, on which different airs were played; sound being, according to the principles of Mesmer, a conductor of Magnetism. The patients, thus ranged in great numbers round the *baquet*, received the magnetic influence at once, by all these means of communication. By the branches of iron which transmitted to them the magnetism of the *baquet*—by the cord entwined round the body—by the union of thumbs, which conveyed to each the magnetism of his neighbour—and by the sound of the music, or of an agreeable voice, which diffused the principle through the air. The patients were, besides, directly magnetised by means of the finger of the magnetiser, and a rod of iron which he moved about before the face, above or behind the head, and over the diseased parts, always observing the distinction of the magnetic poles, and fixing his countenance upon the individual. But, above all, they were magnetised by the application of the hands, and by pressure with the fingers upon the hypochondria and the abdominal regions, which was often continued for a very long time, occasionally for several hours together.

The patients subjected to this treatment at length began to present very various appearances in their condition as the operation proceeded. Some of them were calm and tranquil, and felt nothing; others were affected with coughing and salivation; others again experienced slight pains, partial or universal heats, and considerable perspirations; and others were agitated and tortured with convulsions. These convulsions were extraordinary in their numbers, severity, and duration. The commissioners saw them, in some instances, continue for three hours, when they were accompanied with expectoration of a viscid phlegm, which was ejected by violent efforts, and sometimes streaked with blood; one young man often brought up blood copiously. The convulsions were characterized by violent involuntary motions of the limbs, and of the whole body, by spasms of the throat, by agitations of the epigastrium and hypochondres, and wandering motions of the eyes, accompanied by piercing shrieks, weeping, immoderate laughter, and hiccough. They were generally preceded or followed by a state of languor and rambling, or a degree of drowsiness, and even of coma (or profound sleep and torpitude). The least unexpected noise made the patients start; and it was remarked that even a change of measure in the air played upon the piano-forte affected them, so that a more lively movement increased their agitation and renewed the violence of their convulsions. Nothing can be more surprising or more inconceivable by those who have not witnessed it, than the spectacle of these convulsions, say the commissioners: all seem to be under the power of the magnetiser; a sign from him, his voice, his look, immediately rouses them from a state even of apparent stupor. In truth, they add, it was impossible not to recognise, in these constant effects, a great power or agency, which held the patients under its dominion, and of which the magnetiser appeared to be the sole depositary.†

\* See *Memoire sur la Decouverte du Magnétisme Animal*, par M. Mesmer, Doct. en Med. de la Faculté de Vienne, 1779. Also his *Précis Historique des Faits relatifs aux Mag.* Au jusques en Avril 1781.

† See *Rapport des Commissaires chargés par le Roi, de l'Examen du Magnétisme Animal*; à Paris, 1784.

Such, then, were the phenomena (of the reality of which they could not doubt) produced by the operation of this new agent, the nature and origin of which it was the duty of the commissioners to investigate. This convulsive and lethargic state, it may be noticed, was considered as a crisis, such as the constitution or the art of medicine is enabled to effect, for the purpose of curing diseases; and, for the sake of brevity, we shall adopt the term to express this occurrence, regardless of the hypothesis which led to its use.

A POLYPI-NESIAN WAR.—In those balmy regions of the South, where coral reefs arise, the germs of future continents, there dwelt two Polyypi, celebrated in Polyipian lore, by the names of *Polyerates* and *Polydorus*. Friendship had long united their minds, as much as nature had united their bodies; but chance, or a wayward fate, at length produced discord. A luckless worm, roaming for pleasure through the deep, became entangled in the tentacula of *Polyerates*, by the one extremity, while *Polydorus* at the same instant seized the other end. Each continued his repast; until at length, near the centre of the worm, a fierce conflict of hostile tentacula arose. Like some beings at the other end of the scale of creation, though *but one flesh*, they were of *two minds*. *Polyerates* being the larger and stronger, soon obtained the ascendancy; and, irritated by the contest, not only swallowed the worm, but *Polydorus* also! *Polydorus*, however, by no means disturbed by the novelty of his situation, continued, with philosophical resignation, within the stomach of *Polyerates* to complete the repast which had been thus strangely interrupted; until at length, finding nothing further worth his demolishing in that quarter, and being unwilling to imitate *Jonas* in the length of his captivity, he soon managed, by a retrograde movement of his tentacula, to release himself and worm from this apparently critical situation. *Polyerates* now obtains all the honour and glory of the contest; but *Polydorus* finds the truth of the popular adage, that "solid pudding is better than empty praise."

NEW HOLLAND.—This is New Holland—where it is summer with us when it is winter in Europe, and *vice versa*—where the barometer rises before bad weather, and falls before good—where the north is the hot wind, and the south the cold—where the humblest house is fitted up with cedar (*Cedrela toona*)—where the fields are fenced with mahogany (*Eucalyptus robusta*), and myrtle trees (*Myrtaceæ*) are burnt for fire-wood—where the swans are black and the eagles white—where the kangaroo, an animal between the squirrel and the deer, has five claws on its fore-paws, and three talons on its hind legs, like a bird, and yet hops on its tail—where the mole (*Ornithorhynchus paradoxus*) lays eggs, and has a duck's bill—where there is a bird (*Meliphaga*), with a broom in its mouth instead of a tongue—where there is a fish, one half belonging to one genus (*Raja*), and the other half to another (*Squalus*)—where the pears are of wood (*Xylomebum pyriforme*), with the stalk at the broader end—and where the cherry (*Exocarpus cupressiformis*) grows with the stone on the outside.

ASTRONOMER ROYAL.—Mr Pond has retired from the situation of Astronomer Royal, and Professor Airy has been appointed, with a salary of L.800 a-year.

DREAMS.—By the kind attention of my friend Dr James Gregory, I have received a most interesting manuscript by his late eminent father, which contains a variety of curious matter on this subject. In this paper, Dr Gregory mentions of himself, that having on one occasion gone to bed with a vessel of hot water at his feet, he dreamt of walking up the crater of Mount *Ætna*, and of feeling the ground warm under him. He had, at an early period of his life, visited Mount Vesuvius, and actually felt a strong sensation of warmth in his feet, when walking up the side of the crater; but it was remarkable, that the dream was not of Vesuvius, but of *Ætna*, of which he had only read Brydon's description. This was probably from the latter impression having been the more recent. On another occasion, he dreamt of spending a winter at Hudson's Bay, and of suffering much distress from the intense frost. He found that he had thrown off the bed-clothes in his sleep, and, a few days before, he had been reading a very particular account of the colonies in that country during the winter. Again, when suffering from toothache, he dreamt of undergoing the operation of tooth-drawing, with the additional circumstance, that the operator drew a sound tooth, leaving the aching one in its place. But the most striking anecdote in this interesting document, is one in which similar dreams were produced in a gentleman and his wife, at the same time and by the same cause. It happened at the period when there was an alarm of French invasion, and almost every man in Edinburgh was a soldier. All things had been arranged in expectation of the landing of an enemy, the first notice of which was to be given by a gun from the Castle, and this was to be followed by a chain of signals, calculated to alarm the country in all directions. Farther, there had been recently in Edinburgh a splendid military spectacle, in which five thousand men had been drawn up in Princes' Street, fronting the Castle. The gentleman to whom the dream occurred, and who had been a most zealous volunteer, was in bed, between two and three o'clock in the morning, when he dreamt of hearing the signal-gun. He was immediately at the Castle, witnessed the proceedings for displaying the signals, and saw and heard a great hustle over the town, from troops and artillery assembling, especially in Princes' Street. At this time he was roused by his wife, who awoke in a fright, in consequence of a similar dream, connected with much noise and the landing of an enemy, and concluding with the death of a particular friend of her husband's, who had served with him as a volunteer during the late war. The origin of this remarkable concurrence, was ascertained in the morning to be the noise produced in the room above by the fall of a pair of tongs, which had been left in some very awkward position in support of a clothes screen.—Dr Reid relates of himself, that the dressing applied after a blister on his head having become ruffled, so as to produce considerable uneasiness, he dreamt of falling into the hands of savages, and being scalped by them.—*Abercrombie on the Intellectual Powers.*

ZOOLOGY.

DESCRIPTION OF THE PLATE—THE CAT TRIBE.

THE animals of this tribe have long attracted the attention and admiration of mankind by their strength, magnanimity, and valour; while the extreme ferocity and cruelty of some have equally rendered them objects of fear. To conquer the Nemean lion, was considered, in the earlier periods of human society, as a feat worthy of Hercules himself.

They are tolerably swift of foot, and hunt chiefly during the night. Lying in wait for their prey till it comes within reach, they spring forward upon it at one bound, and seize it by surprize. While eyeing their victim, they move the tail frequently from side to side. In a natural state, they never adopt vegetable food, except in cases of urgent necessity. Most of the species are very agile in climbing trees, for which purpose, the strength of their limbs and hooked claws admirably adapt them. They have the remarkable property of alighting on their feet, whenever they are thrown or fall from a height, by which means the injury attendant on such accidents is often averted.

Fig. 1. The African Lion (*Felis Leo*).—The Lion of Africa is usually about six feet in length from the muzzle to the insertion of the tail, and his height at the shoulders upwards of three feet; the tail is more than three feet long, and terminated by a tuft of blackish-brown hair. Attached to the last joint of the tail is a small dark brown horny prickle, which is concealed by the hair, and surrounded at its base by an annular fold of the skin. The Lion possesses a characteristic peculiarity which at once distinguishes him from all other species of his tribe, namely, a long and flowing mane; and, except in a very young state, his fur is totally divested of spots or stripes.

The courage of the Lion has been proverbial in all ages, yet we cannot ascribe this to any innate elevation of sentiment, but to the consciousness of his own physical powers. He well deserves the title of "the king of beasts," as no animal can singly overcome him; and he roams at large in the boundless desert, in the extensive plains, or skulks in the shades of the vast jungles of his native country. His head is peculiarly large, his jaws have immense strength, and his shoulders and chest have a depth far exceeding all other animals of his size. In his sense of smell and acuteness of hearing, he is far inferior to the dog. This deficiency seems to pervade the whole tribe, and appears to have been destined by Nature for limiting, in a certain degree, their means of destruction.

Fig. 2. The Lioness and Cubs.—The Lioness is at once distinguished from her mate by the want of the mane. Being inferior both in size and strength to the Lion, her make is at the same time more delicate, and she is more agile in her movements, while she greatly surpasses him in the liveliness of her disposition, and the unrestrained ardour of her passions. The sexes differ, in a remarkable degree, in the position and direction of their heads,—that of the Lion being uniformly elevated, impressing him with an air of dignity, while the Lioness carries her head always on a level with the line of her back, giving her a sullen and ferocious aspect. In tender and undivided attachment to her progeny, the Lioness is exceeded by no other animal. In a tame condition, and even when brought to a state of complete gentleness, her character becomes totally changed. While suckling the young, all her native ferocity seems to return with tenfold vigour. At this period she would tear to pieces the hand of her keeper, while at other times she would lick it with affectionate tenderness.

Fig. 3. The Puma (*F. Concolor*).—This animal is a native of the American continent. The colour of its fur is uniformly of a yellow-fawn, or brownish-red; the belly is white, or of a pale cream colour. It has been designated the American Lion, though destitute of a mane, or tuft at the point of its tail. It is about four feet in length, and its height somewhat more than two feet. The head is round, and the ears short. It inhabits the high and mountainous tracts of the United States, and is common in South America. Its power is greatly beyond what might be expected from its size. It leaps on the back of its victim, whom it seldom fails to vanquish, frequently overcoming even the Wild Ass. Sometimes the latter contrives to free itself from its assailant by lying down and rolling over the Puma, and thus crushing him to death.

Fig. 4. The Tiger (*F. Tigris*).—The Bengal Tiger measures six feet in length, besides the tail, which is generally about three feet. There are several varieties of this animal, but all of them have the black stripes on the body.

Such is the physical strength of the Tiger, that he can run at a considerable speed with the body of a man in his teeth; and his general movements are more nimble than those of the Lion. He is the most rapacious and destructive of all carnivorous animals. With strength nearly equal to the Lion, he is much more ferocious in disposition,

and certainly more to be dreaded by the human species. He is a native of all the countries of Southern Asia which lie between the north of China, Chinese Tartary, and the Indies, abounding in Bengal, Tonquin, and Sumatra, and inhabiting most of the larger islands on that side of India. He frequently proves the scourge of many districts which are thickly covered with jungles and forests.

Fig. 5. The Clouded Tiger (*F. Nebulosus*).—A recently discovered species, for a knowledge of which we are indebted to the zeal of the late Sir T. Stamford Raffles. This animal was first observed in the extensive forests of Bencoolen, and was brought alive to England from Sumatra in August 1824. It was taken very young, and became completely domesticated. The Clouded Tiger is equal in size to the Leopard. Its general aspect, even in a state of nature, indicates less ferocity than that of the Bengal Tiger or Leopard. The character of the eyes and general physiognomy bear a considerable resemblance to those of the domestic Cat. The prevailing colour of the fur is ash-coloured or whitish-gray; it is covered with spots and bands, defined posteriorly with a deep black margin. The back has most strikingly the appearance of velvet on the larger discolourations.

Fig. 6. The Leopard (*F. Leopardus*).—The general expression of the Leopard is ferocious and cruel; his eye is restless, his countenance forbidding, and all his motions short and precipitate. In his general habits he resembles the Panther, lying in ambush for prey, and then springing upon, and devouring almost every species of animal which he has strength to overcome. Occasionally Leopards have been known to congregate in large numbers, and, descending from their lurking places, to commit dreadful slaughter among the numerous herds of cattle which graze in the plains of Senegal and Guinea.

The ordinary size of the Leopard is four feet in length, exclusive of the tail, which is about two feet. He is distinguished from the Panther by the regularity of the spots which ornament his skin; these are always disposed in circles of from three to four, inclosing a central area of about an inch in extent, and of a somewhat deeper hue than the general ground-colour of the animal.

Fig. 7. The Ocelot (*F. Pardalis*).—This animal is one of the most beautiful of its tribe; it is about three feet in length, and in height about eighteen inches. There are several varieties of this species, remarkable for their great beauty and elegance of form, but all differing in the intensity of colouring in the fur, and also in the arrangement of the spots. They are natives of South America, and frequent the depths of the forests, where they prey on birds and the smaller quadrupeds. The disposition of the Ocelot is highly predatory, and less susceptible of the mild influence of domestication than most others of its congeners.

Fig. 8. The Sumatra Cat (*Felis Sumatrana*).—This is the Rimau Bulu of Sumatra, about the size of the Kewuk, or somewhat less than the Ocelot. The spots on its skin are very irregular, both in disposition and shape.

Fig. 9. The Newwied Cat (*F. Macrourus*).—The ground-colour of this species is of an ochre-gray, with longitudinal patches, the upper part of the tail being only partly annulated. It is somewhat about the size of the Ocelot, but longer in the legs. It inhabits Brazil.

ANIMALCULES IN SNOW.—Dr J. E. Mure communicated the following information to Dr Silliman:—"When the winter had made considerable progress, without much frost, there happened a heavy fall of snow. Apprehending that I might not have an opportunity of filling my house with ice, I threw in snow, perhaps enough to fill it. There was afterwards severely cold weather, and I filled the remainder with ice. About August, the waste and consumption of the ice brought us down to the snow, when it was discovered that a glass of water which was cooled with it contained hundreds of animalcules. I then examined another glass of water out of the same pitcher, and, with the aid of a microscope, before the snow was put into it, found it perfectly clear and pure; the snow was then thrown into it, and, on solution, the water again exhibited the same phenomenon—hundreds of animalcules, visible to the naked eye with acute attention; and, when viewed through the microscope, resembling most diminutive shrimps, and, wholly unlike the eels discovered in the acetous acid, were seen in the full enjoyment of animated nature. I caused holes to be dug in several parts of the mass of snow in the ice-house, and to the centre of it, and, in the most unequivocal and repeated experiments, had similar results; so that my family did not again venture to introduce the snow into the water they drank. These little animals may class with the amphibia which have cold blood, and are generally capable, in a low temperature, of a torpid state of existence. Hence, their icy immersion did no violence to their constitution, and the possibility of their revival by heat is well sustained by analogy: but their generation, their parentage, and their extraordinary transmigration, are to me objects of profound astonishment."

## ON THE AUTHENTICITY OF THE DODO.

PERHAPS there is no Vertebrated animal, which has existed since the wreck of the former world, whose history is involved in such obscurity as that of the Dodo. Many have doubted that there ever was such a bird; but we hope to show that this is a mistake, although there is every reason to believe that it is now extinct.

This bird has been variously designated by Naturalists, as the Dodar, Didus, and Dodo; but the accounts of its earliest describers are so ambiguous, and their characters so ill defined, that there is much difficulty in tracing their specific distinctions.

There appear to be three distinct representations of this species, which have not been copied from each other; and although two of these are sufficiently rude, yet they bear evident traces of originality, and possess characters so peculiar, that their identity cannot be mistaken.

The above figure is taken from a plate in the "Exotica" of Clusius, published in 1605. He says it was copied from a rough sketch in the journal of a Dutch voyager, who had seen the bird in the Moluccas, in the year 1598. Clusius says, that he had himself seen only a leg of the Dodo, in the house of Peter Pauw, a professor of medicine at Leyden, which was brought from Mauritius. Clusius calls this bird "*Gallus gallinaceus peregrinus*," and mentions that the Dutch sailors called it Walgh-Vogel, "*Nauscam Movenis avis*."

We copy the above from the travels of Herbert in Africa, Asia, and other places, published in 1634. It differs from the former in the shape of the bill, but possesses all the other characters sufficiently marked.

The third, and most perfect, representation of the Dodo, is taken from the "*Historia Naturalis et Medica Indie Orientalis*," by Jacob Bontius, which appeared in 1658. Ray, who published in 1676 and 1688 an edition of Willughby's Ornithology,

after quoting the accounts given of this kind by Clusius and Bontius, says, "We have seen this bird dried, or its skin stuffed, in Tradescant's cabinet," at Lambeth.

We now give a copy of the painting of the Dodo in the British Museum, which Edwards faithfully imitated in his "History of Uncommon Birds," plate 294, published in 1760. He says, "The original picture was drawn in Holland, from a living bird brought from St Maurice's Island, in the East Indies, in the early times of the discovery of the Indies, by the way of the Cape of Good Hope. It was the property of the late Sir Hans Sloane to the time of his death, and afterwards becoming my property, I deposited it in the British Museum, as a great curiosity. The above history of the picture I had from Sir Hans Sloane and the late Dr Mortimer, Secretary to the Royal Society."

There seems to be pretty clear evidence that an entire specimen of this bird was in the Museum of John Tradescant. It is mentioned in his printed catalogue of Stuffed Skins of Birds, in "Section 5, *Whole Birds*—Dodar, from the island Mauritius; it is not able to file, being so big." This specimen was afterwards exhibited in the Ashmolean Museum, and is particularly alluded to by Hyde in his "*Religionis Veterum Persarum Historia*," printed in 1700, who states it to be then existing in the Museum at Oxford. It was destroyed at a later period than 1755, by order of the Visitors, in consequence of its state of decay. In a Catalogue of that Museum made subsequently to 1755, it is recorded that "the Nos. from 5 to 46, being decayed, were ordered to be removed at a meeting of the majority of the Visitors, January 8, 1755." The Dodo was one of these, as it stood No. 29 of the Catalogue, under the name of "*Gallus gallinaceus peregrinus Clusii*," &c. That there was such a bird in the Museum of Tradescant, there can be no doubt, as the head is still preserved in the Ashmolean Museum at Oxford, and one of the feet in the British Museum, which are both well figured in Shaw's Naturalist's Miscellany,—the former in plate 166, and the latter in plate 143. We have carefully examined the latter, and from its construction, we would at once say that it is formed for walking, as the articulation of the hallux or hind toe is not constructed for grasping.

It will be observed, that our fourth figure exactly agrees with that of Bontius, figure 3d; and when we consider that the first and second figures were taken from rude sketches by travellers unacquainted with the art of drawing, we cannot doubt but that they are intended to represent the same bird. The general structure of the head (particularly its hooded appearance), the bill, and the curved and swelling neck, the rounded and clumsy shape of the body, terminating with a curious tuft of feathers on the rump, the short and clumsy legs, and feet with divided toes, all bear striking evidence of their being pictures of the same animal.

The testimonies of the existence of the Dodo are the following, which we arrange in chronological order:—

In the year 1497, Vaseo de Gama, after doubling the Cape of Good Hope, discovered a bay at 60 leagues, Augra de San Blaz, near to an island, where he saw a number of birds which the Portuguese called Solitarios; they were of the form of geese, with wings like bats. On the return of the voyagers, in 1499, they landed and captured a number of these birds.

Castleton informs us, that during his voyage of 1614, he landed at the island of Bourbon, then "uninhabited, although occasionally visited by the early voyagers. Among the birds, he particularizes a kind of bird the size of a goose, very fat, with short wings, which do not permit them to fly. They have since been called the Giant, and the Isle of France also produces plenty of them. They are white, and naturally so tame as to allow themselves to be taken by the hand; or, at least, they were so little afraid at the sight of the sailors, it was easy for them to kill great numbers with sticks and stones."

In the year 1691, Leguat, with seven other individuals, was left upon the island of Rodrigue, with a view to colonize it; and so much struck was he with the appearance and habits of the Dodo, that he not only introduced figures of it into the frontispiece of his work, but also into his general chart of the island, and his plan of the small colony which was formed. No fewer than sixteen figures of the birds were introduced into the former, and twelve into the plan. He gives the following description of the Dodo:—

"Of all birds which inhabit the island, the most remarkable is that which has been designated Solitaire (the Solitary), as they are seldom seen in flocks, although there is abundance of them.

"The plumage of the male is generally grayish, or brown, with feet formed like those of a turkey-cock, as is also the bill, but a little more hooked. They have scarcely any tail, and their rump, covered with feathers, is as much rounded as the croup of a horse. They are higher than the turkey-cock, and have a straight neck, a little longer

than that of the turkey-cock, when it raises its head. The eye is black and lively, and the head destitute of crest or tuft. They do not fly, their wings being too short to sustain the weight of their bodies; they are only used in beating their sides, and in whirling round. When they wish to call one another, they make, with rapidity, twenty or thirty rounds in the same direction, during the space of four or five minutes; in which action the noise made by their wings resembles that made by the Kestrel, and can be distinctly heard at 200 paces distant. The bone of the spurious wing enlarged at its point, forms, under the feathers, a little round mass like a musket bullet; and this and their bill are the principal weapons possessed by these birds. It is excessively difficult to catch them in the woods; but as a man runs swifter than they do in open places, it is not difficult to catch them; sometimes, indeed, they may be very easily approached. From the month of March until September, they are exceedingly fat, and their flesh of a very agreeable flavour, especially when young. The average weight of the males is about 45 lbs., and Herbert says he has known them of 50 lbs.

“The female is of admirable beauty. Some are of a blond, others of a brown colour. I mean by blond, the hue of flaxen hair. They have a band, not unlike the bandeau of a widow, above the beak, which is of a tan colour. One feather does not pass another over all the body, because they adjust and polish them with their bill; the feathers of the thighs are rounded and of a shell shape, and being very thickly clothed in these situations, produce an agreeable effect. Over the crop, they have two elevations, of whiter plumage than the rest of their bodies, which greatly resemble the female bosom. They walk with a graceful and stately air, which excites admiration, and even a love of the bird, which has frequently saved their lives.”

Leguat says that they are incapable of being tamed, and, if taken, refuse all food, and die of hunger. This may account for their extirpation, for had they been susceptible of domestication, a bird so fitted for human food might have been widely spread over Europe at the present day. A remarkable peculiarity is stated by Leguat, that “there is always found in their gizzard a brown stone, the size of a hen’s egg, slightly tuberculated, flat on one side, and rounded on the other, very heavy and hard. We supposed this stone to exist in the bird when hatched, because, however young they might be, they always had it, and never more than one; and besides this circumstance, the canal which passes from the crop to the gizzard is too small by one half to permit the passage of such a mass. We used them, in preference to all other stones, for sharpening our knives.”

It seems to be certain that this bird became extinct towards the end of the seventeenth or beginning of the eighteenth century. Mr John V. Thompson of Cork, a zealous naturalist, was unable to discover any traces of it during a recent residence in the East. He says, “Having resided some years amongst these islands, inclusive of Madagascar, and being curious to find whether any testimony could be obtained on the spot, as to the existence of the Dodo, in any of the islands of this or the neighbouring Archipelagos, I may venture to say, that no traces of any kind could be found, no more than of the truth of the beautiful tale of *Paul and Virginia*, although a very general belief prevailed as to both the one and the other.”

At a late meeting of the Paris Academy of Sciences, the celebrated comparative anatomist, M. De Blainville, gave it as his opinion, that the extinct bird, the Dodo, was a large species of Vulture. He stated that he came to this conclusion, after a careful examination of a plaster cast, taken from the head of the Dodo, which is preserved in the Ashmolean Museum at Oxford. Cuvier seems not decided as to the place it should occupy in his system, but has placed it after the Cassowary of New Holland, and before the Bustards. The mutilated state of the bill prevented him from ascertaining with certainty its true character.

We cannot agree with De Blainville in the opinion which he entertains, as we think the extreme shortness of its wings, and consequent incapability of flight, must remove it from the Predatory order; and we are inclined to the opinion, that it must be nearly allied to the Gallinaceous order, from the construction of the feet, one of which we carefully examined in the British Museum.

MINERALOGY.

GOLD VEINS IN NORTH CAROLINA.—At a meeting of the Sheffield Literary and Philosophical Society, Dr Longstaff, who has been out, during the last twelve months, as the agent of a Company of British Mine Adventurers, to investigate the gold veins of North Carolina, stated that the gold region stretches from the shores of the Atlantic, in the direction of Carolina, through the country towards the Pacific Ocean; and that, judging from appearances, this immense tract promises to yield supplies such as have not been equalled by the most famous gold countries of antiquity. The precious metal is generally found in a matrix of quartz, and in veins, often running in the direction of N.E. and S.W., there being generally one leading vein, and on each side a parallel satellite. In some cases, rich branches pass off at right angles; or, in others, the ore is ramified in every way. It is sometimes enveloped in a rake of talcose slate, passing through the auriferous quartz; in other instances, disseminated in minute particles through oxide of iron; and contrary to what might have been supposed, judging from the effect of other metals, the sulphuret of iron, or martial pyrites, usually indicates a rich locality. The proportions of the precious metal to the quartzose, or other matrix, are amazingly great, the minimum yield of the ore affording a large profit upon the capital invested, while some of the richer sorts (of which Dr Longstaff laid specimens on the table) gave almost incredible results.

Many of the inhabitants of Concord have pieces of pure gold of various weights, one of which weighs 28 lbs. The beds where the gold is discovered, in that locality, are of gravel, and very extensive, covered with water in the winter months, but dry in summer. The manner of searching for gold is, to take shovels and turn over the gravel, always advancing as it is turned back, and picking up what is discoverable to the eye, by which thousands of small grains are lost, as the fingers cannot separate them from the sand. By working this over again with quicksilver, large quantities may be obtained. No machinery is required, or smelting process. The first mine was found by a son of Mr Reed, who, in watering his horse at the creek, discovered a piece of gold quite pure. Two years after, Mr Reed, with two partners, pursued the search

for gold, with six black boys, during the short period of only six weeks. In each of the two first years they obtained the value of 17,000 dollars, besides what was stolen from the streams, supposed to be half as much more. No attempt has been made to open the hills, as the persons there are totally unacquainted with the subject of mining. Messrs Morton and Bedford, of Baltimore, purchased a small tract of about 300 acres, joining the lower end of Reed’s purchase and mine, for which they paid seven dollars an acre. Governor Mercer stated, that they had analyzed the sand and gravel, and found it worth a guinea a bushel, after the lump gold was picked out. The gold, as found, is worth 19 dollars an ounce, while the best East India and African gold dust is not worth more than from 12 to 16 dollars. Mr Thomas Moore got some hickory nuts, and in looking for a stone to break the shell, he went to a tree that had been blown down, and picking up the first stone he met with in the fresh turned-up earth, perceiving it heavy, he washed it, and it turned out to be a piece of solid gold, which he sold for 450 dollars! He then set some men to work, and they made from two to five dollars a-day each. Some of it has been sent to the mint of the United States, where they exchange it for eagles ready coined, weight for weight; but the gold-beaters give a still better price, namely, four per cent., it is so pure and malleable.

DISCOVERY OF COAL ON MOUNT LEBANON.—A bed of coal has been recently discovered at Carnayl, on Mount Lebanon, and the agents of Mahomet Ali, under the guidance of an English gentleman, are exploring it with all the energy which the nature of the country admits. It is about three miles north of the great road leading from Beirut to Damascus, and about 18 miles from the former city. It is the black bituminous coal, and burns readily, with a clear yellow flame.

GEOLOGY AND PHYSICAL GEOGRAPHY.

TEMPERATURE OF THE EARTH.—For the purpose of ascertaining whether a constant stream of water could be obtained by means of an Artesian well, sunk on the south side of the Jura mountains, at the distance of about a league from Geneva, and at an elevation of about 297 feet above the level of the lake, M. Girond, at his country residence at Pregny, bored to the depth of 547 feet without any result. Despairing of success, he offered great facilities to any persons who might wish to prosecute the enterprise, for the purpose of scientific inquiry. On this occasion, MM. Aug. de la Rive and F. Marcet made a successful application to the friends of science, and also to the Government, and funds were obtained sufficient to enable them to continue the operation during eight months, and to extend the boring to the depth of 682 feet. The hole bored was about four and a half inches in diameter. Water began to appear in it at the depth of twenty feet; and, it is worthy of remark, that the height at which the water stood in the opening, as measured from the surface, was lower when the greatest depth was obtained than it was at half the depth. At 275 feet of depth, the water stood at 14 feet from the surface; at 500 feet, it sunk to 22 feet; at 550 feet, to 35 feet. It then rose—at 595 feet it stood at 24 feet 6 inches, but at 675 it again sunk to 35 feet 8 inches. Having attained the extraordinary depth above mentioned, the experimenters devised the means of ascertaining the temperature of this opening at different depths. As the common thermometer would not answer the purpose, they contrived a self-registering thermometer, constructed on a large scale, and whose accuracy was subjected to the most satisfactory tests. The following table exhibits the temperature of the bore hole at the depths specified:—

Depths below the surface in feet.	Corresponding Temperature.	
	REAUMUR.	FAHRENHEIT.
30 . . . . .	8.4 . . . . .	50.9
60 . . . . .	8.5 . . . . .	51.1
100 . . . . .	8.8 . . . . .	51.8
150 . . . . .	9.2 . . . . .	52.7
200 . . . . .	9.5 . . . . .	53.4
250 . . . . .	10.0 . . . . .	54.5
300 . . . . .	10.5 . . . . .	55.6
350 . . . . .	10.9 . . . . .	56.5
400 . . . . .	11.37 . . . . .	57.58
450 . . . . .	11.73 . . . . .	58.39
500 . . . . .	12.20 . . . . .	59.45
550 . . . . .	12.63 . . . . .	60.42
600 . . . . .	13.05 . . . . .	61.36
650 . . . . .	13.50 . . . . .	62.37
680 . . . . .	13.80 . . . . .	63.05

It thus appears that the increase of temperature below the depth of 100 feet from the surface, as far down as 680 feet, is precisely 0.875 of Reaumur (= 1.968 or 2 Fahrenheit very nearly) for every hundred feet. It will be observed that the increase, instead of moving *per saltum*, as in some other cases, moves with remarkable uniformity. This, the experimenters think, may be owing to the care which was taken in this case to remove and avoid every source of error.

Fossil Ferns are rarely found, but numerous impressions of them are met with in various countries. From the fact of the plants themselves not being met with in a mineralized state, there has been much difficulty in ascertaining their analogy with those now existing on the earth’s surface. M. Gœpper has lately succeeded in ascertaining upwards of thirty species, which are analogous to those of the present day. His mode of investigation is, by taking impressions from recent ferns, which affords him a ready and easy mode of comparison.

CHANGE OF CURRENTS.—The following singular fact was elicited during the examination of Captain Fitzroy, of the Beagle surveying ship, upon the recent naval court-martial, held at Portsmouth:—He stated that the late earthquakes in the western coast of South America have had the extraordinary effect of transforming what was once a current of two miles an hour to the northward, into a current of five miles an hour to the southward, and that the soundings along the whole coast have been materially changed. Since the middle of February last, not a day has intervened without a motion of the earth having been experienced in one quarter or another. It appears that the loss of the Challenger was occasioned by the ship being thus set, by a universal and unexpected current, 34 miles of latitude to the southward, between noon of the 17th of May last, to the time of the wreck, on the 19th of the same

month. This latitude, by dead reckoning up to the time of taking the sights, was used to work the sights of the chronometer, and accordingly, on the morning of the 19th May, the ship's situation was estimated 60 miles to the south-west of her actual position at that time.

### GENERAL SCIENCE.

**SATELLITES OF JUPITER.**—At a meeting of the Paris Academy of Sciences, in consequence of M. Paravey having asserted that the ancients had discovered some of the satellites of Jupiter, M. Arago endeavoured to ascertain if it were possible for him to observe any of these satellites with the aid of a magnifying lens, using only one that was darkened, in order to obscure the radiations. The experiment proved abortive, and it was in consequence to be repeated, as the moon at the time was above the horizon. It was suggested by M. Ampère, that it would require a peculiar organization in the visual organs to enable an observer to perceive the satellites without a telescope.

**THE COMET OF HALLEY.**—The following particulars respecting the orbit of this comet are contained in *Le Voleur*:—One of the most remarkable circumstances connected with this comet, is the size of its orbit. It is an elongated oval, the total length of which is about thirty-six times the distance of the sun from the earth, and the greatest breadth of the oval is about ten times that distance. The nearest extremity of its orbit is distant from the sun about half the distance of the earth from that planet; and its most distant extremity is thirty-five times and a half that of the earth from the sun. As the light and heat derived from the sun naturally decrease according to distance, hence it follows that the heat and light from the sun will be, at the most proximate point of the comet, four times more than on the earth, and at its most distant extremity 5000 times less than at the opposite point. At one of the extremities of the comet, the sun would appear four times larger than it does to our earth, while at the other its size would look like that of a star. The vicissitudes of temperature resulting from these positions are evident. Suppose the earth to be transported to the most distant extremity of the comet, liquids would congeal, and it is probable that atmospheric air, and all the permanent gases, would become liquid. On the contrary, were the earth at that part of the comet nearest to the sun, liquids would assume a gaseous form; metals would be liquified, would form a new ocean, and would occupy in the bed of the present one the place of the waters, which had become vapour."

### MISCELLANEOUS.

**AMBER.**—This remarkable substance is found in Prussia, and has for more than three thousand years excited the curiosity of naturalists and the avidity of traders. It is uncertain even at present, whether it belongs to the animal or to the vegetable kingdom: almost all writers agree, that it forms no part of the mineral. It is a sort of solid bitumen, very light, of a vitreous fracture, and generally of a milky white, or yellow colour; although it is sometimes found brown or black, and sometimes quite opaque. It is combustible, evaporates, and diffuses an agreeable odour. *Succin* is that sort which is most crystallized and transparent; and what the Prussians term amber has a less vitreous fracture, and a more earthy appearance. From *Ηλεκτρον* (Electron), the Greek word for amber, is derived the term Electricity; so that an insignificant fossil has, from its power of attracting light bodies, given its name to the cause of the most imposing and terrible phenomena in nature,—

“The lightning's lurid glare, and thunder's awful crash.”

Heinitz supposes that its formation must be attributed to forests submerged by the ocean, and afterwards covered with sand; the resinous particles, being distilled into amber, and the rest of the wood forming a residuum, or *caput mortuum*: and what strengthens this supposition is, that wood is generally found near it, which renders its vegetable origin probable. The supposition of its mineral origin is disproved by distillation, and by the foreign bodies found in its substance.

M. Schweigger, an eminent entomologist, has carefully examined the insects contained in the amber; and he has found that many of them would belong to genera of insects now existing, but that none of them were specifically the same. Professor Germar of Halle has been occupied in a similar investigation, and he also thinks that none of them are identical with analogous species now living.

M. Girtanner affirms, that amber is formed by a large ant (the *Formica rufa* of Linnæus); he conceives it to be a vegetable\* oil, rendered concrete by the acid of those animals, which inhabit old forests of fir trees where the fossil amber is found. The amber, when first dug, is ductile like wax, and becomes hard on exposure to air. Certain it is, that no insect is so commonly found in amber as the ant. Wallerius asserts, that the black and dark-coloured amber is often found in the bowels of cetaceous fishes. Others imagine that it is produced by a fish or an aquatic animal. It is certain, however, that amber must have passed from the fluid to the solid state; for foreign substances, such as leaves, insects, small fish, frogs, water, pieces of wood and straw, are often contained in it; and it is most esteemed when it contains any of these substances.

The Phœnicians were the first who navigated the North Seas in search of this substance. By the ancients it was considered as valuable as gold and precious stones. Its value, at present, is much diminished, though it is still required in some manufactories; for, at Stolpe in Pomerania, and Königsberg in Prussia, workmen are employed in making from it small jewels, scented powder, spiritous acid, and a fine oil, that is used as a varnish. Amber is exported to Denmark and Italy, but Turkey is the chief market for the commodity; and a certain portion of it is carried every year to the Holy Kaaba at Mecca. This substance has long been regarded with superstitious veneration by several of the northern nations of Europe, as well as in Asia Minor; but what gave rise to this we have not been able to trace. Among the peasantry of Scotland amber beads have long been held as a complete antidote to the effects of witchcraft; and, in consequence, one or more beads of it were very commonly carried in the pocket: but, that it might have complete efficacy, it was considered necessary, that it

should be accompanied by the following complot, written on paper, wrapped round the bead, and secured by a red silk thread:—

“Lammar (amber) beads and red thread  
Keep the witches at their speed.”

A twig of the mountain ash, or rowan tree, was supposed to have precisely the same effect. Among the higher classes in Scotland, in former times, amber beads were much worn, and were always strung with red silk thread.

The quantity of amber annually found in Prussia amounts to more than two hundred tons, and the revenue derived from it by the crown is three or four thousand pounds.

Amber is obtained on the Prussian coast, between Pillan and Palmnicken, a tract of land about eighteen miles in length; and sometimes upon the surface of the water, where it is collected by means of nets. It is, however, only after violent north and north-west winds that any large quantity is drawn to the shore. Quarries, or pits, have been opened at Dirshkemen, on the hills near the coast, and their produce is less variable. In digging for it, the first stratum is found to be sand, then clay, then a layer of branches and trunks of trees, then a considerable quantity of pyrites, whence sulphuric acid is prepared, and lastly a bed of sand, through which the amber is dispersed in small pieces, or collected together in heaps. It assumes various shapes, as that of a pea, an almond, a pear, and letters, very well formed; and even Hebrew and Arabic characters. It is found in other places in the interior of Prussia; and the largest piece of amber which has yet been seen was found at Schleppacken, about twelve German miles from the Lithuanian frontier. It is fifteen inches in length, and seven or eight in breadth; it may be seen in the Museum at Berlin. Amber is also to be found in the high hills of Goldapp, seventy-five miles to the south-east of Königsberg, and in the heights and valleys on the Vistula, in the neighbourhood of Thorn and Grandzen. A large piece of amber was cast ashore, about twenty-five years ago, at Peterhead, county of Aberdeen, in Scotland.

The most remarkable properties of amber are, that, being rubbed, it attracts light bodies. The friction which elicits the electric fluid also renders amber visible in the dark. Dr Wall remarked, that by rubbing amber upon a woollen substance in the dark, light was also produced in considerable quantities, accompanied with a crackling noise; and, what is still more extraordinary, he adds, “This light and crackling seems in some degree to represent thunder and lightning.”

**AMBERGRIS** is a substance much of the same nature as amber, but differs from it by its particular consistence, which nearly approaches to that of bees' wax; sometimes it is granulated, and appears opaque, or of a dark gray. Experiments prove that it resembles amber in its nature. When analyzed, it is found to consist of phlegm, a volatile acid partly fluid, oil, and a little coaly matter. It dissolves more readily than amber in spirit of wine. It is most common in the Indian seas, on the eastern coast of Africa, Madagascar, &c. and it is found either floating on the sea, or cast on the sea shore. In this substance, animal and vegetable remains are sometimes found, as, for instance, the parts of birds. The origin of ambergris is probably the same with that of amber. According to M. Aublet (in his *Histoire de la Guiane*), it is nothing more than the juice of a tree, hardened by evaporation; and if this be true, it is a substance which belongs properly to the vegetable kingdom. The tree which is said to produce it grows in Guiana; it is called *cuma*, but has not been examined by other botanists. When a branch is broken by high winds, a large quantity of the juice exudes; and if it chance to have time to dry, various masses (some of which have been so large as to weigh one thousand two hundred pounds, and more) are carried into the rivers by heavy rains, and through them into the sea; afterwards they are either thrown on the shore, or eaten by fish, chiefly by the spermaceti whale (*Physcia macrocephalus*.) This fish swallows such large quantities of this gum resin, that it generally becomes sick, so that those employed in the catching of these whales always expect to find some ambergris in the bowels of the lean whales. Father Santes, who travelled to various places on the African coast, says, in his *Æthiopia Orientalis*, that some species of birds, of whales, and of fish, are fond of eating this substance; and the same assertion has been made by Bomare and various other authors. This accounts for the claws, beaks, bones, and feathers of birds, parts of vegetables, shells and bones of fish, and particularly for the beaks of the cuttle-fish (*Sepia octopodia*), which are sometimes found in the masses of this substance. M. Aublet brought specimens of this gum resin, which he collected on the spot, from the *cuma* tree at Guiana. It is of a whitish-brown colour, with a shade of yellow; while it melts and turns like wax in the fire. M. Ponelle examined very carefully this substance brought over by M. Aublet, and found that it produced exactly the same results as amber. These observations seem to place it beyond a doubt, that both amber and ambergris are vegetable products, and that naturalists were mistaken in supposing these substances to be of an animal nature, from having found them in the intestines of whales.

**AURORA BOREALIS.**—Sir John Ross states, that during his first Arctic expedition the Aurora Borealis sometimes appeared between the two ships, and also between the ships and the icebergs; and found, in his subsequent experience, both in Scotland and during his second voyage, proofs, *satisfactory to his own mind*, that the Aurora takes place within the cloudy regions of the earth's atmosphere. Under this belief, he founds the following extraordinary hypothesis on the subject:—“The Aurora is entirely occasioned by the action of the sun's rays upon the vast body of icy and snowy plains and mountains which surround the poles.”

**NEWTONIAN SYSTEM.**—Mr Walsh, of Cork, addressed a pamphlet to the French Academy, entitled, “Appendix, containing some remarks, and a new theory of Physical Astronomy.” In one of the author's marginal notes, he states, that, barring astrology, the greatest absurdity ever propagated is that of the Newtonian System!\*

ZOOLOGY.

DESCRIPTION OF THE PLATE—CAMELS.

THE only two animals which constitute this genus are in general so mild and inoffensive in their disposition, that they prove extensively serviceable to mankind in those hot and sandy regions, where they are employed as beasts of burthen. Their pace is usually slow; but being able to sustain themselves, even on the longest journeys, with a very small portion of food, and but little water, they undergo fatigues which few, perhaps no other animals, could endure.

Their hair is a valuable article of commerce, and their flesh forms a palatable food.

Like all the other genera of the ruminating order, they are provided with four stomachs, in consequence of which they not only live solely on vegetable food, but ruminate or chew the cud. The food, after being swallowed without undergoing the process of mastication, is received into the first stomach, where it remains for some time to macerate; and afterwards, when the animal is at rest, by a peculiar action of the muscles, it is returned to the mouth in small quantities, chewed more fully, and then swallowed a second time for digestion.

Fig. 1. The Bactrian Camel (*Camelus Bactrianus*, Linn.)—This animal is at once distinguished from its congener the Dromedary, by having two haunches, one of which is situate on its shoulders, and the other at a little distance behind. It is a considerably-larger animal than the other; its legs are proportionally shorter, while the body is longer. An animal of this species, which was exhibited in London in 1829, measured eight feet from the part of the back between the humps to the ground.

Its original country is supposed to be the ancient Bactriana, now called Turkestan. The species has been spread over Persia, Thibet, and China. It is, however, rarely to be met with except in the great middle zone of Asia, to the north of Taurus, and the great Himalaya range of mountains. It is capable of bearing a much colder and mere moist climate than the Arabian species. The Camel has been known to exist in the neighbourhood of Lake Baikal, in Siberia, where its only food, during winter, was the bark and tender branches of the birch.

The Camel lives to a great age. One which was kept in the Menagerie of the *Jardin des Plantes* at Paris was supposed to be nearly fifty years old when it died. The food of this animal is bay or lucern, of which it consumes about thirty pounds a day; while a draught of six gallons of water will suffice for some days.

Fig. 2. The Dromedary (*Camelus Dromedarius*, Linn.)—The Arabian Camel or Dromedary has but one baunch, situate on the middle of the back. Its height at the shoulder varies from five to seven feet. Its hair, which is soft, woolly, and unequal, is longer on the nape of the neck, throat, and haunch, than on any other parts of the body; it is of a pale reddish-fawn colour.

The feet of both the Camel and Dromedary are very singular productions of Nature, being admirably fitted for treading on a smooth or soft surface. They are divided into two toes not separate, each covered with a broad nail; and thus the feet are intermediate between the hoofs of a horse and cloven feet. From the heel forwards, they are protected by a horny sole, uniting the middle part, and leaving the toes free. This sole is part of an elastic substance, which, being bedded in two cavities of the foot, yields to the pressure of the soil; whilst the toes spread open, touching the ground, in the same way as the foot of the Rein-Deer extends itself to present a large surface to the snow. By this formation, the Camel is prevented from sinking into the soft sand of the desert tracts, which it is so frequently obliged to cross.

ANTS.—Colonel Sykes relates an anecdote with regard to an Indian species of Ant, which he calls the *Large Black Ant*, instancing, in a wonderful manner, their perseverance in attaining a favourite object. This was witnessed by himself, his lady, and his whole household. When resident at Poonah, the dessert, consisting of fruits, cakes, and various preserves, always remained upon a small side table, in a verandah of the dining-room. To guard against inroads, the legs of the table were immersed in four basins filled with water, it was removed an inch from the wall, and, to keep off dust through open windows, was covered with a table-cloth. At first the ants did not attempt to cross the water, but as the strait was very narrow, from an inch to an inch and a half, and the sweets were very tempting, they appear at length to have braved all risks, to have committed themselves to the deep, to have scrambled across the channel, and to have reached the object of their desires, for hundreds were found every morning revelling in enjoyment. Daily vengeance was executed upon them without lessening their numbers; at last, the legs of the table were painted, just above the water, with a circle of turpentine. This at first seemed to prove an effectual barrier, and for some days the sweets were unmolested, after which, they were again attacked by these resolute plunderers; but how they got at them seemed totally

unaccountable, till Colonel Sykes, who often passed the table, was surprised to see an ant drop from the wall, about a foot above the table, upon the cloth that covered it; another, and another succeeded. So that though the turpentine and the distance from the wall appeared effectual barriers, still the resources of the animal, when determined to carry its point, were not exhausted, and by ascending the wall to a certain height, with a slight effort against it, in falling managed to land in safety upon the table.

ON THE TAIL-GLAND IN BIRDS.—BY M. REAUMUR.

“WERE I tempted to explain why the hinder part of the hens without tails has not a secretion performed in it like that which is observed in other hens and in other kinds of birds—were I tempted, I say, to explain it, I should be aware of the danger of the possibility of committing mistakes, by the very obligation I think myself under of exposing, as an error, the notion which naturalists and philosophers have framed to themselves concerning the utility of the unctuous liquor that issues from the canals in the tail of birds. All the works of Nature being lavishly filled with wondrous characteristics, fit to raise in us a most just admiration of those who, from the best intentions, expose them to our eyes, in order to force us to acknowledge the *AUTHOR* of them, are, on account of the multitude of those wonders, liable to some reproach, when they happen to mention among them some that are not of the utmost certainty. They all have been of opinion, that the feathers of birds, in order to be sheltered against rain, wanted to be done over with a kind of oil or grease, that might cause the water to run off them without penetrating, and that this unction wanted to be repeated from time to time. I have elsewhere proved, in a memoir on feathers, that they have been wrong to entertain that notion. In consequence of it, they have pretended to make us admire a reservoir of unctuous matter placed in the hinder part of each bird, out of which he expresses, and takes it, with the end of his bill, to convey and spread it all over the feathers that want it.

“I shall not undertake to show here how little the quantity of matter that may be daily supplied by this reservoir is in proportion to the extent of the surfaces resulting from the assemblage of the numberless feathers with which a hen or a duck is covered, nor how long a time would be necessary to enable the reservoir to supply a quantity of the said matter, sufficient to besmear the surface of only one of those feathers. In order to explode a notion that must needs have been pleasing, since it was universally espoused, I need only say that the feathers of our tail-less, or, as I call them, rump-less hens, are as much proof against rain as those of other hens, and of many other birds that are provided with that part in which the secretion of an unctuous matter is made. It is, however, a fact that birds are sometimes seen pecking this part of their body; and this circumstance has been considered by the observers as conclusive evidence that they squeezed, from their tail-gland, the unctuous matter which was afterwards to be applied to their plumage; and in this hasty conclusion they forgot that the bill of the bird was insufficient to convey as much unctuous matter as was necessary to besmear their entire plumage, and render it greasy. A more natural idea would have been to suppose, that the bird pressed this reservoir or extraordinary canal to relieve an irritation of the skin, caused, in all probability, by the matter becoming too thick to flow, in its usual manner, through so small an orifice. Even school-boys are aware that an obstruction in this vessel occasionally takes place, and produces sickness in the birds; for their sparrows look poorly and droop when so afflicted, and almost the first thing they do, is to examine the state of the tail-gland; and when they think that it presents an unusually swelled appearance they press it, and even sometimes prick it with a needle, to allow the thickened matter to escape, so as to force it out. I do not know whether this operation is always attended with complete success, but I would conceive it better to endeavour to cure this obstruction in the excretory canal, produced by the inspissated unction, to moisten, or introduce into it some small solid body. So long as we remain in uncertainty why a secretion of a certain matter takes place in our ears, though in a very small quantity, we shall not think it incumbent on us to account for, how the secretion of a particular matter is effected in the tail-glands of birds.”

In narrating the diseases of Birds, Dr Boeckstein remarks, that “this gland, which contains the oil necessary for anointing the feathers, sometimes becomes hard and inflamed, and an abscess forms there. In this case the bird frequently pierces it itself. It may be softened by applying fresh butter without any salt; but it is better to use an ointment made of white lead, litharge, wax, and olive oil. The general method is to pierce or cut the hardened gland; but if this operation remove the obstruction, it also destroys the gland, and the bird will die in the next moulting for want of oil to soften the feathers.”

When the gland is obstructed, the feathers which surround it are ruffled, and the bird is constantly pecking and adjusting them, and instead of being of a yellow, which is its natural colour, it becomes brown. This complaint is extremely rare

among wild birds, for, being exposed to damp, and bathing often, they make more use of the oil in the gland, consequently it does not accumulate sufficiently to become inconvenient. This shows the necessity of providing birds, in a state of confinement, with water at all times for bathing, as nothing can be more conducive to their health. Dr Handel recommends that after the gland has been pierced, a little magnesia should be mixed with their drink.

**MATERNAL SOLICITUDE.**—A Cat, domesticated at a farm-house about a mile from Lanark, had numerous families, which were invariably taken away from her and drowned. At length the creature adopted an expedient for saving at least a portion of her offspring. She took away two or three of the kittens to a farm about half a mile distant, where she secluded them in the byre. As many, if not more, were deliberately left in her usual layer, and these she partially attended to, till they were taken away and drowned as usual. She then devoted the whole of her attention to the few which she had rescued, and thus succeeded in bringing them up. It was evident to the individuals under whose notice the circumstances occurred, that she left the few at home as a decoy, in order to lead away attention from the rest, as otherwise a search would have been made, which would probably have proved fatal.

**WASPS.**—Lieutenant Holman, in whom the loss of sight has been compensated by a wonderful acuteness of mental vision, relates the following anecdote in the second volume of his *Travels*:—"Eight miles from Grandie, the muleteers suddenly called out, 'Maramundas! Maramundas!' which indicated the approach of a host of wasps. In a moment all the animals, whether loaded or otherwise, lay down on their backs, kicking most violently, while the blacks, and all persons not already attacked, ran away in different directions, all being careful, by a wide sweep, to avoid the swarms of tormentors that come forward like a cloud. I never witnessed a panic so sudden and complete, and really believe that the bursting of a water-spout could hardly have produced more commotion. However, it must be confessed that the alarm was not without good reason, for so severe is the torture inflicted by these pigmy assailants, that the bravest travellers are not ashamed to fly the instant they perceive the terrific host approaching, which is of no uncommon occurrence on the Campos."

### BOTANY AND HORTICULTURE.

**ON THE CHANGE IN THE COLOURS OF THE FLOWERS OF THE HIBISCUS MUTABILIS.**—The Changing Hibiscus has received this name on account of the remarkable and periodical variations which the colours of the flowers present. White in the morning, they become more or less red or carnation-coloured towards the middle of the day, and terminate in a rose colour when the sun is set. This fact has been long known, but we were totally ignorant of the cause. The following observation may assist to discover it, and give some useful ideas on the colouration of flowers:—M. Ramond de la Sagra remarked, on the 19th of October, in the Botanic Garden of Havannah, of which he is the director, that this flower remained white all day, and did not commence to redden till the next day towards noon. On consulting the meteorological tables, which he kept with care, he found, that on this very day, the 19th October, the temperature did not rise above 19° 5' C., whilst ordinarily it was at least 30°, at the period of inflorescence of this plant.—It would appear, then, that the temperature holds a place of some importance in the colouration of certain flowers. The experiments of Mr Macaire have taught, that it seems to be connected with different degrees of oxygenation of the chromule, or colouring matter, contained in the parenchyma. Is this oxygenation altogether, or in part, determined by the temperature, and can the colour of certain petals be modified by variations of heat?

**WARS OF THE PLANTS.**—All the plants of a given country are at war, one with another. The first, which establish themselves by chance in a particular spot, tend, by the mere occupancy of space, to exclude other species—the greater choke the smaller, the longest livers replace those which last for a shorter period, the more prolific gradually make themselves masters of the ground, which species, multiplying more slowly, would otherwise fill.

**GEOGRAPHICAL DISTRIBUTION OF PLANTS.**—The most incurious observer in travelling through a country must be struck with the different vegetation that prevails in different parts of the country, and with the effect which this difference produces on the manners and on the health of the inhabitants. Thus, in some parts of England, the Apple and the Pear are seen growing spontaneously in every hedge-row, while in other parts, apple and pear trees will not flourish, even with the utmost care. Some situations are favourable to the Oak, others to the Beech, others to the Elm. Accordingly, these well-known and beautiful trees predominate in some districts, almost to the exclusion of every other, and thus constitute the leading feature in the landscape. These are familiar examples of partial changes among the larger vegetables of a country; while the general vegetation is supposed to remain nearly the same. Between such partial change, and the complete establishment of a peculiar vegetation, there exists among different localities every possible shade of diversity. Many of these differences in vegetation are obviously connected with differences in soil and in situation. Thus, some plants will thrive only on a calcareous soil; as a few of the Orchis tribe in our own country, and the *Teucrium montanum* in Switzerland. Others, like the *Salsolas* and the *Salicornias*, will only grow in salt marshes. Some plants flourish in sea water, some in fresh, while to others again, water, at least in excess, is so prejudicial that they can exist nowhere unless on bare rocks or in arid deserts. Mountainous situations are most favorable to the increase of some plants, while others abound in plains. The larger number of plants prefer sunshine, but some are most vigorous in the shade, and others are so impatient of light, that they are found only where there is absolute darkness. There are besides parasitic plants, like the Mistletoe, whose nourishment is derived from the plants to which they are attached. In short, the varieties in the nature of plants are countless, nor is the enumeration of them requisite. What has been stated is more than enough to show the wonderful arrangements that have been made to ensure the clothing of every part of the earth's surface with vegetable organization. There is not a soil, however barren, nor a rock, however flinty, that has not its appropriate plant, which plant has no less wonderfully found its way to the spot adapted for it, nay, will perish if re-

moved elsewhere. Saline plants, for instance, will grow only where saline matters are abundant; plants of the marsh, and of the bog, flourish only in marshy and boggy ground; those of the parched desert, and of the cloudy mountain, each in its fitting locality. Thus the soil and its occupant seem to have been made for each other; and hence one source of that astonishing variety exhibited in Nature.

There are still more remarkable deviations among the plants of different countries remote from one another, even where the circumstances of climate and of soil are in every respect alike. The plants of the Cape of Good Hope, for instance, differ exceedingly from those of the south of Europe, though the climate and much of the soil be not dissimilar. Often on the same continent, nay, on the same ridge of mountains, the plants on the opposite sides have no resemblance. Thus, in North America, on the east side of the Rocky Mountains, Azalias, Rhododendrons, Magnolias, Vacciniums, Actæas, and Oaks, form the principal features of the landscape; while, on the western side of the dividing ridge, these genera almost entirely disappear, and no longer constitute a striking characteristic of the vegetation.

In general, the plants of America are different from those of the Old World, except towards the north, where, as it might be expected, from the near approximation of the two continents, many individuals are common to both. The plants of islands, and those growing in isolated situations, are often quite peculiar. Thus the plants of New Holland, with comparatively few exceptions, differ from those of all the rest of the world; and, "of sixty-one native species in the little island of St Helena, only two or three are to be found in any other part of the globe." These facts are quite inexplicable upon any known principles, and are calculated to excite a more than ordinary degree of attention, as being solely referable to the will of the Great Creator, who has chosen to provide infinite diversity where all might have been uniform and monotonous, and has thus rendered more conspicuous his wisdom, his power, and his goodness.—*Proust's Bridgewater Treatise.*

### GEOLOGY.

**ERUPTION OF FISHES.**—Baron Humboldt gives an account of a wonderful eruption of fishes that sometimes takes place from the volcanos of the kingdom of Quito. These fishes are ejected in the intervals of the igneous eruptions in such quantities as to occasion putrid fevers by the miasmata they produce. They sometimes issued from the crater of the volcano, and sometimes from lateral clefts, but constantly at the elevation of between two and three thousand toises above the level of the sea. In a few hours, millions are seen to descend from Cotopaxi with great masses of cold and fresh water. As they do not appear to be disfigured or mutilated, they cannot be exposed to the action of great heat. Humboldt thought they were identical with fishes that were found in the rivulets at the foot of the volcanos, and to which he assigns the name of *Pimelodus Cyclopus*.

### GENERAL SCIENCE.

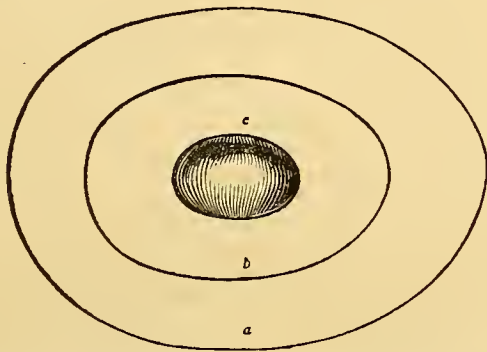

**ON THE COLOUR OF THE SEA.**—Persons who have spent their lives in the interior of great continents, and have only been accustomed to observe the flow of brooks and shallow rivers, the source of clear fountains, or the roll of muddy currents, must view with some emotion the first sight of the sea, with its waters of sparkling green—a colour which appears peculiar to itself. When we pour a portion of its water into a vessel, we are struck at its perfect limpidity, and its colourless appearance. So great is the transparency of the ocean, in situations where it is not subjected to the contamination of rivers or of impure substances, that the sand in the bottom of its bed, even at a considerable depth, can be distinctly seen, while stones and small shells are quite perceptible through the medium, and shine with resplendent brightness. Marine plants and corallines beam with dazzling splendour, exhibiting their varied tints, while immersed in the water; but no sooner are they removed from it than their beauty vanishes. The *Iridea* and *Aleyonia*, which there possess all the varied tints of the rainbow, or wear a garb of glittering purple or orange, soon change their vivid lustre when cast upon the strand, and become black, yellow, or of a dingy violet, from their exposure to atmospheric air. When we enjoy an aquatic excursion during a cloudless day, on the smooth, unruffled bosom of the sea, and behold the sunbeams penetrate the abyss of waters, the deepness of its green impresses us with the idea of a verdant and liquid meadow. In proportion as we recede from the shore, and the water deepens around, the tint changes into a blue; and when we have reached the open sea, where the depth exceeds fifty or sixty fathoms, the water assumes a tint of the finest azure blue. The green shade usually indicates danger, or an approach to shallow water; but along those coasts which are interspersed with peaks or mountains, and near which the sounding line descends to great depths, the azure blue invariably appears, and assumes a more lively hue, as the depth becomes more considerable. This blue, which is generally considered as a characteristic of the ocean, and which appearance is accounted for by the rays of the sun becoming more decomposed as they penetrate into the depths of the waters, is not, however, peculiar to it, as every deep bed of water presents the same appearance under similar circumstances. Deep fresh-water lakes, especially in mountainous regions, exhibit the azure blue tint, which even extends itself to the beds of torrents. At the bottom of the torrent where the water fills the hollow cavity of a rock, the serene sky produces, in a modified degree, this beautiful colouring effect upon the water.

Sir Isaac Newton has demonstrated that the colours of all bodies arise from their power of reflecting or transmitting to the eye certain rays of which white light is composed, and of stopping or absorbing the remaining rays. This followed from his observing that bodies, of whatever colour they may appear, exhibit this colour only in white light. Every thing appears red in red light; and the leaf of the rose then presents the same hue as its flower. Even the most transparent bodies in Nature possess this absorbing power when in large masses. Thus, the air which appears perfectly colourless when seen from one end of an apartment to the other, tinges with a soft blueish gray the distant hills; and at length, when we look into the deep and cloudless expanse of the heavens, it deepens into a bright and azure blue. If we descend in a diving bell to a considerable depth below the surface of the sea, the sun appears of a bright red. In great depths of water objects become nearly invisible;

but when we ascend to the top of a lofty mountain, the azure tint of the heavens deepens into a black, and a greater number of stars become visible to the eye. The cause of these different hues must be sought in that unknown constitution of bodies, by which the one set of coloured rays are absorbed in passing through the transparent medium, while the remainder of them are reflected to the eye.

## MISCELLANEOUS.

**SINGULAR STRUCTURE OF A HEN'S EGG.**—The Egg, of which a representation is given in the annexed wood-cut, was accidentally discovered, during breakfast, by a young lady, residing at Irvine, Ayrshire, who has kindly transmitted it to us for examination.

On breaking open the outward shell, *a*, a second egg, *b*, was found covered with shell, and, within this second body a third substance, *c*, consisting of a spherical membrane, one side of which was partially encrusted with shell, was also discovered. The first and second shells contained the usual albuminous matter or white of egg, and it is presumed that the substance in the third cavity was similar, although our informant does not state precisely whether a red yolk was present or not. On the inner side of both the first and second shells the usual membrane of the egg is distinctly visible; the matter of the shell differs in no respect from that of the common egg, except in being rather more porous and brittle. The inner membrane has all the appearance of being destined for the yolk, but, as we have remarked, there is reason to suspect that the contents within the membrane were of a white albuminous nature.

The most obvious explanation of this curious *Lusus Naturæ* is, that the three membranous coats common to the egg have become ossified, or rather encrusted with carbonate of lime; that this has taken place in the second membrane from an unusual action of its secreting vessels; and that the same process had commenced, and was rapidly extending to the membrane of the yolk.

It would be a curious circumstance to ascertain whether the ossification began first on the yolk membrane, *c*, and being checked here by the production of the middle membrane, *b*, was subsequently covered by the membrane and shell, *a*,—or whether the ossification of the inner membranes proceeded subsequently to their development by the outer shell, *a*. If the latter were the case, it would show that the internal membranes of the egg have the power of secreting and depositing carbonate of lime, that is, of exercising a vital action when excluded from any of the vessels of the parent hen, and previous to, or independent of, the action which develops the chick. Such a circumstance would still farther tend to embarrass the curious question not yet solved, as to where the chick obtains the phosphate and carbonate of lime of its bones, for it has been ascertained that the albumen contains none, and it is probable that little or none is obtained by absorption from the shell.

**PECULIARITIES OF THE DAYAK.**—The most numerous class of the inhabitants of Borneo, and probably the Aborigines, are the Dayak. Their manners are characterized by some strange peculiarities and uncommon features of barbarism; but the spirit of these traits has never been elucidated, nor the system of religious or superstitious opinion with which they are connected examined.

In appearance, the Dayak are fairer and handsomer than the Malays; they are of a more slender make, with higher foreheads and noses; their hair is long, straight, and coarse, generally cut short round their heads. The females are fair and handsome. Many of the Dayak have a rough, scaly scurf on their skin, like the Jakong of the Malay peninsula. This they consider as an ornament, and are said to acquire it by rubbing the juice of some plant on their skin. The female slaves of this race which are found among the Malays have no appearance of it.

With regard to their funeral ceremonies, the corpse is placed in a coffin, and remains in the house till the son, the father, or the nearest of blood, can procure or purchase a slave, who is beheaded at the time that the corpse is burnt, in order that he may become the slave of the deceased in the next world. The ashes of the deceased are then placed in an earthen urn, on which various figures are exhibited, and the head of the slave is dried, and prepared in a peculiar manner with camphor and drugs, and deposited near it. It is said that this practice often induces them to purchase a slave guilty of some capital crime, at five-fold his value, in order that they may be able to put him to death on such occasions.

With respect to marriage, the most brutal part of their customs is, that nobody can be permitted to marry till he can present a human head of some other tribe to his proposed bride, in which case she is not permitted to refuse him. It is not, however, necessary that this should be obtained entirely by his own personal prowess. When a person is determined to go a head hunting, as it is very often a very dangerous service, he consults with his friends and acquaintances, who frequently accompany him, or send their slaves along with him. The head hunter then proceeds with his party in the most cautious manner to the vicinity of the villages of another tribe, and lies in ambush till they surprise some heedless, unsuspecting wretch, who is instantly decapitated. Sometimes, too, they surprise a solitary fisherman in a river, or on the

shore, who undergoes the same fate. When the hunter returns, the whole village is filled with joy, and old and young, men and women, hurry out to meet him, and conduct him, with the sound of brazen cymbals, dancing in long lines to the house of the female he admires, whose family likewise comes out to greet him with dances, and provide him a seat, and give him meat and drink. He still holds the bloody head in his hand, and puts part of the food into his mouth, after which, the females of the family receive the head from him, which they hang up to the ceiling over the door.

If a man's wife die, he is not permitted to make proposals of marriage to another, till he has provided another head of a different tribe, as if to revenge the death of his deceased wife. The heads procured in this manner they preserve with great care, and sometimes consult in divination. The religious opinions connected with this practice are by no means correctly understood: some assert, that they believe that every person whom a man kills in this world becomes his slave in the next. The *Idaan*, it is said, think that the entrance into Paradise is over a long tree, which serves for a bridge, over which it is impossible to pass without the assistance of a slave slain in this world.

The practice of stealing heads causes frequent wars among the different tribes of the *Idaan*. Many persons never can obtain a head, in which case they are generally despised by the warriors and the women. To such a height it is carried, however, that a person who had obtained eleven heads has been seen, and at the same time he pointed out his son, a young lad, who had procured three.

**WALKING ON THE WATER.**—A great inventor (in his own estimation) published to the world that he had solved the important problem of walking safely upon the water, and he invited a crowd to witness his first essay. He stepped boldly upon the wave, equipped in bulky cork boots, which he had previously tried in a butt of water at home; but it soon appeared that he had not pondered sufficiently on the centres of gravity and of flotation, for, in the next instant, all that was to be seen of him was a pair of legs sticking out of the water, the movements of which showed he was by no means at his ease. He was picked up by help at hand, and with his genius cooled, and schooled by the event, was conducted home.

**THE TIDES.**—The English Government has requested the co-operation of the Dutch Government in making simultaneous observations on the tides on their respective coasts. The King of Holland appointed Professor Moll, with the assistance of a certain number of naval officers, to make the necessary observations, from the 9th to the 30th July 1835.

**EFFECTS OF MERCURY.**—There is a curious case mentioned in the *Lancet*, in which the secretary of a public institution was twice attacked with a very violent fit of salivation, so as to render medical aid indispensable, from his wafering 500 circulars with red wafers, which he had wetted in his mouth. Red wafers are coloured with vermilion, which is a preparation of mercury.

**THE TATTY.**—The tatty is a trellise frame, very neatly made of split bamboo, thickly interwoven with a species of long grass, called *kuss-kuss*. During the hot winds in India, this is fixed at the door-way, and constantly wetted by a servant outside, who throws the water on it with a small jug from an earthen jar. The air passing through it is rendered delightfully cool and fragrant in the hottest weather. This is a luxury which is allowed even to the common European soldiers; their barracks being numerously attended by *beesties*, or water-carriers.

## REVIEWS.

*Wanderings in New South Wales, Batavia, Pedir Coast, Singapore, and China; being the Journal of a Naturalist, during 1832, 1833, and 1834. By George Bennett, Esq., F.L.S. &c. &c. London. 1834.*

THIS is a work of unusual merit and interest. The excursions into the interior of New South Wales were made during the intervals of disengagement from professional duties, and at periods of the year best calculated for observations in Natural History. Though written from notes taken down at the instant of observation, and without any regard to studied composition, it is not deficient in many eloquent and vivid descriptions. Where the whole work is filled with interesting and popular matter, it becomes difficult to select a passage as a specimen of its style. We quote the following description of that splendid phenomenon, usually called

## THE PHOSPHORESCENCE OF THE OCEAN:—

“Occasionally our attention was excited during the voyage by the remarkable luminosity assumed by the ocean in every direction, like rolling masses of liquid fire, as the waves broke and exhibited an appearance inconceivably grand and beautiful. The phosphoric light given out by the ocean, exists to a more extensive and brilliant degree in tropical regions, although in high latitudes it is occasionally visible, more especially during the warm months of the year. The cause of it has excited much speculation among naturalists; and although many of the marine Molluscous and Crustaceous animals, such as *Salpa*, *Pyrosoma*, *Cancer*, and several *Medusa*, have been found to occasion it; yet no doubt *debris*, from dead animal matter, with which sea water is usually loaded, is also one of the exciting causes.

“As the ship sailed with a strong breeze through a luminous sea on a dark night, the effect produced is then seen to the greatest advantage. The wake of the vessel is one broad sheet of phosphoric matter, so brilliant as to cast a dull, pale light over the after-part of the ship; the foaming surges, as they gracefully curl on each side of the vessel's prow, are similar to rolling masses of liquid phosphorus; whilst in the distance, even to the horizon, it seems an ocean of fire, and the distant waves breaking, give out a light of an inconceivable beauty and brilliancy. In the combination the effect produces sensations of wonder and awe, and causes a reflection to arise on the reason of its appearance, as to which, as yet, no correct judgment has been formed, the whole being overwhelmed with mere hypothesis.

“Sometimes the luminosity is very visible without any disturbance of the water, its surface remaining smooth, unruined even by a passing zephyr; whilst on other occasions no light is emitted unless the water is agitated by the winds, or by the passage of some heavy body through it. Perhaps the beauty of this luminous effect is seen to the greatest advantage when the ship, lying in a bay or harbour in tropical climates, the water around it has the resemblance of a sea of milk. An opportunity was af-

forded me when at Cavité, near Manilla, in 1830, of witnessing, for the first time, this beautiful scene. As far as the eye could reach over the extensive bay of Manilla, the surface of the tranquil water was one sheet of this dull, pale phosphorescence; and brilliant flashes were emitted instantly on any heavy body being cast into the water, or when fish sprang from it or swam about. The ship seemed, on looking over its side, to be anchored in a sea of liquid phosphorus, whilst in the distance the resemblance was that of an ocean of milk.

"The night to which I allude, when this magnificent appearance presented itself to my observation, was exceedingly dark, which, by the contrast, gave an increased sublimity to the scene. The canopy of the heavens was dark and gloomy, not even the glimmering of a star was to be seen; while the sea, of liquid fire, cast a deadly pale light over every part of the vessel, her masts, yards, and hull; the fish, meanwhile, sporting about in numbers, varying the scene by the brilliant flashes they occasioned. It would have formed, I thought at the time, a sublime and beautiful subject for an artist like Martin to execute, with his judgment and pencil; that is, if any artist could give the true effect of such a scene, on which I must express some doubts.

"It must not be for a moment conceived that the light described as brilliant, and like to a sea of 'liquid fire,' is of the same character as the flashes produced by the volcano, or by lightning, or by meteors. No; it is the light of phosphorus, as the matter truly is pale, dull, approaching to a white or very pale yellow, casting a melancholy light on objects around, only emitting flashes by collision. To read by it is possible, but not agreeable; and, on an attempt being made, it is almost always found that the eyes will not endure the peculiar light for any length of time, as headaches and sickness are often occasioned by it. I have frequently observed at Singapore, that, although the tranquil water exhibits no particular luminosity, yet, when disturbed by the passage of a boat, it gives out phosphoric matter, leaving a brilliant line in the boat's wake; and the blades of the oars, when raised from the water, seem to be dripping with liquid phosphorus.

"Even between the tropics, the phosphoric light is increased or diminished in its degree of brilliancy, in a very slight difference of latitude; on one day it would be seen to a most magnificent extent, on the next it would be perhaps merely a few luminous flashes. It might proceed from the shoals of marine animals, that caused the brilliancy, to be less extensively distributed over one part of the ocean than another. That I am correct in asserting that some of the animals which occasion the phosphoric light emitted by the ocean do travel in shoals, and are distributed in some latitudes only in a very limited range, I insert two facts which occurred during this voyage, and which will no doubt be regarded as interesting.

"On the 8th of June, being then in latitude 00° 30' south, and longitude 27° 5' west, having fine weather and a fresh south-easterly tradé wind, and range of the thermometer being from 78° to 84°, late at night the mate of the watch came and called me to witness a very unusual appearance in the water, which he, on first seeing, considered to be breakers. On arriving upon the deck, this was found to be a very broad and extensive sheet of phosphorescence, extending in a direction from east to west as far as the eye could reach; the luminosity was confined to the range of animals on this shoal, for there was no similar light in any other direction. I immediately cast the towing net over the stern of the ship, as we approached nearer the luminous streak, to ascertain the cause of this extraordinary and so limited a phenomenon. The ship soon cleaved through the brilliant mass, from which, by the disturbance, strong masses of light were emitted; and the shoal (judging from the time the vessel took in passing through the mass) may have been a mile in breadth; the passage of the vessel through them increased the light around to a far stronger degree, illuminating the ship. On taking in the towing net, it was found half-filled with *Pyrosoma (Atlanticum)*, which shone with a beautiful pale greenish light; and there was also a few small fish in the net at the same time. After the mass had been passed through, the light was still seen astern, until it became invisible in the distance; and the whole of the ocean then became hidden in darkness as before this took place. The scene was as novel as it was beautiful and interesting, more so from having ascertained, by capturing the luminous animals, the cause of the phenomenon.

"The second was not exactly similar to the preceding; but, although also limited, was curious, as occurring in a high latitude during the winter season. It was on the 19th of August, the weather dark and gloomy, with light breezes from North-north-east, in latitude 40° 30' South, and longitude 138° 3' East, being then distant about 368 miles from King's Island (at the western entrance of Bass's Straits). My journal remarks the atmosphere to have been very chilly during the day, but much milder in the evening; the range of the thermometer during the day being from 49° to 56°. It was about eight o'clock P.M. when the ship's wake was perceived to be luminous, and scintillations of the same light were also abundant around. As this was unusual and had not been seen before, and it occasionally also appeared in larger or smaller detached masses, giving out a high degree of brilliancy, to ascertain the cause, so unusual in high latitudes during the winter season, I threw the towing net overboard, and in twenty minutes succeeded in capturing several *Pyrosoma*, giving out their usual pale green light; and it was no doubt detached groups of these animals that were the occasion of the light in question. The beautiful light given out by these Molluscous animals soon subsided (being seen emitted from every part of their bodies); but by moving them about, it could be reproduced for some length of time after. As long as the luminosity of the ocean was visible (which continued most part of the night) a number of *Pyrosoma Atlanticum*, two species of *Phyllosoma*, an animal apparently allied to *Septocephalus*, as well as several Crustaceous animals, all of which I had before considered as inter-tropical species, were caught and preserved. At half-past ten P.M. the temperature of the atmosphere on deck was 52°, and that of the water 51½°. The luminosity of the water gradually decreased during the night, and towards morning was no longer seen, nor on any subsequent night."

In a paper which Mr Bennett read before the Zoological Society, 25th June 1833, these luminous animals are more fully described.

Specimens taken from the sea, and placed in a glass vessel containing sea-water, ceased altogether to emit light, or emitted it but sparingly, while they remained at rest. On the water being agitated, or when one from the masses of animals was taken into the hand, the whole became instantly illuminated by myriads of bright dots,

much resembling in hue the points on the elytra of a diamond beetle (*Curculio imperialis*, Fab.)

The *Pyrosoma*, thus enveloped throughout its whole extent in a flame of bright phosphorescent light, gleaming with its peculiar hue, presented a most splendid spectacle; the light shed by it was sufficient to render objects distinctly visible in every part of an otherwise dark room. If long retained in the hand, or returned to a quiescent state in the water, the luminous spots gradually faded, and no light was visible until the animal was again disturbed, when the illumination instantly returned with all its vivid splendour. After death it emitted no light.

The mass of *Pyrosoma*, of the usual cylindrical form and gelatinous substance, was about four inches in length, and one-and-a-half in circumference. The tube, passing along its middle, is described as being open at both ends; the orifice at the broader extremity being much better defined in its circular form, larger, and more distinct than that of the opposite end. The surface of the mass appeared to be studded with numerous prominent, rigid, and pearly tubercles, intermingled with small specks of a brown or red colour. In these latter the power of emitting light appear chiefly to be seated, these being frequently bright, while the remainder of the body exhibited only its natural white, or yellowish-white hue—a hue which changed after death into a red tinge. The brown specks, when removed from the body, did not emit light.

The extensive field of bright luminous matter, from which these specimens were taken, emitted so powerful a light as to illuminate the sails, and to permit a book of small print to be read with facility near the windows of the stern-cabins. Above this luminous field numerous sea-fowl were hovering in search of their prey. The light appeared to be entirely owing to the *Pyrosomata*.

The phosphorescence of the ocean often proceeds from other causes besides this one ascertained by Mr Bennett. Frequently it arises from putrescent particles of animal matter, dissolved by the sea water. Sometimes it is occasioned by minute animalcules, which possess the same remarkable property of shining in the dark with the fire-fly of tropical climates (*Elater noctilucus*), and the common glow-worm (*Lampyris noctiluca*). But many observers have examined sea-water, and were unable to perceive any animal matter in it. Professor Rennie states, that, being at Havre-de-Grace, he could not discover the slightest trace of animalcules, although the water which he examined was so strongly luminous, that it shone upon the skin of some night-bathers like scattered clouds of lambent flame, appearing more as a property of the water itself than any thing extraneous diffused through it.

In all these cases, the phosphorescent bodies merely emit, during the night, the solar rays which had been absorbed during the preceding day. The presence of salt seems necessary to phosphorescence, as the water of ponds and lakes is never luminous. It may probably proceed from a similar cause with the luminous appearance observed by chemists during the crystallization of some salts, as the hydro-fluate of soda, and sulphate of potash.

A recent writer has described five varieties of these luminous appearances. The first shows itself in scattered sparkles in the spray of the sea, and in the foam created by the way of the ship when the water is agitated by the winds or currents; the second is a flash of pale light, of momentary duration, but often intense enough to illuminate the water to an extent of several feet; the third, of rare occurrence and peculiar to gulfs, bays, and shallows, in warm climates, is a diffused pale phosphorescence, resembling sometimes a sea of milk, or of some metal in a state of igneous liquefaction; the fourth presents itself to the astonished voyager, under the appearance of thick bars of metal, of about half a foot in length, ignited to whiteness, scattered over the surface of the ocean, some rising up and continuing luminous as long as they remain in view, while others decline and disappear; and the fifth variety is in distinct spots on the surface, of great beauty and brilliancy. The light of the first variety is more brilliant and condensed than that of any of the others, and very much resembles every way the red gold and silver rain of the pyrotechnist. The first and the third kind are produced by myriads of various minute Crustaceous animals, the smaller *Medusæ* and *Mollusca*, and perhaps some *Annelides*; the second appears to proceed from the gelatinous *Medusa*, of a larger size; the *Pyrosomata* are the cause of the fourth kind, which may be often witnessed by vessels bound to India, or the eastward of the Cape of Good Hope, occurring in the calm latitudes near the line. The *Sapphirina indicator*, an insect somewhat resembling in appearance the wood-louse (*Oniscus*), and about one-third of an inch in length, emits the last variety enumerated, which appears to be limited to the seas situate on the north and west of a line drawn from the Cape of Good Hope to the southern extremity of the island of Ceylon.

Every page of Mr Bennett's excellent work is filled with interesting matter. There are some trifling inaccuracies, which we shall pass over in silence. We remark, however, that the author seems disposed to indulge in rather a satirical mode of expression towards the fair sex; and some remarks are made, which we think might have been omitted without prejudice to the work. Thus, in describing the town of Sydney, he observes—"Parrots are perhaps, of all the feathered tribe, the most numerous in the colony; and different species are lauded for speaking, whistling, and other noisy accomplishments. These birds are evidently gifted with the hump of *talkativeness*. It was once asserted that ladies kept the birds to converse with when alone, which served a double purpose—that of being to them both practice and amusement." We also find a chapter headed "Female Curiosity;" and, on examination, it turns out to be merely, that as the white men passed their dwellings, the ladies came forth to view the strangers, "with the usual feminine curiosity." Yet, immediately afterwards, we find that the *natives* (men as well as women) seemed to regard them as wonders.

We hope to return, on another occasion, to these otherwise interesting pages; and, in the meantime, we can recommend every student of Nature, to whom these books are accessible, to peruse them attentively.

SATURDAY, JANUARY 30, 1836.

ZOOLOGY.

DESCRIPTION OF THE PLATE—THE HUMMING BIRDS.

THE genus *Trochilus* comprises some of the smallest, but, at the same time, some of the most beautiful of the feathered tribe. Observers of every description have been struck with admiration at the elegance and variety of the tints which adorn them; but the extreme delicacy of their constitution generally unfits them for enduring the variable climates of the temperate zone, or the restraints of confinement. They have almost always died on the passage homewards; and their admirers, in this country, are compelled to view only the preserved specimens in their cabinets, or such representations as we now offer.

All the objects on the accompanying plate are drawn the exact size of Nature; and we cannot fail to observe the striking contrast between the Gigantic Humming Bird, No. 7 (*T. Gigas*), which is about the size of a Sparrow, and the Least Humming Birds, Nos. 8 and 9 (*T. Minimus*). The latter scarcely surpasses the humble bee in magnitude, and is the smallest of Birds.

Those persons who have not seen them, numerous as Butterflies, sporting in the sunny prairies of America, would hesitate at first to believe that Birds of so minute a construction could exist. Yet we find the same perfection in the smallest as well as in the largest of Nature's works, and a structure prevails in these minute objects equally complicated with those of the Ostrich and Eagle.

It was long supposed, as they resemble the Butterfly in fluttering from flower to flower, that they also partook of the same food, and subsisted on honey. It seems now to be clearly ascertained that they do not feed on honey, but on the insects which prey upon it. This might have readily been discovered upon comparing the structure of their bills, which are long, pointed, and altogether incapable of sucking up a fluid, or saccharine matter, with the haustellum or sucker, used by certain insects for that purpose.

During their flight, they sometimes keep their bodies motionless in the air for hours together, emitting a loud humming noise, from which they derive their name. This sound is not emitted by the birds, but is occasioned solely by the exceedingly rapid vibration of their wings. They are generally confined to the tropical climates of America, although they have been found as far south as the Straits of Magellan, and as far north as the Elk River. They frequent the woods as well as prairies; and are often observed to enter the houses of the Americans in pursuit of Insects, sometimes venturing to insert their delicate bills into a bouquet of flowers, and rapidly retreating on being approached.

Figs. 1 and 2. The Tufted-necked Humming Bird (*Trochilus Ornatus*), Male and Female.—This species derives its name from the singular tuft of feathers which surrounds the neck of the male, but of which the female is altogether deprived.

Fig. 3. The Azure Blue Humming Bird (*T. Lazulus*) is distinguished by the brilliant hue of its breast.

Fig. 4. The Harlequin Humming Bird (*T. Multicolor*) is so singular and fantastic in its colours, that the specimen in the British Museum was long suspected to have been formed of feathers belonging to different species. This is now generally believed not to have been the case.

Fig. 5. The Ruby-crested Humming Bird (*T. Moschitus*) is very common in the West Indies and in tropical America.

Fig. 6. Gould's Humming Bird (*T. Gouldii*) possesses one of those singular tufts round the neck, which the French term *Coquets*, and have been not unaptly compared to the ruffs worn by ladies during the age of Queen Elizabeth.

Fig. 7. The Gigantic Humming Bird (*T. Gigas*).—This is the Patagonian of the Humming Bird genus. In strength and size it is equalled by none.

Figs. 8. and 9. The Least Humming Birds (*T. Minimus*), Male and Female, resemble the preceding only in the dullness of their colours, which are much inferior to their congeners. Yet we view these little creatures with singular interest, forming, as they do, one of the limits, in regard to size, of a numerous and interesting class of animated beings.

Fig. 10. The White Striped Humming Bird (*T. Mesoleucus*) differs but slightly from Fig. 11, the Evening Humming Bird (*T. Vesper*). Both these species have but a rudimentary tuft around the neck, which however is of a brilliant hue.

Fig. 12. The Tri-coloured Humming Bird (*T. Tricolor*) appears to be surpassed in beauty by few of its tribe.

REMARKABLE PECULIARITY OF THE FEMALE ASS.—It is universally known that many animals will continue to give milk not only after the young are removed, but even for years, when the impression of having had young must have been entirely forgotten. The Cow and Goat are instances of this kind; but in the Ass the secretion of milk is not continued after the mother has lost the impression of her foal's existence. This is a fact so well known to the keepers of Asses, that whenever an Ass's foal dies, they take every means in their power to keep up the impression, in the mother, of the foal being still alive, to keep her in milk. For this purpose they take off the skin of the foal and preserve it, so that it may be occasionally thrown over the back of another foal, and smelled by the mother, more particularly at the time they are milking her. The Ass, under the deception of having her own foal, gives down her milk, and the secretion is carried on as usual; but if this artifice be neglected she soon goes dry. To ascertain this fact more accurately, the celebrated Mr John Hunter put it to the test of experiment. He took an Ass, in milk, and kept her apart from her foal every night, but had the mother milked in the morning in presence of the foal. This was done for more than a month, without there being any diminution in the morning's milk. The foal was then taken away altogether, and the mother was milked instead of being sucked by the foal, particularly in the evening, at the same hour at which the foal had been taken from her, and again in the morning at the usual hour. The milk taken in the morning was always compared with that taken in the morning before, but in three mornings the quantity was lessened; and the fifth morning there was hardly any. The foal was then restored to her; but she would not allow it to suck. The experiment was repeated with similar results.

THE CANARY BIRD.—The Canary Bird is remarkable for its tractability and intelligence, as an instance of which the following anecdote may be given:—A bird-catcher in Prussia, who had rendered himself famous for educating and calling forth the talents of the feathered tribe, had a Canary Bird, which was introduced by the owner to a large party at Cleves, to amuse them with his wonderful feats. The Canary being produced, the owner harangued him in the following manner, placing him upon his fore-finger:—"Bijou (jewel), you are now in the presence of persons of great sagacity and honour; take heed, therefore, that you do not deceive the expectations they have conceived of you from the world's report. You have got laurels; beware of their withering: in a word, deport yourself like the bijou of Canary Birds, as you certainly are." All this time the bird seemed to listen, and indeed placed himself in the true attitude of attention. He sloped his head to the ear of the man, then distinctly nodded twice, when his master had left off speaking; and if ever nods were intelligible and promissory, these were of that nature. "That's good," said the master, pulling off his hat to the bird. "Now let us see if you are a Canary of honour? Give us a tune." The Canary sang. "Pshaw! that's too harsh: tis the note of a raven with a hearseness upon him—something pathetic." The Canary whistled as if his little throat was changed to a lute. "Faster," says the man; "slower—very well. What the plague is this little foot about, and this little head? No wonder you are out, Mr Bijou, when you forget your time. That's a jewel; Bravo! bravo! my little man." All that he was ordered, or reminded of, did he to admiration. His head and foot beat time; humoured the variations both of tone and movement; and the sound was a just echo to the sense, according to the strictest laws of poetical, and (as it ought to be) of musical composition. "Bravo! bravo!" re-echoed from all parts of the room. The musicians declared the Canary was a greater master of music than any of their band. "And do you not show your sense of this civility, sir?" cried the bird-catcher with an angry air. The Canary bowed most respectfully, to the great delight of the company. His next achievement was going through the martial exercises with a straw gun; after which, "My poor Bijou," said the owner, "thou hast had hard work, and must be a little weary: a few performances more, and thou shalt repose. Show the ladies to make a curtesy." The bird here crossed his taper legs, and sunk and rose with an easy grace that would have put half our subscription assembly *belles* to the blush. "That's my fine bird! and now a bow, head and foot corresponding." Here the striplings for ten miles round London might have blushed also. "Let us finish with a hornpipe, my brave little fellow; that's it, keep it up, keep it up." The activity, glee, spirit, and accuracy with which this last order was obeyed, wound up the applause (in which all the musicians joined, as well with their instruments as their clappings) to the highest pitch of admiration. Bijou himself seemed to feel the sacred thirst of fame, and shook his little plumes, and carolled an *Jo paan*, that sounded like the conscious notes of victory. "Thou hast done all my biddings bravely," said the master, caressing his feathered servant; "now then take a nap, while I take thy place." Hereupon the Canary went into a counterfeit slumber, so like the effect of Morpheus, first shutting one eye, then the other, then nodding, then dropping so much on one side that the hands of several of

the company were stretched out to save him from falling; and just as their hands approached his feathers, suddenly recovering, and dropping as much on the other. At length sleep seemed to fix him in a steady posture; whereupon the owner took him from his finger, and laid him flat on the table, where the man assured us he would remain in a good sound sleep, while he himself had the honour to do his best to fill up the interval. Accordingly, after drinking a glass of wine (in the progress of which he was interrupted by the Canary Bird springing suddenly up to assert his right to a share, really putting his little bill into the glass, and then laying himself down to sleep again), the owner called him a saucy fellow, and began to show off his own independent powers of entertainment, when a huge black cat, who had long been on the watch, sprang unobserved, from a corner, upon the table, seized the poor Canary in its mouth, and rushed out of the window in spite of opposition. And though the room was deserted in an instant, it was a vain pursuit; the life of the poor bird was gone; and its mangled body was brought in by the unfortunate owner, under such dismay, and accompanied by such looks and language, as would have awakened pity in a misanthrope.

**ANECDOTE OF A RAVEN.**—At the seat of the Earl of Aylesbury, in Wiltshire, a tame Raven, that had been taught to speak, used to ramble about in the park; there he was commonly attended and beset by crows, rooks, and others of his inquisitive tribe. When a considerable number of these were collected around him, he would lift up his head, and with a hoarse and hollow voice shout out the word *Holla!* This would instantly put to flight and disperse his sable brethren, while the Raven seemed to enjoy the fright he had occasioned.

**CURIOUS MECHANISM IN THE FEET OF THE FLY AND LACERTA GECKO.**—It is well known that the house-fly is capable of walking upon the ceiling of rooms, in which situation its body is not supported on the legs. The principle upon which it does so remained for a long time unexplained, because the animal is too small for the feet to be anatomically examined. Animals of a much larger size are endowed with the same power. The Lacerta Gecko, a native of the Island of Java, is in the habit of coming out of an evening from the roofs of the houses, and walking down the smooth, hard, polished chunam walls in search of flies that settle upon them, and then of running up again. Sir Joseph Banks, while at Batavia, used to catch this animal by standing close to the wall with a long flattened pole, which being made suddenly to scrape the surface, knocked it down. Sir Everard Home procured a specimen of a very large size, which enabled him to ascertain the peculiar mechanism by which the feet of this animal keep their hold of a smooth hard perpendicular wall, and carry up so large a weight as that of its own body. He found that the foot of this lizard was so constructed as to enable it to produce a number of small concavities which act like so many cupping glasses, and atmospheric pressure retains them in this position. It appears that the fly's foot possesses concave surfaces capable of acting in the same manner as those of the Lacerta Gecko, and therefore its progressive motion against gravity is effected by the same means.

## BOTANY AND HORTICULTURE.

### RAFFLESIA PATMA.

THIS is one of those anomalous vegetable productions which are so numerous in some of the Islands of the East Indian Archipelago, being without either root or leaves, as the flower constitutes the whole of the plant. Dr Blume, in his excellent work on the *Flora Javae neon Insularum adjacentium*, has given an engraving of this flower, from which the following has been reduced.

The *Rafflesia Patma* of Blume is found in the shady thickets of the little island of Nusa Kambagan, which adjoins Java on the south. It grows upon the roots of the *Cissus Scariosa* of Blume, and seems exceedingly partial to moist ground, where the diameter of the expanded flower is found to reach the size of two Dutch feet (about one foot seven inches English), but in dryer, and consequently less favorable situations, it does not exceed one English foot in diameter.

The plants of the genus *Rafflesia* have been found on the stems, as well as upon the roots, of the genera *Cissus* and *Vitis*; they form the only instances of parasites on roots, which likewise proceed from other parts of the plant. Isert, in his *Reise nach Guinea*, p. 283, mentions a plant, which he had observed in equinoctial Africa, parasitic on the roots of trees, consisting almost entirely of a single flower of a red colour, which is probably allied to *Rafflesia*, the smaller species of which it seems to resemble in appearance.

Dr Blume was convinced, after a careful examination of the *R. Patma*, that it had no connexion whatever with the woody layers of the root of the *Cissus Scariosa*, but that it was only united with the substance of the bark of the root. It is a singular fact, that the growing bark, having its continuity interrupted by the collet of the *Rafflesia* entering into its substance, swells into a cup-shaped process round about the flower buds of the *Rafflesia*, and that this cup-like process varies in diameter according to the length of time which must elapse between the first rising of the flower bud, and the ultimate fall of the flower itself and of its remains.

The *R. Patma* differs from the *R. Arnoldi*, figured in a former number (4), in having the inside of the perianth red; and further, in having the columnar processes of its disc more numerous, stronger, and more unequal in length. It seems to depart still more widely from the general character of our ordinary diœcious plants.

The successive development of the flower, from its first appearance upon the original stock, until it is just ready to blow, is represented in the following cuts.

With respect to the place which the genus *Rafflesia* holds in the Vegetable Kingdom, the learned Dr Robert Brown has the following observations:—"As to which of the two primary divisions of phænogamous plants the genus belongs, it may, I think, without hesitation be referred to *Di-cotyledones*; yet, if the plant be parasitic, and consequently no argument on this subject to be derived from the structure of the root, which is exactly that of the Vine, the exclusion from *Mono-cotyledones* would rest on no other grounds, that I am able to state, than the quinary division of the perianthium, which, in other respects, also bears a considerable resemblance to that of certain *Di-cotyledonous* orders; the number of stamina and the ramification of vessels in the bractæe.

"Assuming, however, that *Rafflesia* belongs to *Di-cotyledones*, and considering the foliaceous scales which cover the expanded flower, both from their indefinite number and imbricate insertion as bractæe, and consequently the floral envelope as simple, its comparison with the families of this primary division would be limited to such as are apetalous, either absolutely, as *Aserinæ*; those of a nature intermediate between the apetalous and polypetalous, in which the segments of the perianthium are generally, though not always, disposed in a double series, as *Passifloræ*, *Cucurbitacæ*, and *Homalinæ*; or those which have a simple-coloured floral envelope, but are decidedly related to polypetalous families, as *Sterculiacæ*."

It is difficult to ascertain in what manner the impregnation of the female flower is effected, when the anthers are so completely concealed as those of *Rafflesia* seem to be in all states of the flower; for it does not appear either that they can ever become exposed by a change in the direction of the limb under which they are inserted, or even that this part of the column, in any stage, projects beyond the tube of the perianth.

It is probable, therefore, that the assistance of insects is absolutely necessary; and it is not unlikely, both as connected with that mode of impregnation, and from the structure of the anther itself, that in *Rafflesia* the same economy obtains as in the stamina of certain *Aroidæ*, in which it has been observed that a continued secretion and discharge of pollen takes place from the same cell; the whole quantity produced greatly exceeding the size of the secreting organ. The passage of the pollen to the bottom of the flower, where it is more easily accessible to insects, seems likewise to be provided for, not only by the direction of the anther, but also by the form of the corresponding cavities in the neck of the column, in the upper part of which they are immersed.

That insects are really necessary to the impregnation of the *Rafflesia*, is confirmed by Dr Arnold's statement in regard to the other species, *R. Arnoldi*. By the fact of the swarms actually seen hovering about and settling in the expanded flower, it is more than probable that they were attracted by its peculiar odour.

The modes of union between a parasite and the stock from which it springs, may be divided into such as are entirely dependent on the stock during the whole of their existence, and such as, in their more advanced state, produce roots of their own. Among those that are in all stages absolutely parasitic, to which division the genus *Rafflesia* probably belongs, very great differences exist in the mode of connexion. In some of these the nature of the connexion is such as can only be explained on the supposition that the germinating seed of the parasite excites a specific action on the stock, the result of which is the formation of a structure, either wholly or in part, derived from the root, and adapted to the support and protection of the undeveloped parasite; analogous therefore to the production of galls by the puncture of insects.

On this supposition the connexion between the flower of *Rafflesia*, and the root from which it springs, though considerably different from any other known plant, may also be explained. But until either precisely the same kind of union is observed in plants known to be parasite, or, which would be still more satisfactory, until the leaves and fructification belonging to the root to which *Rafflesia* is attached, shall have been found, its being a parasite, though highly probable, cannot be considered as absolutely ascertained.

## MINERALOGY.

**THE MATTAN DIAMOND.**—The Rajah of Mattan, in the island of Borneo, possesses the finest and largest diamond which has hitherto been discovered. It weighs 367 carats, and is said to be of the finest water. The celebrated Pitt Diamond weighs only 127 carats. The Mattan Diamond is shaped like an egg, with an indented hollow near the smaller end. It was discovered at Landak about ninety years ago; and though the possession of it has occasioned numerous wars, it has been about eighty years in the possession of the Mattan family. Many years ago, the Governor of Batavia sent a Mr Stewart to ascertain the weight, quality, and value of this Diamond, and to endeavour to purchase it; and in this mission he was accompanied by the late Sultan of Pontiana. After examining it, Mr Stewart offered 150,000 dollars for the Diamond, the sum to which he was limited; and, in addition to this sum, two war-brigs, with their guns and ammunition, together with a certain number of great guns, and a quantity of powder and shot. The Rajah, however, refused to deprive his family of so valuable an hereditary possession, to which the Malays attach the miraculous power of curing all kinds of diseases, by means of the water in which it is dipped, and with which they imagine the fortune of the family is connected.

## GEOLOGY AND PHYSICAL GEOGRAPHY.

**INUNDATIONS OF MEXICO.**—The Mexican Lakes are natural reservoirs, into which the torrents, rushing from the surrounding mountains, deposit their waters. The capital is situate in the centre of a valley, around which the encircling mountains rise in successive stages, until they are lost in the distance. The city of Mexico occupies the lowest part of the valley, and is scarcely more elevated than the level of the Lake Tezcuco. Several lakes rise above each other, such as those of Xaltocan, Xochimilco, Tzompango, and Chalco. In consequence of the different elevations of these natural reservoirs, the city of Mexico has for a long series of ages been exposed to the ravages of mighty inundations. The Lakes of Chalco and of Xochimilco must necessarily overflow their banks whenever a violent eruption of an adjoining volcano causes the snows which cover its summit to melt. "When I was at Guayaquil, on the borders of the province of Quito, in 1802," says the Baron Al. De Humboldt, "the cone of Cotopaxi was heated by subterranean fire to such a degree, that, in a single night, it lost the vast garment of snow with which it had long been covered." In the New World, eruptions and great earthquakes are often followed by heavy showers, which continue for several months. It may easily be imagined how dangerous the situation of Mexico must be in a climate where, in the driest years, the rain falls to the depth of 15 decimetres (about 59 inches).

The inhabitants of New Spain think that these violent inundations follow each other at nearly equal periods of time. Past experience seems to prove that a violent eruption of the waters occurs every 25 years. Since the arrival of the Spaniards, Mexico has experienced five very great inundations, in 1553, 1580, 1604, 1607, and 1629. In consequence of the opening of a canal, these evils were partially averted; and since that time their effects have been less violent, occurring at intervals of 27, 24, 3, 26, 19, 27, 32, 25, 16, 24, and 23 years. These numbers do not follow each other with so great a regularity as may be observed in the periods marking the returns of the earthquakes at Lima.

The situation of Mexico is rendered daily still more dangerous, by the circumstance that the difference of level between the surface of the lake Tezcuco and the soil on which the houses are constructed diminishes annually. This soil forms a fixed plane, especially since the streets of Mexico were paved. The bottom of the lake of Tezcuco, on the contrary, is continually elevated by the mud washed down by the surrounding torrents. It was to avoid a similar danger that the Venetians turned from their lagunes, the Brenta, Livenza, and other rivulets,\* which form their alluvial deposits within them. If we could place much reliance upon the results of the levelling made in the sixteenth century, there would be no doubt that the *Plaza Mayor*, or Great Square of Mexico, had formerly been elevated eleven decimetres (43½ inches) above the level of the lake of Tezcuco, and that the mean level of the lake varies from year to year. On the one hand, the moisture of the atmosphere has diminished by the destruction of the forests, and consequently the sources of the streams flowing from the mountains which surround the valley have been lessened; but, on the other hand, the clearing of the ground has increased the quantity of alluvial deposit, and the rapidity of the inundations. General Andreossi, in his excellent work upon the Canal of Languedoc, has explained these causes, which are the same under all climates. The waters which glide over the declivities covered with a green sward, form less alluvial deposit than those which rush over the uncovered bank. This vegetable covering, which may be formed either by the grasses, as in Europe, or by the little Alpine plants, as we find them in Mexico, can only be preserved under the shadow of the forest. Again, the thickets and brushwood present obstacles to the waters which roll down the declivity of the mountains, upon the melting of the snows. When these declivities are destitute of vegetation, the rivulets of water are less retarded, they unite more rapidly in torrents, and their deposits swell the lakes adjoining the city of Mexico.

**ASCENT OF THE ANDES.**—Don Juan de Ulloa, who went to Peru in company with the French academicians, to measure a degree of the meridian, gives the following curious description of his ascent of the Andes:—

"After many days sailing up the river Guayaquil, I arrived at Caracol, a town situate at the foot of the Andes. Nothing can exceed the inconveniences we had experienced in this voyage from the flies and mosquitoes. We were the whole day in continual motion to keep them off, but at night our torments were excessive. Our gloves, indeed, were some defence to our hands, but our faces were entirely exposed; nor were our clothes a sufficient defence for the rest of our bodies, for the stings of these insects, penetrating through the cloth, caused a very painful itching. One night, on coming to anchor near a very handsome house that was uninhabited, we were no sooner seated

in it than we were attacked on all sides by swarms of mosquitoes, so that it was impossible to have one moment's quiet. Those who had covered themselves with clothes made for this purpose found not the smallest defence; wherefore, hoping to find some relief in the open fields, they ventured out, although in danger of suffering in a more terrible manner from the serpents. But both places were equally obnoxious. On quitting this inhospitable retreat, we took up our quarters, the next night, in a house that was inhabited; the master of which being informed of the terrible manner we had passed the preceding night, told us gravely that the house we so greatly complained of had been forsaken on account of its being the purgatory of a soul; but we had more reason to believe that it was quitted on account of its being the purgatory of the body. After having journeyed upwards of three days, through boggy roads, in which the mules sank knee-deep at every step, we began at length to perceive an alteration in the climate; and after having been long accustomed to heat, we now felt it grown very sensibly colder.

"It is remarkable that at Taraguagua we often see instances of the effects of two opposite temperatures in two persons happening to meet; one of them leaving the plains below, and the other descending from the mountain. The former thinks the cold so severe that he wraps himself up in all the garments he can procure, while the latter finds the heat so great that he is scarcely able to bear any clothes whatever. The one thinks the water so cold that he avoids being sprinkled by it, the other is so delighted with its warmth that he uses it as a bath.

"The ruggedness of the road from Taraguagua, leading up the mountain, is not easily described. The declivity is so great, in some parts, that the mules can scarcely keep their footing; and in others, the activity is equally difficult. The trouble of sending people before to mend the road, the pain arising from the many falls and bruises, and the being constantly wet to the skin, might be supported, were not these inconveniences augmented by the sight of such frightful precipices and deep abysses, as excite incessant terror. The road in some places is so steep, and yet so narrow, that the mules are obliged to slide down, without making any use whatever of their feet except as a support. On one side of the rider, in this situation, rises an eminence of several hundred yards, and on the other is an abyss of equal depth, so that, if he should give the least check to his mule, and thus destroy the equilibrium, they must both inevitably perish.

"Having travelled nine days in this manner, slowly winding along the side of a mountain, we began to find the whole country covered with a hoar frost, and a hut, in which we reposed, had ice in it. At length, after a perilous journey of fifteen days, we arrived upon the plain, at the extremity of which stands the city of Quito, the capital of one of the most charming regions in the world. Here, in the centre of the torrid zone, the heat is not only very tolerable, but in some places the cold is even painful. Here the inhabitants enjoy all the temperature and advantages of perpetual spring; the fields being constantly covered with verdure, and enameled with flowers of the most lively colours. However, although this beautiful region be more elevated than any other country in the world, and it took up so many days of painful journey in the ascent, it is overlooked, nevertheless, by tremendous mountains—their sides covered with snow, while their summits are flaming with volcanoes. These mountains seem piled one upon the other, and rise to an astonishing height, with great coldness. However, at a determined point above the surface of the sea, the congelation is found at the same height in all the mountains. Those parts which are not subject to a continual frost, have here and there growing upon them a rush, resembling the Genista, or broom, but much softer and more flexible. Toward the extremity of the part where the rush grows, and the cold begins to increase, is found a vegetable with a round bulbous head, which, when dried, has an amazing elasticity. Higher still, the earth is entirely bare of vegetation, and seems covered with eternal snow. The most remarkable of the Andes are the mountains of Cotopaxi, Chimborazo, and Pichincha. On the top of the latter was my station for measuring a degree of the meridian, where I suffered particular hardships, from the intenseness of the cold, and the violence of the storms. The sky around us, in general, was involved in thick fogs, which, when they cleared away, and the clouds, by their gravity, moved nearer to the surface of the earth, appeared surrounding the foot of the mountain, at a vast distance below, like a sea encompassing an island in the midst of it. When this happened, the horrid noises of tempests were heard from beneath, then discharging themselves on Quito and the neighbouring country. I saw the lightning issue from the clouds, and heard the thunders roll far beneath me. All this time, while the tempest is raging below, the mountain top where I was placed enjoyed a delightful serenity. The wind was abated, the sky clear, and the enlivening rays of the sun moderated the severity of the cold. However, this was of no very long duration; for the wind returned with all its violence, and with such velocity as to dazzle the sight, while my fears were increased by the dreadful concussions of the precipice, and the fall of enormous rocks, the only sounds that were heard in this frightful situation."

**IRISH BOG.**—The moving bog on Lord O'Neill's estate, near Randalstown, has changed its situation to a considerable extent. It has overspread the surrounding land, and precipitated its mass into the river Maine, so as to obstruct the course of the current, and lying in some places nearly twenty feet deep.

## METEOROLOGY.

**DEW-BUTTER.**—The following singular fact is recorded in one of the first numbers of the *Philosophical Transactions*:—In the year 1695, during a great part of the winter and spring, a fatty substance, somewhat like butter, was deposited by the atmosphere, instead of the usual dew, in Ireland, and particularly in the provinces of Leinster and Munster. This substance is said to have been of a dark yellow colour, and felt clammy, whence the natives called it Dew-butter. It fell in the course of the night on the moorish low grounds; and it was found in the morning attached to the leaves of grass, to the thatches of houses, &c., in the form of pretty large lumps; and it is added, that it seldom fell twice in the same place. It had an offensive smell.

\* Andreossi sur le Canal du Midi, p. 19.

yet it lay upon the ground a fortnight before it changed colour, after which it dried up and became black; but it never bred worms, nor did it prove noxious to cattle that fed in the fields where it fell. During the winter of the above-mentioned year some very disagreeable fogs were observed on the same places where the *dew-butter* fell.

During a great part of the year 1783, when the repeated earthquakes of Calabria and Sicily destroyed almost the whole of the former, and a great part of the latter place, a very large meteor was observed, in the month of September, by most European countries. At the same time the Hecla, in Iceland, made a vast eruption of ignited matter; and it is said that many persons observed, in Ireland, a peculiar kind of clamminess upon the leaves of trees, as if a dew of a glutinous nature had been deposited from the atmosphere; but we do not find that any particular experiments were made for the purpose of ascertaining its nature.

**SNOW IN JUNE.**—On the morning of Tuesday the 23d June 1835, the Argyleshire mountains were covered with snow, particularly a hill on the Drimsynie estate, named Benvullo, the highest ridge of the mountains in Cowal, and Craigen Hill, or the Duña of Argyle's bowling green, on the western side of Loch Long.

## MISCELLANEOUS.

### NO. II.—ANIMAL MAGNETISM.

ON witnessing the same experiments, frequently repeated, the commissioners remarked, that among the patients who fell into the *crises* there were always many women and very few men; that the *crises* were not effected in less than the space of an hour or two, and that as soon as one person was thus taken, the rest were similarly seized in a very short time. But they were unable to obtain any satisfactory results from experiments made upon so many persons at once. They resolved therefore to endeavour, by experiments on individuals, in a more private way, to ascertain the direct effects of the newly-discovered agent on the animal economy, in a state of health, which, if the agent existed, could of course be rendered manifest by its effects; and they determined to become themselves the subjects of the first experiments. No inquiry was ever conducted in a more philosophical manner, or terminated in a more complete and unequivocal development of the nature of the subject. Great and extraordinary as the powers of this new agent seemed to be, the phenomena were proved to be referable solely to the imagination of the parties magnetised.

The commissioners submitted to be magnetised together, excluding all strangers, by M. Deslon, once a-week, for the space of two hours and a half. They were ranged round the *baquet*, encircled by the cord of communication, with an iron branch from the *baquet* resting upon the left hypochondre of each, and forming from time to time the communication of thumbs: they were magnetised by the fingers, or the metallic rod, being moved about and presented to different parts of the body, as well as by the pressure of hands on the pit of the stomach and sides of the belly. The most irritable and delicate of the commissioners were magnetised the most frequently, and for the longest time; but none of them experienced any effects or sensations, or at least any that could be ascribed to magnetism. Three of them were valetudinarians, and some of their usual uneasy feelings were excited partly by the fatigue, and partly by the strong pressure made on the stomach. They submitted to the experiment on three days successively; still without any effect. The quiet and silence of the eight commissioners, thus magnetised, without any uneasiness or any new sensation, formed the most perfect contrast with the noise, agitation, and disorder of the public magnetism: here was the magnet without any influence, and the operator despoiled of his power. They were warranted, therefore, in concluding, "that magnetism has no agency in a state of health, or even in a state of slight indisposition."

They resolved, then, to make their next trials of its influence upon persons actually diseased, and seven persons, of the lower class, were magnetised by M. Deslon, in the presence of the commissioners, at Dr Franklin's house. Two women, the one asthmatic, the other with a swelling on the thigh, and two children, the one six, and the other nine years of age, felt nothing, and remained unaffected. One man, with diseased eyes, felt a pain in the ball of one of them, which also discharged tears when the finger of the magnetiser was brought near it, and moved quickly about for a considerable time; but when the other eye, which was most diseased, was magnetised, he felt nothing. A nervous, hysterical woman, to whom the pressure of the abdomen was painful, and who had a *hernia*, said she felt a pain in the head when the finger was pointed near the rupture, and that she lost her breath when it was brought opposite the face. When the finger of the magnetiser was repeatedly moved up and down, she experienced some catchings of the muscles of the head and shoulders, like one surprised and afraid. The seventh patient, a man, suffered some effects of the same sort, but much less marked.

Four persons, two ladies and two gentlemen, of good education, and in bad health, were afterwards magnetised. Three of these underwent the operation several times, and felt nothing; but the fourth, a nervous lady, being magnetised during an hour and twenty minutes, generally by the application of the hands, was several times on the point of falling asleep, and felt some degree of agitation and uneasiness. On a subsequent occasion, a large company assembled at Dr Franklin's (who was confined by an illness) were all magnetised, including some patients of M. Deslon, who had accompanied him thither. There were present several Americans, one of whom, an officer, had an intermittent fever; yet no person experienced any effects except M. Deslon's patients, who felt the same sensations to which they had been accustomed at his public magnetising.

These experiments, then, furnished some important facts. Of fourteen invalids, five experienced some effects from the operation, but nine felt none whatever. All the effects observed in the nervous lady, however, might be occasioned by the irksomeness of the same posture for so long a time, and by her attention being strongly fixed upon her feelings: for it is frequently sufficient to think of these nervous attacks, or to hear them mentioned, in order to reproduce them when they are habitual. The three other instances occurred among persons of the *lower class*; and this circumstance was remarked with surprise by the commissioners, that the only effects which could be ascribed to magnetism manifested themselves in the poor and ignorant, while

those who were better able to observe and to describe their sensations felt nothing. At the same time, it was observed that *children*, although endowed with the peculiar sensibility of their age, likewise experienced no effect. The notion, that these effects might be explained by natural causes, therefore suggested itself to the commissioners: "If we figure to ourselves," they observe, "a poor, ignorant person, suffering from disease, and anxious to be relieved, brought before a large company, partly consisting of physicians, with some degree of preparation and ceremony, and subjected to a novel and mysterious treatment, the wonderful effects of which he is already persuaded that he is about to experience; and if, moreover, it is recollected that he is paid for his compliance, and supposes that the experimenters will be gratified in being told that he perceived certain operations, we shall have natural causes by which these effects may be explained, or at least very legitimate reasons for doubting that the real cause is magnetism."—(*Rapport des Commiss.* p. 30.)

Since the supposed effects of the *Animal Magnetism*, then, were not discoverable in those who were incredulous, there was great reason to suspect that the impressions which were produced were the result of a previous expectation of the mind, a mere effect of the *imagination*. The commissioners, therefore, now directed their experiments to a new point; namely, to determine how far the imagination could influence the sensations, and whether it could be the source of all the phenomena attributed to magnetism.

**GREECE.**—M. M. Saugny, Von Hammer, and other learned individuals, have resolved on making travels in Greece, for the purpose of geographical and historical discoveries. Their intention is fully to explore Eubœa, and other parts of Asia Minor, and more especially the shores of the Propontis.

**BALLS OF FROZEN MERCURY AND ALMOND OIL.**—On one occasion, during Captain Ross's late detention in the northern regions, some of the officers fired a ball of frozen mercury through an inch plank; and at another time, they froze oil of almonds in a shot mould, at a temperature of 40 degrees below zero, and discharged this new species of projectile against a target, which it split, rebounding unbroken.

**THE HEDGEHOG PROOF AGAINST POISONS.**—It has been said that the hedgehog is proof against poisons. M. Pallas states that it will eat a hundred cantharides, or Spanish flies, without receiving any injury. More recently, a German physician, who wished to dissect a hedgehog, gave it prussic acid, but the poison did not take effect; he then tried arsenic, opium, and corrosive sublimate, with the same results.

**HEALTH.**—Without health what are we? And yet how little do we care about it, till, by some unexpected stroke, the vision of perpetual vigour vanishes, the blessing has fled. In vain we then wish that we had adopted some of those plain, easy, and agreeable precautions, which an acquaintance with medicine and good common sense would have ensured.

**PERSIAN PHILOSOPHY!**—A meteoric stone fell near Bombay, 5th of November 1814, and an account of the phenomenon is given by the Persian philosopher, Syed Abdulla. After enumerating the number of stones found, he observes, "The causes of this may be, that in the course of working the ground, air being extricated, may have entered into combination and come near elemental fire, and from this fire had received a portion of heat. It may then have united with brimstone and terrene salt, as, for instance, saltpetre; when the mixture, from some cause, being ignited, the fire bestows its own property on the mass, and the stones which have been above it are blown into the air. God knows the truth."

**EXTINCT RACE OF MEN.**—Mr J. B. Pentland, in a paper read before the British Association at Edinburgh, 1834, states the reasons which have led him to conclude that there existed, at a comparatively recent period, a race of men very different from any of those now inhabiting our globe, characterised principally by the anomalous forms of the cranium, in which two-thirds of the entire weight of the cerebral mass is placed behind the occipital foramen, and in which the bones of the face are very much elongated. Mr Pentland entered into details to prove that this extraordinary form cannot be attributed to pressure or any external force similar to that still employed by many American tribes, and adduced, in confirmation of this view, the opinion of Cuvier, of Gall, and of many other celebrated naturalists and anatomists. The remains of this race are found in ancient tombs among the mountains of Peru and Bolivia, and principally in the great inter-alpine valley of Titicaca, and on the borders of the lake of the same name. These tombs present very remarkable architectural beauty, and appear not to date beyond seven or eight centuries before the present period.

The race of men to which these extraordinary remains belong, appears to Mr Pentland to have constituted the inhabitants of the elevated regions, situate between the 14th and 19th degrees of south latitude before the arrival of the present Indian population, which, in its physical characters, its customs, &c., offers many analogies with the Asiatic races of the Old World.

ZOOLOGY.

DESCRIPTION OF THE PLATE—THE SQUIRRELS.

ALL the animals of this tribe are light, nimble, and elegant, climbing trees with the utmost agility, and springing from branch to branch with astonishing security. They reside almost exclusively upon trees, where many of the species form their nests of moss and other soft substances. They subsist upon fruits and nuts of various kinds, which they instinctively store up for their winter's food, in the fissures of the trees, or in some other place of security.

Most of the Squirrels may be rendered perfectly tame and docile, with the utmost facility, owing to their natural gentleness of disposition, and the cheerfulness and contentment which they manifest in a state of captivity. They are playful and frolicsome, and become extremely attached to those whom they are accustomed to see. The progressive motions of the Squirrels, while on the ground, are performed by a succession of leaps. While eating they sit erect, and hold the food in their fore-paws. They are widely diffused over every quarter of the globe, with the exception of New South Wales.

Few animals of the order Rodentia, of which they are members, can be compared to the Squirrels, for the elegance of their form, the beauty of their fur, and the rapidity of their movements.

Modern Naturalists divide the Squirrels into three sub-genera, and a new genus, under the name of *Pteromys*. The first sub-genus consists of the true Tree Squirrels, which form a pretty extensive group, distinguished by the absence of the lateral folds of the skin which characterise the Flying Squirrels, now grouped under the generic name of *Pteromys*, and being devoid of the cheek pouches which are found in the *Tamias* or Ground Squirrels of America. Further, they are distinguished from the *Guerlinguets* by their tail being distichous throughout, whereas those of the latter sub-genus are round and distichous only at the extremity.

Fig. 1. The Malabar Squirrel (*Sciurus Maximus*) is perhaps the largest of its tribe, being from 8 to 9 inches in height, and from 15 to 16 inches in length, exclusive of the tail, which is somewhat longer than the body. It inhabits the coast of Malabar, and resides chiefly on palm trees; its food consists of various nuts, but particularly of cocoa-nuts, and the milky juice contained within them; both of which it is said they are remarkably fond.

Fig. 2. The Grey Squirrel (*S. Cinereus*), is a native of the United States of America. Though considerably inferior in size to the last species, it is still larger than all our European Squirrels.

This species associates in numerous bodies; it is particularly abundant in North and South Carolina, and also in Pennsylvania, where it feeds upon the young shoots of trees, buds, acorns, various nuts, and even descends to the fields and destroys grain. In summer it builds its nest on the extreme branches of the trees, and in winter retreats to the hollow of some decayed tree, in which it had previously laid up its winter store.

Fig. 3. The American Black Squirrel (*S. Niger*).—This squirrel has a pretty wide geographical range, having been found in the woody regions of Mexico, Florida, North and South Carolina, and Pennsylvania. It feeds on nuts like the rest of its congeners, and is said to be very destructive to crops of grain. Its flesh is considered a delicate food, and the animal is hunted on this account as well as for its fur, which is of a beautiful glossy black.

Fig. 4. The Chickaree (*S. Hudsonius*) is a native of those extensive white spruce forests which are so numerous in the fur countries of North America. It burrows only at the root of the largest trees, and generally forms four openings to its retreat for egress and ingress. Its principal food consists in the cones of the pine, under which its retreat is constructed; and it appears seldom to quit the same tree. Its skin is of little value, and has never formed an article of commerce. Its flesh is eaten by the natives, but that of the male has a strong murine flavour.

Fig. 5. The Plantain Squirrel (*S. Plantani*) is usually seven inches in length, although many of them are found not to exceed six and a half inches; the tail is somewhat longer than the body and head together. It is called the Bajjog by the natives of Java, in which island it is very abundant, both on the sea-coasts and in those districts of the interior which are but slightly elevated above the level of the ocean. It is often found on tamarind trees, and indeed on all fruit trees, but is notorious for the injury it occasions to the cocoa-nut tree. It is, consequently, hunted by the natives, as the preservation of the cocoa-nut in a great measure depends upon their being driven out of the district. The Javanese kill numbers, and suspend their skins about their dwellings as trophies. It is a very prolific animal.

Fig. 6. Javanese Squirrel (*S. Insignis*).—This is the *Bokhol* of the Javanese. Its height is three inches and a half; from one extremity to the other, exclusive of

the tail, it measures seven and a half inches; the tail is as long as the neck and body together. It is a very scarce animal in Java, and has only been met with in the extensive forests of Bambangan. It has also been discovered in Sunatra, but is rare on that island.

Fig. 7. The Two-coloured Squirrel (*S. Bicolor*).—This figure represents the animal in its common dress, in the eastern part of Java. On the continent of India, and in Cochin-China, it is found almost entirely black above, and a golden yellow below. It retires to the deepest forests, where its food consists of wild fruits of various kinds. It is not at all destructive to the cocoa-nut trees. The inhabitants occasionally feed on its flesh; and some of them keep it in a domesticated state.

Fig. 8. White-eared Squirrel (*S. Leucotis*).—This is another large-sized species, measuring twelve inches from the nose to the insertion of the tail, and the tail itself is thirteen inches. It is a native of Upper Canada, and is also found in the State of New York.

Fig. 9. Raffles' Squirrel (*S. Rafflesii*).—This beautiful and singularly-marked species was discovered by Sir Stamford Raffles, at Sumatra. Its length, exclusive of the tail, is eight inches; the tail itself, eight inches and a third; and its height at the shoulder, three inches and three quarters.

DESCRIPTION OF THE PLATE—THE ORIOLES.

ALL the birds which compose the genus *Oriolus*, as it is now restricted by Naturalists, inhabit Asia, Africa, or Europe; and the Orioles of America form another and a separate genus.

The plumage of the Orioles consists of two prevailing colours, namely, black and yellow. In most of the male birds, these are the only tints, but the females are frequently of a greenish cast above. The birds of this genus are said to be but partially gregarious, and to live in pairs in thickly wooded districts; previous to their migration, they are sometimes seen in very small flocks before leaving the districts in which they have bred. Their common food is fruits, berries, insects, and larvæ. They are very shy birds, and permit no one to approach.

The Orioles build their nests with great art; and generally place them in the fork of a small branch, from which the nests are suspended by their rims.

Fig. 1. The Javanese Oriole (*O. Leucogaster*).—This species has nothing to distinguish it from the true character of the genus *Oriolus*, in the shape of the body, or form of the bill and claws. In respect to size, it is somewhat smaller than the Asiatic variety of the Golden Oriole. This bird is of extremely limited distribution, being found only in a few circumscribed situations in the Island of Java, where it leads a solitary life. Dr Horsfield found it at Blitar, a district nearly covered with vast forests, the closest shades of which it seldom quits.

Fig. 2. The Golden Oriole, male (*O. Galbula*), and Fig. 3. Female.—This elegant bird is widely distributed, inhabiting Asia, Africa, and Europe. It breeds in the warmer parts of Europe, and solitary instances are recorded of pairs having been seen in Britain. Those which incubate in Europe invariably migrate, about September, to Asia or Africa, where they pass the winter. The song of the Golden Oriole is very sweet.

Fig. 4. The Kink Oriole (*O. Sinensis*) has been found in Cochin-China, and also in the woods of Senegal. These Orioles are said to be much devoted to their young. Like many other species, when in the act of incubation, their true character entirely forsakes them, and they will fly at any person who attempts to approach their nests.

Fig. 5. The Black-headed Oriole (*O. Melanocephalus*).—This species, by some authors, has been considered merely as a variety of the Golden Oriole; but in all those individuals which have come under our notice, we have observed that their bills were somewhat longer than those of the Golden Oriole. It inhabits Africa and Asia.

Fig. 6. The Two-coloured Oriole (*O. Bicolor*) inhabits South Africa, and is that described by Le Vaillant as the Condougnan. The female bird is represented in the plate.

The specimens from which we took the last five birds are in the superb collection of the Edinburgh University Royal Museum.

RECUNTY OF THE COD.—Three persons undertook to number the Roe in a very fine Cod. One of them took as much of the roe as weighed a drachm, and after having counted the eggs contained in it, passed it to the others, who did the same; and as the numbers all agreed, they wrote down the total of the whole drachm, after which they weighed all the mass of eggs, and repeated eight times the sum of one drachm for every ounce. The addition of all these sums produced a total of 9,344,000.

## ON THE HYBERNATION OF ANIMALS.—NO. I.

It is a remarkable fact, and one which has attracted considerable attention, that while many animals migrate to a more genial climate when the cold of winter approaches, others betake themselves to some hiding place, where they fall into a deep lethargy, in which they remain until the revival of spring. This state is usually designated by the term Hybernation, and is best marked among the Insects, the Mollusca, the Reptiles, and a few of the Mammalia. In all probability it occurs also in a considerable number of Fishes; indeed it seems absolutely necessary for the preservation of many of them during the winter, in cold climates, when the surface of the lakes is frozen over for months together. This state is apparently intimately connected with the preservation of the individuals subject to its influence, under circumstances where they would otherwise find it difficult or impossible to exist, and it has therefore received from Mangili the appropriate term of the Conservative Lethargy. According to Humboldt, a lethargic state similar to hybernation is also induced in some animals under the influence of a tropical heat.

The hybernating animals belonging to the class Mammalia resemble the other animals of that class in every other respect. They possess no uniformity of structure or appearance, by which we might be enabled, *a priori*, to predict that they would become lethargic when placed under certain circumstances. Some belong to the Carnassiers, as the Bats, the Hedgehog, and Tanrec; a greater number to the Rodentia, as the Marmot, the Hamster, and the different kinds of Dormice. They differ also from each other in the nature of their food. The Bats live on Insects; the Hedgehogs on Worms and Snails; and the Marmots, Hamsters, and Dormice, on nuts, roots, and herbs. Most of them are crepuscular or nocturnal feeders.

Prunelle denies that the Bear of the Alps can be properly said to hybernate. "No doubt," he says, "he lies in a drowsy state for days together, but he is never so lethargic as to allow the hunters to approach him. He also adds that tame Bears never become lethargic. It appears, however, from numerous and authentic sources of information, that the Bears of more northern regions pass the winter in a state of actual hybernation.

When an animal is examined in this state, it is found to be under the influence of a lethargy more or less deep, and with all its vital actions nearly at a stand. This lethargy only occurs within a certain range of temperature, apparently varying to a small extent in the different hybernating animals of the same country, but probably to a considerable extent in different, or in the same hybernating animals, of dissimilar countries. The *Dipus Sagitta* is said to become equally lethargic, during the winter months, in Egypt and in Siberia. The Tanrec (*Centetes ecoudatus*) is also said to remain lethargic for six months of the year in the climates of India and Madagascar, of which places it is a native.

To produce this state in a Marmot, the temperature must not be raised much above 50° Fah., and should not be carried below the freezing point. When the temperature is lowered beyond this, the animal becomes lively, its respirations and the pulsations of the heart increase in frequency, its animal heat rises, and it endeavours to escape or protect itself from the cold. If it should remain exposed for some time to this diminished temperature, it proves fatal in the same manner as in the other Mammalia, viz. by inducing coldness, torpor, and complete cessation of the heart's action, and other vital functions. This torpor, which precedes death in the hybernating animals when exposed to extreme cold, is quite a different thing from the conservative lethargy peculiar to them; and these must never be confounded in any discussions or experiments on this subject. The lethargy resembles a deep sleep, from which the animal may be roused in perfect health,—the other is the failure of the vital functions, which precedes death in every animal placed under similar circumstances. Those who compare this lethargy to the irresistible torpor which creeps over the human species when exposed to extreme cold, must entertain very erroneous notions concerning its nature. Mangili, on placing the fat Dormouse (*Myoxus glis*) in a temperature equal to 17° Fah., found that it struggled to escape; but when placed in a temperature of 48°, it became lethargic. He killed a Muscardin (*Mus*, or *Myoxus avellanarius*) in twenty minutes, by exposing it to a temperature equal to about 8° Fah. He also found, that when Bats were placed in a temperature one degree above the freezing point, they were lively for some time, then became torpid, stiffened, and died. Prunelle killed a Hedgehog (*Erinaceus Europæus*) by confining it in a temperature of about 5° Fah. for twenty-two hours. He also found that a Hedgehog was lively and fed in a temperature of 41° Fah., and was dormant when it rose to 50°. Marshall Hall states, that when Dormice are supplied with cotton or wool, they become sooner lethargic than those to whom this is denied. In fact, all the hybernating animals can easily be killed by their exposure to severe cold in this manner, and nothing appears more effectual in rousing them from their lethargy than its application, as the experiments of John Hunter long ago proved. In this manner we can easily explain the circumstance of the Bat having been occasionally seen flying about houses in the middle of winter. The place to which it had retired for the winter had not been sufficiently sheltered to prevent the temperature falling below what was compatible with the lethargic state; it had become roused, and had betaken itself to the wing to look out for a warmer retreat.

All the hybernating animals instinctively take precautions against the fatal consequences of severe cold. They either retire into caverns, into holes, or make nests for themselves. The Bats retire into caverns, hang suspended by their claws to the roofs in clusters, and cover each other with their wings. The Marmots (*Arctomys narmotta*) retire to their holes at the end of September, and reappear at the end of April. As several of them retire to the same hole, and as they stuff the mouths of these with grass and other materials, the temperature can never fall very low. Prunelle states that the temperature at the bottom of their holes is from 46° to 48° Fah. The Hedgehog and Dormice make warm nests for themselves at the approach of winter.

This lethargy is not generally so profound as many have been led to believe. Mangili states that the slightest disturbance of the animal sometimes causes signs of irritability. Prunelle and Marshall Hall have dwelt upon this as one of the principal difficulties in making accurate observations upon the functions of the circulation and

respiration in these animals, even while fairly under the influence of this lethargy. These signs of irritability are marked by muscular motion, increased respiration, pulsation, and animal heat. Prunelle also states that they can be roused by electricity, or by the fumes of ammonia applied to the nostrils. The stories told of dissecting these animals under a state of lethargy, without their exhibiting signs of sensation, must have been entirely a mistake; the authors of them must have confounded the state of torpor from extreme cold with that of lethargy.

This lethargy seems to vary in degree in different animals, and in different individuals of the same species. Mangili descended into the famous Grotto of Entrastico, in the month of December 1775, the temperature of the interior being about 53° Fah. He discharged a musket near 300 Bats, the *Vespertilio murinus* of Naturalists, without observing the slightest movement among them. He next discharged a loaded musket among them, and though many fell killed and wounded, those that remained untouched were perfectly quiescent. He returned into the same grotto in February 1804, the temperature of the interior being nearly the same as on the former occasion. Most of the Bats observed at this visit belonged to the *Vespertilio noctula*, which visits England during the summer, but retires to Italy to pass the winter in a lethargic state. The light of the torch, on this occasion, was sufficient to make some of them change their places. The same author preserved a Marmot for two years, which never became lethargic under all the different changes of temperature. M. Bossi kept two Marmots for two years, which were exposed for a time to a temperature from 18° to 20° Fah. without becoming lethargic.

Prunelle states, that having entered into the ancient aqueducts at Lyons and Vienne several times during the winter, he found, that while the greater number of Bats were in the lethargic state, some flew about as in the middle of summer. In the end of January 1807, he descended into a subterranean passage at Brunette, and found a great number of Bats collected upon the roof, in groups of from ten to twelve in number; others had placed themselves in holes, the greater part of them lethargic and cold as the stones upon which they rested; while others still flew about, but very feebly. The temperature of the place was 50° Fah.; the external air was nearly 39°; the temperature of the animals themselves was from 41° to 63°.

J. R.

EXTRAORDINARY!—The larvæ of a certain fly (*Eristalis tenax*, Meig) will admit of being pressed in a bookbinder's press, as broad and thin as a card, without being killed, when freed from its confinement and restored to its usual dwelling-place.—*Dr Hermann Bermeister's Manual of Entomology.*

## BOTANY AND HORTICULTURE.

## GENERAL REVIEW OF THE VEGETABLE KINGDOM.—NO. 1.

BY C. F. BRISSEAU MIRBEL, MEMBER OF THE INSTITUTE OF FRANCE.

[The following subjects will be treated of briefly in a series of articles, of which this is the first. 1. The laws which regulate the distribution of the different tribes of plants over the globe. 2. The influence which climate, elevation, aspect, and soil, have upon these beings. 3. The effect which plants, in their turn, produce on the exterior bed of soil, on the temperature from latitude or position, as well as on the general constitution of the atmosphere.]

MULTITUDES of different species of plants are found spread over the whole surface of the globe. Like animals, these are endowed with the faculty of increasing their races to infinity; and differ from each other as much by their interior structure as external appearance; each has its peculiar wants, and, if we may be allowed the terms, its separate habits and instinct.

We see that some species belong to the mountains, others to the valleys, and others to the plains; some affect a clayey soil, some a chalky one, others one of a quartzose nature, while many will thrive in no place but where the soil is impregnated with soda and muriatic salt. There are some that confine themselves entirely to water; dividing themselves again into those of the marsh, the lake, the river, and the ocean. Some require the hottest climates, others delight in mild and temperate ones, others thrive nowhere but in the midst of ice and frost. A large proportion must have a constantly humid atmosphere, several do very well in a dry air, but the major part are equally averse to the extremes of both dryness and moisture. There are those which flourish when exposed to the action of a strong light, while others prefer the weaker action of that element. The result of this variety of wants is, that nearly the whole surface of the earth is occupied by vegetation.

Excess of heat, cold, or drought, a total privation of air or light, are the only bars to vegetation; and yet we find some agamous species (such as are presumed to propagate themselves without the intervention of the organs of fructification) which grow in caverns where the light has never gained admission.

Seeing that the forms of vegetables are infinitely various, and that certain species, genera, and even tribes, are attached exclusively to particular countries; and that this distribution of races, a consequence of the first order of creation, has maintained itself to our day by the effect of climate and situation, without perceptible deviation,—it must be admitted that the soil takes one of its distinctive features from the vegetation it bears.

Some species are confined to the narrowest limits. The *Origanum Tournefortii*, discovered by Tournefort in 1700, in the little island of Amorgos, upon one rock only, was found 80 years afterwards by Sibthorp, on the same island and upon the same rock; but no one has ever observed it any where else. Two of the *Orchideæ*, *Disa longicornis*, and *Cymbidium tobulare*, grow upon the Table Mountain, at the Cape of Good Hope; and Thunberg, who has described them, found them on no other spot.

Mountainous countries afford many of these local species, such as dwell secluded on the heights without ever migrating to the plains below. Thus we find that the Pyrenees, the Alps, the Appenines, &c., have their peculiar Floras, and that even some separate mountains of those great chains have species allotted to them alone, and which are not to be found on the adjoining summits.

Speculatively, we might presume that all the individuals of one species would establish themselves under the same, or nearly the same, degrees of latitude, as they

would find a nearly similar climate. But, in reality, some species extend themselves in the direction of the longitude, and never swerve to the right or to the left. This is one of those anomalies of which it is not easy to trace the cause. The *Phalangium bicolor* begins to show itself in the country round Algiers; it crosses over to Spain, clears the Pyrenees, and terminates its career in Brittany. *Menziesia polifolia* belongs to Portugal, France, and Ireland. The heaths are confined exclusively to Europe and Africa; they extend themselves from the regions bordering on the Pole to the Cape of Good Hope, over a surface which is very narrow in proportion to its breadth. The *Ramonda pyrenaica*, as yet only found in the Pyrenees, follows, without deviating from its course, the valleys in those mountains which run from north to south, and so closely that not a single plant of it has been described in those which skirt the chain in the other direction. But we will now quit insulated facts, and turn our attention to vegetation in general.

It may be observed that, with the exception of the Lichens, which bid defiance to all climates alike, a vastly greater proportion of species is calculated to endure a very high degree of warmth, than is calculated to bear severe cold. The progressive course of the proportion demonstrates itself most clearly if we direct our view from the polar towards the equinoctial regions. Botanists compute that at Spitzberg, which lies near the 80th degree of northern latitude, there are only about 30 species; in Lapland, which lies in the 70th degree, about 534; in Iceland, in the 65th degree, about 553; in Sweden, which reaches from the southern parts of Lapland to the 55th degree, 1300; in Brandenburg, between the 52d and 54th degree, 2,000; in Piedmont, between the 43d and 46th degree, 2,800; nearly 4,000 in Jamaica, which is between the 17th and 19th degree; in Madagascar, situate between the 13th and 24th degree, under the tropic of Capricorn, more than 5,000. But such computations are very wide of the true proportion of species which belong to hot climates, as opposed in that respect to cold or temperate climates. To come at the real amount of the difference, we must first know the number of species spread over the whole globe; how many belong to the same space, under the same longitudes, at different latitudes; how many are common to several countries at the same time; how many belong exclusively to peculiar regions;—points that will require the lapse of ages for the Botanist to enable himself to resolve.

The general face of the vegetation of a country does not depend solely upon the number, it depends also upon the more or less remarkable characters of the species found there. The chief part of these characters are fixed, and are derived, as I have said before, from primitive creation, not from the effect of climate. As to the proposition, that certain vegetable forms are necessarily co-existent and dependent upon certain other animal forms in a given climate (an occult law of nature, of which some ingenious writers have endeavoured to find the proof, in those harmonies and contrasts which always result from the approximation of different beings), we do not presume to controvert it; but sound reasoning rejects its adoption as a doctrine, while the connection and reciprocal control of the phenomena of nature are unknown to us. Cautious and exact observers of those things which are the objects of our senses, let us leave to the fancy of the poet the bold task of unfolding the purposes of the Creator in his works, while we confine ourselves to the less presumptuous one of describing them as we find them.

Vegetation, within the tropics, fills the European traveller with amazement, by the majesty and vigour of its aspect. The proportion of the woody to the herbaceous species, is vastly more considerable towards the Equator than in Europe; and the difference is therefore in favor of the equinoctial regions, for trees give the character of grandeur to vegetation.

ON THE DURATION OF THE GERMINATIVE POWER OF THE SEEDS OF PLANTS.—The Society for the Improvement of Horticulture in Prussia, proposes from time to time certain questions, to which it directs the attention of Horticulturists. The following was proposed by the Society:—"Is it true that the seeds of the Melon and Cucumber, being preserved for some years, yield a greater abundance of fruit?" Most observers remark, that the plants obtained from the seeds of the preceding year produce many leaves, but few fruitful flowers, and almost entirely male ones; but that these same seeds, dried by the heat of the sun or of a stove, yield a greater number of fruitful plants, and that it is particularly at the end of some years that they acquire this property. These experiments vary from three to twenty years. The heat of the human body may be useful, but it must be used with discretion, or the germinating powers of the seeds will be destroyed.

The author of the preceding remarks made experiments of the same kind on balsams and gillyflowers. He sowed at the same time some seeds of the last, part of which were of the preceding year, others of some years previous. The first came up much sooner than the second, and gave only simple flowers; the others produced only sixteen out of several hundred plants.

M. Schmidt employs seed from five to twelve years old; those of twenty years do not grow. Professor Sprengel of Halle says, he obtained no fruit from seed a year old. M. d'Arenstorff, of Drebleau, obtained fruit, remarkable for flavour and size, from seed of twenty years old. The observations of Professor Treviranus, of Berlin, have afforded the same result. A vigorous vegetation induces, in numerous plants, male flowers in the greatest abundance, sometimes even exclusively. This has been proved as far as regards Cucumber seeds; but those which are too old produce an opposite result. He has seen seeds of five years old produce only female flowers; they were fecundated by male flowers of another bed, and yielded fruit.

M. Voss, head gardener at Sans Souci, sowed on the 17th February 1827, twenty-four seeds of a Spanish Melon of the year 1790, being consequently thirty years old, and he obtained eight plants which gave good fruit. This experiment, the most remarkable of all, will excuse our citing eleven others, which he made with seed of a less age, and of different species. Cucumber seeds of seventeen years afforded the same results. M. Voss adds, that some seeds of the *Athæa rosea*, of twenty-three years old, afforded very well-conditioned plants.

We admit, as incontestable, the above-mentioned observations. It is known that the seeds of different families retain for a greater or less time their germinative power. To cite only one example from among the Leguminous plants: About twenty-

six years since, we believe, fruit was obtained in the Royal Garden, from a species of *Phaseolus* or *Dolichos*, taken from the herbarium of Tournefort.

The Rev. Mr White makes the following observations on this subject:—"The naked part of the Hanger at Selborne," says he, "is now covered with thistles of various kinds. The seeds of these thistles may have lain probably under the thick shade of the beeches for many years, but could not vegetate till the sun and air were admitted. When old beech trees are cleared away, the naked ground in a year or two becomes covered with strawberry plants, the seeds of which must have lain in the ground for an age at least. One of the *slidders*, or trenches, down the middle of the Hanger, close covered over with lofty beeches, near a century old, is still called *strawberry-slitter*, though no strawberries have grown there in the memory of man. That sort of fruit did once, no doubt, abound there, and will again, when the obstruction is removed."

Sir Thomas Dick Lauder, Bart., made some curious and interesting experiments in 1817, on the germination of seeds, which we shall describe in his own words:—"A friend of mine possesses an estate in Morayshire, a great part of which lying along the Moray Frith, was, at some period not very well ascertained, but certainly not less than sixty years ago, covered with sand, which had been blown from the westward, and overwhelmed the cultivated fields, so that the agriculturist was forced to abandon them altogether. My friend, soon after his purchase of the estate, began the arduous, but judicious, operation of trenching down the land, and bringing to the surface the original black mould. These operations of improvement were so productive, as to induce the very intelligent and enterprising proprietor to undertake lately a still more laborious task, viz., to trench down the superincumbent sand on a part of the property, where it was no less than eight feet deep.

"Conceiving this to be a favourable opportunity for trying some experiments relative to the length of time which seeds preserve their power of vegetation, even when immersed in the soil, I procured from my friend a quantity of the mould, taken fresh from under the sand, and carefully avoiding any mixture of the latter. This was instantly put into a jar, which was stopped up close, by means of a piece of bladder tied tightly over its mouth. Having prepared a couple of flower-pot-slats, by drilling small holes in the bottoms of them, so as to admit of the ascent of water, I filled the slats with some of the mould, and placing them in a very wide and shallow tub, made on purpose, I covered each of them with a large glass receiver. Each receiver, however, was provided with a brass rim, having little brass nobs on it, so as to raise its edge from the bottom of the tub, and leave a small opening for the admission of air. The whole apparatus was placed in my library, of which the door and windows were kept constantly shut.

"This was done on the 17th February last. It is now the 6th of May; and, on examining the slats, I find about forty-six plants in them, apparently of four different kinds; but as they are yet very young, I cannot determine their species with any degree of accuracy."

Sir Thomas has since informed us, that the seeds which germinated were all highly oleaginous; and the plants produced were the mouse-ear (*Myosotis scorpioides*), scorpion grass (*Lanum purpureum*), purple archangel, and (*Spergula arvensis*), corn-spurrey. The earth thus experimented upon was taken from the lands of Invergie.

## GEOLOGY.

THE MUD VOLCANO OF GROBOGAN.—Having received an extraordinary account of a natural phenomenon in the plains of Grobogan, 50 pals or miles N.E. of Solo, a party, of which I was one, set off from Solo on the 8th of September to examine it.

On approaching the village of Kuhoo, we saw, between two trees in a plain, an appearance like the surf breaking over rocks, with a strong spray falling to leeward. The spot was completely surrounded by huts for the manufacture of salt, and at a distance looked like a large village. Alighting, we went to the Bludugs, as the Javanese call them. They are situate in the village of Kuhoo, and by Europeans are called by that name. We found them to be on an elevated plain of mud, about two miles in circumference, in the centre of which immense bodies of salt mud were thrown up to the height of from ten to fifteen feet, in the forms of large globes, which hursting, emitted volumes of dense white smoke. These large globes or bubbles, of which there were two, continued throwing up and bursting seven or eight times in a minute, by the watch. At times they threw up two or three tons of mud. We got to leeward of the smoke, and found it to smell like the washing of a gun barrel. As the globes hurst, they threw the mud out from the centre with a pretty loud noise, occasioned by the falling of the mud upon that which surrounded it, and of which the plain is composed. It was difficult and dangerous to approach the large globes or bubbles, as the ground was all a quagmire, except where the surface of the mud had become hardened by the sun. Upon this we approached cautiously to within fifty yards of the largest bubble or mud pudding, as it might very properly be called, for it was of the consistency of a custard pudding, and of very considerable diameter; here and there, where the foot accidentally rested on a spot not sufficiently hardened to bear, it sunk, to the no small distress of the walker.

We also got close to a small globe or bubble (the plain was full of them of different sizes), and observed it closely for some time. It appeared to heave and swell; and when the internal air had raised it to some height it burst, and the mud fell down in concentric circles, in which shape it remained quiet until a sufficient quantity of air was again formed internally to raise and burst another bubble. This continued at intervals, from about one half to two minutes. From various other parts of the quagmire, round the large globes or bubbles, there were occasionally small quantities of mud shot up like rockets, to the height of 20 or 30 feet, and accompanied by smoke. This was in parts where the mud was of too stiff a consistency to rise in globes or bubbles. The mud at all the places we came near was cold on the surface, but we were told it was warm beneath. The water which drains from the mud is collected by the Javanese, and by being exposed, in the hollows of split bamboos, to the rays of the sun, deposits crystals of salts. The salt thus made is reserved exclusively for the Emperor of Solo. In dry weather it yields 30 dudgins, of one hundred catties each, every month, but in wet or cloudy weather less.

In the afternoon we rode to a place in a forest, called Ramsam, to view a salt lake, a mud hillock, and various boiling, or rather bubbling pools. The lake was about half a mile in circumference, of a dirty-looking water, boiling up all over in gurgling bodies, but more particularly in the centre, which appeared like a strong spring; the water was quite cold, and tasted bitter, salt, and sour, and had an offensive smell. About 30 yards from the lake stood the mud hillock, which was about 15 feet high from the level of the earth. The diameter of its base was about 25 yards, and its top about eight feet, and in form an exact cone. The top is open, and the interior keeps constantly working and heaving up mud in globular forms, like the Bludugs. The hillock is entirely formed of mud which has flowed out of the top; every rise of the mud was accompanied by a rumbling noise from the bottom of the hillock, which was distinctly heard for some seconds before the bubbles burst. The outside of the hillock was quite firm. We stood on the edge of the opening and sounded it, and found it to be 11 fathoms deep. The mud was more liquid than the Bludugs, and no smoke was emitted from the lake, hillock, or pools.

Close to the foot of the hillock was a small pool of the same water as the lake, which appeared exactly like a pot of water boiling violently; it was shallow, except in the centre, into which we thrust a stick twelve feet long, but found no bottom. The hole not being perpendicular, we could not sound it with a line.

About 200 yards from the lake were several large pools or springs, two of which were eight and ten feet in diameter. They were like the small pool, but boiled more violently, and smelt excessively. The ground around them was hot to the feet, and the air which issued from them quite hot, so that it was most probably inflammable; but we did not ascertain this. We heard the boiling 30 yards before we came to the pools, resembling in noise a waterfall. The pools did not overflow; of course the bubbling was occasioned by the rising of air alone. The water of one of the pools appeared to contain a mixture of earth and lime, and, from the taste, to be combined with alkali. The water of the Bludugs and the lake is used medicinally by the Javanese, and cattle drinking of the water are poisoned.—*Extract of a letter from S. T. Goad, Esq. East India Company's Service, Java.—May, 1815.*

## GENERAL SCIENCE.

### MOUNTAINS AND VOLCANOS OF THE MOON.

We are less ignorant regarding the physical constitution of the moon than of any other heavenly body, in consequence of the smallness of its distance from us. By the assistance of the telescope we are able to observe the nature of those spots and shadows with which its surface is always marked. Some parts cast a shadow on the side farthest from the sun, and these must be mountains; others again throw their shadows on the side next to the sun, and hence are cavities. The appearance of these spots on the moon varies according to the position of the sun, as the shadows may be thrown in different directions, or they may be entirely destroyed by the sun being exactly vertical to them. Further, the shadows appear exactly in proportion to the length they ought to have, if we consider the inclination of the sun's rays to that part of the moon on which they appear. Thus we must conclude that the spots on the moon are mountains and valleys analogous to those on our own globe.

"The convex outline of the limb turned towards the sun is always circular and very nearly smooth," observes Sir J. F. W. Herschell; "but the opposite border of the enlightened part, which (were the moon a perfect sphere) ought to be an exact and sharply-defined ellipse, is always observed to be extremely ragged, and indented with deep recesses and prominent points. The mountains near this edge cast long black shadows, as they should evidently do, when we consider that the sun is in the act of rising or setting, to the parts of the moon so circumstanced. But as the enlightened edge advances beyond them, *i. e.* as the sun to them gains altitude, their shadows shorten; and at the full moon, when all the light falls in our line of sight, no shadows are seen on any part of her surface. From micrometrical measures of the lengths of the shadows of many of the more conspicuous mountains, taken under the most favorable circumstances, the heights of many of them have been calculated, the highest being about  $1\frac{3}{4}$  English miles in perpendicular altitude. The existence of such mountains is corroborated by their appearance, as small points or islands of light beyond the extreme edge of the enlightened part, which are their tops catching the sun-beams before the intermediate plain, and which, as the light advances, at length connect themselves with it, and appear as prominences from the general edge."

"The generality of the lunar mountains," continues the same accurate observer, "present a striking uniformity and singularity of aspect. They are wonderfully numerous, occupying by far the larger portion of the surface, and almost universally of an exactly circular or cup-shaped form, fore-shortened, however, into ellipses towards the limb; but the larger have, for the most part, flat bottoms within, from which rises centrally a small, steep, conical hill. They offer, in short, in the highest perfection, the true *volcanic* character, as it may be seen in the crater of Vesuvius, and in a map of the volcanic districts of the Campi Phlegreæ or the Puy de Dôme. And in some of the principal ones decided marks of volcanic stratification, arising from successive deposits of ejected matter, may be clearly traced with powerful telescopes. This I state from my own observations. What is, moreover, extremely singular in the geology of the Moon is, that although nothing having the character of seas can be traced (for the dusky spots which are commonly called seas, when closely examined, present appearances incompatible with the supposition of deep water), yet there are large regions perfectly level, and apparently of a decided affluvial character."

Sir William Herschell, in 1787, observed three volcanos in the moon; one of which, he says, was an actual eruption of fire or luminous matter. Captain Kater remarked, on the 4th February 1821, a luminous appearance in the dark part of the moon, represented at A.

This spot is believed to be identical with the mountain called Aristarchus. Hevelius called it Mons Porphyrites, and he considered it to be volcanic.

This volcano, as observed by Captain Kater, appeared like a small nebula, subtending an angle of about 3 or 4 seconds. Its brightness was very variable; a luminous point, like a small star of the sixth or seventh magnitude, would suddenly appear in its

centre, and as suddenly disappear, and these changes would sometimes take place in the course of a few seconds. On the evening of the 5th the same phenomena were observed as before, only in an inferior degree. It had become more faint on the 6th, and the star-like appearance less frequent; and on the 7th it was scarcely visible.

The existence of volcanos in the moon must therefore be considered as fairly established by observation. Independently of these observed facts, analogy would lead us to expect that the same laws which are found to regulate the internal constitution of our globe should also prevail in the other heavenly bodies.

## MISCELLANEOUS.

**HUMAN HORNS.**—Excrescences of a horny nature have been occasionally observed on the human head. A portrait of a woman with excrescences of this description is deposited in the British Museum, and one of the horns is, we believe, still preserved in the Museum at Oxford.

A far more recent instance, however, was observed by Dr Wm. Roots, of Kingston-upon-Thames, who, in February 1811, amputated an excrescence of this sort, exactly resembling a *ram's horn*, from the head of a man, between fifty and sixty years of age, a drawing of which, in its growing state, as well as the horn itself, were presented by him to the collection of Sir Astley Cooper.

The account given by Dr Roots of this extraordinary case is, that John Kennedy, a gardener at Thames-Ditton, in Surrey, in the year 1796, had a tumour growing on the superior part of the occiput, which was taken off with the knife by the Doctor's father in about three years from its commencement. Soon after its removal, a horny substance began to make its appearance on the same place, which continued growing for four years, till it accidentally fell off in a most unexpected manner, being at that time not more than three inches in length; and it should be observed, that the surface of the part it grew from, on its dropping off, was perfectly smooth, without the slightest hemorrhage, and resembling the superficies of the stag's head when his horns have recently dropped. In a short time afterwards, a new horny sprout shot forth, which, as it grew, took on the exact form and crooked figure of the *ram's horn*. Having increased during seven years, without any disposition to fall off, to the great inconvenience of the poor man, he consented at length to its removal; in the performance of which, from the parts underneath being very vascular, a considerable hemorrhage ensued.

It appears probable from this, says Dr Roots, that had the horn been suffered to remain longer on the head it would have attained a much larger size, as Nature, in a playful mood, had most abundantly supplied it with vessels for that purpose. Its having likewise been shed, in the former instance, *without bleeding*, induces Dr Roots to conclude, that as the sources of its nutriment continued open, it had not arrived at that state of perfection, when the gradual closing of the vessels would occasion spontaneous removal without any hemorrhage taking place, as is always observed to be the case with animals which drop their horns at regular and stated periods. It would appear that these horny excrescences, which are occasionally formed on the skin of the human subject, were originally encysted tumours, the cyst of which very curiously assumes the power of secreting horn instead of fat, a pappy substance, or a fluid like honey, as sometimes happens in particular cases. This case mentioned by Dr Roots tends to corroborate the above opinion, since, before any horn made its appearance, there was observed a tumour; and after the first horn dropped off, a surface, which was quite smooth, and did not bleed at all, presented itself to notice.

We may remark that the case of the human head assuming the power of secreting horn, is an example of that tendency, in the higher animals, to assume the characters of others lower than themselves in the scale of creation.

**THE ROGUE ELEPHANT** is a curiosity in Natural History. He is an individual completely banished from the herd, which will not suffer him to approach or mingle with them. No cause can be assigned for the fact; but this animal is always more savage and ferocious than any of the rest. He attacks man, and faces every danger which the others would avoid.

## DESCRIPTION OF THE PLATE—THE WHIDAH BUNTING.

FROM the remarkable characters of this section of Buntings, we have devoted a whole plate to the illustration of a single species (the *Emberiza Paradisea*), in its various states of plumage. This bird is an inhabitant of Africa, and is said to be plentiful in the neighbourhood of Fort Whidah, near Angola, whence it derives its name. It is very commonly designated the *Widow Bird*, being a corruption of its real appellation.

Like most of the feathered tribe, it undergoes two moults during the year; and when it has assumed its perfect garb, after each of these, presents appearances so very dissimilar, that it seems a totally distinct species. In its full summer dress it is adorned with four central tail feathers, which are both long and black, as exhibited at fig. 1. Its head and throat are also black; the sides of the neck are of a high orange brown. While in its winter attire it is denuded of these elegant appendages, and presents the more humble aspect of our common Corn Bunting. As the seasons in South Africa are opposite to those of Britain, the summer plumage of this bird appears during our winter, or about November and December; while its winter plumage appears during our summer, or in May and June. This bird appears to undergo an almost perpetual moult. After it has shed the long tail feathers, which usually takes place about the 6th December, it is something like fig. 3: but gradually changes till it assumes the Sparrow-like appearance of fig. 4; and finally acquires its winter plumage as seen at fig. 5. This is about the 20th of June in Britain. It remains but a very short time in this garb, when black feathers begin to sheet out in various places, and it soon acquires an appearance something like fig. 4. The moult continues; and the external appearance of the bird changes until it has assumed the dress as represented by fig. 3; shortly after which the long central tail feathers begin to appear, and it is seen, as in fig. 2, on or about the 1st of October. The central tail feathers increase in length until it has again acquired its full summer habit, as at fig. 1. Different as are the various appearances of the bird in the plate, it is subject to many more, during the transitions from one condition to another.

The bill undergoes considerable change, both in shape and colour, which are produced by exfoliation. It is deep blueish-black in summer, and pale lead-colour in winter.

The female Whidah Bunting, when young, has much the appearance of the male bird in its winter attire, but is considerably deeper in the tone of its plumage, which annually becomes darker till it arrives at mature age, which is said to be four years. It is represented at fig. 6.

Our figures of the male bird have been drawn from a living specimen which has been in the possession of Sir Patrick Walker of Drumsheugh since 1827. This specimen is supposed to have been two years old when he first procured it. Being a long-lived species, it has been known to survive in Europe to the age of sixteen years when in a captive state.

## DESCRIPTION OF THE PLATE—THE BEETLES.

THE Insects which compose the order *Coleoptera* are the most perfect of this class of beings, and are, therefore, placed at its head. A striking characteristic which prevails generally throughout the order is, that their lower wings are covered by a scaly sheath. There are, however, a few species which possess all the other characters, but are destitute of this protection to their under wings.

Coleopterous Insects are remarkable for the perfection of their organic structure, the singularity of their forms, and the splendour of their colouring. Many of them exhibit hues of the most brilliant metallic lustre, sparkling with all the varied tints of the rainbow. The order comprehends some of the largest species of Insects, while many of them are the most minute which have yet been discovered; the perfection of whose structure is well calculated to excite our highest admiration of that infinite skill and adaptation manifested in all the works of the creation. Is it not truly wonderful that beings invisible to the naked eye, and measuring only the ninetieth part of an inch, should possess as complicated a form as their congeners which measure six inches in length!

Fig. 1. The Fiery Beetle (*Onthophagus Igneus*) is remarkable for the brilliancy of its head and thorax, which assume a fiery appearance, contrasted with the dull black of its lower wing covers, or *elytra*. It is a native of India.

Fig. 2. The Kangaroo Beetle (*Scarabæus Macropus*).—There is something very singular in the conformation of this Beetle. Only one specimen has yet been discovered, and is said to be in the cabinet of Mr Macleay. It is supposed to have been brought from South America.

Fig. 3. The Atlas Beetle (*S. Atlas*).—This large and curious Insect is a native of Java, and is said also to occur on the continent of Asia.

Fig. 4. The Gigantic Beetle (*S. Tityus*), Male, and fig. 5, the Female.—It will be remarked that there is a considerable difference between the male and female of this species; the male is provided with two strong horns, while the female is destitute of them. It is a very rare species, and inhabits Carolina, Virginia, and other states of North America.

Fig. 6. The Hercules Beetle (*S. Hercules*).—This gigantic species inhabits the Antilles, where it is very plentiful; it is sometimes found in several of the other American islands.

Fig. 7. The Elephant Beetle (*S. Elephas*) may be justly ranked as one of the most beautiful and interesting of its tribe. It is a native of the West Indies.

Fig. 8. The Golden Beetle (*Chrysophora Chrysochlora*).—This species is nearly allied, in many particulars, to the Kangaroo Beetle, and was first discovered in Peru, by Baron Humboldt. It lives in societies.

Fig. 9. The Prodigal Beetle (*Rutela Sumptuosa*).—This is a beautiful Insect, and forms a fine addition to a genus whose colours are almost all of a sombre hue. It is a native of Brazil.

Fig. 10. The Shining Beetle (*R. Nitescens*), so named from the glossy appearance of its body, is a native of Brazil.

Fig. 11. The Clubbed Beetle (*Macraspis Clavata*).—This is the appearance presented by the Insect when in a living state, but when dead it assumes a much darker colour. It is a native of Brazil.

Fig. 12. The Goliath Beetle (*Goliathus Magnus*).—This superb beetle is a native of the West Coast of Africa, and only one specimen has hitherto been found, which is preserved in the Hunterian Museum of Glasgow.

Fig. 13. The Hieroglyphic Beetle (*Gymnetis Hieroglyphica*) is a native of Brazil.

Fig. 14. Macleay's Beetle (*Euchlora Macleayana*) is a very beautiful Insect, and a native of Madras.

Fig. 15. The Peruvian Beetle (*Chryseina Peruviana*).—This very handsome beetle has one remarkable peculiarity which distinguishes it from its congeners. The green colour, at least on its upper surface, is merely superficial, and may be removed by friction, when it exposes the black colour beneath.

A CURIOUS FACT CONCERNING BEES.—As a small vessel was proceeding up the Channel from the coast of Cornwall, and running near the land, some of the sailors observed a swarm of Bees on an island; they steered for it, landed, and took the bees on board, succeeded in hiving them immediately, and proceeded on their voyage. As they sailed along the shore, the Bees constantly flew from the vessel to the land to collect honey, and returned again to their moving hive; and this was continued all the way up the Channel.

FIRE FLY.—At Baltimore I first saw the Fire Fly. They begin to appear about sunset, after which they are sparkling in all directions. In some places ladies wear them in their hair, and the effect is said to be very brilliant. Mischievous boys will sometimes catch a bull-frog and fasten them all over him. They show to great advantage; while the poor frog, who cannot understand the "new lights" that are breaking upon him, affords amusement to his tormentors by hopping about in a state of desperation.—*Vigne's Six Months in America.*

ATTACK OF SPARROWS ON A MOUSE.—In the summer of 1831, one of the residents of the Temple, London, turned a Mouse loose in the open grand space, and the little intruder had no sooner made his appearance than he was simultaneously attacked by the Sparrows. So furious was their onset, that he was compelled to run in all directions. Endeavouring to escape their fury, he leaped up in great agony from the severe pecks with which he was assailed, and in a very few minutes a period was put to his existence.

UTILITY OF CROWS.—In a field near a gentleman's house, about a mile from Caernarvon, there are some out-buildings much infested with Rats. Four or five traps are set on the premises every night, and it is the business of a servant-man to go to the spot between five and six in the morning. He is always punctually met by a company of Crows that station themselves at a little distance, and most narrowly watch all his proceedings. No sooner does he remove his captives from the traps, and throw them into the field, than the carnival begins. The Crows seize upon their booty, scientifically perforate the integuments, and scoop out and devour every particle of flesh, even in the head. In a very short time the skins are turned inside out, and a few clean-picked bones are the only memorials of the banquet. In hard winters Crows suffer severely; they have been observed to fall down in the fields and on the roads, exhausted with cold and hunger. In one of these winters, a few years ago, during a long-continued deep snow, more than six hundred were shot on the carcass of a dead horse, which was placed in the stable-yard, the discharges being made through a hole in the stable. The Crow is easily domesticated; and it is only when placed on terms of

familiarity with man that the traits of his genius and native disposition fully develop themselves. In this state he soon learns to distinguish all the members of the family; flies towards the gate, screaming at the approach of a stranger; learns to open the door by alighting on the latch; and attends regularly at the hours of dinner and breakfast.

**DEATH FEIGNED BY A CORNCRAKE.**—Mr Ballard of Islington mentions a marked instance of a Corncrake feigning death, an instinct which that bird possesses in common with several other animals, and more particularly with certain insects. A gentleman had a Corncrake brought him by his dog, which was dead to all appearance. As it lay on the ground he turned it round with his foot; it showed no symptoms of life. Standing by, however, some time in silence, he suddenly saw it open one eye. He took it up, its head fell, its legs hung down, it appeared again to be quite dead. He attributed this to an involuntary muscular exertion, and put it into his pocket. It was not long before he felt it struggling to escape; he took it out, when it appeared as lifeless as before. He laid it on the ground, and retired to some distance to watch its motions; in about five minutes it warily raised its head, looked round, and decamped at full speed.

### BOTANY AND HORTICULTURE.

**AGE OF PLANTS.**—Some of the minute Fungi, commonly termed mould, live only a few hours, and seldom exist above a few days. The greater number of mosses exist only one season, which is also the case with all plants called Annuals. These die of old age immediately after their seeds have ripened. Those termed Biennials survive but for two seasons; although the lives of several of them are occasionally prolonged to three years, if their flowering be prevented.

On the other hand, some trees live for centuries. The Olive may live three hundred years; the Oak six hundred; a Chestnut is said to have existed nine hundred and fifty; the Dragon's-blood tree of Teneriffe two thousand; and we are informed by Adanson that Banians are conjectured to be six thousand years old.

When the wood of the interior of trees becomes so close in its texture that the passage of sap or pulp is prevented, or the formation of new vessels cannot be admitted, then it dies; and as all its moisture passes off into the younger wood, the fibres shrink, and are ultimately reduced into dust. The centre of the tree loses its vitality, while the outer parts continue to exist, and may thus live for many years before a total dissolution takes place.

**ON THE EFFECTS OF ELECTRICITY IN PLANTS.**—Colonel Capper observes, that "many experiments in electrifying plants have been made by M. Nuneberg and the Abbé Nollet; according to the former, most of them increased in height, and flourished far beyond those not electrified." Some bulbous roots, he says, which had been frequently electrified, grew 82 lines and a half; whilst others of the same species, not electrified, grew only in the same period 52 lines and two-thirds. But the report of Abbé Nollet is not so favorable; he found that the plants electrified by him, at first, made vigorous shoots, but he thought their perspiration being, by these means, too much increased, their juices might have been too quickly dissipated, in consequence of which the plants became gradually weak, and at length prematurely perished. We do not hesitate to yield due credit to both of these reports, although they seem in some measure incompatible with each other. They may have been made on various plants, at different seasons. M. Nuneberg, therefore, might have succeeded, although those of the Abbé in some measure failed. Besides, when administered by art, either to animal or vegetable bodies, the electricity may be given when the plants may already have the proper natural quantity; and, therefore, in some instances, it may be too strong; in others not strong enough, not sufficiently diffused; or it may not be applied to the proper part. The various modifications of electricity cannot well be comprehended excepting by those who profess considerable knowledge of the theory, and likewise the practice of it, so as to judge of its effects, not only in the atmosphere, but likewise on all animal and vegetable bodies; some of them may benefit by the aura or mild state of the fluid, and yet be injured by a spark, or even killed by a severe shock.

**HARMONIES OF COLOUR AND FORM IN PLANTS.**—Dr Castles remarks that "Nature, in the creation of the universe, has very beautifully modulated the influence of colour. To the firmament she has given a beautiful azure tint; to the earth itself a variety of shades, all more or less harmonizing with the blue on high, and the agreeable green of plants. If she had given to plants a yellowish hue, they would have been confounded with the sky and waters. In the first case, all would have appeared earth; in the second, all would have been sea; but their verdure forms the most delightful contrast between them and the grounds of the grand picture, as well as consonances highly agreeable with the yellow colour of the earth, and with the azure of the heavens."

In giving to vegetable productions a green shade, though only one single colour is employed, there are certain tints which appear to be given according to the situation or circumstances under which a plant may grow. Those that are destined to grow immediately on the earth, on strands, or on dusky rocks, are entirely green, leaves and stem, as the greater part of reeds, grasses, mosses, taper-trees, and aloes. Such, on the contrary, as are intended to issue from amidst herbage, have stems of a brownish hue, like the trunks of most trees and shrubs. The elder, for example, which thrives in the midst of green turf, has the stem of an ash-gray; but the dwarf elder, which otherwise resembles it in every respect, and grows immediately on the ground, has the stem quite green.

Not only the green of the plant is grown to harmonize with other objects, but even the flower and fruit have their shades apparently proportioned accordingly.

It seems correct that the blue colour is not to be found in the flowers, or in the fruits of lofty trees, for, in that case, they would assimilate with the sky; but is very common on the ground in the flowers of herbs, as in the corn-bottle, the scabiosa, the violet, the liver-wort, and others. On the contrary, the colour of the earth is very common in the fruits of lofty trees, as in those of the walnut, the cocoa, the pine, and many others.

In the form of flowers, the most perfect specimens of harmony might be selected which would faithfully show that, even in pleasing the sight, the greater object of utility is combined, if not increased.

This is very sweetly shown in the structure of compound flowers, particularly such as the sunflower and daisy. What would these flowers be in appearance without their radii? Yet are the radiated petals of the circumference, not only given to complete a pleasing harmony of light, to the tubular florets of the centre, but they answer an important purpose of moderating the influence of heat, &c. Thus is the double object of utility and beauty combined.

Another point, productive of some very pleasing deductions, is founded on the harmonies from contrast. Plants opposite in Nature are almost always associated.

Thus, round the faded trunks of trees, twines the creeping Ivy, or the great Convolvulus, compensating the apparent want of blossoms. The Fir rises in the forests of the north, like a lofty pyramid, of a dark green colour, and with motionless attitude. Near this tree you almost always find the Birch, which grows to the same height in the form of an inverted pyramid, of a lively green, and whose moveable foliage is incessantly playing with every breath of wind. The Reed, on the banks of rivers, raises erect into the air its radiated leaves and its embroidered stems, while the Nymphaea spreads at its feet its broad heart-shaped leaves, and its gold coloured flower; the dark blue violet is contrasted, in the spring, with the yellow tints of the cowslip and the primrose. On the herbiaged angles of the rock, the fungus, white and round, rises from amidst beds of moss of the most beautiful green.

### MINERALOGY.

**GOLD.**—This is one of the few metals only found native, and in this state, is easily recognized by colour, malleability, &c.; it is found crystallized, filamentous, and disseminated in rounded lumps of various sizes in alluvial soils.

Geologists consider gold as one of the most ancient of the metals, for it is invariably found in primitive rocks. Its gangue is quartz, calcareous spar, felspar, carbonate of lime, and sulphate of barytes. Africa and America are the richest countries in Gold. In Africa, it always occurs in the beds of rivers and in the alluvial soils of the plains, either in small grains, or in masses of different sizes. The principal tracts, rich in this precious metal, are in the western parts of Africa, to the south of the great desert of Zara, and between Darfur and Abyssinia; and the sands of the Gambia, Niger, and Senegal, are all auriferous; it is supposed that Ophir, whence Solomon obtained Gold, was a country on the south-east coast; and Herodotus relates, that when the messengers of Cambyses waited upon the king of Æthiopia, they were shown the prisoners bound in chains of gold. As this metal is found in a ductile, tenacious, and workable state, it is almost the only one employed by savage nations, and various ornaments and utensils are frequently made of it. These untutored tribes have always regarded the eagerness of their European invaders to obtain it with the utmost astonishment; of this the history of America furnishes us with many curious instances. In one of the early incursions into the interior of that continent, the Spaniards contested with such eagerness about the division of some Gold, that they were on the point of proceeding to acts of mutual violence, when a young Casique, who was present, tumbled it out of the balance with indignation, and turning to the invaders, "Why," said he, "do you quarrel about such a trifle—if it be for Gold that you abandon the regions of your fathers, and disturb the peaceful tranquillity of these distant nations, I will conduct you to a region abundant in this mean object of your admiration and desire." The thirst for Gold was the principal incentive to the almost more than human enterprises performed by the followers of Columbus. Animated by the certain prospect of gain, they pursued discovery with greater eagerness than when excited only by curiosity and hope. The riches of Peru, Mexico, and Brazil, are well known, and the Gold is there principally found in the beds of rivers, although veins have been successfully worked.

Asia cannot at present be deemed rich in Gold, although it has been found in Ceylon, Berne, Sumatra, and some of the Archipelago islands. Of the abundance of Gold which once enriched the Pactolus we now know nothing.

Nor can Europe boast of Golden treasures. According to Diodorus Siculus, and Pliney, the Phœnicians and Romans procured considerable quantities of Gold from Spain. The poets too found it in the sands of the Tagus. In France it has been found in the department of the Isere; in the Rhone, at its junction with the Araw; in the Rhine near Strasbourg and Germersheim, but neither above nor below it; and in the Garonne near Toulouse. In Piedmont, in the vallies at the foot of Mount Rosa, and of the Simplon; and also in the small streams that intersect the red alluvion, about Chivasso. The only important Gold mines of Europe are those of Hungary.

The metallurgic processes for obtaining Gold from its ores are sufficiently simple. They are broken in the stamping mill and washed, by which the lighter and earthy parts are separated; they are then submitted to the action of mercury, which dissolves the Gold, and this metal is afterwards obtained by distillation.—*Brande*.

### GEOLOGY AND PHYSICAL GEOGRAPHY.

**FILLING UP OF LAKE SUPERIOR.**—This mighty Lake is the largest body of fresh water in the known world; its length is 480 miles, its breadth 161, its circumference about 1100 miles, and its depth 900 fathoms. Its waters are remarkable for their unrivalled transparency. About 1000 streams empty themselves into this lake, sweeping in sand, primitive boulder-stones, and drift timber, which sometimes accumulate so as to form islands in the estuaries. A lignite formation, indeed, is said to be now in progress similar to that of Bovey, in Devonshire. Within a mile from the shore the water is about 70 fathoms; within eight miles, 136 fathoms. From the above causes the lake is gradually filling up.

**LAKE ERIE,** from similar causes, is also filling up. This sheet of water is 270 miles in length, 60 in breadth, and 200 fathoms in depth. It is gradually becoming shallower. Long Point, for example, has, in three years, gained no less than three miles on the water. On its southern shore serious encroachments have been made in

many places. For a considerable distance above the mouth of Black River the bank of the lake is low and without rock. Thirteen years ago the bank was generally sloping, with a wide beach; now the waves beat against a perpendicular bank, which, from continual abrasion, often falls off. From one to three rods in width are worn away annually.

**HOT AND COLD SPRINGS.**—In the Blue Mountains, about 37 miles from Batavia, in the Island of Java, there is a spring of water, so hot, that few persons can bear immersion in it; within little more than two feet of this almost boiling cauldron another spring arises, so cold, that it almost instantly benumbs those who attempt to use it. Those waters overflowing, join in a current, and supply a bath formed by the natives, of such a temperature as to be delightful at all seasons of the year.

### GENERAL SCIENCE.

**FIXED STARS.**—Dr Brinkley, Bishop of Cloyne, has found, by computation, that the star Lyra has a parallax of  $1''.1$ ; or, what is the same thing, that the radius of the earth's annual orbit would, if seen from that star, subtend an angle of  $1''.1$ ; hence it follows that its distance is 20,153,665,000,000 miles, or 20 billions of miles. Sir William Herschel, from repeated measurements, considered the diameter of this star as three-tenths of a second; and, consequently, its diameter must be 3000 times greater than that of the sun, 2,659,000,000 miles, or three-fourths of the size of the whole Solar System, as circumscribed by the Georgium Sidus. It has, however, been thought probable, by many eminent Astronomers, that this apparent parallax is due only to the defects of the instruments employed; and we are inclined to attach much importance to this opinion, especially as we find that the amount of this observable parallax has always diminished with the improvements of the instruments.

Under any circumstances, the distance of the Fixed Stars must be enormous. Such is the amazing remoteness, even of the nearest Fixed Star, that its light would take three years in travelling to the earth; and light is computed to travel 195,072 English miles in a second. If the nearest of these Stars be at such an immense distance from us, what must be that of the smaller Stars? Astronomers conceive it possible that there may be Stars so remote, that the beams of their light may not have reached us since the creation; and others, that have been destroyed for many centuries, will continue to shine in the heavens till the last ray which they emitted shall have reached our earth.

### MISCELLANEOUS.

#### PORCUPINE MEN.

IN the year 1731, Mr John Machin introduced to the notice of the Royal Society of London a boy, about fourteen years of age, the son of a country labourer residing in the neighbourhood of Euston Hall, in the county of Suffolk, exhibiting those singular characters peculiar to that rare variety of the human race commonly called Porcupine Men.

Instead of a skin, his body was enveloped in a dusky-coloured case, resembling a rugged bark or hide, with bristles in some places. This case fitted every part of his body excepting his face, the soles of the feet, and the palms of the hands. His body thus presented the appearance of being partially clothed. It would have been difficult to mention any other integument which resembled it exactly. Some persons considered it to be like one large wart, or number of warts uniting and spreading over the whole body. Others thought it like the hide of the Elephant, or the skin around the legs of the Rhinoceros; while others again compared it to Seal-skin, or to the bark of a tree. The bristly parts, which were chiefly near the abdomen, and on the sides of the body, made a rustling noise when he moved like the quills of a Hedgehog, and seemed as if shorn within an inch of the skin. The following is a representation of a portion of this extraordinary epidermis, which was probably nothing more than a prolongation of the nervous papillae, grown to the size of common pack thread. These stood as close together as the bristles in a brush—and seemed, like them, to be all shorn off of the same length, being about half an inch above the skin, as in fig. 1. When magnified, these stumps or bristles appeared of various forms; some were concave, others were flat on the top, and others again were of a conical form, as in fig. 2.

This skin was callous and insensible to external injury in every part. But one very remarkable circumstance attending it was, that in every year about autumn it usually grew to the thickness of three quarters of an inch, and was then thrust off and shed by a new skin, which came up beneath the former. This rugged covering gave the boy no pain or uneasiness, except after hard labour it was apt to cleave and start, so as to cause slight bleeding. His face was well featured and of a good complexion, if not rather too ruddy, while the palms of his hands were not harder or in a worse condition than is usual to workmen or labourers. His size was proportioned to his age—his body and limbs were straight, and otherwise well shaped—and there was nothing unusual either in his habits or disposition.

1

2

His father reported that, at birth, the skin of this boy resembled that of other children, and continued so for seven or eight weeks; when, without any apparent cause, and without his being even sick, it began to turn yellow, as if he had had the jaundice: that it afterwards changed gradually into black, then thickened, and finally appeared as we have already described.

When this boy grew up, he gained a subsistence by exhibiting himself publicly as "the Porcupine Man," along with a son of his, also in the same condition. His name was Edward Lambert, and at the age of forty years he was thus described by

Mr Henry Baker:—"He is a good-looking, well-shaped man, of a florid countenance—and, when his body and hands are covered, seems nothing different from other people; but, except his head and face, the palms of his hands, and the soles of his feet, his skin was covered in the same manner as in the year 1731. This covering seems to me most nearly to resemble an innumerable company of warts, of a dark brown colour, and a cylindrical figure rising to a like height, and growing as close as possible to one another, but so stiff and elastic, that when the hand is drawn over them they make a rustling noise.

"When I saw this man, in the month of September last, they were shedding off in several places, and young ones of a paler brown succeeding in their room, which he told me happens annually in some of the autumn or winter months; and then he commonly is let blood, to prevent some little sickness which he else is subject to whilst they are falling off. At other times he is incommoded by them no otherwise than by fretting out his linen, which, he says, they do very quickly; and when they come to their full growth, being then in many places near an inch in height, the pressure of his clothes is troublesome.

"He has had the small-pox, and been twice salivated, in hopes of getting rid of this disagreeable covering; during which disorders the warting came off, and his skin appeared white and smooth, like that of other people; but, on his recovery, soon became as it was before. His health at other times has been very good during his whole life.

"But the most extraordinary circumstance of this man's story, and indeed the only reason of my giving you this trouble, is, that he has had six children all with the same rugged covering as himself; the first appearance whereof in them, as well as in him, came on in about nine weeks after his birth. Only one of them is now living, a very pretty boy, and who is exactly in the same condition, which it is needless to repeat. He also has had the small-pox, and during that time was free from this disorder."

The annexed wood-cut exhibits the hand of this boy in such a manner as to show the palm free from these excrescences, and its other parts covered with them.

"It appears, therefore, past all doubt," continues Mr Baker, "that a race of people may be propagated by this man, having such rugged coats or coverings as himself: and, if this should ever happen, and the accidental original be forgotten, it is not improbable they might be deemed a different species of mankind; a consideration which would almost lead one to imagine, that if mankind were all produced from one and the same stock, the black skin of the Negroes, and many other differences of the like kind, might possibly have been originally owing to some such accidental cause."

This young man afterwards married, and had two sons in all respects resembling himself, as well as their grandfather. They went over to Germany in 1801, where they exhibited themselves. Dr Blumenbach, who saw them, says that the palms of their hands and soles of their feet were of the usual appearance, but seemed to him rather red.

Dr Autenrieth (who endeavours to trace an analogy between these men and negroes, and even suspects them to be of African origin), rather thinks that the soles of the feet, of both brothers, are plain and flat, as we see them in children and adult negroes. The skin of the remaining parts of the body was covered with corneous excrescences, or pegs of greater or less size, differing in their horny consistence. The longest, strongest, and hardest, were on the fore-arm and thighs; the thinnest were on some parts of the abdomen. Those of the younger brother were in general smaller, and in several places the skin was soft, and comparable to black coarse morocco leather. The largest were from four to five lines long, and of an irregular prismatic form, with blunt edges; most of them seemed as if pressed flat. The thickest of them were

about three lines in diameter at their extremities, either split or diverging like a fork. As to the cylindrical figure ascribed to them by Baker (who, besides, supposed them to be hollow), Dr Blumenbach scarcely observed one of that form.

Dr Telesius observed that these men look quite different in autumn from what they do at other seasons, because they then lose their outer skin, or oldest crust, and appeared spotted.

On examining the fragments, he found that those which he had broken off were softer to the touch than those which had fallen off spontaneously; probably on account of their being under the immediate influence of the exhaling vessels and the sebaceous glands. Where the excrescences were longest and thickest, they appeared to Dr Blumenbach to be like those of the Elephant, under the forehead and above the proboscis; their colour, in general, appeared of a chestnut or coffee-brown. This, however, was the case at their surface only; for the inferior parts, especially of the largest ones, were of a yellowish-gray. Some of the hair of the skin appeared as if grown into the horny substance of the excrescences. The skin on the top of the head before, especially in the eldest, formed a kind of broad callosity, somewhat like the top of the Camel. As for the perspiration of these men, it had nothing uncommon connected with it, nor any perceptible odour.

Of cases really analogous to that of the Porcupine Man, Dr Blumenbach mentions other two which came under his notice; the one was of the boy of Bifeglia, of whom Stalp Vanderwiel has given a description and figure in his Observations; the other, a female child at Vienna, described by Professor Brambilla, in his Memoirs of the Jos. Med. Chirurg. Academy. In both the face was free from any excrescences, but the palms of the hands and soles of the feet were most defaced by them.

#### CARGUEROES, OR MAN-CARRIERS OF QUINDIU.

THE mountain of Quindiu is considered as the most difficult passage in the Cordilleras of the Andes. It is a thick uninhabited forest, which, in the finest season, cannot be traversed in less than ten or twelve days. Not even a hut is to be seen, nor can any means of subsistence be found.

Travellers, at all times of the year, furnish themselves with a month's provision, since it often happens, that by the melting of the snows, and the sudden swell of the torrents, they find themselves so circumstanced, that they can descend neither on the side of Carthago, nor on that of Ibague. The highest point of the road, the Garito del Paramo, is three thousand five hundred and five metres (11,500 feet) above the level of the sea. As the foot of the mountain, towards the banks of the Cauca, is only nine hundred and sixty metres (3,150 feet high), the climate there is in general mild and temperate. The pathway which forms the passage of the Cordilleras is only three or four decimetres in breadth (from a foot to a foot and a half), and has the appearance, in several places, of a gallery dug, and left open to the sky. In this part of the Andes, as almost in every other, the rock is covered with a thick stratum of clay. The streamlets, which flow down the mountains, have hollowed out gullies, six or seven metres deep (from 20 to 23 feet). Along these crevices, which are full of mud, the traveller is forced to grope his passage, the darkness of which is increased by the thick vegetation that covers the opening above. The oxen, which are the beasts of burden commonly made use of in this country, can scarcely force their way through these galleries, some of which are two thousand metres (2,200 yards) in length; and if, perchance, the traveller meets them in one of these passages, he finds no means of avoiding them but by turning back, and climbing the earthen wall which borders the crevice, and keeping himself suspended, by laying hold of the roots which penetrate to this depth from the surface of the ground.

We traversed the mountain of Quindiu in the month of October 1801, on foot, followed by twelve oxen, which carried our collections and instruments, amidst a deluge of rain, to which we were exposed during the last three or four days, in our descent on the western side of the Cordilleras. The road passes through a country full of bogs, and covered with bamboos. Our shoes were so torn by the prickles, which shoot out from the roots of these gigantic Gramina, that we were forced, like all other travellers who dislike being carried on men's backs, to go barefooted. This circumstance, the continual humidity, the length of the passage, the muscular force required to tread in a thick and muddy clay, the necessity of fording deep torrents of icy water, render this journey extremely fatiguing; but however painful, it is accompanied by none of those dangers with which the credulity of the people alarm travellers. The road is narrow, but the places where it skirts precipices are very rare. As the oxen are accustomed to put their feet in the same tracks, they form small furrows across the road, separated from each other by narrow ridges of earth. In very rainy seasons these ridges are covered with water, which renders the traveller's step doubly uncertain, since he knows not whether he places his foot on the ridge or in the furrow. As few persons in easy circumstances travel on foot in these climates, through roads so difficult, during fifteen or twenty days together, they are carried by men in a chair tied on their back; for, in the present state of the passage of Quindiu, it would be impossible to go on mules. They talk in this country of going on a man's back (*andar en carguero*), as we mention going on horseback, no humiliating idea is annexed to the trade of cargueros; and the men who follow this occupation are not Indians but Mulattoes, and sometimes even whites. It is often curious to hear these men, with scarcely any covering, and following a profession which we should consider so disgraceful, quarrelling in the midst of the forest because one has refused the other, who pretends to have a whiter skin, the pompous title of *don*, or *of su merced*. The usual load of a carguero is six or seven arrobas (about 180 lbs.); these who are very strong carry as much as nine arrobas (about 250 lbs.). When we reflect on the enormous fatigue to which these miserable men are exposed, journeying eight or nine hours a day over a mountainous country; when we know that their backs are sometimes as raw as those of beasts of burden, and that travellers have often the cruelty to leave them in the forest when they are sick; that they earn by a journey from Ibague to Carthago only twelve or fourteen piastres (from L.2, 10s. to L.3), in a space of fifteen, and sometimes even twenty-five or thirty days, we are at a loss to conceive how this employment of a carguero, one of the most painful which can be undertaken by man, is eagerly embraced by all the

robust young men who live at the foot of the mountains. The taste for a wandering and vagabond life, the idea of a certain independence amidst forests, leads them to prefer this employment to the sedentary and monotonous labour of cities.

The passage of the mountain of Quindiu is not the only part of South America which is traversed on the backs of men. The whole of the province of Antioquia is surrounded by mountains so difficult to pass, that they who dislike entrusting themselves to the skill of a carrier, and who are not strong enough to travel on foot from Santa Fé de Antioquia to Becca de Nares or Rio Samana, must relinquish all thoughts of leaving the country. I was acquainted with an inhabitant of this province, so immensely bulky, that he had not met with more than two Mulattoes capable of carrying him; and it would have been impossible for him to return home if these two carriers had died, while he was on the banks of the Magdalena, at Mompox or Honda. The number of young men who undertake the employment of beasts of burden at Choco, Ibague, and Medellin, is so considerable, that we sometimes met a file of fifty or sixty. A few years ago, when a project was formed to make the passage from Nares to Antioquia passable for mules, the cargueros presented formal remonstrances against mending the road, and the government was weak enough to yield to their clamours. We may here observe, that a class of men near the mines of Mexico, have no other employment than that of carrying other men on their backs. In these climates the indolence of the whites is so great, that every director of a mine has one or two Indians at his service, who are called his horses (*cavallitos*), because they are saddled every morning, and supported by a small cane, and, bending forwards, they carry their master from one part of the mine to another. Among the *cavallitos* or cargueros, those who have a sure foot and easy step are known and recommended to travellers. It is distressing to hear the qualities of man spoken of in terms by which we are accustomed to denote the gait of mules and horses. The persons who are carried in a chair by a carguero must remain several hours motionless and leaning backwards; the least motion is sufficient to throw down the carrier; and his fall would be so much the more dangerous, as the carguero, too confident in his skill, chooses the most rapid declivities, or crosses a torrent on a narrow and slippery trunk of a tree. These accidents are, however, rare, and those which happen must be attributed to the imprudence of travellers, who, frightened at a false step of the carguero, leap down from their chairs.

When the cargueros reach Ibague and prepare for their journey, they pluck in the neighbouring mountains several hundred leaves of the *Vijao*, a plant of the family of the Bananas, which forms a genus approaching the *Thalia*, and which must not be confounded with the *Heliconia bilai*. These leaves, which are membranaceous and silky, like those of the *Musa*, are of an oval form, fifty-four centimetres (twenty inches) long, and thirty-seven centimetres (fourteen inches) in breadth. Their lower surface is a silvery white, and covered with a farinaceous substance which falls off in scales. This peculiar varnish enables them to resist the rain during a long time. In gathering these leaves, an incision is made in the middle rib, which is the continuation of the footstalk, and this serves as a hook to suspend them when the moveable roof is formed. On taking it down, they are spread out and carefully rolled up in a cylindrical bundle. It requires about a hundred weight of leaves (50 kilogrammes) to cover a hut large enough to hold six or eight persons. When the travellers reach a spot in the midst of the forest, where the ground is dry, and where they propose to pass the night, the cargueros lop a few branches from the trees, with which they make a tent. In a few minutes the slight timber work is divided by the stalks of some climbing plant, or threads of the *Agave*, placed in parallel lines, three or four decimetres from each other. The *Vijao* leaves meanwhile have been unrolled, and are now spread over the above work, so as to cover each other like tiles of a house. These huts thus hastily built, are cool and commodious. If during the night the traveller feels the rain, he points out the spot where it enters, and a single leaf is sufficient to obviate the inconvenience. We passed several days in the valley of Boquia under one of these leafy tents, which was perfectly dry amidst violent and incessant rains. The mountain of Quindiu is one of the richest spots in useful and interesting plants. Here we found the Palm Tree (*Ceroaylon andicola*), the trunk of which is covered with a vegetable wax, the *Passiflora* in trees, and the majestic *Mutisia grandiflora*, with flowers of a scarlet colour, sixteen centimetres, or six inches long.—*Humboldt*.

THE SLEEPING LASSIE OF DUNNINALD.—Margaret Lyall, aged 21, daughter of John Lyall, labourer at Dunninald, near Montrose, was first seized with a sleeping fit on the 27th June 1815; next morning she was again found in a deep sleep. In this state she remained for seven days, without motion or food; but at the end of this time, by the moving of her left hand, and by plucking at the coverlet of the bed and pointing to her mouth, a wish for food being understood, it was given her. This she took, but still remained in her lethargic state till Tuesday the 8th of August, being six weeks from the time she was seized with the lethargy, without appearing to be awake, except on the afternoon of Friday the 30th June. For the first two weeks her pulse was generally about 50, the third week about 60, and previous to her recovery at 70 to 72. Though extremely feeble for some days after her recovery, she gained strength so rapidly, that before the end of August she began to work at the harvest on the lands of Mr Arkley, and continued, without inconvenience, to perform her labour. This account was drawn up by the Rev. James Brewster, Minister of Craig.

ZOOLOGY.

DESCRIPTION OF THE PLATE—DOGS.

THE Dog has been the companion of Man from the earliest state of society; but the period when he was first domesticated, and the stock from which he was produced, are hidden by the cloud of antiquity. Innumerable attempts have been made to trace his origin, but these have resolved themselves into mere conjectures. The fidelity, caution, and perseverance of the Dog, have secured to him the friendship of Man, in all ages and in every country; and by his aid we are enabled to acquire the most necessary and certain means of conquest and dominion over all other creatures. His exquisite sense of smell enables him to pursue steadily, and with unerring certainty, all other beasts; their artifices and speed are unavailing; for by the strength and perseverance of combined numbers, he overtakes, overcomes, and destroys them.

It is almost universally believed that all Dogs are merely varieties of one species only; and many persons imagine the Shepherd's Dog to be the parent stock, whence all these varieties have sprung. Buffon, and more recently Dr Richardson, conceive that Dogs have been propagated from more than one common stock; that they have sprung from Wolves, Jackals, and other congenerous species. This opinion was also entertained by Desmoulins, who, in an ingenious paper in the "Memoirs of the Museum of Natural History of Paris," adduces a number of striking facts in illustration of his hypothesis. Dr Knox, during his residence in Africa, remarked that all the native Dogs in the neighbourhood of the Cape, bore the same general resemblance to the Hyæna that those of northern countries bear to the Wolf.

As we shall enter more deeply into this subject in the Animal Kingdom, it will be unnecessary to pursue it further at present, but proceed to a description of the Dogs figured in the accompanying plate.

Fig. 1. SPANISH POINTERS.—This breed, as its name implies, was introduced from Spain at an early period, and was long the chief companion of Sportsmen while in pursuit of game birds. It is one of the most steady Dogs used in field sports, and remarkable for the facility with which it can be trained to set all kinds of game. Indeed, it not unfrequently happens that puppies, when taken to the fields, instinctively set game when they have come upon the scent of them for the first time. In more recent times this Dog, however, has got into disuse, as its weight renders it too unwieldy for grouse shooting.

The beautiful Dogs from which our representations are taken, were a brace belonging to the late celebrated sportsman, Colonel Thornton; and as a proof of the steadiness and perseverance of both, they kept their point for upwards of an hour and a quarter, during the time that Mr Gilpin was engaged in sketching them.

Fig. 2. THE ENGLISH POINTER.—This Dog is sprung from the Spanish Pointer and Fox-hound, re-crossed with the Harrier; he is much lighter in his form, and more rapid in his movements, than the Spanish Pointer. They have been produced of great variety in point of size, according to the tastes of sportsmen. It has, however, been found, that as they diverge from their Spanish progenitor, the difficulty of training them, and rendering them stanch for the field, increases in proportion to the remoteness of their lineage. The following is a beautiful instance of stanchness in a Pointer, and was communicated to us by James Webster, Esq. of Lively Bank, Forfarshire. In 1829, that gentleman was out on a shooting party, near Dundee, when a female Pointer, having traversed the field which the sportsmen were then in, proceeded to a wall, and, just as she made the leap, got the scent of some partridges on the opposite side of the wall. She hung by her fore-feet until the sportsmen came up; in which situation, while they were at some distance, it appeared to them that she had got her leg fastened among the stones of the wall, and was unable to extricate herself. But, on coming up to her, they found that this singular circumstance proceeded from her caution, lest she should flush the birds, and thus suspended herself in place of completing her leap. He adds, "It is impossible, adequately, to convey to you, in writing, a just idea of the beauty of this point."

Fig. 3. THE ENGLISH SETTER.—This beautiful and active Dog is the produce of the Spanish Pointer, the English Water Spaniel, and the Springer. He is remarkable for the elegance of his figure, the beauty of his fur, and the diversity of his colours. He possesses most of the excellent qualities of the Pointer, with a much greater degree of activity and speed, and a more buoyant vivacity of temper. But with all these recommendations, he is much more difficult to break in than the Pointer, and requires an annual training to preserve his education.

Fig. 4. THE OLD ENGLISH SETTER.—This breed was originally acquired by a mixture of the Spanish Pointer with the larger Water Spaniel, and was noted for its olfactory qualities and steadiness in the field; the hair over its whole frame was much more curled than the modern breed of Setters, and it was much less active than they were. The old English Setters were also famous for their sagacity.

Fig. 5. THE SPRINGER.—The chief difference between this dog and the Setter is in point of size, and in his head being larger, in proportion to the size of his body, than the latter variety; his ears are also longer, and he is more delicate in his general conformation. This dog is chiefly used in shooting Woodcocks, Pheasants, and Snipes, and, contrary to the practice of the Pointers and Setters, always gives tongue when in pursuit of game.

Fig. 6. THE COCKER differs from the Springer in his form being more compact, his head rounder, and muzzle shorter, and in being at least a third smaller than the Springer, while his habits and uses are exactly similar; the ears are also longer in proportion, and his tail more truncated. He is supposed to have had his origin in a cross between the Springer and the smallest Water Spaniel. The Cocker is a most affectionate dog, and in general of a mild and gentle disposition.

Fig. 7. KING CHARLES' SPANIEL is considerably smaller than the Cocker, differing from him in the greater proportional length of his ears, and in his tail being much more villous towards its point. His habits are nearly allied to those of the Springer and Cocker, but he is seldom used in field sports, owing to his diminutive size. He acquired his name from the circumstance of King Charles II. being much attached to him, so much so, that he was generally followed by eight to a dozen of them.

Fig. 8. THE COMFORTER.—This diminutive creature had its origin in the Maltese Dog and King Charles' Spaniel. He is principally used as a Lap-Dog, or as an attendant on the toilet and drawing-room. These Dogs were anciently denominated Spaniels-gentle. In the Life of Mary Queen of Scots, published at Glasgow some years ago, it is recorded, that, after she was beheaded, "her little favourite Lap-Dog, which had affectionately followed her, and, unobserved, had nestled among her clothes, now endeavoured by his caresses to restore her to life, and would not leave the body till he was forced away. He died two days afterwards, perhaps from loneliness or grief."

DESCRIPTION OF THE PLATE—THE WOODPECKERS.

THIS singular race of Birds live almost entirely on Insects and their larvæ, which they pick out of decayed trees, and also from the bark of such as are sound. These they transfix and draw from the crevices by means of their long extensile tongue, which is bony towards its point, and tipped with a barbed process. The tongue is provided with a curious muscular apparatus, which enables the birds to throw it forward with great force and rapidity. The bills are also strong, powerful, and generally wedge-shaped, by means of which they are enabled to perforate trees which are perfectly sound, and to make holes large enough for incubation. Most of the genus are provided with four claws, two placed before and two behind, by means of which they climb trees with great facility; and in this operation they are aided by their tails, the feathers of which are very strong, and generally sharp-pointed. Most of the species have a harsh, acute, and unpleasant voice.

Fig. 1. THE RED-HEADED WOODPECKER (*Picus Erythrocephalus*) is a native of North America, and notorious for its predatory habits. It is a bold and active bird, most abundant in the neighbourhood of all farms, and even frequents the vicinity of large cities. Wilson mentions instances of their nests being found within the boundaries of Philadelphia. These went to feed in the woods about a mile distant, and on returning to their nests they "preserved great silence and circumspection." Although Insects are the principal food of this Bird, yet it will occasionally feed on various kinds of fruit. Its total length is 9½ inches.

Fig. 2. THE YELLOW-BELLIED WOODPECKER (*P. Varius*) is a resident Bird of the United States of America, spending its winter in orchards, and retiring to the woods in summer for the purpose of incubation. It is 8½ inches long.

Fig. 3. THE DOWNY WOODPECKER (*P. Pubescens*).—This is one of the smallest of the North American Woodpeckers, being only 6½ inches in length. They generally build in apple, pear, or cherry trees; the direction of the hole being bored downwards in an angle of thirty or forty degrees for a depth of six or eight inches, and then straight down for a distance of ten or twelve inches; it is made roomy and capacious, and as smoothly polished as if executed by the hands of an experienced carpenter. During this operation they carry the chips of wood to some distance to prevent detection.

Fig. 4. THE BENGAL WOODPECKER (*P. Bengulensis*).—This handsome Bird is a native of Bengal, where it builds in places remote from towns or villages. Its habits are similar to those of its congeners.

Fig. 5. THE RED-BELLIED WOODPECKER (*P. Carolinus*).—The habits of this Bird are solitary; it prefers the largest high-timbered woods of North America, and the tallest of the decayed trees of the forest, seldom appearing on the ground or near fences. It has a very hoarse voice, which resembles the bark of a small Lap-Dog. It is 10 inches in length.

Fig. 6. LEWIS'S WOODPECKER (*P. Torquatus*).—This beautifully-coloured Bird was discovered in the remote regions of Louisiana, in North America.

Fig. 7. THE BLACK-BREASTED WOODPECKER (*P. Multicolor*).—This Bird inhabits India. The bill is remarkably long in proportion to the size of its head.

Fig. 8. THE RED COCKADED WOODPECKER (*P. Querulus*) is a native of North and South Carolina, and also extends through Georgia. It is seven inches in length; and, although possessed of no variety of colours, is a beautiful Bird, from the strong contrast of the black and white markings.

Fig. 9. THE HAIRY WOODPECKER (*P. Villosus*) is a resident Bird of North America; and haunts apple-trees in orchards, but retires to the woods in summer for incubation, although in some instances they have been known to remain and breed in their winter haunts. This species has been found in England.

#### DESCRIPTION OF A NEW SHELL.

THE Shell of which the three representations are given below was in the possession of Mr R. Weekes, who was uncertain of its locality, but supposed it to be a native of New Holland. It possesses characters different from every Shell with which we are acquainted, and cannot be referred to any of the Lamarckian genera. We, therefore, propose giving it the generic appellation of

#### FISSILABIA.

**GENERIC CHARACTER.**—Shell strong, acutely spiral; body about half the length of the spire; aperture nearly circular; outer lip resting on the body; columella interrupted by a fissure, having by its side a tooth-like process.

**SPECIFIC CHARACTER.**—*Fissilabia fasciata* (the BANDER SLIT-LIP).—Shell spiral, with seven well-defined volutions, terminating in a somewhat obtuse apex, the body occupying about two-thirds of the Shell; outer lip acute at its edge, but internally flattened for about an eighth of an inch; the columella interrupted by a deep fissure; of a pale yellowish cast; volutions with three bands of interrupted spots of a deep chestnut colour—these are distinctly marked in the aperture, and extend to the margin of the outer lip; the whole external surface is smooth, but not glossy; with obsolete, longitudinal striae.

This beautiful and elegant Shell is very thick in proportion to its size, and is evidently a Marine species.

The situation which it will occupy in the Lamarckian arrangement is between the genera *Turbinella* and *Pleurotoma*.

#### ON THE HYBERNATION OF ANIMALS.—NO. II.

We have seen that the lethargy peculiar to hibernating animals is not so profound as to prevent them from being roused by other external impressions besides the application of heat, so there are circumstances which render it probable that they may also be roused by internal sensations, particularly that of hunger. The Dormice lay up a store of provisions in their nests, which they eat during the winter; and they have been observed, when kept in places where they could be watched, to awake, eat, and soon again become lethargic. The Marmots have been observed to come out of their holes early in spring, when the temperature was still lower than when they became lethargic at the commencement of winter. These facts may admit of another explanation, and we only mention them as circumstances which seem to render this opinion very probable.

The circumstances which appear to conduce to this lethargy, in these animals susceptible of it, are partly ascertained and partly conjectural. A certain degree of cold appears to be absolutely necessary to it in animals inhabiting temperate climates. We know too little about the lethargy which appears to be induced in some animals, inhabitants of tropical regions, to enable us to form any conclusions on its nature and character. We have already shown that it is only within a certain range of temperature that this lethargy exhibits itself in the Mammalia of our climate, generally commencing when the temperature is below 50°, and ceasing when it approaches the freezing point. The season of the year, apart from the diminished temperature, does not appear to have any effect in its production. When these animals are supplied with food, and kept in a uniform and temperate atmosphere during the winter, their usual lethargy does not take possession of them; on the contrary, they remain lively and active. Saissy induced this state during summer, by the application of artificial cold, without any injurious effects upon the animal. It has been objected to this experiment, that, at the same time he reduced the temperature, he also prevented the free access of air. This objection must, however, be in a great measure obviated, when we remember that most of these animals, if not all, appear to take precautions against the free admission of air when they are about to fall into their dormant state, and this even has been enumerated as one of the circumstances which favors its production. The Hamster does not become lethargic as long as it is exposed to the free influence of the air. The Marmots stuff the mouths of their holes with earth, hay, or grass, and its removal seems sufficient to rouse them at all times. The Hedgehog and Dormice roll themselves up like a ball in the midst of their nests. The Bats cover each other with their wings. No doubt, some of these precautions are principally to provide against too low a temperature, but they must also, at the same time, impede more or less the free access of air.

A certain degree of fat is also generally believed to favor the production of this lethargy. The hibernating animals generally abound in fat towards the end of autumn, when the dormant state comes on, and they generally come out from their hiding-place exceedingly lean. It is stated, that, in some parts of North America, those Bears that remain lean at the approach of winter migrate southwards, while those that have had an opportunity of fattening themselves become lethargic, and spend the winter in their native districts. It has been supposed, that as the Marmot in a state of domestication never becomes as fat in autumn as those living in a wild state, this explains the circumstance formerly mentioned of some tame Marmots that were observed not to hibernate. Spallanzani, however, states that he has found leaner Dormice as susceptible of the lethargic state from the application of cold as those which were fatter.

Dr Marshall Hall has mentioned some circumstances which seem to show that Bats undergo a daily lethargy, a kind of diurnation. On observing a Bat during summer, he found that it exhibited the permanent characters of lethargy, viz., imperfect respiration, diminished temperature, and the capability of supporting, for a long time, the deprivation of atmospheric air.

J. R.

**PETRIFICATION OF ANIMALS BY ARTIFICIAL MEANS.**—A pamphlet has lately issued from the press at Florence, giving an account of some remarkable discoveries by Girolamo Segato (constructor of the Maps of Tuscany, Africa, and Morocco), the principal facts of which are attested by the chief Professors in Florence. The account commences by a statement, that while M. Segato was traversing the deserts of Africa for the purpose of perfecting his Map, he was overtaken, in the valley between the Second Cataract and Mograb, by one of these whirlwinds, or rather sand-spouts, which are not uncommon phenomena in Upper Nubia. After it had passed by, and M. Segato was proceeding in its tract, he observed, in one of the hollows which had been ploughed up by the Spout, some remains of carbonized matter, and on searching still farther, he discovered a body completely charred, both the bones and flesh of which were in good preservation. It immediately occurred to him that the process of Charring could only have been effected by the scorching sand; and that, if the heat of the sand had in this instance effected the complete desiccation and carbonization of animal substances, might it not be possible to effect something similar by artificial means? No sooner had he returned to Italy than he instituted a series of experiments to effect his purpose, and ultimately succeeded in imparting to the limbs and bodies of animals solidity and indestructible durability. So great has been his success, that entire bodies, as well as separate parts, have been preserved; acquiring a firm and compact consistence, which is more decided and obvious according to the hardness or softness of the parts respectively. The skin, muscles, veins, nerves, and even the fat and blood, become consolidated; and what seems still more extraordinary is, that intestines do not require to be removed, and speedily acquire the same durable consistence. Contrary to the Mummies of the Egyptians, and all other modes hitherto practised, the colour, form, and general character remain unchanged; while both limbs and joints continue as flexible and moveable as when alive, and yet they are perfectly free from any smell. After animal bodies have acquired this hardened consistency, they are proof against damp, air, moths, or mites. They may be immersed in water, and allowed to remain for several days without injuring their texture. There is but a very slight diminution of weight; and so far from hairs being lost or injured, they seem more firmly rooted than in the living subject. The skin and feathers of birds and scales of fishes remain unaltered, and insects and worms preserve their natural appearance. These singular facts require no further proof than an examination of the cabinet of Segato, which is rich in specimens preserved by this process. We may mention that he possesses a Canary-bird which was preserved ten years ago, and has been proof against water and the attacks of moths. In the first year after being carbonized it was placed 30, and in the second 40 days under water; and, for a much longer period, was put into a box with a quantity of moths, but was not injured by them. Experiments of a similar kind were made on other animals, attended with the same results. He possesses the band of a female who died of consumption, which exhibits all the delicate emaciation peculiar to that disease. He has also the hand of a man which is entirely unchanged, and is even flexible at the joints. The most remarkable object in his collection is a table, composed of 214 pieces of animal matter joined together. They look like so many different kinds of stone, and yet are nothing more than pathological portions of human members!

#### BOTANY AND HORTICULTURE.

**THE GINGO TREE** is a native of Japan, and has not only flowered in the botanic garden of Montpellier, but has also brought to maturity its fruit, the kernel of which, when roasted, has a very agreeable flavour. It will, in all probability, be naturalized in the south of Europe, where the climate appears to be favourable to its growth.

**SUGAR OBTAINED FROM INDIAN CORN.**—M. Pallas lately laid before the Académie des Sciences of Paris, a sample of sugar extracted from the stem of this plant. It has been found to contain nearly six per cent. of syrup boiled to forty degrees, a part of which will not crystallize before fructification; but it condenses and acquires more consistency from that period to the state of complete maturity. The time most favourable for obtaining the greatest quantity of sugar is immediately after the fruit is mature, and the time of gathering. The residue, after the extracting of the sugar, is excellent for feeding cattle; or it may be usefully employed in the manufacture of packing paper.

**GIGANTIC LIME TREE.**—A gigantic specimen of the Lime or Linden Tree is now to be seen at Ivory, which has reached the unusual stature of 100 feet, while its branches extend over a surface of 245 feet; and these branches commence at a height of not more than 10 feet from the ground. The circumference of the trunk near the ground is 46 feet. It is supposed that this tree is unique in point of magnitude.

## ON THE ORIGINAL COUNTRY OF THE CEREALES, ESPECIALLY OF WHEAT AND BARLEY.—NO. I.

THE period when Corn first began to be cultivated for food to Man, marks an important era in the progress of civilization, and in the happiness of the human race. Yet this time, so interesting to the inquirer, is enveloped in the darkness of antiquity; and it is only by a careful comparison of opposite probabilities, that we can arrive at a satisfactory conclusion regarding the time of that Aurora of civilization which marked its introduction.

It is very difficult to determine the native country of the Cerealia, upon principles purely Botanical, because these plants have been cultivated in all civilized countries from time immemorial. Also, we find from the universal experience of the Agriculturist, that Wheat and Barley will perpetuate themselves for two years in our climate after a first tillage, and yet they will die out in the third year. Oats have been observed to grow wild in parts of the woods at Beulogne, which had been occupied by foreign armies, so long as from 1815 to 1819, and then perished. They were also found near the ponds of Auteuil, and along the walls on the road to Neuilly. This same species of Oats (*Avena sativa*) was carried by the Europeans to Rio de la Plata, and there becoming wild, perpetuated itself for more than forty years without any cultivation. This curious fact is stated by M. A. de Saint Hilaire, who resided for six years in that country. Those Botanists, therefore, who fancied that they had discovered, in various places, the native country of the Cerealia, from finding them growing wild, should have remained there a sufficient time to examine carefully whether they continued to grow by spontaneous reproduction for a long course of years.

As we cannot hope for a satisfactory solution of this question from the mere examination of Nature, we must resort to the most ancient traditions. It is requisite to compare the most ancient sculptures with the passages of the Bible. We must contrast the accounts of the origin and migrations of the worship of Ceres, which was probably nothing but the migrations of these plants, with the figures of the spike of corn represented upon the zodiacs in the sign Virgo, and with the grains themselves found in the tombs of Thebes. We may then arrive at a satisfactory result, by applying that rule of criticism proposed by Humboldt, Robert Brown, and other eminent botanists,—that when the native country of a cultivated species is unknown, we must regard that as the probable place of its nativity, where we find indigenous the greatest number of known species belonging to the same genus.

In this way we may circumscribe, within a small zone, the district where the Cerealia must have originally sprung.

The common Wheat (*Triticum hibernium* and *Triticum aestivum*), as well as Barley (*Hordeum vulgare*, *hexastichon*), are often destroyed by frosts in our climate and on the neighbouring continent. They neither grow in equatorial countries of a medium elevation, nor beyond the tropics at any great height above the level of the sea. From these circumstances, we may infer that the native country of these plants was in the temperate zone, and of no great elevation.

We know positively that they do not reproduce spontaneously, either in the Old or New Continent, or in any place where Europeans have carried their colonies and cultivated this grain, so necessary to the progress of civilization and the happiness of society.

It may also be inferred that the Cerealia do not exist in the wild state in those extensive countries inhabited by tribes of Hunters or Shepherds; for these people would assuredly have exchanged a precarious and uncertain subsistence for an agreeable food, which yields an abundant return, and which would increase their population, concentrate their power, and ensure the existence as well as happiness of their families.

The Egyptians, Hebrews, Greeks, and many other nations of Asia and Europe, afford examples of this transition from the Pastoral to the Agricultural state, as soon as they had discovered the Cerealia, or that these had been introduced into their country.

We shall attempt to prove that, according to the most ancient monuments of Egyptian history, it was at Nysa or Bethsane, in the valley of the Jordan, that Isis and Osiris found the Wheat, the Barley, and the Vine growing wild.

It is proper, in the first place, to ascertain the situation of the city of Nysa. Homer is the most ancient writer who mentions it. "There is a town of Nysa, situate upon a lofty mountain covered with flowering trees, rather farther from Phœnicia than from the waters of Egypt." This passage, quoted by Diodorus, and four others from the latter writer, fix, with considerable precision, that Nysa lay between the Nile and Phœnicia. Pliny is more precise; he places Nysa or Scythopolis in Palestine, on the borders of Arabia. Stephen of Byzantium relates the same thing; and Josephus informs us that this town of Nysa, called by the Greeks Scythopolis, was in his time styled Bethsane, and was situate in the middle of a plain, beyond the Jordan.

The position of this city is thus laid down by the text of Diodorus, Pliny, Josephus, and Stephanus. It seems also that Nysa, Scythopolis, and Bethsane, are the same city. At the time of Osiris, and even in that of Diodorus, the boundaries of Arabia were as usual very loosely defined on the north and west; and that portion of Palestine, adjoining Arabia, was often included with Syria by one writer, and with the peninsula of Arabia by another. In the ancient history of Java, according to Sir Stamford Raffles, Barley is mentioned to have been imported under the name of *Javanusa*. The similarity of these names is striking.

But there is another historical fact which confirms the position of Nysa in the neighbourhood of Palestine. Osiris, or the Egyptian Bacchus, whom Diodorus and the best informed of the Greeks regarded as the same king, found the Vine growing wild, and entwined round the largest trees near Nysa. It was also in the land of Canaan that Noah discovered the Vine. Moses alludes particularly (Numb. c. xiii.) to the size of the bunches of Grape in the neighbourhood of Hebron; and it is well known that the Vine is a small shrub, inclining in general towards the basin of the Mediterranean. It does not grow wild in Ethiopia, nor in Arabia Proper, nor in Egypt; but though it has been found in Armenia and Madagascar, these situations are foreign to our present purpose.

Thus, the Sacred Scriptures, the ancient history of the Egyptians, and Natural

History agree upon this important point,—that Agriculture commenced in Palestine. It was here that Wheat, Barley, and the Vine were first cultivated, and the latter was transported to Egypt by Osiris. These facts follow necessarily from the geographical position of Nysa, determined as above.

It appears, then, that Isis and Osiris discovered Wheat, Barley, and the Vine growing wild in the Valley of the Jordan, that they transported it to Egypt, demonstrated its utility, and taught its culture.

"The Egyptian history assures us," says Diodorus, "that Osiris, originally from Nysa, situate in the fertile Arabia, loved Agriculture, and found the Vine in the neighbourhood of Nysa. This shrub was wild, very abundant, and hung generally from trees."—"It was there also," he adds, "that Isis discovered Wheat and Barley, previously growing wild in the country among the other plants unknown to Man."—*Diod. Sic. l. 1, c. 14 and 27.*

One of the first fruits of this valuable discovery was the cessation of those horrid feasts of Cannibalism, which had hitherto prevailed in Egypt. Instead of these revolting spectacles, processions with sheafs of Corn and vases filled with Wheat and Barley, served to perpetuate its memory. Diodorus quotes some writers which mention that there existed at Nysa a monument inscribed with Hieroglyphics, which served to perpetuate this discovery of Isis. It bore this inscription, "I am the queen of all this country. I am the wife and sister of Osiris. I taught mortals first to know the use of Corn. I am her who rises in the constellation of the Dog. Rejoice, Egypt, my nurse."

It is in Palestine, according to Genesis, c. iv. that the Cerealia were discovered, and that Agriculture commenced.

Moses recalls to the memory of the Hebrews this circumstance, which ought to have made the Promised Land still more dear to them.

"For the Lord thy God bringeth thee into a good land, a land of brooks of water, of fountains, a land of Wheat, Barley, and Vines, Fig-trees and Pomegranates, a land of Oil-olive, and Honey,—whose stones are iron, and out of whose hills thou mayest dig out brass (copper)."—*Deut. viii. 7.*

It is in Palestine that Noah found the Vine (Genesis, ix. 20, 21). It was likewise the country of Bitumen (Genesis, vi. 4). This same Palestine, the land of the Wheat and Barley, is represented in the Bible as the country or situation of the Cedar of Lebanon, of the Balm-tree (*Amyris opobalsamum*), of the Egg-plant (*Solanum melongena*), of the Date-Palm, and of the Sycamore-Fig. It is also the country of the Dromedary, the Jackal, the Deer, the Jerboa, the Lion, the Bear, and the Gazelle. Thus far the Hebrew and Egyptian histories entirely agree as to the origin of the Cerealia and of the Vine.

We shall now see whether Palestine, according to the most ancient records, unites these conditions. Although the origin of the Cerealia may remain unknown; yet if the country or *habitat* of these different species of indigenous Animals, Vegetables, and Minerals have been correctly stated, one term of the proposition becomes known, and it is then easy to eliminate the remainder.

ANOMALY IN GRAPES.—In a garden at Fernay, a magnificent and solitary cluster of white grapes has been propagated from a vine, which has hitherto produced, and continues to bear, black grapes only.

## MINERALOGY.

EXTRAORDINARY APPLICATION OF GAS.—Mr Smith, who gave evidence before the Parliamentary Committee appointed to report upon accidents in mines from gas, in speaking of the coal mines of Nova Scotia, says, "When we first struck the coal at the depth of 180 feet, it was highly charged with water;—the water flew out in all directions with considerable violence;—it produced a kind of mineral fermentation immediately. The outburst of the coal crossed the large river which passed near the coal-pit. We were not aware of the precise outcrop, on account of a strong clay paste, eight to ten yards thick. It is rather difficult to find the outburst of coal, where the clay paste is thickly spread over a country. At the river, the water boiled similarly to that of a steam-engine boiler, with the same kind of rapidity; so that, on putting flame to it on a calm day, it would spread over the river, like what is commonly termed setting the Thames on fire;—it often reminded me of the saying. It is very common for the females, the workmen's wives and daughters, to go down to the river with the washing they have to perform for their families. After digging a hole in the side of the river, about ten or twelve inches deep, they would fill it with pebble stones, and then put a candle to it,—by this means they had plenty of boiling water without further trouble, or the expense of fuel. It would burn for weeks or months, unless put out. I mention this to show how highly charged the coal was with gas. What I am now going to describe may be worth a little attention. There was no extraordinary boiling of the water or rising of the gas, before we cut the coal at the bottom of the pit, more than is usually discernable in a common pond of stagnant water, when a long stick is forced into the mud. As soon as the coal was struck at the depth of 180 feet, it appeared to throw the whole coal mine into a state of regular mineral fermentation. The gas reared as the miner struck the coal with his pick. It would often go off like the report of a pistol, and at times I have seen it burst pieces of coal off the solid wall; so that it could not be a very lightly charged mine under such circumstances. The noise which the gas and water made in issuing from the coal, was like an hundred thousand snakes hissing at each other."

MERCURY MINES OF ALMEYDA.—Almeyda is situate in Beira, Portugal, on the Spanish frontier. Its mines are very ancient, for it is recorded by Pliny that the Greeks extracted vermilion from them seven hundred years before the Christian era. The Romans procured from them annually 100,000 livres value of Cinnabar.

Such is their present flourishing condition, that 22,000 quintals of mercury are annually taken from them, and 700 men are constantly employed in mining, 200 in extracting the ore, besides a great number of Mulcters, in conveying the mercury to Seville. The veins are so rich, that although these mines have been worked for ages, the mining has only been extended to the depth of 300 varas, or 300 French

metres. They extract the whole vein, which, after being distilled, yields ten per cent. of mercury.

The Mercury produces fatal effects on the industrious miners, most of whom, in the prime of life, present a deadly aspect. These miners possess highly honourable coactors, and are gentle and discreet in their manners.

### GEOLOGY.

**INFLAMMABLE GAS ARISING AFTER BORING FOR SALT.**—In Jameson's Philosophical Journal it is stated, that from a Salt Mine at Rheine, in Germany, an uninterrupted current of inflammable gas has issued for upwards of sixty years; which is used, not only for light, but also for cooking. In the United States of America currents of inflammable gas are frequently to be met with, issuing from perforations in rocks which have been bored for salt water. The following are some of the instances mentioned in the Transactions of the Philosophical Society of New York:—

In the year 1824, while a company were boring through a rock in Elk Creek, Ohio, at the depth of 24 feet the miners penetrated to a vein of very cold water, somewhat brackish to the taste. At the distance of 116 feet they passed through a rich vein of copper ore, of about three feet in thickness; and at 180 feet they opened a powerful vein of air, which instantly found vent at the top of the shaft or well which they were sinking, and a loud roaring and spouting of water, to the height of 30 feet into the atmosphere. For some distance round this perpendicular jet of water plays a gas, so inflammable in its nature as instantly to take fire whenever a torch is applied to it. The verge of the circumference of this gas is not perceptible; therefore those who are unacquainted with its inflammable quality have found themselves enveloped in flame when attempting to set it on fire. The intervals between the spouting are irregular and uncertain.

Mr Denton mentions, that, "while boring for salt, in the year 1824, about three miles from the village of Sparta, in Tennessee, he hit upon a vein of gas, which in ascending found another vent than the tube, through the natural fissure of a rock in the bed of the Calf-Killer river," forcing a passage through the superincumbent waters, which produced great commotion round the place of escape. A lighted torch being applied, a column of fire, nearly 40 feet high, ascended from nearly the centre of the river, which was about 50 yards wide at that place. Mr Denton met with a similar phenomenon, on the following year, a short distance below the same place. The well was situated on the margin of the river. A bore three inches in diameter was perforated in the limestone rock to the depth of 400 feet; the salt water was forced by the gas through the hole in the rock, in which was placed a tube, the upper end of which was composed of copper, to the extent of 50 feet above the surface of the rock: at the distance of 45 feet a copper faucet was inserted into the wooden tube, and into another of the same kind, standing two feet apart from the first one. The salt water forced up was conducted by the copper faucet into the second tube, from whence it descended 25 feet to a cistern holding 25,000 gallons. While the water was escaping from the first to the second tube, the gas passed up to the top of the first tube—and, upon a lighted candle being applied, it immediately ignited, and flashed up in a flame from 20 to 30 feet in perpendicular height. This place is encircled on three sides by high mountains, which were partly illuminated by this jet of gas, and produced an effect at once magical and sublime.

### METEOROLOGY.

**GREATEST ASCENTS IN THE ATMOSPHERE.**—On the 16th of December 1831, M. Boussingault, in company with Colonel Hall, ascended Chimborazo, to the height of 19,699 feet, which is the greatest terrestrial elevation yet accomplished. Baron Humboldt was unable to reach a greater height than 19,400 feet. M. Gay Lussac ascended in a balloon from Paris, and obtained an elevation of 22,900 feet. The barometer used by Boussingault fell to 13 inches 8 lines. He found the temperature in the shade was 7.86 (46.6 of Fah.) He conceives it possible for a human being to live in rarified air. It would thus appear, that at a height nearly equal to that of Mount Blanc, where Saussure felt such oppression that he was hardly able to consult his instruments, young females may be seen, in South America, dancing the whole night. During the War of Independence, the celebrated battle of Pichinca was fought at a height little less than that of Mount Rose. Saussure was informed by his guides that they had seen stars in broad day; but Boussingault never observed them, although he reached a much greater altitude.

### GENERAL SCIENCE.

**SUBMARINE REGISTER BAROMETER, TO BE USED AS AN ORDINARY DEEP SEA-LEAD.**—Mr Payne of the Adelaide Street Gallery of Practical Science, has made and proved the use of an instrument bearing this name. The accuracy with which the mercury rises in descents, and its fall in ascents, has been sufficiently proved by the use of the Barometer; and more recently, by that admirable instrument invented by Mr Adie of Edinburgh, denominated the Sympiesometer, for denoting the heights of mountains and depths of valleys. The invention of Mr Payne, however, differs in many respects from these; but he proposes measuring depths at sea by its means. It is constructed of a tube of glass (or it may be made of iron), rendered tight at top, and the tube then filled with one atmosphere of air or of hydrogen gas. The pressure of the water upon the surface of the mercury in the cistern, is similar to the pressure of the atmosphere upon the surface of the mercury in the Sympiesometer and common Barometer; but in Mr Payne's instrument, the water is prevented from coming in actual contact with the mercury, by the intervention of a piece of fine membrane. The compression of the air in the tube is indicated by a float, somewhat similar to that of the register Thermometer. The glass tube is graduated in atmospheres, and tenths of atmospheres, and also by tables of corrections for temperature, saltness of water, and the depth to which the instrument has sunk,—all of which can be accurately ascertained in fathoms or pounds weight. This Barometer has been graduated by Mr Gordon from 1 to 45 atmospheres, or

247 fathoms, upon the same principle as he graduated the portable gas pressure gauges, which have proved remarkably accurate. By means of this instrument the greatest depth of the ocean may be ascertained with precision.

### MISCELLANEOUS.

**FIELDS OF POLAR ICE.**—Of the inanimate productions of Greenland, none, perhaps, excites so much interest and astonishment, in a stranger, as the Ice in its great abundance and variety. The stupendous masses known by the names of Ice-Islands, Floating-Mountains, or Icebergs, common to Davis' Straits, and sometimes met with here, from their height, various forms, and the depth of water in which they ground, are calculated to strike the beholder with wonder; yet the fields of ice, more peculiar to Greenland, are not less astonishing. Their deficiency in elevation is sufficiently compensated by their amazing extent of surface. Some of them have been observed near a hundred miles in length, and more than half that breadth; each consisting of a single sheet of ice, having its surface raised in general four or six feet above the level of the water, and its base depressed to the depth of near twenty feet beneath.

The occasional rapid motion of fields, with the strange effects produced on any opposing substance, exhibited by such immense bodies, is one of the most striking objects this country presents, and is certainly the most terrific. They not infrequently acquire a rotatory movement, whereby their circumference attains a velocity of several miles per hour. A field thus in motion coming in contact with another at rest, or more especially with a contrary direction of movement, produces a dreadful shock. The weaker field is crushed with an awful noise; sometimes the destruction is mutual; pieces of huge dimensions and weight are not unfrequently piled upon the top, to the height of twenty or thirty feet, whilst doubtless a proportionate quantity is depressed beneath. The view of those stupendous effects *in safety*, exhibits a picture sublimely grand; but where there is danger of being overwhelmed, terror and dismay must be the predominant feelings.

On arriving at the point of collision, between two immense bodies of ice, I discovered that already a prodigious mass of rubbish had been squeezed upon the top, and that the motion had not abated. The fields continued to overlay each other with a majestic motion, producing a noise resembling that of complicated machinery, or distant thunder. The pressure was so immense that numerous fissures were occasioned, and the ice repeatedly rent beneath my feet. In one of the fissures I found the snow on the level to be three and a half feet deep, and the ice upwards of twelve. In one place hummocks had been thrown up to the height of twenty feet from the surface of the field, and at least twenty-five feet from the level of the water; they extended fifty or sixty yards in length, and fifteen in breadth, forming a mass of about two thousand tons in weight. The majestic unvaried movement of the ice, the singular noise with which it was accompanied, the tremendous power exerted, and the wonderful effects produced, were calculated to excite sensations of novelty and grandeur in the mind of even the most careless spectator.

Sometimes these motions of the ice may be accounted for. Fields are disturbed by currents, the wind, or the pressure of ether ice against them. Though the set of the current be generally towards the south-west, yet it seems occasionally to vary; the wind forces all ice to leeward with a velocity nearly in the inverse proportion to its depth under water; light ice consequently drives faster than heavy ice, and loose ice than fields; loose ice meeting the side of a field in its course becomes deflected, and its re-action causes a circular motion of the field. Fields may approximate each other from three causes; first, if the lighter ice be to windward, it will, of necessity, be impelled towards the heavier; secondly, as the wind frequently commences blowing on the windward side of the ice, and continues several hours before it is felt a few miles distant to leeward, the field begins to drift before the wind can produce any impression on ice, on its opposite side; and thirdly, which is not an uncommon case, by the two fields being impelled towards each other by winds acting on each from opposite quarters.

The closing of heavy ice, encircling a quantity of bay ice, causes it to run together with such force that it overlaps wherever two sheets meet, until it sometimes attains the thickness of many feet. Drift-ice does not often coalesce with such a pressure as to endanger any ship which may happen to be beset in it; when, however, land opposes its drift, or the ship is a great distance immured amongst it, the pressure is sometimes alarming.— *Scoresby.*

### LEARNED SOCIETIES.

**EFFECTS OF EARTHQUAKES.**—At a meeting of the "Geological Society," on the 2d December 1835, a communication was read from Lieutenant Bowers, R.N., stating that he did not observe any change produced on the coast of Chile, or on the relative level of the sea and land, by the earthquake which took place on that coast in November 1822. He was at Valparaiso in 1822, and in February 1823.

A letter was afterwards read from Mr Cumming, who was at Valparaiso during the earthquake, and for some years after, which agreed with the testimony of Lieut. Bowers. Mr Cumming is a collector of shells; and from his frequent and minute investigations, must have noted any variation.

A paper was then read from Mr Parish, Sec. Geological Society, containing a historical account of the effects produced by earthquake waves on the coast of the Pacific Ocean; from which it appeared that heavy inundations of the ocean accompanied many of the earthquakes which have laid waste the western coast of South America since the year 1590.

ZOOLOGY.

DESCRIPTION OF THE PLATE—THE GROUSE.

THESE Birds belong to the order Gallinæ, of which our domestic Cock is considered the type. Modern Ornithologists have subdivided the Linnæan genus *Tetrao*. Latham re-established the genus *Perdix*, which was originally instituted by Brisson, and more recently, the Quail and Ptarmigan have each been formed into a distinct genus. The red or common Grouse of Scotland is removed from *Tetrao*, and placed with the Ptarmigan, under the common appellation of *Lagopus*.

Figs. 1 and 2. The Pinnated Grouse, Male and Female (*T. Cupido*).—This is the most remarkable Bird of its genus; it is a native of the United States of America, occupying a tract known by the name of the Brushy Plains of Long Island, in the Queen's County, State of New York, extending for about fifty miles. The soil is a sandy or gravelly loam, covered with trees, shrubs, and small plants. The trees are mostly pitch-pines and white-oaks of inferior size.

This singular species is 19 inches long, and weighs about 3½ pounds. The neck is provided with a pair of supplemental wings, each composed of 18 feathers: the head has a small crest, and a semi-circular comb of orange-yellow extends over each eye. But the most remarkable peculiarity of the Male Bird consists in two curious wrinkled bags of yellow skin situate near the bottom of the neck. When the Bird is at rest these hang loose; but during the breeding season, in particular, they are inflated with air, resemble in colour and magnitude a middle-sized ripe orange, and appear to be formed by an expansion of the gullet with the external skin of the neck. By means of these inflated bags, the Male Bird has the power of uttering a very extraordinary ventriloqual sound, which can be distinctly heard at some miles distant. "It does not strike the ear of a bystander with much force, but impresses him with the idea, though produced within a few yards of him, of a voice a mile or two distant. This note is highly characteristic. It is termed *tooting*, from its resemblance to the blowing of a conch or horn, from a remote quarter." During the period of mating, and while the females are occupied in incubation, the males have a practice of assembling, principally by themselves, in some select and central spot where there is very little underwood; and, from the exercises performed there, is called a *scratching place*. The time of meeting is the break of day, and the numbers assembling in one spot are from forty to fifty. When the dawn is past, the ceremony commences by a low tooting by one of the cocks, which is answered by another; they then come forth one by one from the bushes, and strut about like Turkey Cocks, their tail and wings being arranged as represented in the plate, they pass and re-pass each other, uttering notes of defiance. These are signals for battles, in which they engage with great spirit and fierceness; frequently leaping a foot or two from the ground, uttering a crackling, screaming, and discordant cry.

Figs. 3 and 4. The Spotted Grouse, Male and Female (*T. Canadensis*).—This species inhabits Hudson's Bay during the whole year, where it frequents low grounds; but, in other parts of North America, it is frequently seen on mountains of considerable elevation. The Spotted Grouse has an extensive geographical range, extending from Hudson's Bay as far as the State of New York, where it is frequently a winter visitant. This game is often sent from Nova Scotia and New Brunswick to Boston in a frozen state; as in the North it is known to be kept hanging throughout the winter, and when wanted for use to be taken down and thawed. In winter these Birds feed on spruce, and consequently their flesh is strongly flavoured with that tree. They are very unsuspecting Birds, and are therefore easily approached and killed by the sportsman. They are about 15 inches in length. Frequently they resort to trees, although usually seen on the ground.

Fig. 5. The Sharp-Tailed Grouse (*T. Phasianellus*).—The disposition of these Birds is very different from that last described, as they are extremely shy, living solitary in pairs during summer, and assembling in packs in autumn, in which state they continue during the winter. Their principal food consists of juniper buds and various sorts of berries; and in winter they eat the tops of evergreens, and sometimes those of birch, alder, and poplar. They are usually seen on the ground, but, if disturbed, resort to the tops of the highest trees.

This beautiful Bird is 16 inches long. It inhabits the southern parts of Hudson's Bay, and is met with on the shores of Lake Superior. In America it is called "the Pheasant."

DESCRIPTION OF THE PLATE—THE SOU-MANGAS.

This splendid tribe of Birds principally inhabits Africa. Their food consists chiefly of Insects, to which some add the nectar of flowers; these they pierce or sip with their toogue. This organ is capable of elongation beyond the bill, and is terminated by a

forked point. During the season of incubation, the plumage of the males shines with the most splendid iridescent and metallic lustre, nearly equal in brilliancy to that of the Humming-Birds. They have an agreeable song, and their disposition is gay and lively. During the rainy season they are subject to a complete change of plumage, which is of the most sombre hues.

Figs. 1 and 2. The Cardinal Soui-Manga (*Cinnyris Cardinalis*).—This Male Bird is remarkable for the harmonious arrangements and beautiful contrast of its colours; the vivid green of its head and neck is subject to reflections of the most beautiful burnished gold, when subjected to a varied play of light; its whole form is very graceful, and the central tail feather being considerably elongated, adds much to the elegance of the bird. Contrary to what is usually the case, the female plumage, although consisting of different colours from that of her mate, is not less beautiful.

Figs. 3 and 4. The Orange Soui-Manga (*C. Orangea*).—The male of this species exhibits a combination of tints of great beauty, the green of the head and neck being subject to the prismatic reflections of the amethyst, ruby, and topaz. The female attire is of a more sober kind, on which account she is less attractive than the male bird.

Figs. 5 and 6. The Red Soui-Manga (*C. Rufa*).—Although a Bird as remarkable for the brilliancy of its attire as any of the preceding, it is less elegant, being divested of the elongated central tail feathers, which add so much to the grace of the others. The more subdued colouring of the female is of a deeply rich tone on the breast and back.

Fig. 7. The Shining Soui-Manga (*C. Famosa*).—This Bird will yield to none of the feathered tribe for the lustre of its plumage, the whole shining and sparkling by the slightest variation in the play of light, exhibiting colours of the most vivid kinds, which blend and contrast like a galaxy of the most splendid gems. The feathers of the breast present the hues of ruby and gold, bordered with ultra-marine. It is about the size of a Linnet.

Fig. 8. The Black-breasted Soui-Manga (*C. Melanogaster*), is still more elegant in its formation than any of its congeners, and yields to none of them in point of beauty. It is an extremely lively Bird, flitting among the branches of low flowering shrubs with exceeding nimbleness.

Fig. 9. The Fig-eating Soui-Manga (*C. Ficulnea*), although less varied than some others of the genus, is nevertheless beautiful and elegant in its form.

INCONGRUOUS ASSOCIATES.—A gentleman in Teignmouth had a fine large Dog of the Newfoundland breed, a Rabbit, and a bird of the Gull genus, all inhabitants of the same court yard. The friendship between these animals continued for several months; the Rabbit would follow the Dog round the court, attended by the Gull, without betraying the least symptom of fear, as if confident of security in the protection of the noble animal. At the usual time of giving the Dog his meat, his two companions would invariably attend, and the Gull would eat from the same vessel. The Rabbit would join the Dog in all his tricks and gambols. The Dog possessed all its natural fierceness, and would not permit any stranger to enter the court, unless in company with some who had been accustomed to him. He bit several persons, amongst whom was a lady who had been in the habit of feeding him daily, for several months. A workman who was employed on the premises was attacked by him, and with great difficulty escaped by jumping in at a window which had been left open. His affection for the Rabbit never decreased. Since we have been gratified with the sight, the Rabbit escaped into the street, and was worried to death by Dogs. The Dog and Gull remained companions till the owner leaving Teignmouth for his seat at Newry, in Ireland, gave the Dog and Gull to different persons.

A GANDER IN LOVE.—From the *Dunfries Courier*.—"We have the authority of Captain Brown, in his curious work on Dogs, for stating that, brutes though they be, the tender passion is not unknown to the species, whether setter, eur, colly, or mongrel, and why may it not be equally developed in the feathered tribe? Some time since a Gander was located on a farm on the Craigs Barony, and provided with a helpmate that survived the union but a very brief period. The Gander was provided with a wife the second; but meanwhile he had taken a better thought—conceived a devoted attachment to a buxom inhabitant of a cottage, and to this day (1835) gives very unequivocal proofs of it. Though chary of entering the house, morning, noon, and night he stands at the door, and in a moonlight eve serenades his fair one in a fashion peculiarly his own; whenever she appears, he looks so overjoyed, that wings and feet appear all in motion, and the steps of the damsel are actually impeded by his fluttering. The woman confesses that the only way she can get rid of him is by "jouking out o' the house, and whipping hard round the corner;" but once

seen, the feathered suitor accompanies her go where she may. If on the harvest rig, there is the Gander by her side; and during the last season, when the farmer conceived it necessary to prolong the labours of his people till after midnight, the Gander accompanied all the motions of the team with which his lady-love was engaged, and watched every sheaf that was placed on it by her hands."

**SNAKES.**—Professor Luigi Mtoxa, of Rome, has published an account of some singular experiments made by him upon Snakes. Among others, he endeavoured to ascertain the truth of the assertions of the ancients, respecting the predilection of snakes for music and dancing. In July 1822, about noon, he put into a large box a number of different kinds of snakes, all quite lively, with the exception of some vipers, which were enclosed in a separate box. As soon as they heard the harmonious tones of an organ, all the non-venomous serpents became agitated in an extraordinary manner; they attached themselves to the sides of the box, and made every effort to escape. The *Elaphis* and the *Coluber Aesculapii* turned towards the instrument. The vipers exhibited no symptoms of sensibility. This experiment has been frequently repeated, and with the same results.

**EELS.**—M. Girardin, Professor of Chemistry at Rouen, while in the act of superintending the digging of a well, the water rushed into it from the neighbouring springs, and contained in it two specimens of small Eels, which have been identified by the celebrated naturalist Dumeril. These must have had a subterranean existence in the springs. At Tours, Eels of various kinds were also brought up by the water of a well in a similar manner.

**HORSE WITH TOES ON HIS FEET.**—In *Le Globe*, No. 58, we have an account of several papers read in the Academy of Sciences on the 15th August 1827. M. Geoffroy St Hilaire read a Memoir on a Horse which had on his fore-feet three toes, connected by a membrane. This monster is preserved at Lyons, in the private collection of M. Bredin, Director of the Veterinary School of that city. It has been recorded that Julius Cæsar had a favorite horse with toes upon his feet.

## BOTANY AND HORTICULTURE.

### GENERAL REVIEW OF THE VEGETABLE KINGDOM.—NO. II.

PLANTS of the Dicotyledonous class within the tropics are frequently conspicuous for the height and circumference of their stems, the richness and variety of their foliage, as well as the bright and finely contrasted colours of their blossom. By the irregularity of their forms, they set off to advantage the arborescent Monocotyledones of the Palm tribe, which have in general the simple sober forms of our columns, of which they were the models. It is towards the Equator that the gigantic climbers, which grow to the length of several hundred yards, are found; as well as those magnificent herbs of the Scitamineæ and Musæ, as tall as the trees of our orchards; with flowers and foliage not less pre-eminent in their dimensions. For instance, the *Corypha umbraculifera*, an East Indian palm, with leaves in the form of an umbrella, and more than six yards across; and the *Aristolochia*, that grows on the river of La Madalena, the flowers of which, according to M. de Humboldt, serve the children for hats. The far greater part of the aromatic plants belong also to the equatorial regions.

By the side of this rich and varied vegetation, that of Europe appears poor and tame. Here the species of trees are few, and all have a port and foliage in which much sameness prevails. Their flowers make so little show, that the generality of people, who think nothing a flower except a coloured corolla, being ignorant of the use and importance of the other parts, believe that most trees have none at all.

The inferiority in the vegetation of our regions will appear in a still stronger light, if we compare the species of the same genera or tribes which grow both in Europe and under the line. In South America, plants of the Fern tribe, with a foliage and fructification not very unlike our common Brake and Polypody, grow like Palms, and have a stalk in the form of a column.

The cold and temperate climates of our quarter of the world abound in dwarf herbaceous turf *Gramineæ*; hot countries have also many plants of this tribe, but they are on a much larger scale. This difference begins to be perceived even when we reach Italy, where the Millet attains the height of four or five yards. The Bamboos, Panic-grasses, and the Sugar-cane of Asia, Africa, and America, reach the height of eight or nine yards.

It is said that in parts of the East Indies there are antiquated Bamboos, which are real trees, with a haulm of such girth, that a piece divided lengthwise makes two entire canoes.

The herbaceous Monocotyledones of the tropics, such as the *Liliacæ*, are greatly superior to ours in the beauty of their flowers. The Heaths of the Northern parts of Europe are low bushes, with feeble stems and small bloom; those of the coasts of the Mediterranean have also a small bloom, but their stems are taller and more robust; those of the Cape fascinate by the form, splendor of colour, and size of the corolla. The *Geraniums* of Europe do not approach those of Africa in point of stature or beauty of flower.

All the plants of the Mallow tribe with us are herbaceous; those of hot climates either shrubs or trees. A tribe of so little account in these parts, holds a place among the vegetables of the most note in the equinoctial regions. There it counts among its species the *Baobab* and the *Ceiba*, the colossi of the vegetable creation; besides the "hand-tree" of Mexico, so called from the form and disposition of the stamens of the flower, which represent very tolerably a hand or paw with five fingers.

The *Leguminosæ* or Pulse tribe furnish Europe with many herbaceous species, several shrubs, and one middle sized tree; all of which, however, have leaves composed of but few leaflets. The same tribe in the hot climates of Asia, Africa, and America, teems with lofty trees, graced with leaves of the most delicate texture, divided and subdivided into numberless leaflets, and playing in the wind like plumes.

The *Aroidæ* in Europe never exceed the height of a yard; those of Mexico, the Brazils, and Pern, sometimes tower into the air like the Banana, of which they assume the appearance; at other times lengthening themselves into supple climbers, they mount to the tops of the highest trees.

Differences as strongly marked are exemplified in the *Orchideæ*. In Europe the species are low; their flowers, although equally interesting to the Botanist by the singularity of their structure, as in other regions, are too insignificant to attract the attention of any who do not make plants an object of their study. In the Torrid Zone, the case is quite different in regard to this tribe, the greater portion of which consists of species that excite our wonder by the size and brilliancy of their blossom; and many, as the Vanilla, suspend their long branches covered with a foliage of shining green, and terminated by magnificent garlands of flowers from the summits of trees.

The *Apocynæ*, *Boraginæ*, *Convolvulacæ*, and many other tribes, are equally examples of contrasts of a like nature. The European Naturalist, whom the ardent thirst of science leads under the Equator, views with ecstasy those fertile regions, which exhibit at every step forms familiar to him, decked in the rich attire bestowed from the hand of a more bountiful and powerful Nature.

There are beauties in a land yet wild and savage, which disappear at the approach of civilization. In Europe the soil abounds chiefly in plants which are of use to Man. Domestic vegetables, by the aid and protection of the cultivator, have so trenchoned upon the domain of the wilderness, that space is scarcely left for the existence of those for which Man has no call. The primeval forests of the Gauls and Germans have disappeared; our forests are mere formal plantations of large extent. They are intersected in all directions by roads and paths; are explored without difficulty; and the wild animals no longer find safe refuge in them. Generations of trees are renewed in quick succession, on a soil which the industry of the proprietor keeps in constant requisition, and it is mere chance when a single stick is left to end its career by old age. Far in the North there are several forests which still preserve some traces of the primeval vegetation of Europe. In these the Oaks, spared by the axe, acquire an enormous size; while others, worn out by age, fall of themselves, are decomposed, and help unceasingly to augment the surface of the soil covered with high mosses and thick lichens, that preserve a prolific moisture.

None, however, approach in magnificence to the forests which shade the equinoctial regions of Africa and America. One is never satiated with admiring there the endless multitude of vegetables brought into near contact with each other, and mingled promiscuously together; so different among themselves, and often so extraordinary in structure and produce; those enormous trees still exhibiting no symptoms of decay, though their age goes back to a period at but little distance from the last revolution of our globe; those towering Palms, contrasting by their simple forms with all that surrounds them; those extensive climbers; those Rattans, which, knitting together their long and flexible branches by numberless knots and turns, encircle as one group the whole vegetation of these extensive regions. To clear a path through these, neither fire nor axe is sufficient; the one extinguishes for want of circulation in the air, the other is broken or blunted by the hardness of the wood it meets. The soil cannot afford place to the numberless germs which it develops. Each tree disputes with others, which press from all sides, the soil it wants for its existence; the strong stifle the weak; while rising generations obliterate even the slightest trace of destruction and death; vegetation never flags; and the earth, so far from becoming exhausted, acquires new fertility from day to day. Hosts of animals of every kind, Insects, Birds, Quadrupeds, Reptiles, beings as diversified and strange as the vegetation of the place itself, retire under the vast canopy of these ancient thickets as into a citadel, proof against the attack of Man.

**MANNA OF THE DESERT.**—M. Bore, formerly principal gardener and conductor of farming operations to the Pacha of Egypt, has discovered that the Tamarix Mannifera used in medicine grows abundantly about a day's journey from Mount Sinai. He was assured by the Arabs, that after this Manna was purified, it was equal to honey. The Arabs perform this operation by putting it in hot water, and afterwards skimming it. M. Bore gathered some drops himself, which were as large as ordinary sized peas, as they fell from the branches. It was agreeable to the taste, but there was very little gummy or saccharine matter about it. It has been supposed that it was this kind of Manna upon which the Jews subsisted, as mentioned in Scripture, and which some authors have thought was produced from the *Alhagi Mauro-rum*—a small plant found, according to their account, only in the confines of the desert, where the atmosphere is very humid, which is necessary to the growth of this plant.

**MANDRAKE.**—In the vicinity of Ushakan are found two remarkable roots. With one, called *toron*, is made a red colour, which is used in Russia, and the Russian name of which is *morena*; the other, *leschtak* or *manrakor* (mandrake), bears an exact resemblance to the human figure, and is used by us medicinally. It grows pretty large. A Dog is usually employed to draw it out of the ground; for which purpose the earth is first dug from about it, and a Dog being fastened to it by a string, is made to pull till the whole of the root is extracted. The reason of this is a superstitious belief prevalent among the Russian boors, that if a man were to pull up this root, he would infallibly die, either on the spot or in a very short time, and that, when it is drawn out, the moan of a human voice is always heard.

## GENERAL SCIENCE.

**SCORESBY'S EXPERIMENTS ON MAGNETISM.**—This gentleman has shown that bars of steel could be rendered highly magnetic by hammering them in a vertical position, with the lower end resting upon a poker or rod of iron. This process, however, he greatly improved by hammering the steel bars between two bars of iron. The steel bars used by him were the eighth part of an inch in diameter.

When only one bar of iron was used, a steel wire, six inches long, lifted a nail weighing 186 grains; but when two bars of iron were used, the wire lifted 326 grains. When the new process was employed with an iron bar eight feet long, a steel wire, six inches long, lifted 669 grains, or four times its own weight.

Mr Scoresby's theory of this process is, that percussion on magnetizable substances in mutual contact inclines them to an equality of condition, in the same manner as all bodies of different temperatures tend to assume the same temperature when in con-

tact. The two great iron bars being made magnetical by position, the interposed bar of steel will, therefore, when thrown into a state of vibration by percussion, receive a portion of their magnetism. In like manner, a magnet, when struck in the air with a piece of flint, or upon a body of inferior magnetic quality, will have its magnetism diminished.

MISCELLANEOUS.

LAWS OF HARMONIOUS COLOURING.

ACCORDING to the theory of Sir Isaac Newton, there are seven primary colours, viz. violet, indigo, blue, green, yellow, orange, and red. Artists, however, have long considered that there are only three, namely, red, yellow, and blue; and this opinion has recently been adopted by Sir David Brewster and other philosophers. It is quite certain that, by a combination of these three colours, every other can be made.

“If we look steadily (says Mr Hay\*) for a considerable time upon a spot of any given colour, placed on a white or black ground, it will appear surrounded by a border of another colour. And this colour will uniformly be found to be that which makes up the triad; for if the spot be red, the border will be green, which is composed of blue and yellow; if blue, the border will be orange, composed of yellow and red; and if yellow, the border will be purple, being in all cases the complement of the three colours called by artists homogeneous.

“It is well known to all who have studied music, that there are three fundamental notes, viz. C, E, and G, which compose the common chord, or harmonic triad, and that they are the foundation of all harmony. So also there are three fundamental colours, the lowest number capable of uniting in variety, harmony, or system.

“By the combination of any two of these primary colours, a secondary colour of a distinct kind is produced; and as only one absolutely distinct denomination of colour can arise from a combination of the three primaries, the full number of really distinct colours is seven, corresponding to the seven notes in the complete scale of the musician. Each of these colours is capable of forming an archæus, or key, for an arrangement, to which all the other colours introduced must refer subordinately. This reference and subordination to one particular colour, as is the case in regard to the key-note in musical composition, gives a character to the whole.

“This characteristic of an arrangement of colour is generally called its tone; but it appears that this term is more applicable to individual hues, as it is in music to voices and instruments alone. Yet, to avoid obscurity, I shall continue to use it in the sense in which it is generally applied to colouring.

“From the three primary colours, as will be afterwards shown, arise an infinite variety of hues, tints, and shades, so that the colourist, like the musician, notwithstanding the extreme simplicity of the fundamental principles upon which his art is built, has ample scope for the production of originality and beauty, in the various combinations and arrangements of his materials.

“The three homogeneous colours, yellow, red, and blue, have been proved by Field, in the most satisfactory manner, to be in numerical proportional power as follows—yellow three, red five, and blue eight.

“When these three colours are reflected from any opaque body in these proportions, white is produced. They are then in an active state, but each is neutralised by the relative effect that the others have upon it. When they are absorbed in the same proportions, they are in a passive state, and black is the result.

“From the combination of the primary colours the secondaries arise, and are Orange, which is composed of yellow and red, in the proportion of three and five; Purple, which is composed of red and blue, in the proportion of five and eight; and Green, composed of yellow and blue, in the proportion of three and eight. These are called the accidental or contrasting colours to the primaries, with which they produce harmony in opposition, in the same manner in which it is effected in music by accompaniment; the orange with the blue, the purple with the yellow, and the green with the red. They are therefore concords in the musical relation of fourths, neutralising each other at sixteen.

“This neutralising or compensating power, as will be afterwards shown, is the foundation of all agreement and harmony amongst colours, and upon it depends also the brilliancy and force of every composition.

“From the combination of these secondaries arise the tertiaries, which are also three in number, as follow: Olive from the mixture of the purple and green, Citron from the mixture of the green and orange, and Russet from the mixture of the orange and purple. These three colours, however, like the compounds produced by their admixture, may be reckoned under the general denomination of neutral hues, as they are all formed by a mixture of the same ingredients; the three primaries, which always, less or more, neutralise each other. The most neutral of them all being grey, the mean between black and white, as any of the secondaries are between two of the primaries, it may appropriately be termed the seventh colour. These tertiaries, however, stand in the same relation to the secondaries that the secondaries do to the primaries—olive to orange, citron to purple, and russet to green; and their proportion will be found to be in the same accordance, and neutralising each other integrally as 32.

“Out of the tertiaries arise a series of other colours, such as brown, marone, slate, &c. in an incalculable gradation, until they arrive at a perfect neutrality in black, as shown in diagram 2. To all of these the same rules of contrast are equally applicable.

“Besides this relation of contrast in opposition, colours have a relation in series, which is their melody. This melody or harmony of succession is found in all the natural phenomena of colour. Each colour on the prismatic spectrum, and in the rainbow, is melodised by the two compounds which it forms with the other two primaries. For instance, the yellow is melodised by the orange on the one side, and the green on the other; the blue by the green and purple, and the red by the purple and orange. These coincidences can be shown by a diagram where the chromatic scale of the

colourist is accommodated to the diatonic series of the musician, showing that the concords and discords are also singularly coincident.

“The following diagram exhibits a general harmony of all the colours of any distinctive character, simple and compound, except the neutral grey. It will be observed, that each limb of this diagram forms a series of hues proceeding from one of the primaries, and producing a distinct melody or harmony, in succession, of that colour. It will also be seen, that in each of these harmonies, although the primary colour or key-note predominates, the other two primaries enter, in combination, into the arrangement. This, however, is more plainly shown when these three melodies are exhibited separately. There is also shown, upon this diagram, the progress from light to darkness, or from white to black; as also in its nine central divisions, the harmony in succession, and contrast of the primary and secondary colours. The arrangement of this diagram, I trust, will likewise show that all the colours, in their greatest intensity, may be brought together without crudity or harshness:

“In all general arrangements of colours, which are not necessarily confined to any particular leading colour or (to continue the analogy) key-note, it ought to be kept in view, what Nature has pointed out in the most distinct manner in all her colouring, namely, that those cool-toned and neutralised colours which are most agreeable to the eye should predominate, and that vivid and intense colours should, upon all occasions, be used with a sparing hand.

“White is produced by the reflection of all the colours simultaneously in their relative neutralising proportions. Its contrasting colour is black, with which it is co-relative, being the opposite extreme of neutrality. It lies nearest in series to yellow, which may be reckoned its melodising colour. It, however, harmonises in conjunction and opposition with all other colours. Every colour in its series of tints becomes subdued in force proportionally as it approaches towards white. It is the representative of light as black is of darkness; its effect on the eye is therefore cheerful and enlivening.

“Yellow, of the three primary colours, partakes most of the nature of white, being the lightest of all decided colours, and the brightest on the prismatic spectrum. Its contrasting colour is purple, a compound of the other two primaries; its proportional power to which is as three to thirteen, either in quality or intensity. It constitutes, in combination with red, the secondary orange; and, when compounded with blue, it produces the secondary green. These two colours are therefore its melodising hues. It is the most powerful of the positive colours, and consequently the least agreeable to the eye, when unaccompanied, or when predominating in a pure state. Being the lightest of positive colours, it, next to white, forms the most powerful contrast to black. Yellow, of course, forms a component part of all the tertiary or neutral hues, either in predomiance or subordination.

“The tertiary, in which it is the archæus or ruling colour, is that called citron, which, being a compound of orange and green, the two secondaries into which yellow enters, has a greater proportion of that colour than either of the other two tertiaries. Citron is of itself a soft and pleasing colour to the eye, and is the lightest of all distinct hues arising out of the treble combination of the primaries. It is very useful as a contrasting colour among low tones of purple and crimson. In tracing yellow still further down

\* The Laws of Harmonious Colouring, adapted to interior Decorations, Manufactures, and other useful Purposes, by D. R. Hay, House-painter, Edinburgh, 3d edition. This is a work of great merit, and ought to be in the hands of all persons of taste.

in the scale, the next understood colour in which it predominates is the semi-neutral hue brown, a most efficient colour in all the low parts of every warm-toned arrangement.

"In artificial lights pure yellow apparently loses much of its intensity, because it cannot be easily distinguished from white. This occurs from all such lights being less or more of a yellow tone, and consequently diffusing this colour over all objects within their influence; white thereby becoming yellow, and yellow remaining unaltered.

"Orange is the next colour in power; it is a compound of yellow and red, in the proportions of three of yellow to five of red. Between these two colours it appears in the prismatic spectrum, rainbow, and other natural phenomena; they may, therefore, be termed its melodising colours. Its contrasting colour is blue. Orange is the extreme point of warmth in colouring, as blue is of coldness; they, therefore, form the most perfect contrast in this respect, as they do in their numerical proportional power, being eight to eight. In its combination with green it produces the tertiary citron, and with purple the tertiary russet.

"Red is the third in the chromatic series, and second of the primaries. It is the most positive of all colours, holding the middle station between yellow, which is most allied to light, and blue, which is most allied to shade; it is, as Field expresses it, pre-eminent among colours. The hues with which it melodises in series are, of course, orange and purple, being its combinations with the other two primaries. Its contrasting colour is green, a compound of yellow and blue, in the proportion of three yellow to eight blue. Red is decidedly a warm colour, and, to a certain extent, communicates this quality to every hue into which it enters.

"This effect of warmth is most apparent in its combinations with yellow; for in those with blue it becomes more cool and retiring. From the medial situation of red, and from its power in subduing the effect of such colours as enter, in minute proportion, into combination with it, its name is very indiscriminately applied. The first decided hue produced, in its approach towards yellow, is scarlet; and, in its approach towards purple, it produces the most splendid of all hues of this description, crimson.

"The tertiary in which red predominates is russet, a medial hue between purple and orange, and consequently having a double occurrence of red in its composition; therefore, it is the most positive and warm of the neutral colours. It is of great power and value in all the deep parts of any warm-toned arrangement, as a contrasting colour to the deep hues of green, necessarily brought in as relieving colours. The semi-neutral marone is the next understood hue in its descent to black.

"Purple lies next in series to red, of which colour and blue it is composed, in the proportion of five of the former to eight of the latter. In this state of intensity it forms the proper contrasting or neutralising colour to pure yellow. The two primaries of which it is compounded are its melodising colours. Although red be one of its component parts, it is rather a cool colour, and very retiring in effect: being also the darkest of the secondary colours, it bears the nearest relation to black or shade, as its contrasting colour, yellow, does to white or light. From these qualities, purple is a pleasing and agreeable colour to the eye; in this respect it is second only to green. In its combination with green it produces that soft and useful tertiary colour, olive, and with orange, the most powerful of this class, russet.

"Blue is the third of the primary colours, and fifth of the chromatic series. It is, of the primaries, the nearest in relation to shade, as yellow is to light. It is the only absolutely cool colour, and communicates this quality to all hues into the combination of which it enters.

"Green, although the last in the general series which I have adopted, is the medial or second of the secondary colours, being a compound of yellow and blue, in the proportion of three of the former to eight of the latter; the one primary being most allied to light, and the other to shade. Its melodising colours are of course these two primaries, and its contrasting colour the remaining primary, red. As red is the most decided or pre-eminent of the primaries, so green is the most neutral and soft of the secondaries, and the most pleasing and agreeable of all decided hues to the eye. It is also unlike the other two secondaries in this respect—that, in its approximation to either of its component parts, it produces no other distinct denomination of colour; all its hues retaining the same name. Out of the union of green with orange arises the lightest of the tertiary colours, citron; and out of that with purple, the deepest olive, to which it appears particularly allied.

"Green is the natural clothing of the vegetable world, and, in a certain degree of purity, predominates in the same ratio of quantity that red is held subordinate. It is in its greatest intensity and depth when the sun's rays are most powerfully directed to the earth, thereby counteracting the intensity of their reflection, and refreshing the eye by its soft and soothing influence, in that infinite wisdom so conspicuous in all the laws which govern the universe. Green, however, like every other hue in Nature's colouring, seldom appears in vegetation in its primitive purity. Hence the beautiful accordance between the green of the landscape and the blue of the sky, so evidently assisted in both harmony and melody by the intervention of the warm and neutral gray, which prevails intermedially in the distance of the one and the horizon of the other. In its various hues, green, as may naturally be supposed, is a favourite colour in decoration, and would be much more so, were it not that in artificial light its effect is much deteriorated, becoming in most cases dull and heavy.

"Black, as already noticed, is produced by the absorption of the three primaries, and its natural contrast is white. It can only be used in large quantities in arrangements of a cool and sombre character, and ought always to be pure and transparent.

"In the decorative painting, however, of Pompeii and Herculaneum, it was used in much profusion; and in combination with the intense and brilliant colours which accompanied it, produced the most splendid effect."

Edinburgh, February 16, 1836.

SIR,—This last season, I sailed as surgeon in the Sisters, whale ship, and should you deem the following singular phenomenon, which I do not recollect ever having noticed in any work on the Arctic Regions, worthy of insertion in your excellent Journal, you are at liberty to use my name in any manner you think fit.

About midnight, on the 19th September last, being then in latitude 71° N., and

about 76° of longitude, it was necessary to warp the ship through some ice, which, I may mention, is done by fixing or striking grapnels, or, as they are called, ice-anchors, into the ice, to which warps are attached, and the ship is then hoven through by the capstan on board the vessel. One of the seamen, in striking the grapnel into the ice for this purpose, a vivid flash of light was emitted at each stroke. I shall not attempt to assign any reason for this singular circumstance, but I may add, that the sea at the same time was beautifully phosphorescent, a phenomenon I frequently observed in those regions; and during the congelation of the ocean and in newly formed ice, even when it has attained the thickness of three or four inches, I have observed phosphorescent flashes, evidently produced on the surface, in the substance and below the ice; the temperature at the time being from 18° to 20° of Fahrenheit's scale.

Sea water ice is perfectly fresh until it attains the thickness of a quarter or half an inch, but after that it is quite salt.

To Captain Thomas Brown.

(Signed) NICHOLAS OLIVER.

PUBLIC LIBRARIES.—"There are at least nine which greatly exceed the British Museum Library in extent, those of Berlin, Göttingen, Dresden, Naples, Vienna, Copenhagen, St Petersburg, Munich, and Paris; and several others of about equal extent, as those of Wolfenbützel (190,000), Stuttgart (197,000), Madrid (200,000) The extent of the first nine, as nearly as I am able to ascertain it, is as follows:—

	Printed Books.	MSS.	Population.
Berlin, . . .	250,000 vols.	5,000 vols.	248,816
Göttingen, . . .	300,000 ...	5,000 ...	9,594
Dresden, . . .	300,000 ...	2,700 ...	69,000
Naples, . . .	300,000 ...	6,000 ...	354,000
Vienna, . . .	350,000 ...	16,000 ...	320,000
Copenhagen, . . .	400,000 ...	20,000 ...	109,000
St Petersburg, . . .	400,000 ...	16,000 ...	320,000
Munich, . . .	500,000 ...	16,000 ...	95,718
Paris, . . .	700,000 ...	80,000 ...	890,431
London (Brit. Museum)	220,000 ...	22,000 ...	1,528,301."

The above is extracted from "A Letter to B. Haves, Esq., M.P., being Strictures on the Minutes of Evidence taken before the Select Committee on the British Museum," by Edward Edwards, Esq., London, 1836. In reference to our own immediate subject, we can readily bear testimony to the absolute deficiency of the public libraries of Britain in works on all branches of Natural History; and were it not for the monthly draughts of information which we derive from the Continent, answered by drafts of another kind on the Proprietors, the extensive undertaking in which we are engaged would find a speedy termination.

#### REVIEWS.

*The Tower Menagerie, comprising the Natural History of the Animals contained in that establishment.* 8vo. Jennings, London. 1829.

*The Gardens and Menagerie of the Zoological Society Delineated.* 2 vols. 8vo. Tegg, London. 1830.

It may be wondered at by our readers, why we notice at this period two works which have been so long before the public. Our simple reasons are, that they do not seem to be well known and appreciated, and that we consider it a duty to the proprietors and our readers to point out their excellencies.

These two works were of cotemporary projection, and intended to illustrate, from living specimens, the two Menageries whose names they bear. They are, in all respects, twin sisters of exceeding beauty. Both are edited by E. T. Bennet, Esq., the accomplished Vice-Secretary of the Zoological Society; the drawings for both were from the pencil of Mr William Harvey, at the head of his profession as an animal painter, and the engravings for both were executed by Messrs Branstone and Wright, who have brought the art of Wood Engraving to its present high state of excellence. Both are from the justly-celebrated press of Mr Charles Whittingham.

We cannot speak too highly in praise of the graphic and truly scientific manner in which the animals in these three volumes are described. The natural-historical details of the various objects are full of interest, and exhibit proofs of much discrimination and research. They are worthy of the Society under whose auspices they have appeared.

The illustrations are faithful delineations of the different objects, exhibiting a freshness and vigour which at once carry with them a conviction of the accuracy of the character and expression of the animals. They are not merely representations of the animals, but each cut has a pictorial effect, the objects being surrounded with a picturesque and appropriate landscape, giving relief to the figure, and leading the mind to such scenes as are likely to be the accustomed haunts of the beings represented.

Will it be believed, after the high but just character which we have given of these works, they met with such a poor reception, that, within twelve months after their publication, they fell to nearly half their original price?—a libel on British taste. But we are happy to understand they have again risen in value, and we foresee that the day is not far distant when they will bring double their original cost.

ZOOLOGY.

DESCRIPTION OF THE PLATE—THE QUAILS.

This genus was instituted by Mr Stephens, in his continuation of "Shaw's General Zoology," for the reception of such of the Partridges as had thick bills. These are only found in North and South America. They frequent the borders of woods, and reside among brushwood, or in plains where the grass is thick and high, or among grain in fields which are cultivated. If disturbed, they fly to trees, where they perch for safety, and "walk with ease on the branches," according to Audubon; who says they perform occasional migrations from north-west to south-east, usually in the beginning of October, and somewhat in the manner of the Wild Turkey.

Figs. 1 and 2. The Virginian Quail, male and female (*Ortyx Virginiana*).—This handsome bird abounds in the Eastern and Middle States of America, and is to be found in most districts of the Union, where it is called "the Partridge." It emigrates about the beginning of October, at which time, the north-eastern shores of the Ohio are literally covered with them. During these excursions, they frequently fall into the water, and many of them perish, but if they drop at no great distance from the land, they easily reach the shore by swimming, which Audubon affirms they can do "surprisingly."

If Virginian Quails are molested, they take refuge in trees, always resorting to the middle branches; and if they think they are noticed by the sportsman, they erect the feathers on the crown of their head, emit a low note, and escape to another part of the tree, or to a more distant one. When they take to flight without being disturbed, the whole covey pursue the same course; but when frightened they disperse in various directions, and after having alighted call to each other, and are soon congregated by the note of the patriarch-bird of the flock.

The nest of this bird is of a circular form, in which it leaves an aperture not unlike in shape to that of a common oven. It is placed at the side of a thick tuft of grass, and is partly sunk in the ground. The female lays from ten to eighteen pure white eggs; and is assisted by the male in the tedious operation of incubation. They only rear one breed during a year.

Their manner of reposing at night is rather curious, as mentioned by Audubon. He says, "the Partridge rests at night on the ground, either amongst the grass or under a bent log. The individuals which compose the flock form a ring, and moving backwards, approach each other until their bodies are nearly in contact. This arrangement enables the whole covey to take wing when suddenly alarmed, each flying off in a direct course, so as not to interfere with the rest." The flesh of this bird is considered a delicate and agreeable food.

Figs. 3 and 4. The Californian Quail, male and female (*O. Californica*). The first person who noticed these beautiful birds was an Editor of the voyage of the unfortunate La Pérouse, who also figured them in the plates illustrating that work. They are known to assemble in flocks of two or three hundreds in the low woods and plains of California. The flesh is said to be of a fine flavour. These quails are easily tamed, and soon become quite reconciled to a state of captivity. They are birds of an elegant bearing, the crests giving them a fine and striking appearance.

Fig. 5. The Long-tailed Quail (*O. Macroura*).—Nothing is known of the history of this species; it is a native of Mexico.

Fig. 6. Montezuma's Quail (*O. Montezuma*).—This is also a Mexican species, but its locality is not known. Some years ago there was a fine specimen of the bird in the Zoological Gardens of London, which is now dead, and its skin is preserved in the Museum of the Zoological Society.

DESCRIPTION OF THE PLATE—THE KINGLETS.

THESE very beautiful Birds were formerly ranked among the Wrens, but Cuvier, following Ray, formed a new genus for their reception under the title of *Regulus*. They subsist almost entirely on Insects, in the pursuit of which they exhibit great nimbleness of action. They construct their nest with much neatness. The British species usually suspend them to the extreme branch of a tree, and cover them externally with mosses, selecting the same kind which is on the tree for their purpose.

Figs. 1 and 2. The Ruby-crowned Kinglet (*Regulus Calendulus*).—This beautiful species is a native of North America. They are birds of passage, and visit the United States from the South, about the beginning of April. Their food at this season consists of the blossoms of the Maple Tree, and when these fail, they have recourse to those of the Peach, Apple, and other fruit trees. They eat only the sta-

mens of these flowers, but they also subsist upon the Insects which hover round them. These Birds penetrate far to the North, and even build and incubate in the country around Hudson's Bay. The Ruby-crowned Kinglet is only four inches long, and six in extent of wings.

Fig. 3. Cuvier's Kinglet (*R. Cuvierii*) is a native of Pennsylvania, and was first discovered by Audubon. We know nothing of its history.

Figs. 4 and 5. The American Kinglet (*R. Americanus*).—Wilson and other naturalists confound this Bird with the European Kinglet—fig. 8 of this plate—from which it differs in several essential particulars. The length of the American *Regulus* is three inches and seven-eighths, while the European species varies from three inches and a half to three inches and three quarters; the bill is also longer, and more dilated at the base, and the crest differs materially.

The American Kinglet is an active, unsuspecting Bird, climbing and hanging occasionally among the branches, and sometimes even on the body of the tree, in search of the larvæ of Insects. It also retires northwards to incubate, and is seldom to be met with in the State of Pennsylvania from May to October; after which it becomes very abundant in orchards, and assists greatly in thinning them of the numerous Insects with which they are infested at this time of the year. It is four inches long, and six in extent.

Fig. 6. Byron's Kinglet (*R. Byronensis*).—This interesting species is a native of Chili, whence it was brought by Lord Byron, who presented it to the British Museum. Its habits are unknown.

Fig. 7. The All-Coloured Kinglet (*R. Omnicolor*) is a native of Brazil, and inhabits the extensive forests which border the Rio-Grande. It is remarkable for the brilliancy of its plumage; and differs from its congeners in being provided with an ample tuft of feathers on the crown of the head; its bill differs, also, in being somewhat straighter.

Fig. 8. The European Kinglet (*R. Cristatus*). This species is to be met with all over Europe, and is plentiful in some parts of this Island. It is a resident with us the whole year round; but Selby records two instances where it migrated; in October 1822 and January 1823. In the latter case, the whole tribe disappeared. This happened a few days prior to the long-continued snow-storm, so severely felt through the Northern Counties of England, and along the eastern parts of Scotland. It is the smallest British Bird, being only three inches and three quarters in length, and seldom exceeds sixty grains in weight. It is commonly known by the name of "The Golden-crested Wren."

MATERNAL AFFECTION OF THE ÆTHIOPIAN SOW.—In chasing the old Sows of this species, with their young ones, Dr. Sparrmann observed that the heads of the females became suddenly enlarged and more shapeless than they were before. This momentary and wonderful change astonished him so much the more, as, riding bard over a country full of bushes and pits, he had been prevented from giving sufficient attention to the manner in which it was brought about. The whole of the mystery, however, consisted in this: each of the old ones, during its flight, had taken a pig in its mouth; this also readily explained the reason of his surprise, upon finding that all the pigs which he had been chasing along with the old ones, had vanished on a sudden. In this action we find a kind of unanimity among these animals in which they resemble the tame species, and which they have in a greater degree than many others. It is likewise very astonishing, that the pigs should be carried about in this manner, between such large tusks as those of their mother, without being hurt or crying out in the least.

MIGRATION OF WHALES.—It is now well ascertained that all the Whales which frequent the Polar Seas pass annually to the southward, in large bodies, in the months of March and April, about midway between the coasts of Ireland and Newfoundland. From the late report of the Committee of the House of Commons on the public works of Ireland, we learn that Whales appear in great numbers on the western coast of that country in the Spring months, and are totally neglected and unpursued, in consequence of the poverty and want of means of equipment of the people of that coast. This being the case, it is evident that the Polar Seas have been too long and needlessly visited in search of cetaceous animals, at the expense of much loss of property, time, and human life; as Whales may be equally well encountered and captured in the Atlantic Ocean, as in the dangerous northern regions.

THE POISON OF SNAKES.—Sir Thomas Brisbane mentions, that one of the poisonous Snakes which he kept at home, while Governor of New South Wales, bit two of his Pointers, one of which died in three minutes, and the other in about thirty minutes; thus equalling prussic acid in the rapidity of its effects.

## ON THE HYBERNATION OF ANIMALS.—NO. III.

We shall now examine more in detail the distinguishing Physiological Conditions of this interesting class of animals, and first shall make some observations on their Respiration.

It has been ascertained by experiment that all the warm-blooded animals, when asleep, consume less oxygen than when awake. In the hibernating animals, during their lethargic state, this is carried to a much greater extent. Mangili carefully observed the fat Dormouse (*Mus Glis*) in this state, and found that its respirations were irregular, with long intervals between them: at one time the animal breathed from 13 to 15 times in succession, then followed an intermission of from 24 to 28 minutes, without any respiration. In another Dormouse (*Mus avellanarius*) he found its respiration only 3 in the minute, though the temperature was as high as 65°. Prunelle placed a Hedgehog, in a state of lethargy, under water for 4 minutes, without injury to the animal. He also found the respirations so imperfect, in a state of lethargy, when the temperature was about 44° or 45° that they could not be reckoned. They became sensible when the temperature was raised to 59°, and in a low temperature they were 3 or 4 per minute, with intervals. Dr Marshall Hall has made the most accurate experiments upon this point, and they fully bear out the statements made by Mangili and Prunelle, that the function of respiration is nearly suspended. He placed a lethargic Bat under an instrument which he has invented for experiments of this kind, and which he has termed a pneumotometer, for 10 hours, and found no perceptible absorption of oxygen. He then roused the animal, and the absorption became immediately apparent. Another lethargic Bat was placed 24 hours under the instrument, and a cubic inch of the oxygen only had disappeared. A Bat placed sixty hours under the instrument, at a temperature varying from 38° to 41°, occasioned an absorption to the extent of 3.8 inches. In a state of activity equal quantities of gas disappeared in less than half that number of minutes.

He retained a lethargic Bat for 16 minutes, and a lethargic Hedgehog for 22½ minutes, under water, without any injurious effects. The same animals, in a state of activity, expire when placed under water for three minutes. Spallanzani enclosed a Marmot and a Bat for four hours in carbonic acid gas without injury.

Great care should be taken, in an experiment of this kind, to observe that the animal is sufficiently lethargic, and that it does not become roused, for immediately the respiration becomes more frequent, more oxygen is consumed within a given time, and if not supplied the animal soon dies. It is only in this manner that we can explain the different results obtained from similar experiments by Prunelle. No doubt these animals, supposing them to remain lethargic, would ultimately perish when confined in an atmosphere deprived of oxygen; but these experiments at least show that when in a state lethargy they consume exceedingly little oxygen. In this respect they resemble the cold-blooded animals, such as the fishes, frogs, &c., which, it is well known, consume a comparatively small quantity of oxygen; and as we proceed with the enumeration of their physiological peculiarities, we shall be surprised to find that they resemble them in almost every particular, affording the strange anomaly of a warm-blooded adult mammiferous animal assuming for a time the physiological condition of a cold-blooded animal. There is an experiment mentioned by Prunelle, which, under this point of view, deserves our attention. It is well known that a warm-blooded animal, when confined in a fixed quantity of air, dies before all the oxygen is exhausted; while, on the other hand, a cold-blooded animal may breathe for a while with impunity in an atmosphere which cannot support the warm-blooded animal, and rarely dies until all the oxygen is exhausted. Prunelle states that he found all the oxygen had been removed from the air, in which a lethargic animal had been confined until it had proved fatal. Sir A. Carlisle was in error when he affirmed that those animals, in the active state, can subsist with a smaller quantity of oxygen than the other Mammalia.

We shall now consider the state of the Circulation of the Blood.

The circulation, like the respiration, in the state of lethargy appears to be very languid. Prunelle states that the pulsations of the heart of the Bat are 200 per minute, in a state of activity, and that they are reduced to 50 or 55, in a state of lethargy. According to the same author, the pulsations of a Marmot, in a state of activity, are 90 in a minute, and are only from 8 to 10 in the minute, and at the same time weak, in the state of lethargy. Marshall Hall found the pulsations of the heart of the Bat 28 in the minute, and regular. The flow of blood in the minuter arteries and veins was slow. Prunelle found the blood in the arteries not florid as it is in a state of activity, but nearly as dark coloured as the blood in the veins, which is exactly what we would expect from the small quantity of oxygen consumed. Buffon states erroneously that the blood of a hibernating animal, in a state of lethargy, will not coagulate.

In the reptiles, the movements of the heart are slower and feebler, and the blood is darker coloured, than in the warm-blooded animals. A state of the circulation, in these respects, which is natural to the cold-blooded animals, would be incompatible with the continuance of life in the warm-blooded animals. During the state of hibernation, however, we find the circulation of the blood in these animals to resemble that in the Reptiles.

With regard to animal heat, numerous observations show that the temperature of the hibernating animals, during their state of activity, is equal to that of the other Mammalia. On the other hand, while in a state of lethargy, their temperature is little elevated above the surrounding media.

The heat of the external surface is generally found to be the same as the surrounding atmosphere, while the internal parts are from 2° to 3° higher. This is a reduction of temperature from which the other adult warm-blooded animals would never recover. Dr Edwards' experiments go to prove that the temperature of the hibernating animals is more easily reduced, by the application of cold in their state of activity, than in the other Mammalia. Marshall Hall has objected to the accuracy of these experiments. We shall not here stop to inquire into the grounds of his objections. Dr Edwards' experiments at least prove that their temperature is more easily reduced, under certain circumstances, than the other Mammalia, and that they

resemble the cold-blooded animals and the young of certain of the Mammalia, which are born with their eyes shut, as the kitten and puppy, in admitting of a great reduction of temperature with impunity.

We have already seen that the heart contracts less frequently in a state of lethargy than in a state of activity, and that it circulates dark blood, as in the Reptiles and other cold-blooded animals, and we also find that they resemble them still farther in their tenacity of muscular contractility. It is well known to physiologists that the heart of a Frog, or of a Turtle, or the other muscles of the same animals, will continue to contract, upon the application of a stimulus, for many hours after they have been decapitated, and are apparently dead, and long after the same parts have lost their contractility in the warm-blooded animals. Mangili observed the heart of a Marmot, in a state of lethargy, to beat three hours after decapitation, and after all the principal vessels leading to and from it had been cut through. Upon applying galvanism to the other muscles also, three hours after death, he found them to contract vigorously. In a Marmot, killed in a state of activity, the heart was quiescent fifty minutes after decapitation. The contractility of the muscles, upon the application of galvanism, was scarcely sensible two hours after death. Marshall Hall has confirmed these observations of Mangili.

The other vital functions of Secretion, Digestion, Absorption, are also performed in a very languid manner during the state of lethargy, as in the cold-blooded animals. These animals, in a state of lethargy, throw off very little excrementitious matter. Some do not appear to eat during the whole of their hibernation, and others but sparingly. The fatness of these animals at the commencement of their hibernation, and their leanness at its termination, show that absorption must have been going on, though this, of course, is to a much less extent than would have happened had they remained in a state of activity. Mangili found that a Dormouse (*Myoxus avellanarius*), weighing 19 oz. 5 grains, lost 2½ oz. of its weight in three months. When killed it had a considerable quantity of fat around its intestines. Prunelle states that two Bats had lost ⅓ part of their weight in 21 days. Dr Monro found that a Hedgehog, which weighed 13 oz. and 3 drachms on the 25th December, weighed 11 oz. and 7 drachms on the 8th March. This loss was at the rate of 13 grains a-day. According to Mr Cornish, both Bats and Dormice lose from 5 to 7 grains in weight during a fortnight's hibernation.

The astonishing and unexpected fact, that a warm-blooded adult animal should, when placed under certain circumstances, take on the physiological condition of the cold-blooded animals, naturally leads us to inquire if they have any peculiarity in their anatomical structure which accounts for so interesting a phenomenon.

Notwithstanding the labours of Mangili, Otto, Sir A. Carlisle, Prunelle, and others, no satisfactory explanation of the cause of hibernation can be derived from the structure of these animals. It will be unnecessary to point out here the pretended explanations which some of these celebrated men have advanced, as we would require to enter into minute anatomical descriptions, which would be out of place in an account of this kind.

We cannot refrain, however, from stating an interesting particular mentioned by Prunelle and Pallas, and that is, that during hibernation the thymus gland becomes much enlarged. Now when we remember that the thymus gland is much larger during the fetal existence than in the adult, and that the fetus is to a great extent a cold-blooded animal, we have here again another point of resemblance between the hibernating animals, in a state of lethargy, and the cold-blooded animals.

J. R.

**SPEED OF THE BULL-FROG.**—The Bull-Frog (*Rana Catesbeiana* of Shaw) can leap with very great velocity. It is a well known fact, that an American Indian is able to run almost as fast as the best Horse in his swiftest course. In order, therefore, to try how well the Bull-Frogs could leap, some Swedes laid a wager with a young Indian, that he could not overtake one of them, provided the Frog had two leaps before hand. The wager was accepted, and they carried a Bull-Frog, which they had caught in a pond, into a field, and burned his tail. This application stimulated the creature to such a degree, that he made his long leaps across the field with wonderful celerity. The Indian pursued with all his might, and the noise he made in running, added to the fear the poor Frog was probably in of a second burning, made him redouble his efforts, and reached the pond before the Indian could overtake him.

**THE WATER SPIDER.**—The Insects that frequent the waters require predaceous animals to keep them within due limits, as well as those that inhabit the earth, and the Water Spider (*Argyroneta aquatica*) is one of the most remarkable upon whom this office is devolved by her Creator. To this end her instinct instructs her to fabricate a kind of Diving-Bell in the bosom of that element. She usually selects still waters for that purpose. Her house is an oval cocoon, filled with air, and lined with silk, from which threads issue in every direction, and are fastened to the surrounding plants; in this cocoon, which is open below, she watches for her prey, and even appears to pass the winter, when she closes the opening. It is most commonly, yet not always, entirely under the water, but its inhabitant has filled it with air for her respiration, which enables her to live in it. She conveys the air to it in the following manner:—She usually swims upon her back, when her abdomen is enveloped in a bubble of air, and appears like a globe of quicksilver. With this she enters her cocoon, and displacing an equal mass of water, again ascends for a second lading, till she has sufficiently filled her house with it, so as to expel all the water. The males construct similar habitations by the same manoeuvres. How these little animals can envelop their abdomen with an air-bubble, and retain it till they enter their cells, is still one of Nature's mysteries that have not been explained. We cannot help, however, admiring and adoring the Wisdom, Power, and Goodness manifested in this singular provision, enabling an animal that breathes the atmospheric air to fill her house with it under water; and has instructed her in a secret art, by which she can clothe part of her body with air as with a garment, which she can put off when it answers her purpose.—Kirby.

## BOTANY.

## BRUGMANSIA ZIPPELLII.

THIS singular plant is nearly allied to the Genus *Patma*, of which we have already illustrated two species in our former Numbers. Like them it is a parasite, and has hitherto been found only in the Island of Java. It was discovered on the mountain Salax, growing at the height of 1200 to 1500 feet above the level of the sea. This mountain lies in the province of Buitenzorg, on the west of Java, and it almost seems, from the singularity of its vegetable productions, as well as the marked volcanic character of its minerals, to be the favorite shrine both of Flora and Vulcan.

The Genus *Brugmansia* was constituted by Persoon; but Blume first included this Plant under that denomination. The characters which he assigned to the Genus *Brugmansia* are the following:—Perianth with one leaf; the crown of the throat interrupted; limb five-parted; segments or partitions twice or thrice cleft; the æstivation valvate induplicate; the central column, subglobose, hollowed above and naked; anthers monadelphous, two-celled, opening by two pores.

This Plant, when it first bursts from the roots of its parent tree, exhibits merely a small tubercle or bud; as it gradually expands, it assumes the different appearances represented above, until finally it acquires the utmost extent of its growth, which is limited in these remarkable parasites to a simple development of their reproductive organs, or mere blowing of the flower. Just before its ultimate expansion it has the following appearance.

The root upon which it grows, or rather blows, belongs to the *Cissus tuberculata* of Blume—a tree very plentiful in the moist woods on the south-west of Mount Salax. The *Brugmansia Zippellii* is stated to have the property of being remarkably stypitical; its specific name *Zippellii* was given in compliment to the individual who first discovered this curious vegetable production.

## THE GUIJANO TEA PLANT.

WE are indebted to M. Bonpland for the important information, that South America contains a plant capable of affording a beverage very much resembling the common tea of China. It is found in the neighbourhood of Popayan. The inhabitants of this town make an infusion of its leaves, which have all the properties of Tea, and may be applied to the same purpose. M. Gujano, a distinguished citizen of that place, was the discoverer. Perceiving a great analogy between the leaves of this *Melastoma* and the common Tea-leaves, he at first thought that his country possessed the real Chinese Tea. He immediately gathered a great quantity of its leaves, and prepared them in the same manner as the Chinese *Bohea* (*Camellia bohea*). On making the infusion, he at once perceived that the plant under examination was not that of China, but at the same time he ascertained that it could be employed for the same purposes, and would answer equally well in most cases. "We have often drunk with pleasure," says M. Bonpland, "the infusion of the *Melastoma Theezans*. It has the colour of Tea, and is much less astringent, but more aromatic. Many persons would doubtless prefer this drink to Tea, and I think it will be found as useful in most cases. The *Melastoma* Tea would thrive very well at Toulon, at the Hyères, and other southern countries which enjoy a mild temperature." At a time when our commercial relations with China stand on a very precarious footing, this fact is well worthy the attention of our enterprising countrymen. The *Melastoma Theezans* is a shrub from 12 to 15 feet high; smooth in all its parts; its leaves are from three to four inches long, oval, and slightly petiolated, of a fine green above, paler below, slightly dentated, and with five nerves. The flowers are white, and exhale during the night a very pleasing odour. They are disposed in a terminal panicle, are small, numerous, and sessile. The limb of the calyx is membranous,

with five small short teeth; the petals of the same length as the calyx; the filaments articulated in the middle, compressed, membranous in the lower part, and charged towards the summit with a very small tubercle; the anthers are wedge-shaped; the ovary almost free; the stigmata flattened. It has a spherical berry; blue when ripe, crowned by the teeth of the calyx, and having three many-seeded cells. Further details regarding this plant may be seen in Bonpland, l. c. p. 17, t. 9.

## GEOLOGY.

ON A SINGULAR DETACHED BLOCK OF STONE OCCUPYING THE SUMMIT OF A HILL AT DUNKELD.—Those who are acquainted with the natural history of Cornwall, cannot fail to recollect the theory of Dr Borlase, respecting detached blocks of granite so conspicuous in that country. The Doctor's notions, however, were not exclusively his own, as other antiquaries, over whose judgments the absurdities of the druidical worship seem to have shed their influence, have imagined these and similar appearances to be monuments of that superstition or religious government, all our knowledge of which is comprised in a very few casual hints contained in the Roman historians. The recent increase of attention to natural history, and more particularly to geological investigation, has, however, put to flight all these visions, and left us at no loss to distinguish betwixt the appearances produced by the efforts of art and design, and those which have resulted from the ordinary operations of Nature. Whatever interest, in a historical view, these phenomena may therefore have lost, they have gained a countervailing one in natural objects; in many cases illustrating, either in a curious or useful manner, the changes which time is daily, but slowly, making on the surface of the earth.

In Scotland, as in Cornwall, antiquaries have not been wanting, who were ready to attribute some of these remarkable natural appearances to a Druidical origin; and among these may be enumerated the Rocking Stone in Strathairdle, which has furnished a page to some of the writers of the day. The Rock, of which the following is a sketch, has also been called a Cromlech, which it resembles in the peculiarity of its position:—

But we can have no scruple in admitting it as an example, and a peculiar one at the same time, of those transported stones often found occupying situations so unexpected, as to render an explanation of the course which they have taken a matter of no small difficulty.

This rock occupies the summit of a hill near Dunkeld, in Perthshire, known by the name of Craig-y-barns (the Serrated Rock). Its shape is so irregular, that it cannot be described, but the above cut will supersede the necessity of saying any thing on this part of the subject. The same irregularity renders it difficult to form an accurate notion of its weight, but it probably exceeds fifty tons; a judgment founded on comparing it with other stones of known weights resembling it in shape. The greatest length is twelve feet, and the greatest thickness five, from which circumstances, with the aid of the cut, a sufficiently accurate notion of its form and dimensions may be conveyed.

From the above figure, it will be seen that the lower flat surface is supported on three loose stones; and in this circumstance consists that resemblance to a Cromlech,\* which has led to the unfounded notion of its druidical and artificial origin. These loose stones also lie at liberty on a flat and solid surface of rock; a circumstance which adds much to the appearance of artifice.

It is now necessary to remark, that this rock, as well as the supporters, consists of the same materials as the hill on which they rest, which is micaceous schist. It is indeed from this circumstance alone that is derived the proof of its not lying in its native place; but of its having, on the contrary, been moved to its present position, together with the stones by which it is supported. On examining the direction of the laminae in all these pieces, it is easy to see that they all lie in different ways, and all different from that of the laminar structure of the solid rock on which they repose. Hence, it is evident that the large block has been placed on the three loose stones which lie on the solid rock; exhibiting an appearance, it is true, of artifice, as perfect as if it had been the result of the hand of man, though really an accidental operation of Nature.

In accounting for it, however, by natural causes, there seems no reason to doubt that the whole is the result of the accidental fall, or transportation of the larger mass, combined with some posterior circumstances of waste. Originally it had probably been deposited on a bed of loose materials, the smaller of which have disappeared, leaving those three only which were essential to its support, and have been retained by its pressure.

\* Cromlechs in British antiquities are huge, broad, flat stones, lying upon other stones set upon end. Mr Rowland and Dr Borlase describe them as altars. They have also been considered as originally tombs; but that, in after times, sacrifices were performed upon them to the heroes deposited within. King Herod is said to have been buried in a monument of this kind in Denmark; and Mr Wright discovered a skeleton beneath one in Ireland.

The circumstance, in a geological view, most remarkable is, that it now lies on a point, which, if it be not absolutely the highest eminence of the surrounding hill, is yet so nearly at the same elevation with the other summits, that it could not have travelled from any of them to its present place; supposing the surrounding parts to have always been in the state in which they now are. The nearest summit is too little elevated to have permitted a stone of so irregular a form to have moved over the intermediate surface; and that which is higher, is now separated by a hollow or depression, which would equally have prevented its transportation from that point, unless the intermediate ground were restored to an uniform declivity. The integrity of the mass is indeed sufficient to prove that it has not been carried far; and it affords, in fact, a singular example, rather of the results which follow from the degradation of hills, than from the transportation of blocks. Its appearance may probably be explained by imagining that the summit on which it now stands was once higher; and that, in the progress of waste, this mass has now fallen from its original position, on the solid rock on which it now lies; overwhelming in its fall a heap of small materials or rubbish, of which the three supporting stones are the last remains.

We are indebted to Dr Macculloch for the principal part of the above observations.

### MISCELLANEOUS.

**HAZEL NUTS FOUND IN A SINGULAR STATE AT A GREAT DEPTH.**—These nuts were found upon one of the farms at Bonnington, the property of Sir John Hay, Bart., about one mile south from Peebles, in a bog about eight feet below the surface. The top soil was three feet of meadow clay, beneath which was a layer of grayish coloured gravel about four and a half feet thick. The bottom of the bog consisted of a mixture of gray sand and brown moss, with some branches of stumps of trees quite decayed, and the nuts were found near the bottom of this substance. The bog is part of a meadow about 1500 yards long, by about from 300 to 600 feet broad, having a declivity of about one foot in 400.

Upon opening these nuts, it was found that the kernel in all of them had entirely disappeared, though the membrane which enclosed it, and the nut itself, were as entire as if they had been fresh and ripe. By opening the nut carefully, the membrane could be taken out in the form of a perfect bag, without the least opening. The substance of the kernel must, therefore, have escaped through the membrane and the shell in a gaseous form, or must have passed through them when decomposed or dissolved by the water. In some of the nuts that had not arrived at maturity, the bag was very small, and was surrounded, as in the fresh nuts, with the soft fungous substance which had completely resisted decay.

**MAGNETISM.**—The attention of the "Westminster Medical Society" has lately been directed to the supposed influence of magnetism in the cure of various diseases. This subject was brought forward by Dr Schmidt, when he pointed out the distinction between mineral and universal magnetism, and contended that fluid acted solely on the nervous system.

Contrary to the opinion entertained by the greatest authorities on this science, he conceived that more magnetic influence existed between the friendly poles than the opposite; but this opinion was successfully overturned by Dr Ritchie and other members, from experiments made at the time.

Dr Schmidt exhibited a very simple instrument for obtaining the magnetic spark. This consisted of a piece of soft iron, round which copper wire was twisted. The extremities were amalgamated with quicksilver, and placed over the poles of a magnet; on one was fixed a plate of copper, and the connexion then being forcibly broken, a vivid magnetic spark was evolved.

**ANOMALIES IN THE HEN'S EGG.**—In a former Number we described a remarkable instance of three shells in the same egg. Since that communication was made, we have been favored with the following observations by an intelligent Correspondent:—

"It is not an uncommon circumstance to find two yolks in a single egg; and it is much rarer to find one egg surrounded with its shell, contained in another egg of a larger size. But I am not aware that there was any case on record, before your notice appeared, of three shells being in the same egg. Schurigio has collected many interesting facts relating to anomalies of the Hen's egg, which had been observed from the time of Bartholin to his own. Harvey, Ruisch, Haller, and many others, have also collected a number of similar cases.

"Mery showed to the Academy of Sciences at Paris in 1706, a boiled Hen's egg, in the white of which he found another Egg surrounded with shell, having an internal membrane, and filled with a white substance without yolk.

"Other instances have been recorded by Petit in 1742, and by M. Menière in September 1810."

**DISSECTION OF A FEMALE MUMMY.**—In the year 1825, Dr Granville dissected a female Mummy before the Royal Society. After depriving the body, by ebullition and maceration, of the bees-wax, myrrh, gum, resin, bitumen, and tannin, with which it had been impregnated and preserved, the parts resembled recent pathological preparations; and though the body must have lived 3000 years ago, Dr Granville was enabled to ascertain the age at which the lady died of ovarian dropsy, and also that she had borne children. Dr Granville gave the dimensions of its various parts, and it is truly singular that these happen to be precisely the same as of the *Venus de Medicis*, whose claims to be considered the most perfect model of the Caucasian female are undoubted.

**THE STUDY OF NATURE.**—The Mind of man, if it work upon Matter, which is the contemplation of the creatures of God, worketh according to the stuff, and is limited thereby; but if it work upon itself, as the Spider worketh its web, then it is endless, and brings forth indeed cobwebs of learning, admirable for the fineness of thread and work, but of no substance or profit.—*Bacon*.

**CAT HOSPITAL AT DAMASCUS.**—When M. Baumgarten was at Damascus, he saw there a kind of hospital for Cats; where they were kept in a large house walled round; and it was said that the apartments were quite filled with them. He was told, when he inquired into the origin of this singular institution, that Mahomet, when he once lived there, brought with him a Cat, which he kept in the sleeve of his gown, and carefully fed with his own hands. His followers in this place, therefore, ever afterwards paid a superstitious respect to these animals; and supported them in this manner by public alms, which were very adequate to the purpose.

### REVIEWS.

*Aperçu d'Histoire Naturelle, ou Observations sur les limites qui separent le Regne Végétal du Regne Animal, par Benj. Gaillon. Boulogne-sur-Mer. 1833. In 8vo. Imprimerie de Leroy-Mabile.*

(Sketches of Natural History, or Observations on the limits which separate the Vegetable from the Animal Kingdom, by Benj. Gaillon, &c.)

THE author of this *Aperçu* has long been engaged in studying the characters of Microscopic beings, and some of the results to which he has arrived exhibit no small degree of perseverance and talent. He has discovered some curious facts relating to the marine body hitherto called after Linnæus the *Conferva comoides*. While observing the mucous filaments of this supposed water-plant, he saw some small yellowish bodies like mere points issue from the filaments. They gradually became oval, and disengaging themselves from these mucous filaments, were finally deposited in immense quantities under the form of a chocolate brown paste, upon the salt water vase which contained them. There they expanded and emitted a globule of small coloured grains, which is evidently their fry. Each of these grains acquired motion and development; the small globular mass gradually extended and ramified itself, and ultimately produced that elongated and plant-like form, which has deceived all Botanists into the belief that it is a plant.

Such is the theory of M. Gaillon, who here proposes to remove the *Conferva comoides* from the vegetable to the confines of the animal kingdom, towards that point which the illustrious Lamarck has represented by the apex of the letter V, where the two branches approach indefinitely near at the base, without ever being confounded.

M. Gaillon proposes to give this new group of animals the name of *Girodella*, and to preserve its specific name *comoides*. He is also convinced, from his Microscopic investigations, that fresh water is still more abundant in productions of this nature than salt. Thus, the bodies which Botanists call *Confervæ*, and included by them in the vegetable kingdom, are, according to M. Gaillon, microscopic animalcules, to which he assigns the name of *Némazoaires*.

These new views have met with much opposition from several Naturalists of eminence; but the observations of MM. Desmazières of Lille and Chauvin of Caen have confirmed the remarks of M. Gaillon. The former of these able observers has declared the pellicules, called *Mycodermes*, which grow on beer, ink, paste, or sour wine, to be composed, like the *Némazoaires*, of an innumerable quantity of corpuscles, endowed at a certain period with the power of locomotion. M. Chauvin also confirms them by his remarks on the *Conferva zonata*. He observes that the green matter, which fills the interior of its filaments, is at first collected in spheroidal masses, and then forms corpuscles, which grow, burst their tube, escape from the envelop, and disperse themselves over the field of the microscope, where they move about with a swiftness of motion, of which none but an observer can form an adequate idea.

M. Gaillon publishes several elaborate tables of the families and genera of the *Némazoaires*. He also announces that he will receive, with pleasure, fresh samples of any not included in that table, as well as observations either for or against the animal nature of these bodies; and requests all who make their communications to add microscopic drawings, in order to render their arguments more clear. The last is a gentle hint to non-microscopic Naturalists, which they will readily understand.

ZOOLOGY.

DESCRIPTION OF THE PLATE—THE DOGS.

Fig. 1. THE BLOODHOUND.—There was, in early times, a popular belief that this Dog had the instinct to pursue murderers, and, if once put on their scent, that he could trace them with unerring certainty. This exaggeration proceeded from his being able to track fugitives, to follow them through the most secret coverts, and to seize them when found. There is an old law in Scotland, enacting that any person denying a Bloodhound entrance into a house, while in the act of searching for felons, should be treated as an accessory.

The Bloodhound is a large and beautifully-formed Dog; he possesses great strength, and his sense of smell is exquisite. In proof of this, the Hon. Robert Boyle relates the following anecdote:—"A person of quality, to make trial whether a young Bloodhound was well instructed, desired one of his servants to walk to a town, four miles off, and then to a market-town three miles from thence. The Dog, without seeing the man he was to pursue, followed him by the scent to the above-mentioned places, notwithstanding the multitude of market people that went along the same road, and of travellers that had occasion to cross it; and when the Bloodhound came to the cross-market town, he passed through the streets without taking notice of any of the people there, and ceased not till he had gone to the house where the man he sought rested himself, and there he found him in an upper room, to the wonder of those who had accompanied him in the pursuit."

The fame of the English Bloodhound has been deservedly transmitted to posterity by a monument in Bas-relievo, which is said to remain at present in the chimney-piece of the grand hall at the Castle of Meotargis, in France. The sculpture, which represents a dog fighting with a champion, is illustrated in a very well known narrative.

Fig. 2. THE STAGHOUND is the largest and most powerful Dog now in general use in Britain for the pleasures of the chase, being employed, as its name implies, for Stag-hunting. It is a mixture of the Bloodhound, old English Southern-hound, and the Foxhound.

Fig. 3. THE FOXHOUND.—No country in Europe can boast of Foxhounds equal in swiftness, strength, and agility, to those of Britain, where the utmost attention is paid to their breeding, education, and food. The climate also seems congenial to their nature, for, when taken to France or Spain, and other southern countries of Europe, they quickly degenerate, and lose all the admirable qualities they possess in this country. In the words of the Poet of the Chase—

"In thee alone, fair land of liberty,  
Is bred the perfect hound, in scent and speed  
As yet unrivall'd; while in other climes  
Their virtue fails,—a weak degenerate race."

It is a trait in our national character to be excessively attached to hunting, and in no country is the same strict attention paid to the breeding and comfort of hounds as in Britain. The kennel of the Duke of Richmond at Goodwood cost L. 19,000; and a thousand guineas have been paid for a pack of hounds.

Fig. 4. THE HARRIER.—This Dog is much smaller than the Foxhound, and is now universally used in Britain for Hare-hunting. It is possessed of great eagerness and perseverance, allowing the Hare but little time to breathe or double; and the keenest sportsmen frequently find it no easy matter to keep up with a good pack of Harriers.

Fig. 5. THE BEAGLE.—This is the smallest of all those Dogs of the Chase which pursue their prey by the scent alone. Its sense of smell is equal to any of those hunting Dogs comprised under the general denomination of Hound. It is a very eager Dog, but its diminutive size renders it incapable of taking the Hare by means of speed, and it succeeds in running down its prey by perseverance alone.

Fig. 6. THE ENGLISH TERRIER is a handsome and sprightly Dog, usually black above, with tan-coloured throat, breast, abdomen, and legs. This Dog, though but small, is very resolute, and a determined enemy to all kinds of game and vermin, in the pursuit of which it evinces an extraordinary and untaught alacrity. Some of the English Terriers will even draw a Badger from its hole. This Dog varies considerably in size and strength, and is to be met with from ten to eighteen inches in height.

Fig. 7. THE SCOTCH TERRIER.—There are several sub-varieties of this Dog in Scotland. Some persons consider that variety with strong and rather long bristly

hair and pricked ears to be the model of a real Scotch Terrier, but we believe the form in the plate has greater claims to that title. It is taken from a fine painting of a Terrier well known for his excellent qualities, and once the property of the late Duke of Buccleuch. The most esteemed breed are always of a sandy brown, varying in intensity.

Fig. 8. THE ISLE-OF-SKYE TERRIER.—This differs from the last in the hair being fully longer, the tail being more villous, the ears being larger and semi-pendulous, the body larger, the legs much shorter, and invariably crooked in front. The most esteemed breed is usually of the same colour as the common Scotch Terrier, although there are exceptions to this rule, and varieties in the colour often appear. Thorough-bred ones may be gray or even black, and recently we have seen a very beautiful and characteristic specimen, the property of Sir John Naesmith of Posso, which was of a pure white. The Isle-of-Skye Terrier is excellent for destroying vermin, to which he is an implacable enemy.

DESCRIPTION OF THE PLATE—THE WARBLERS.

The Warblers are very numerous, and are widely diffused in their Geographical range. They feed chiefly on Insects and their larvæ, and subsist occasionally on fruits. They are migratory in all countries where they are found, passing to the warmer regions during winter, in quest of insect food, and returning to more northern latitudes as the summer advances, for the purpose of incubation. The colours of the plumage, in most of the species, consist of strong and decided contrasts of green, yellow, and black. Nearly the whole species of this extensive genus are Songsters. All those figured on the plate are the size of life.

Fig. 1. The Palm Warbler (*Sylvia Palmorum*). This lively bird is an inhabitant of St Domingo, and other West India islands, extending its migrations to South Carolina and Philadelphia, in the United States. Its food consists of insects, fruits, and small seeds. It builds its nest on the very top of some lofty palm tree, from which it takes the name of "the Palmist." Its song is limited to five or six notes, and is full, soft, and mellow, although consisting of little variety. There is no difference in the form or hues of the male and female, but the winter plumage is more dull than the summer garb.

Fig. 2. The Blue-Mountain Warbler (*S. tigrina*). This species inhabits the lofty American range of alpine scenery, whose name it bears, seldom descending from the airy heights and gloomy silence of those dreary fastnesses. It is four inches and three quarters in length, and its song is merely a feeble screech, three or four times repeated. Its food consists chiefly of insects. It is not yet known whether there be any difference of colour between the male and female.

Fig. 3. The Hemlock Warbler (*S. parus*) was discovered by Wilson in the Great Pine Swamp of Pennsylvania. It is an active and lively bird, climbing and hanging among the twigs like a Titmouse. Its song consists of a few sweet notes, which it never utters while in motion, always singing while in a quiescent state. In pursuit of insects, its usual habit is to commence at the foot of a tree, and hunt, with much spirit and vigour, every branch as it ascends.

Fig. 4. The Autumnal Warbler (*S. autumnalis*) visits Pennsylvania in the month of October, and gleams its food principally from such insects as inhabit the willow trees; during which time, the male birds warble out some low, but sweet notes. The size of the bird is four inches and three quarters.

Fig. 5. The Black-throated Green Warbler (*S. Arvens*) is a very transient visitor of the United States, passing through Pennsylvania, in the end of April and beginning of May, on its way to the north to breed. It is seldom to be met with after the 10th of May. It frequents the high branches and tops of trees, in search of the larvæ of insects that prey on the opening buds. Its song consists only of a few chirruping notes, and its habits are active and lively.

Fig. 6 and 7. The Maryland Yellow-throat Warbler (*S. Marylandica*), male and female. This species inhabits the whole United States from Maine to Florida and Louisiana, and abounds in Maryland, Pennsylvania, and New Jersey, frequenting the low swampy thickets, and feeding on insects and their larvæ, which are to be met with among briars, brambles, and alder bushes. It sometimes also visits the cultivated fields of rye, wheat, and barley, ridding the stalks of insects, that might otherwise lay waste the fields. Its song is simple, consisting of the repetition of a twitter, resembling *twititittee*.

Fig. 8. The Kentucky Warbler (*S. Formosa*) inhabits the country in the United States whose name it bears, and is also to be met with between Nashville and New Orleans, frequenting the solitary and gloomy morasses of those countries, twittering

among the high rank grass, which principally covers these desolate regions. In this situation it usually builds its nest, or in the fork of some low shrub. Its notes are loud, and consist of *tweedle* three times repeated. It is said to be a very pugnacious bird, fighting with great violence during the amorous season. The female is destitute of the black under the eye.

Fig. 9. The Yellow-throat Warbler (*S. flavicollis*) remains in the United States for nine months of the year, quitting them during the three winter months. It is principally to be met with among Pine trees, ranging after Insects with much nimbleness, both spirally and perpendicularly, in the manner of a Titmouse. Every three or four minutes it utters its song, which is pretty loud, and somewhat resembling the notes of the Indigo bird.

ON THE SPINE AT THE EXTREMITY OF THE LION'S TAIL.—It has been observed by Homer and many other ancient poets, that the enraged Lion stimulates himself with blows of his tail. Pliny calls the tail the index of the Lion's mind, for, says he, "When the tail is at rest, the animal is quiet, gentle, and seems pleased, which is seldom, however, the case; and anger is much more frequent with him, in the commencement of which he lashes the ground, but as it increases, his sides, as if with the view of rousing it to a higher pitch." Again, we find among the Problemata of Alexander Aphrodisæus the following query:—"Why, since the moving of the tail is, in most animals, a sign of their recognition of friends, does the Lion lash his sides when enraged, and the Bull in the same manner?"

Didymus Alexandrinus, the ancient commentator of Homer, has a note upon that passage of the Iliad where the Lion's rage is mentioned—

\* \* \* \* \*  
"Such the Lion's rage,  
Lash'd by his tail, his heaving sides resound,  
He calls up all his rage."—*Iliad* xx. line 199, &c.

He asserts, "that the Lion has a black prickle on his tail among the hair, like a horn, when punctured with which, it is still more irritated by the pain." This opinion was by many looked upon as a mere fiction, the more so, as no anatomist, who possessed an opportunity of dissecting a Lion, had hitherto made mention of a spine of this kind. But the matter was put beyond a doubt, some years ago, by Professor Blumenbach, to whom a friend had presented a Lioness, which died a few days previous. He determined to satisfy himself regarding the assertion of the Greek Scholiast. He commenced his dissection, and discovered, on the very tip of the tail, a small dark-coloured prickle, as hard as a piece of horn, and surrounded at its base with an annular fold of the skin; and on cautiously dissecting the hide in this place, he discovered a singular follicle of a glandular appearance, to which the prickle formerly adhered, as represented beneath.

All these parts, however, were so minute, and the little horny apex so buried among the tufted hairs of the tail, that the use assigned by the ancient Scholiasts cannot be regarded as any thing else than imaginary; but the structure of the organ is so elegant, and its form so singular, that it cannot possibly be considered as fortuitous, or what is commonly called a *lusus nature*. This simple fact, however, seems to prove that the ancients were better acquainted with some departments of anatomy than could have been supposed.

TORMENTORS OF THE REIN-DEER.—Whale Island, during the summer months, is never without three or four families of Laplanders (Fieldfinner), with their herds of Rein-Deer. The causes that induce, nay even compel these people to undertake their long and annual migrations from the interior parts of Lapland to its coast, though they may appear singular, are sufficiently powerful. It is well known from the account of those travellers who have visited Lapland during the summer months, that the interior parts of it, particularly its boundless forests, are so infested by various species of gnats and other insects, that no animal can escape their incessant persecutions. Large fires are kindled, in the smoke of which the cattle hold their heads, to escape the attack of their enemies; and even the natives themselves are compelled to smear their faces with tar, as the only certain protection against their stings. No creature, however, suffers more than the Rein-Deer from the larger species (*Aestrus tarandi*), as it not only torments it incessantly by its sting, but even deposits its egg in the wound it makes in the hide. The poor animal is thus tormented to such a degree, that the Laplander, if he were to remain in the forests during the months of June, July, and August, would run the risk of losing the greater part of his herd, either by actual sickness, or from the Deer fleeing of their own accord to mountainous situations from the gad-fly. From these causes the Laplander is driven from the forests to the mountains that overhang the Norway and Lapland coasts, the elevated situations of which, and the cool breezes from the ocean, are unfavourable to the existence of these troublesome insects, which, though found on the coast, are in far less considerable numbers there, and do not quit the valleys, so that the Deer by ascending the high lands can avoid them.—*De Broke's Travels in Lapland*.

## BOTANY AND HORTICULTURE.

### BOTANICAL EXCURSIONS IN EGYPT, THE THREE ARABIAS, PALESTINE, AND SYRIA. NO. I.

BY N. BOVE, LATELY CONDUCTOR OF FARMING OPERATIONS AT CAIRO TO HIS HIGHNESS IBRAHIM-PACHA.

#### Arrival in Lower Egypt—Review of the vegetation and cultivation of the country—Visit to Fayoum.

On the 10th April 1829, I disembarked at Alexandria, and spent six hours in traversing the city and its environs; but the excessive heat of the weather had already parched up most of the annuals. The harvest was now over. I found nothing else to do here but to visit some gardens where I had remarked several trees from different foreign countries, but perfectly naturalized in this place. Among those trees which seemed to me to thrive best were the following:—the Apricot, Quince, Fig, Pomegranate, Orange, Citron, Olive, Mulberry, Peach, and Vine. Some of our common fruit trees, such as the Apple, Pear, Plum, and Cherry, vegetate very feebly in this place. Among the ornamental plants were the common Bead-tree (*Melia Azedarach*), the Sponge-tree (*Acacia Farnesiana*), the Pomegranate with double flowers, the Rose Laurel, the large flowered Jessamine, the Rose with a hundred leaves, the common Caruation, and several varieties of Thyme.

On the 17th April, I set out for Cairo, and remarked on the banks of the Nile the Egyptian Reed (*Arundo Ægyptiaca*), the Egyptian Sugar-cane, the Sea Ambrosia, thickets of the Gum Arabic tree (*Acacia Arabica*), and here and there some isolated tufts of *Acacia Lebbek*. The Cotton tree, the Mulberry, the Maize, and many species and varieties of the Cucurbitaceæ, were cultivated in the open fields.

I arrived at Cairo on the 25th April, and resided there continually during nineteen months. The same plants were cultivated in the fields and gardens as at Alexandria; but I also observed, especially in the gardens of the prince, many species, which seemed to have been introduced from the interior of Africa, and other distant countries.

The luxuriant vegetation of some plants in Egypt is truly surprising, for it is no uncommon thing to see annual shoots which are four or five metres long (from 13 to 16½ feet), especially with the Gleditschia, Cassia fistula, and some others.

The Sycamore Fig (*Ficus Sycomorus*), the trunk of which is from three to four metres broad (10 to 13 feet), and about twenty metres high (65½ feet), may give a still greater notion of the luxuriance of vegetation in Egypt. The branches of this tree, numerous and extensive, form a shade as dense as it is durable; for the leaves are persistent, and always of a beautiful verdure. The fruit is very nearly the size of the common figs, but flattened, and of a yellowish orange colour, approaching to brown. Their taste is more insipid, and not so sweet as that of the common Fig. This tree produces three crops of fruit every year. The latter grows on the branches deprived of leaves, and ends in forming tufts, which might be mistaken at a distance for our Mistletoe. To quicken the ripening of the Figs, the Egyptians nip or cut off their upper extremity with a knife. Three or four days afterwards, the fruit acquires a fine golden colour, and a sweet taste, when it is considered as sufficiently ripe. The wood of the Sycamore Fig has the name of being indestructible, or at least of undergoing scarcely any alteration in water. After this maceration, it is susceptible of a very fine polish. The greater number of the wooden amulets of the ancient Egyptians appear to have been formed of it; and at present it is employed with advantage for Hydraulic works.

While visiting the country residences of Ibrahim-Pacha, one of his Inspectors pointed out to me, near the village of Kouba, a stump of St John's Bread Tree (*Ceratonia Siliqua*), which he said had been planted under the reign of a Sultan who governed Egypt three hundred years ago. This Tree had been cut down by the French during their expedition in Egypt. Its roots remained in the earth, without giving any signs of vegetation, until his Highness Ibrahim having cleared the surrounding earth in 1826, and having sunk a well, the moisture occasioned three branches to shoot, which in three years acquired the height of three or four metres (10 to 13 feet), and their base was three decimetres in circumference. Some flower-buds seemed even to show themselves on the branches. Thus, this stump had remained buried in the earth for nearly thirty years, without perishing, and probably without ceasing to increase in size. This fact appears still more surprising than that related by M. Dutrochet, of a species of Pine.—(See Arch. de Bot. 1833, t. 2, p. 231, and Ann. des Scien. Nat. 1833, t. 29, p. 300).

In my Botanical Excursions round Cairo, I found some beautiful and remarkable kinds of Grasses, such as the *Panicum obtusifolium* of Delile, *Poa Ægyptiaca* of Linnaeus, and several others. The untilled lands are much infested with the *Poa cynosuroides*. Its roots spread to the depth of more than a metre (about 3 feet). The stalk rises to two metres, and furnishes the material for ropes to the inhabitants, as well as fuel for their ovens, brick fields, and potteries. The *Saccharum cylindricum* serves for the same purposes.

The Lotus (*Nymphaea Lotus*) grows about two leagues from Cairo, in a ditch which contains no water, except when the Nile overflows. In summer this ditch is completely dry, and serves as a public road during seven months of the year, from February to September. At this time, the Nile overflowing fills the ditch, which is covered two months after with Lotus flowers of the purest white.

In the moist sands of the desert, I found among other plants the *Tribulus terrestris*, and *Alhagi Maurorum*, or Manna Tree.

It is in the month of November, after the inundation, that a delightful verdure begins every where to appear. But before this period, the country is completely parched up, and shows the saddest aspect, which contrasts strangely with a cloudless sky. In order to enjoy the splendid prospect which the vegetation occasions, when in its vigour, it must be viewed from some neighbouring height. I witnessed the ensemble of this beautiful country, partly wild and partly cultivated, from the mountains Mokadam and Achmar, on the east of the city. An immense horizon, extending over the whole plain of Lower Egypt, presented to the eye villages one beyond the other, surrounded with fruit-trees, and thickets of Dates and the Gum Arabic Tree. Lebbeks and Sycamore Figs were scattered over this plain. Finally, the entire scene

was beautifully varied by small sheets of water presenting the dazzling reflections of the solar rays.

Following the desert on the north, I visited the gardens of a village called Madrea, about four leagues from Cairo, where it was pretended that the Balm of Gilead grew (*Amyris Opobalsamum*). This shrub had been naturalized there by one of the Turkish Sultans, who had introduced several plants from the neighbourhood of Mecca, at the time of the conquest of Arabia. It was in vain that I made diligent inquiries of the Arabs, in my attempts to find this plant, which Linnæus places in Egypt, and he probably received some specimens proceeding from these ancient cultures.

In the month of November, I visited the province of Fayaum, and found here nearly the same plants as formerly stated to grow on the banks of the Nile. Among those few which are not found in Lower Egypt, I observed the magnificent *Asclepias gigantea*, and the *Cyperus alopecuroides*, which the natives use for fabricating their pretty mats.

At three leagues distance from Medinetta-el-Fayaum, there is a small town called Fedamin, the most ancient in the province, and the environs of which are the best cultivated. It is the only place where the Christians still make wine. The Vines acquire here an enormous size, and their plantation mounts back probably to a very remote age.

The Olives, whose trunks are sometimes more than two metres ( $4\frac{1}{2}$  feet) in diameter, produce three or four thick branches which are about half a metre in diameter, and 5 or 6 metres high. Around them spring up thousands of offsets, which are cultivated at present to be planted out in tufts in the same manner as our Lilacs. These trees appear to have been standing before the era of Mahomet, for since that epoch no plantation has been made in Egypt, excepting those of the reigning princes.

### GEOLOGY AND MINERALOGY.

ACCOUNT OF THE TRAVELLED STONE NEAR CASTLE-STUART.—This mass of stone, of which the following is a representation, is composed of granite, gneiss, quartz, and other rocks of the primitive series, cemented together by a highly indurated ferruginous claystone.

It is apparently the very same as the rocks through which the romantic stream of Cawdor cuts its deep and narrow bed, near Cawdor Castle, in Nairnshire; and no rock of the same kind as the Travelled Stone is found nearer to it than seven or eight miles. Its present situation is on the sands in the little bay near Castle-Stuart, on the Moray Frith; and as it is left entirely dry by every receding tide, it is easily approached over the sands at low water. It is about five feet high at its most elevated point, calculating from the surface of the sand, and being to all appearance about one foot imbedded in it. In its horizontal diameters it measures nearly six feet in one way, by nearly seven in the other; its weight being about eight tons.

This large mass of stone is remarkable for having been removed from a situation which it formerly occupied, about 260 yards farther to the E.S.E., by natural means, and in the course of one night, to the position where it now stands. This remarkable circumstance took place on the night between Friday the 19th and Saturday the 20th February 1799. There had been a long-continued and severe frost; and the greater part of the little bay had been for some time covered with ice, which was probably formed there the more readily, owing to the quantity of fresh water from the stream running near Castle-Stuart emptying itself into this inlet of the sea. The stone was, by means of a projecting ledge all around it, bound fast by a vast sheet of ice, of 18 inches in thickness; and when the influx of the tide took place it was floated in the direction above described, and left in its present situation, the wind having blown with great violence in that direction.

Alexander Macgillivray, of the Sea Mill of Petty, witnessed the fact of the stone being removed, and was the first to discover its absence next morning after it took place. This storm was accompanied by a heavy fall of snow, and as soon as it abated he missed the stone, and perceived that it had been removed much nearer to low water mark, to the position it now occupies. The circumstance soon became generally known in the neighbourhood, and many flocked to the spot on the 20th to see it; among those was Mr Brodie of Brodie, at which time, the hole in which it had been for so many years imbedded still remained to mark distinctly yesterday's site, whilst its tract across the flat oozy sand was very perceptible, extending in a line all the way from its old to its new situation; and an extensive cake of ice still adhered to the stone, and attached to the projecting ledge.

This singular phenomenon will serve as one mode of accounting for the removal of stones to a distance from their original sites, which have long puzzled geologists.

Any person visiting the neighbourhood of Castle-Stuart can see the distance and direction to which this stone has been removed, as the original spot is marked by a wooden post, which was immediately put up as a substitute for the large stone, which served as a *march-stone* between the property of Castle-Stuart, belonging to the Earl of Moray, and the estate of Culloden, belonging to Duncan Forbes, Esq.

Woodside, near Airdrie, 16th March 1836.

SIR—I have in my possession the wing of a fly, encrusted with calcareous spar, found last summer about twenty-four feet from the surface, and near the bottom of a freestone rock twenty feet in thickness, at Fairybank, parish of Bathwell. It was discovered by a lad while quarrying the rock in one of its horizontal joints, in a spot from which a mass of stone about two tons in weight had just been removed, and where it could not possibly have found its way from the surface. The wing is rather larger than that of the dragon fly; it is of a golden colour, and beautifully membranous. It retains all the freshness of the natural wing, having undergone no petrifying process, and is set, as if by the art of the Lapidary, in the spar. I am not aware of any thing of the kind having hitherto been found in the coal formation, at least I have read of none in Geological works. The relic in my possession must at all events be regarded as a very singular and beautiful monument of Insect existence at a very remote geological epoch; the rock in which it was found being that which lies immediately above the lowest, save one, of our coal strata. I am, &c.

(Signed) JOHN CRAIG.

To Captain Thomas Brown.

This sketch accompanied the above communication.

SCENERY OF THE VAL DEL BOVE, MOUNT ÆTNA.—Let the reader picture to himself a large amphitheatre five miles in diameter, and surrounded on three sides by precipices from two thousand to three thousand feet in height. If he has beheld the most picturesque scene in the chain of the Pyrenees, the celebrated '*cirque of Gavarnie*,' he may form some conception of the magnificent circle of the precipitous rocks, which inclose on three sides the great plain of the Val del Bove. This plain has been deluged by repeated streams of lava, and although it appears almost level when viewed from a distance, it is in fact more uneven than the surface of the most tempestuous sea. Besides the minor irregularities of the lava, the valley is in one part interrupted by a ridge of rocks, two of which, Musara and Capra, are very prominent. It can hardly be said that they

“like giants stand,  
To sentinel enchanted land;”

for although, like the Trossachs, they are of gigantic dimensions, and appear almost isolated as seen from many points, yet the stern and severe grandeur of the scenery which they adorn is not such as would be selected by a poet for a vale of enchantment. The character of the scene would accord far better with Milton's picture of the infernal world; and if we imagine ourselves to behold in motion, in the darkness of the night, one of these fiery currents, which have so often traversed the great valley, we may well recall

“yon dreary plain, forlorn and wild,  
The seat of desolation, void of light,  
Save what the glimmering of these vivid flames  
Cast pale and dreadful.”

The face of the precipices is broken, in the most picturesque manner, by the vertical walls of lava which traverse them. The masses usually stand out in relief, are exceedingly diversified in form, and often of immense altitude. In the autumn, the black outline may often be seen relieved by clouds of fleecy vapour which settle behind them, and do not disperse till mid-day, continuing to fill the valley, while the sun is shining on every other part of Sicily, and on the higher regions of Ætna.

As soon as the vapours begin to rise, the changes of scene are varied in the highest degree, different rocks being unveiled and hid by turns, and the summit of Ætna often breaking through the clouds for a moment with its dazzling snows, and being then as suddenly withdrawn from the view.

An unusual silence prevails, for there are no torrents dashing from the rocks, nor any movement of running water in this valley, such as may almost invariably be heard in mountain regions. Every drop of water that falls from the heavens, or flows from the melting ice and snow, is instantly absorbed by the porous lava; and such is the dearth of springs, that the herdsman is compelled to supply his flocks, during the hot season, from stores of snow laid up in hollows of the mountains during winter.

The stripes of green herbage and forest land, which have here and there escaped the burning lavas, serve by contrast to heighten the desolation of the scene. When I visited the valley, nine years after the eruption of 1819, I saw hundreds of trees, or rather the white skeletons of trees, on the borders of the black lava, the trunks and branches being all leafless, and deprived of their bark by the scorching heat emitted from the melted rock; an image recalling these beautiful lines—

“As when heaven's fire  
Hath scath'd the forest oaks, or mountain pines,  
With singed top their stately growth, though bare,  
Stands on the blasted heath.”

*Principles of Geology, by Charles Lyell.*

IGNES FATUI.—We know that animal substances, in a state of putrefaction, always emit phosphorus, which, taking fire from the contact of the atmosphere, produces light and wandering flames. Such is probably the origin of those *Ignes fatui* which flitter at night over church-yards and fields of battle, and which have given rise to pretended apparitions of spirits in churches, where it is the pernicious and superstitious

custom to accumulate the remains of the dead. Hydrogen gas is often combined with phosphorus; this mixture is not fit for respiration; it quickly suffocates. There is also a circumstance which seems to have given rise to many histories of spirits and apparitions, namely, the luminous appearance of the inflammable air disengaged from marshes, and composed of hydrogen gas mixed with azotic. The air which inflames on the surface of certain springs, known by the name of *burning fountains*, arises from the presence of hydro-phosphoric gas, or, as it is otherwise termed, phosphoretted hydrogen. One of these springs is met with in the parish of St Bartholomew, in the department of the Isère. The disengagement of inflammable gas during the summer is so considerable, that we frequently see a flame seven feet high; and when travellers first behold it, they imagine that the whole village is on fire.—(Bouvier, *Journal de la Médecine Eclairées par les Sciences Physiques*, tom. iii. No. 8.)

### MISCELLANEOUS.

#### NO. III.—ANIMAL MAGNETISM.

SINCE the supposed effects of the Animal Magnetism, then, were not discoverable in those who were incredulous, there was great reason to suspect that the impressions which were produced were the result of a previous expectation of the mind, a mere effect of the Imagination. The Commissioners, therefore, now directed their experiments to a new point, namely, to determine how far the Imagination could influence the sensations, and whether it could be the source of all the phenomena attributed to Magnetism.

The Commissioners had recourse now to a M. Jumelin, who magnetised in the same way with MM. Mesmer and Deslon, except that he made no distinction of the magnetic *poles*. Eight men and two women were operated on by M. Jumelin; but none of them experienced any effect. At length a female servant of Dr Le Roy, who was magnetised in the forehead, but without being touched, said she perceived a sense of heat there. When M. Jumelin moved his hand about, and presented the extremities of his five fingers to her face, she said that she felt as it were a flame moving about; when magnetised at the stomach, she declared that the heat was there; at the back, and the same heat was there: She then affirmed she was hot all over the body, and suffered a headache. Seeing that only one person, out of eleven, had been sensible to the Magnetism, the Commissioners thought that this person was probably possessed of the most mobile imagination. They, therefore, tied a bandage over her eyes, and she was magnetised again; but the effects no longer accorded with the parts to which the Magnetism was directed!

When it was directed successively to the stomach and to the back, the woman only perceived the heat in her head, and a pain in her eyes, and in the left ear! The bandage was removed, and M. Jumelin applied his hands to the hypochondres; she immediately perceived a sense of heat in those parts; and, at the end of a few minutes, said that she was faint, and actually swooned. When she was sufficiently recovered, her eyes were again bandaged. M. Jumelin was then removed to a distance, silence was commanded, and they made the woman believe that she was again magnetised. The effects were now precisely the same, although no one operated, either near her or at a distance; she felt the same heat, particularly in the back and loins, and the same pain in the eyes and ears! At the end of a quarter of an hour, a sign was made to M. Jumelin to magnetise her at the Stomach; he did so, but she felt nothing; he magnetised her back, but without effect; in fact, the heat of the back and loins gradually ceased, and the pains in the head remained! Here, then, was demonstrative evidence of the operation of the Imagination. When the woman saw what was done, the sensations were placed in the parts magnetised; but when she could no longer see, they were referred to the most distant parts, where no Magnetism was directed; and, above all, they were equally felt when she was not magnetised at all, and not felt when she was magnetised, after a little repose, but unknown to herself. The fainting of a nervous woman, when made the subject of a mysterious experiment, and continued in a posture of restraint for a considerable time, is explicable upon natural causes. This experiment also showed, that the distinction of poles was purely chimerical. It was repeated the following day upon a man and a woman, with the same results. Sensations felt when they were not magnetised, could only be the effect of the Imagination: and it was found only necessary to excite and direct the Imagination, by questions, to the parts where the sensations were to be felt, instead of directing the magnetism upon those parts, in order to produce all the effects. A child of five years old was then magnetised; but it felt nothing, except the heat which it had previously contracted in playing.

These experiments were repeated by the Commissioners in various ways, upon many different persons, of all classes, and with the same results, differing only according to the difference of susceptibility in the imaginations of the individuals. They found effects constantly experienced, when no Magnetism was used, and *vice versa* (when the eyes were covered), according to the direction of the patient's attention by questions put to him with address. Now this practice could not lead to any error; since it only deceived their Imagination. For, in truth, when they were not magnetised, their only answer ought to be that they felt nothing.

Some facts communicated to the Commissioners by M. Sigault, an eminent physician at Paris, place the power of the Imagination in a strong light. "Having announced," he says, "in a great house, that I was an adept in the art of Mesmer, I produced considerable effects upon a lady who was there. The voice and serious air which I affected made an impression upon her, which she at first attempted to conceal, but having carried my hand to the region of the heart, I found it palpitating. Her state of oppression indicated also a tightness in the chest, and several other symptoms speedily ensued: The muscles of the face were affected with convulsive twitches, and the eyes rolled; she fell down in a fainting fit, vomited her dinner, and felt herself in a state of incredible weakness and languor. A celebrated artist, who gives lessons in drawing to the children of one of our Princes, complained during several days of a severe headache, which he mentioned to me when we met accidentally on the Pont-Royal. Having persuaded him that I was initiated in the mysteries of Mesmer, almost immediately, by means of a few gestures, I removed his pain to his great aston-

ishment." Dr Sigault justly remarks, that it is probably by such an impression on the mind, that the sight of the dentist removes the toothache when the patient has gone to him for the purpose of having his tooth drawn. He adds, that being one day in the parlour at a convent, a young lady said to him, "You go to M. Mesmer's, I hear." "Yes," he replied, "and I can magnetise you through the grate;" presenting his finger towards her at the same time. She was alarmed, grew faint, and begged him to desist; and, in fact, her emotion was so great, that, had he persisted, he had no doubt that she would have been seized with a fit.

But although the Commissioners were convinced by their experiments, that the *Imagination* was capable of producing different sensations, of occasioning pain, and a sense of heat, and even actual heat in all parts of the body; and therefore that it contributed much to the effects which were ascribed to *Animal Magnetism*; yet the effects of the latter had been much more considerable, and the derangements of the animal economy, which it excited, much more severe. It was now, therefore, to be ascertained, whether, by influencing the Imagination, convulsions, or the complete *crisis* witnessed at the public treatment, could be produced. In proof of this point, their experiments were not less conclusive, as the following relation of one or two of them will evince. As M. Deslon acknowledged that the complete success of the experiments would depend upon the subjects of them being endowed with sufficient sensibility, he was requested to select some of his patients, who had already proved their susceptibility of the magnetic influence, upon whom the trials might be made.

According to the principles of the Magnetisers, when a tree had been touched by them, and charged with Magnetism, every person who stopped near the tree would feel the effects of this agent, and either fall into a swoon or into convulsions. Accordingly, in Dr Franklin's garden at Passy, an apricot tree was selected, which stood sufficiently distant from the others, and was well adapted for retaining the Magnetism communicated to it. M. Deslon, having brought thither a young patient of twelve years of age, was shown the tree, which he magnetised, while the patient remained in the house under the observation of another person. It was wished that M. Deslon should be absent during the experiment; but he affirmed that it might fail, if he did not direct his looks and his cane towards the tree. The young man was then brought out, with a bandage over his eyes, and successively led to four trees, which were *not magnetised*, and was directed to embrace each during two minutes;—M. Deslon at the same time standing at a considerable distance, and pointing his cane to the tree actually magnetised. At the first tree the young patient, on being questioned, declared that he perspired profusely; he coughed, and expectorated, and said that he felt a pain in the head: he was still about twenty-seven feet from the tree magnetised. At the second tree he found himself giddy, with the headache as before: he was now thirty feet from the magnetised tree. At the third, the headache and giddiness were much increased; he said he believed he was approaching the magnetised tree; but he was still twenty-eight feet from it. At length, when brought to the fourth tree, *not magnetised*, and at a distance of twenty-four feet from that which was, the *crisis* came on; the young man fell down in a state of insensibility, his limbs became rigid, he was carried to a grass plot, where M. Deslon went to his assistance, and recovered him.

This experiment, then, was altogether adverse to the principle of Magnetism, not negatively, but positively and directly. If the patient, said the Commissioners, had experienced no effects under the tree actually magnetised, it might have been supposed that he was not in a state of sufficient susceptibility; but he fell into the *crisis* under one which was not magnetised; therefore, not from any external physical cause, but solely from the influence of the Imagination. He knew that he was to be carried to the magnetised tree; his imagination was roused, and successively exalted, until, at the fourth tree, it had risen to the pitch necessary to bring on the *crisis*.

THE FIRE OF SAINT ELMO is generally considered as an accumulation of electric matter round a point which moves in the air. This fire, then, may be expected to appear frequently at the top of the masts of a vessel sailing along with rapidity. The ancients observed this phenomenon. These fires, when seen in pairs, were called *Castor and Pollux*; when the flame was single, it bore the name of *Helen*. The spears of an army often appeared ornamented with these electrical plumes. (Pliny, *Hist. Nat.* II. cap. 37). A Swedish naturalist, travelling on horseback in snowy weather, saw his fingers, his switch, and the ears of his horse, covered with a fire of this description.—(Forskael, in *Bergmann, Géogr. Phys.* § 130).

THE GLOW-WORM.—Mr John Murray, in a communication made to the Royal Society, on the luminous matter of the Glow-worm, states some curious facts as the result of his own observation and experiments. His observations tend to show that this light is not connected with the respiration, nor derived from the solar light; that it is not affected by cold, nor by magnetism, nor by submersion in water. Trials of submersion in water, in various temperatures, and in oxygen, are detailed. When a Glow-worm was immersed in carbonic acid gas, it died shioing brilliantly; in hydrogen it continued to shine, and did not seem to suffer. Mr Murray infers, that the luminousness is independent, not only of the respiration, but of the volition and vital principle. Some of the luminous matter, obtained in a detached state, was also subjected to various experiments, from which it appears to be a gummo-albuminous substance, mixed with muriate of soda, and sulphate of alumina and potash, and to be composed of spherules. The light is considered to be permanent, its eclipses being caused by the interposition of an opaque medium.

ZOOLOGY.

DESCRIPTION OF THE PLATE—THE GIRAFFE (*Camelopardalis giraffa*).

It was long a matter of doubt in modern times, whether there existed such an animal as the Giraffe. This doubt was, however, set finally at rest by the zeal and exertions of the indefatigable traveller Levaillant, who saw, chased, overtook, and killed one in the interior of Africa.

The Giraffe is the tallest of quadrupeds, measuring eighteen feet from the hoofs to the tip of the horns. In its native wilds it feeds principally on a tree called *Acacia Giraffe*. Mr Richard Davis, animal painter to the King, who studied the manners of the young one which arrived in this country in August 1827, says, "In its natural habits, I cannot conclude that the Giraffe is a timid animal, for, when led out by its keepers, the objects which caught its attention did not create the least alarm, but it evinced an ardent desire to approach whatever it saw; no animal was bold enough to come near it. Its docile, gentle disposition, leads it to be friendly, and even playful, with such as are confined with it; a noise will rouse its attention, but not excite its fear.

"I do not think it very choice of its food when out, so that it be green and sweet. It is fond of aromatics; the wood of the bough it also eats; our acacia, and others of the mimosa tribe, it did not prefer; and it never attempted to graze; it seemed a painful and unnatural action when it endeavoured to reach the ground. I have seen it try to do so when excited by an object which curiosity led it to examine; its feet were then two yards apart. It was constantly in motion when the doors of its hovel were open; but it had no sense of stepping over any obstruction, however low.

"It is asserted by travellers, that it resembles the Camel, in having callosities on the breast and thighs, and that it lies on its belly like that animal. There are between the fore-legs what, to the casual observer, may appear to be such, but these are folds of loose skin, which enable it to separate its fore-legs when reaching downwards. Its mode of resting is, like most quadrupeds, on one side; but the operation of lying down is curious and peculiar: I will endeavour to describe it:—

"We will suppose it to be preparing to lie down on the right side; the first action is to drop the fetlock of the right fore-leg, then, on one knee of the left one, to bring down the other knee; it then collects its hind-legs to perform the next movement, the left one being brought rather forward, but wide, until the right hind-leg is advanced between the fore ones"—pretty nearly in the position represented in the second figure of the plate.—"This requires some time to accomplish, during which it is poised with the weight of its head and neck, until it feels that its legs are quite clear and well arranged; it then throws itself on one side and is at ease. When it sleeps, it bends the neck back, and rests the head on the hind quarters."

M. Acerbi, who saw this Giraffe and its companion at Alexandria, differs from Mr Davis in one essential particular. He says, "There are few naturalists who have not contributed to perpetuate the vulgar error, that in eating and drinking from the ground, the Giraffe is compelled to stretch his fore-legs amazingly forwards. Some even assert that he is obliged to kneel down. Of the few animals which fell under my observation, three took their food from the ground without inconvenience; and I am of opinion that when any difficulty exists in this respect, it is the effect of habit, acquired in the progress of domestication."

We hope that these and other discrepant points in the history of this interesting animal will not long remain unsettled, as four beautiful and healthy Giraffes have lately arrived in this country, and are now in the Zoological Gardens, London.

M. Thibaut, who has the charge of the Giraffes in the Gardens, Regent's Park, says they are extremely fond of society, and very sensible; he has observed one of them shed tears when it no longer saw its companions, or the persons who were in the habit of attending it. The Giraffe eats with great delicacy, and takes its food leaf by leaf, collecting them from the trees by means of its tongue. It rejects the thorns, and in this respect differs from the Camel. As the grass on which these Giraffes are now fed is cut for them, they take the upper part only, and chew it until they perceive that the stem is too coarse. Great care is required for their preservation, especially great cleanliness. M. Thibaut says, that he found the flesh excellent eating; the Arabs are very fond of it. On the 15th of August, last year, Thibaut saw the first two Giraffes; a rapid chase, on horses accustomed to the fatigues of the desert, put him and his companions in possession, at the end of three hours, of the larger of the two, the mother of one of these now in his charge. Unable to take her alive, the Arabs killed her with blows of the sabre; and cutting her to pieces, carried the meat to the head-quarters, where it was cooked and eaten.

The Giraffe has its eyes placed on the extreme convex sides of the skull, by which means it can see objects behind it as well as before. This will be observed, as also its manner of lying on the ground, by a back view, which we have given in the most distant figure on the plate.

Some idea will be formed of its mode of laying hold of branches, from the above cut, copied from the excellent paper of Sir E. Home on the Giraffe.

DESCRIPTION OF THE PLATE—THE OWLS

Of all the birds of prey, Owls are the most useful to man; as their food consists principally of rats, mice, and other vermin which steal abroad, under the cloud of night, to lay waste our corn fields and granaries. Yet it is strange that vulgar prejudice prevails over common sense and daily experience, so that these birds are viewed with hatred, and even dread. A singular appearance, and doleful cry, with their retired and lonely habits, have gained for them a superstitious character which is not likely soon to be wiped away. But their utility demands our kindest regard.

Fig. 1. THE VIRGINIAN HORNED-OWL (*Strix Virginiana*).—This is one of the largest of its tribe, the male bird measuring twenty inches in height, while the female is upwards of two feet. It is to be found in almost every quarter of the United States, and extends its range as far north as Hudson's Bay. It is a bold and noble bird, exhibiting courage equal to that of the Golden Eagle. It builds on high trees, usually fixing its nest on a horizontal branch. A characteristic anecdote of the superstitious notions of our countrymen, in which an Owl of this species was concerned, is related by Dr Richardson. "A party of Scottish Highlanders," says he, "in the service of the Hudson's Bay Company, happened, in a winter journey, to encamp after nightfall in a dense clump of trees, whose dark tops and lofty stems, the growth of more than a century, gave a solemnity to the scene that strongly tended to excite the superstitious feelings of the Highlanders. The effect was heightened by the discovery of a tomb, which, with a natural taste often exhibited by the Indians, had been placed in this secluded spot. Our travellers having finished their supper, were trimming their fire preparatory to retiring to rest, when the slow and dismal notes of the Horned Owl fell on the ear with a startling nearness. None of them being acquainted with the sound, they at once concluded that so unearthly a voice must be the moaning of the spirit of the departed, whose repose they supposed they had disturbed, by inadvertently making a fire of some wood of which his tomb had been constructed. They passed a tedious night of fear, and, with the dawn of day, hastily quitted the ill-omened spot."

Fig. 2. THE LONG-EARED OWL (*S. Otus*).—This species is common both to Europe and America. Like the Great Horned Owl, it also breeds on trees. It is fourteen inches and a half long, and three feet two inches in extent from the tip of one wing to that of the other. In America, Wilson found this species building in the midst of the nests of other birds, and some were even on the same tree; this is identically the same with the habits of this bird in Britain and other places of Europe.

Fig. 3. THE MOTTLED OWL (*S. Navia*, male), and fig. 4, a young female.—The male and female of this species are considerably different in the colour and markings of their plumage, as well as in the mottling. This has caused authors to describe them as distinct species. There is, besides, a marked difference in the

young and adult garbs of both sexes, and this has induced a still further multiplying of specific names. This bird is a native of the Northern States of America, and migrates southward on the approach of winter. It constructs its nest in the hollow of a tree.

## DESCRIPTION OF TWO NEW SHELLS.

The two Shells represented beneath were procured from Orkney, and are now in the Cabinet of William Nicol, Esq., Edinburgh. It is difficult to determine whether they are new species, or only greatly produced varieties of the *Buccinum Anglicanum* and *B. undatum*.

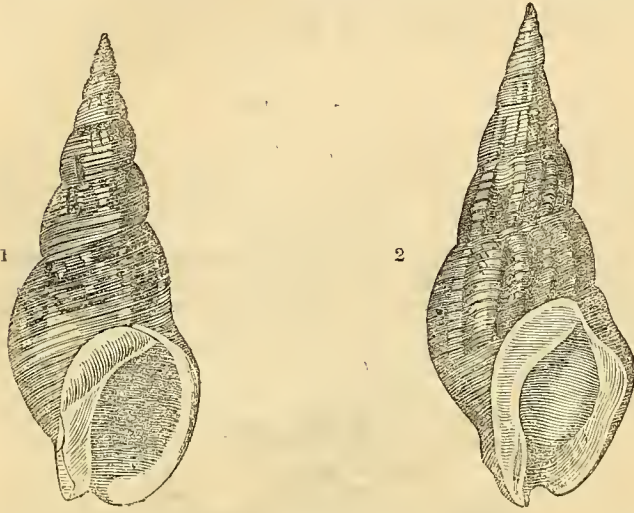

Fig. 1. agrees in all its characters with the *B. Anglicanum* of Lamarck, except in the spire being much longer and more fusiform, the breadth of the body of the shell being only about a third of its length; while in the *B. Anglicanum*, it measures nearly the half of the shell; it is of a reddish brown colour, fasciated and clouded with darker shades of the same colour. If it be really distinct from the *B. Anglicanum*, it might with propriety be distinguished by the name of *B. elongatum*. But until we have seen and examined the animal, the name must remain in abeyance.

Fig. 2. has all the characters and appearance of *B. undatum*, except in its greatly elongated shape, and if the animals really differ, it might be distinguished by the specific name of *acutissimum*.

These Shells are said to be obtained by their adhering to the fishermen's lines in deep sea water; and probably their greatly lengthened shape may be peculiar to this locality.

## BOTANY AND HORTICULTURE.

**SACCHARINE PLANTS.**—The most valuable plants producing Sugar in this country are Beet-Root and Parsnip. The White Beet (*Beta cicla*) is a hardy biennial plant, a native of the Sea Coasts of Spain and Portugal, and introduced into this country in 1570. It was from the roots of this plant that the French and Germans obtained sugar with so much success during the late war, while all their West India colonies were in the hands of the British. The following is the ordinary process of extracting the sugar from this plant:—The roots are reduced to a pulp by pressing them between two rough cylinders; the pulp is then put into bags, and the sap it contains is pressed out. The liquor is then boiled, and the saccharine matter precipitated by quicklime; the liquor is now poured off, and to the residuum is added a solution of sulphuric acid, and again boiled; the lime uniting with the acid, is got rid of by straining; and the liquor is then gently evaporated, or left to granulate slowly, after which it is ready for undergoing the common process of refining raw sugars. The French manufacturers have acquired so much experience in this process, that, from every 100 lbs. of Beet, they extract 12 lbs. of sugar in the short space of twelve hours.

The Parsnip (*Pastinaca sativa*) is next in value to the White Beet as a saccharine root. It is a biennial British plant, common in calcareous soils, and used in England chiefly as a vegetable. One thousand parts of Parsnips contain ninety parts of sugar, nine parts of starch, the rest being water and fibre. An excellent ardent spirit is obtained by distillation from this plant; but the wine manufactured from it, in the opinion of many, possesses a finer flavor, and more nearly approximates to foreign wine than that obtained from any other British produce. The process of manufacturing Parsnip Wine is more clearly and fully described, in an interesting little work entitled "The British Wine-Maker," recently published by Mr W. H. Roberts, than in any other work on the same subject. We may refer generally to Mr Roberts' useful and practical treatise as affording comprehensive and scientific information, while it seems a safe guide in the manufacture of wines from British produce. By the use of the *Saccharometer*—an instrument remarkable for the accuracy of its results—the process, as detailed in the work referred to, is rendered simple and of un-failing success, while, without its aid, wines of uniform quality, from year to year, cannot be otherwise produced. This circumstance arises from the fruits themselves yielding in some years a greater or less proportion of saccharine matter than they do in others, and this difference in quality is accurately determined by the application of the *Saccharometer*.

**RINGING OF WALNUT-TREES.**—The Baron de Trehoudi, near Metz, in Lorraine, has successfully introduced into his neighbourhood a practice of ringing Walnut-trees. It is accomplished by abstracting a ring of two inches breadth from the outer bark all around, and then plastering over the part with clay, mixed with moist manure. The Walnut-trees thus treated not only prove more prolific, but the fruit is more early.—*Neill's Horticultural Tour.*

## GEOLOGY.

**THE FOSSIL ELK OF THE ISLE OF MAN.**—In the Royal Museum of the College of Edinburgh there is now the most perfect known specimen of this animal. Its dimensions are given below, but that a more distinct notion may be formed of its great stature, we have placed beside it a human skeleton of six feet, drawn upon the same scale.

	Ft.	In.
Height to the tip of the process of the first dorsal vertebra, which is the highest point of the trunk, . . . . .	6	1
Height to the anterior superior angle of the scapula, . . . . .	5	4
Length from the first dorsal vertebra to the tip of the os coccygis, . . . . .	5	2
Height to the tip of the right horn, . . . . .	9	7½
Lateral or horizontal diameter of the thorax, at the widest part, that is at the eleventh rib, . . . . .	2	0½
Depth of the thorax, from the tip of the process of the eighth dorsal vertebra, to the sternum at the junction of the eighth rib, . . . . .	2	2

This superb fossil was dug up in the parish of Kirk Ralaff, and secured for our University Museum by the late Duke of Atholl. It was found imbedded in loose shell-marl, associated with numerous branches and roots of trees; over the marl was a bed of sand; above the sand a stratum of peat, principally composed of small branches and decayed leaves; and on the surface of all, the common alluvial soil of the country.

**FOSSIL BOTANY.**—The researches of M. Adolphe Brongniart into fossil organic remains, have in a great measure led to a knowledge of what must have been the appearance and temperature of the earth, when these fossils were vegetating on its surface; and also how far the various epochs of the existence of those plants accord with those remote Zoological epochs established by modern geologists.

The primitive vegetation, according to M. Brongniart, corresponded in its periods to the three successive formations of soil, from the earliest times, from the Creation down to that of the great Diluvian Change.

To the first period, which is co-etaneous with the simplest and the oldest formation of the globe, and lasted until the occurrence of deposits of coal strata, belong those vegetable bodies, the structure of which is in the highest degree simple. These organic remains are also remarkable for their rarity and the excessive magnitude of their dimensions. With respect to their rarity, compared to those of an analogous character inhabiting the present world, it is asserted, that of the former there are only six distinct families known; whereas of the latter, at least *two hundred* families exist; and with regard to the magnitude of their dimensions, it will be sufficient to instance the Fern trees, which in the actual world, and under the most favorable circumstances, grow to the height of from 20 to 25 feet only, while the same trees rose, in the primitive world, as high as 40 and even 50 feet. Brongniart thinks that the great coal formation which appeared at the termination of this *vegetable* period is due to the destruction of the plants in question. He arrives at the conclusion *à priori*, as well as from the inspection of the strata in which such plants are found, that life on the surface of the globe began with the vegetable kingdom; that the animals without a vertebrated spine succeeded next; and that probably the oceans contained no fish at the time.

To the second period of Antediluvian vegetation, corresponding to the geological

depositions of the *grès*, or freestone, and conchyliferous calcareous stone, which terminated with the clay formation, belong, first, a number of massive and terrestrial plants deposited in those strata, too small to give a decided character to the vegetation of that time; and, secondly, a series of plants found above those same strata, and below the chalk, totally distinct from those which marked the first period, and the remains of which are now to be met with in the calcareous rock of Jura and other districts. The Cryptogamic plants prevailed to a great extent at this epoch, and among the remains of that period, no vestige can be traced of any of our recent Palm trees, nor even of the Di-cotyledonous Plants of our times. During this period, no Mammiferous animal was in existence, whether terrestrial or aquatic. The Reptiles alone constituted the whole range of the existing vertebrated animals, different in kind and dimension from those of the present world, among which may be mentioned those singular beings destined by nature to fly as well as to swim, and since called, from the structure of their parts or entire skeletons found by geologists, Pterodactyles, Plesiosaurus, and Ichthyosaurus.

The third and last period of Antediluvian vegetation, far more interesting than either the first or second, and separated from the latter by the chalk formation, which contains some traces of marine plants, corresponds to the period when the last marine irruptions took place, between the intervals of which those huge animals were propagated, whose vestiges have been distinctly observed, such as the Palæotherium, Anoplotherium, and other genera now lost; and after them the Antediluvian Elephant, the Rhinoceros, and other contemporaneous races. The plants belonging to this period are distributed in two distinct soils—the one resulting from the depositions after marine irruptions, the other from depositions left by fresh water inundations. Their characters are distinct and peculiar; but they, in a great degree, correspond to the plants of the Postdiluvian world. Animalization was at its highest degree of perfection during the third period of Antediluvian vegetation, but *Man* formed no part of it.

FERMENTING PONDS IN MASSACHUSETTS.—A remarkable pond was discovered not long ago in Sharon, Massachusetts, known by the name of Mash-Bog Pond, from which great quantities of lenticular argillaceous oxide of iron and cake-ore are procured. From about the middle of August to some time in September, this pond presents the singular appearance of working or fermenting, as beer does when new.

#### MISCELLANEOUS.

EFFECTS OF COLD ON NEW-BORN INFANTS.—The excessive mortality which prevails among Infants during the first year after birth, has recently led several eminent physicians to investigate this important subject; and the following are the conclusions at which Dr Trevisan arrived, after a most careful investigation:—

1. In Italy, of 100 infants born in the months of December, January, and February, 66 die in the first month, 15 in the course of the year, and 19 only survive.
2. Of 100 infants born in the spring of the year, 48 survive the first year.
3. Of 100 infants born in the summer, 83 survive the first year.
4. Of 100 infants born in the autumn, 58 survive the first year.

The surplus of mortality, during the cold months, is attributed by MM. Milne-Edwards, Fontenelle, Villerme, and Dr Trevisan, exclusively to the practice of exposing the infants to the cold air a few days after birth, in taking them to the church to be baptized; and these distinguished physicians implore the Ecclesiastical authorities to devise some means, consistent with their religious duties, to put a stop to this fatal mistake.

It is not improbable that a great proportion of the numerous deaths which take place in Britain during the first year after birth may be attributable to a similar cause.

ICEBERGS OF THE SOUTHERN HEMISPHERE.—In the year 1830, Captain Horsburgh turned his attention to Icebergs which have been met with in the Southern Ocean, and on a strict search through the Journals of the East India Company, he could not meet with any record of the occurrence of these for a whole century previous to 1828, although vessels belonging to the Company, in their passage to and from India, had navigated into the parallels 40°, 41°, and 42° south; while in the years 1828 and 1829, icebergs had occasionally been met with by various vessels, so near the Cape of Good Hope as between the latitude 36° and 39°. The most striking instance mentioned by Captain Horsburgh, is that in which the brig *Eliza* fell in with five icebergs, in 1828, latitude 37° 31' south, longitude 18° 17' east of London. They were prodigious masses of ice, from 250 to 300 feet in perpendicular height above the surface of the ocean, and of the shape of church steeples. He accounts for them, by the supposition that a large tract of land exists near the Antarctic Circle, somewhere between the meridian of London and the 20° of east longitude; and attributes their unprecedented descent, during the years 1828 and 1829, to their disruption from the place of their formation by the violent convulsion of an earthquake or volcano. He mentions as a remarkable fact, that icebergs are met with at the same period of the year, namely, April and May, whether in the Northern or Southern Hemisphere, although the seasons are at that time, in each hemisphere, of an opposite character.

SINGULAR CASES OF THE EFFECTS OF NITROUS OXIDE.—The following very remarkable cases of the effects of Nitrous Oxide occurred among Professor Silliman's Students, at Yale College. A gentleman about nineteen years of age, of a sanguine temperament, cheerful disposition, and in the most robust health, inhaled the gas, which was prepared and administered in the usual dose and manner. Immediately his feelings were uncommonly elevated, so that (as he expressed it) he could "not refrain from dancing and shouting." To such a degree was he excited, that he was thrown into a frightful delirium, and his exertions became so violent that he sunk to the earth exhausted; and having there remained till he had in some degree recovered his strength, he again rose, only to renew the most convulsive muscular efforts, and the most piercing screams and cries, until, overpowered by the intensity of the paroxysms, he again fell to the ground apparently senseless, and panting vehem-

ently. For the space of two hours these symptoms continued; he was perfectly unconscious of what he was doing, and was in every respect like a maniac. He stated, however, that his feelings vibrated between perfect happiness and the most consummate misery. After the first violent effects had subsided, he was obliged to lie down two or three times, from excessive fatigue, although he was immediately roused upon any person entering the room. The effects remained in a certain degree for two or three days, accompanied by a hoarseness, which he attributed to the exertions made while under the influence of the gas.

The other case was that of a man of mature age, and of a grave character. For nearly two years previous to his taking the gas, his health had been very delicate, and his mind so gloomy and depressed, that he was obliged almost entirely to discontinue his studies. In this case of debility, he inhaled about three quarts of the nitrous oxide. The consequences were, an astonishing invigoration of his whole system, and the most exquisite perception of delight. These were manifested by an uncommon disposition for mirth and pleasantries, and by extraordinary muscular power. The effects of the gas were felt, without diminution, for at least thirty hours, and to a greater or less degree, for more than a week; but the most remarkable effect was upon the organs of taste. Before taking the gas, he felt no peculiar choice in the articles of food, but immediately after that event, he manifested a taste for such things only as were sweet, and for several days ate nothing but sweet cake. Indeed, this singular taste was carried to such excess, that he used sugar and molasses not only upon his bread and butter, and lighter food, but upon his butcher meat and vegetables; and continued to do so for some considerable time afterwards. His health and spirits recovered their wonted energy, which could only be accounted for from the influence of the nitrous oxide. He afterwards experienced no uncommon exhilaration, but became habitually cheerful, in place of being habitually grave, before he underwent this experiment.

FALL OF THE DENT DU MIDI.—On the evening of the 25th of August 1835, a violent storm raged all around the Dent du Midi. On the 26th, between the hours of ten and eleven in the forenoon, a considerable portion of the summit of this mountain was suddenly dislocated from the eastern ridge, and precipitated towards the glacier, on the southern side of which it carried along with it an enormous quantity. This immense mass of stone, earth, and ice, lodged into a deep ravine, which separates the Dent from the Col de Salenfe, and in which flows the torrent of St Barthelemy. At the straitened pass through which this rapid rushes to the smooth and verdant valley of the Rhone, an extensive mass of black slimy mud was noticed, on the surface of which lay fragments of rocks from the dimensions of twelve feet and downwards. It had all the appearance of a stream of lava, and directed its course towards the Rhone, through the Pine forest which mantles a part of the valley, carrying along with it every thing which stood in its course. Large trees were prostrated before it and broken like reeds; large blocks of stone were carried into the Rhone, the waters of which were forced over the opposite bank, and up the channel to a considerable distance. The high road was entirely blocked up by this mass of slime and stone, which rendered necessary the construction of a new road across by means of faggots. Every sort of communication between the upper and lower Valais was prevented for several days, until a temporary bridge could be constructed at the neck of the pass. Dense clouds of dust ascended to a great height for several days after this catastrophe, giving it all the appearance of a phenomenon produced by means of volcanic agency, and a deep valley was hollowed out of the mass.

#### REVIEWS.

*Neue Wirbelthiere, zu der Fauna von Abyssinien gehörig, entdeckt und beschrieben von Dr E. Rüppell. Frankfurt am Main, 1835. Fol. Erste Lieferung—Säugethiere.*

(*New Vertebrata, belonging to the Fauna of Abyssinia, discovered and described by Dr E. Rüppell. Frankfurt on the Maine, 1835. Fol. First Part—Mammalia.*)

In this important work, the learned author has commenced by describing six new species of Mammalia, being three Monkeys, two Antelopes, and one Goat. The illustrations are got up with great care, and are accompanied by a diagnosis of each species, as well as a circumstantial description; and it is intended that this work shall be annexed to the celebrated Zoological Atlas of the author. Hitherto he has confined himself to the illustration of species previously unknown, and each class of Vertebrata is intended to form a separate series, any one of which may be purchased separately.

The first Monkey is a *Colobus*, to which he assigns the specific name of *Guereza*. It is quick and lively, of a harmless disposition, and lives in small families upon lofty trees. Long hair, white as snow, hangs from the side of its body, which is in every other part, except about the throat and the region around the eyes, of a deep black. Its long tail terminates in a white tuft.

The second species (*Macacus gelada* of Rüppell) is very like the *Cynocephalus Hamadryas* in the colour and quality of its hair, but in every other respect it is a true *Macacus*. Its food consists of seeds and roots, and it often makes great devastations among the cultivated fields. It lives in numerous families, among rocky districts covered with low bushes, and is always seen upon the ground.

The descriptions of the Antelopes are not less interesting than the preceding, as well from the striking manner in which allied species are grouped together, as from the important light thrown upon the geographical distribution of the separate groups of species found in the south and west of Africa.

The *Antelope Defassa* of Rüppell attains the size of a full-grown Cow. It lives in small families upon the grassy plains of Western Abyssinia. Its gait is heavy, and its favourite food consists of the leaves and fruit-cups of the *Holcus Sorghum*. In general character, it approaches nearly to the *Redunca* group of Major Hamilton Smith.

Of the other species, the *Antelope Decula* of Rüppell frequents the bushy mountain-valleys of Abyssinia, and the animals go about in couples. This species may be regarded as the Abyssinian representative of the *A. scripta* of Western Africa, and the *A. sylvatica* of the South. The other species (*Antelope Beisa*) of Rüppell approaches nearly to the South African Oryx, in the entire colour of the body, and in the shape of the horns, which are wanting in the female. It is found on the coast of the Red Sea, and perhaps also in Egypt, at least it was seen by the unfortunate Burckhardt when on his voyage from Schendi to Suakin. It lives in small families among low valleys, with bushes slightly interspersed, and feeds upon grass. When attacked or hardly hunted, it fights courageously, and defends itself with its pointed horns.

The remaining plate represents a Steinbock (*Copra walie*, Rüpp.) Its description is contained in the second part of this valuable work.

*Excursions illustrative of the Geology and Natural History of the Environs of Edinburgh*, by William Rhind. Second Edition, Royal 18mo. Edinburgh. 1836.

IN our third number we noticed the first edition of this useful little work, and we now turn to the second edition with increased interest. The present contains more than double the matter of the first, and the different localities which the author describes are increased in an equal degree. These important additions to the text have rendered it a most valuable companion in our walks around a district which, our author justly remarks, "may truly be said to constitute the classic fields of Geology. Here Hutton first exercised his active and comprehensive intellect in rearing a system that bids fair to be permanent; and here many a contest has been maintained between the chiefs and heroes of opposing theories." Perhaps there is no situation in Europe where the elements of Geology can be more advantageously studied than in the neighbourhood of Edinburgh; for we have, within the very limited space of a few miles, almost all the varieties of formation, except the Primitive. Certainly no district has been more thoroughly investigated, and by men of the first distinction in this branch of science. Mr Rhind has most judiciously availed himself of all that has been written, while he has himself visited every corner which he describes, and has added many interesting observations.

Mr Rhind's remarks on the Coal Fields of this district are very judicious, and give a clear view of the subject. The Fossil Limestone of Burdichouse, which excited so much interest among the Geologists during the Meeting of the British Association here, forms the subject of an interesting chapter, and several well engraved woodcuts of all the fossils have been introduced.

The work contains 152 closely printed pages on a small type; a coloured map of the Environs of Edinburgh; two picturesque and geological views of the "Chain of the Pentland Hills and Arthur Seat from the North, and the Pentland range from the South;" besides 54 distinct figures on wood, representing various sections of stratification and rare natural history objects of the district. The price is three shillings and sixpence.

Under Meteorology, we shall insert in our next number an extract from Mr Rhind's work, which will not only interest our readers, but also give them some idea of the contents of the work itself.

#### OBITUARY.

CAPTAIN JAMES HORSBURGH, F.R.S. died at his house in London on the 14th May last, in the 74th year of his age.

This distinguished individual and valuable man was a native of Elie, a small town on the East coast of Fife, Scotland, where he sprung from humble, pious, and respectable parents. He commenced his career in the obscure capacity of cabin-boy and cook in a merchant vessel. Through long and unswerving good conduct, he at last was elevated to the command of the *Anna*, East Indiaman, in the year 1802, chartered for Bombay; after reaching which he spent two years in coasting the peninsula of India, visiting Canton and the China Sea, and the islands of the Indian Archipelago, whence he returned to England in 1805.

The Captain possessed a dauntless and enterprising spirit, and a strong natural capacity and inquiring mind, which enabled him to acquire a thorough knowledge of every subject of practical importance and scientific bearing in reference to East Indian Hydrography. It was from his letter written on his arrival from India to the Hon. Henry Cavendish, and published in the Philosophical Transactions, that the scientific world became acquainted with the progress of that astonishing regularity in the rising and falling of the barometer, which so peculiarly distinguishes the tropical regions, and becomes disturbed, or again lost, with an increase of latitude in the station of observation. He also fully developed the nature of the circumstances under which it became manifest, or gradually disappeared, as a ship in her progress alternately crosses the Line, and advances into higher Northern or Southern Latitudes.

Soon after his return he married, and never again went to sea, and left his profession to devote himself to higher objects. His first publication in 1805 was "Memoirs" of his voyage, containing much valuable practical information. He next turned his attention to his great work, the "East India Sailing Directory," which has secured to him the admiration and regard of every maritime nation in the world. It was the result of five years indefatigable research among the archives of the East India Company. In 1810, he was appointed Hydrographer to the Company, in which capacity he constructed the numerous inestimable charts, which appeared in succession from the Hydrographical Office by order of the Court of Directors; which arduous and unremitting labours he continued up till the 18th of April last, when the first symptoms of water in the chest appeared. He lingered until his demise under great bodily suffering, which he endured with fortitude and patience.

The principal writings of Captain Horsburgh, besides his "Directory," are "Atmospherical Register for indicating Storms at Sea," 1816. In 1819 he edited Mackenzie's Treatise on Marine Surveying, and afterwards his "Compendium of the Winds," "The East India Pilot of general and particular Charts from England

to the Cape of Good Hope, Madras, and China;" these were in conjunction with Mr Arrowsmith, and on the largest scale ever published. "Remarks on Icebergs which have been met with in the Southern Hemisphere," published in the Philosophical Transactions for 1830.

#### LEARNED SOCIETIES.

ASHMOLEAN SOCIETY, OXFORD.—*May 20.*—The president in the chair.—Dr Buckland communicated to the Society a notice on some very curious recent discoveries of fossil footsteps of unknown quadrupeds, in the new red sandstone of Saxony, and of fossil birds in sandstone of the same formation, in the valley of the Connecticut. The sandstone which bears the impressions of these footsteps is of the same age with that in which, in the year 1828, Dr Duncan discovered the footsteps of land tortoises, and other unknown animals, near Dumfries. In the year 1834, similar tracks of at least four species of quadrupeds were discovered in the sandstone quarries of Hesseberg, near Hildburghausen. Some of these appear to be referable to tortoises, and to a small web-footed reptile. The largest footsteps mark the path of a large quadruped; probably allied to *Marsupialia*, or animals that carry their young in a pouch, like the kangaroo. The name of *Cheirotherium* has been given to this animal, from a distant resemblance, both of the fore and hind feet, to the human hand. The size of the hind foot was twice as great as that of the fore foot, being usually eight inches long and five inches wide: one was found twelve inches long. These footsteps follow one another in pairs, at intervals of fourteen inches from pair to pair, each pair being on the same straight line. Both large and small steps have the great toes alternately on the right and left side, and bent inwards like a thumb. Each step has the print of five toes. The fore and hind foot are nearly similar in form, though they differ so greatly in size. No bones of any of the animals that made these footsteps have yet been found. Another discovery of fossil footsteps has still more recently been made by Professor Hitchcock, in the new red sandstone of the valley of the Connecticut. In three or four quarries of this sandstone he has ascertained the existence of the tracks of at least seven extinct species of birds, referable, probably, to as many extinct genera. All of these appear in regular succession on the continuous track of an animal in the act of walking or running, with the right and left foot always in their relative proper places. The distance of the intervals between each footprint on the same track is occasionally varied, but to no greater amount than may be explained by the bird having altered its pace. Many tracks are often found crossing one another, and they are sometimes crowded, like impressions of feet in the muddy shores of a pond frequented by ducks or geese. All these fossil footsteps most nearly resemble those of *Grallæ* (waders). The impressions of three toes are usually distinct; that of a fourth, or hind toe, is generally wanting. The most remarkable among these footsteps are those of a gigantic bird, twice the size of an ostrich, whose foot measured fifteen inches in length, exclusive of a large claw measuring two inches. The toes of this bird were large and thick. The most frequent distance of these larger footsteps, from one another, is four feet; sometimes they are six feet asunder. The latter were probably made by the animal when running. There are also tracks of another gigantic bird, having three toes, of a more slender character. These tracks are from fifteen to sixteen inches long, exclusive of a remarkable appendage extending backwards from the heel eight or nine inches, and apparently intended (like a snow-shoe) to sustain the weight of a heavy animal walking on a soft bottom. The impressions of this appendage resemble those of wiry feathers, or coarse bristles, which seem to have sunk into the mud an inch deep;—the toes had sunk much deeper, and round their impressions the mud was raised into a ridge several inches high, like that round the track of an elephant in clay. The length of the step of this bird appears to have been six feet; the footsteps on the five other kinds of tracks are of smaller size, and the smallest indicates a foot but one inch long, and a step from three to five inches. The length of the leg of the African ostrich is about four feet, and that of the foot ten inches. All these tracks appear to have been made on the margin of shallow water, that was subject to changes of level, and in which sediments of sand and mud were alternately deposited. And the length of the legs, which must be inferred from the distance of the footsteps from each other, was well adapted for wading in such situations. Professor Powell afterwards gave a short account of the progress of his researches on Light. Professor Brongniart and Dr Milne-Edwards, of Paris, were present at the meeting.—*Literary Gazette.*

GEOLOGICAL SOCIETY.—There was read at the Society a letter from Mr De la Beche, explanatory of the geological position of a collection of fossils from the northern district of Cornwall. He states that, in the grauwacke of Western Somerset, Devon, and Cornwall, natural divisions may be instituted, founded on well-marked characters; but he conceives that the whole of this district belongs to a system older than the Silurian formations of Mr Murchison. Some of these organic remains were procured at Dinas Cove, Padstow Harbour, Tretelga Island (Lower St Columb Porth), and Towan Head, near New Quay, from the slate which is associated with sandstone, conglomerates, and limestone, and which is of the same age with the fossiliferous slate of Tintagel. The other fossils of this collection were procured near Bodmin, by Dr Potts, and in the vicinity of Liskeard. Mr De la Beche also states that there are two distinct evidences, in Somerset, Devon, and Cornwall, of two considerable movements of the land, one to a height of thirty or forty feet above the present level of the sea, and the other to an unascertained depth beneath it, since the production of the existing vegetation of the land, and the Molluscan inhabitants of the neighbouring ocean.

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE—THE CONES.

THE elegance of form, splendid colours, and fine polish exhibited by Shells, have excited admiration in all ages, and procured for them a conspicuous place in Cabinets of Natural History. The Molluscous animals, which once dwelt within these elegant envelopes, perform an important part in the economy of Nature. Their useful as well as noxious qualities render them of high interest. Conchology, however, acquires a higher importance in various points of view. By a knowledge of this branch of Natural History, we are enabled to trace, to a certain extent, the past history of the Earth, in ascertaining the relative antiquity of various strata which lie beneath its surface; for shells are found in general to be the most perfect of all organic fossil remains, and may in truth be termed the "medals of the ancient world." Many kinds of Testaceous animals furnish an excellent and nutritious food, and some tribes supply the table with a delicate luxury. The mother-of-pearl affords materials for ingenuity and art; and the pearl itself, often the rival of the most precious gems, in the estimation of mankind, is the production of testaceous animals. Even the pernicious effects of some tribes demand our attention in studying their history, that we may be the better prepared to avert their depredations. The Snail, in ravaging the garden and the field, marks its progress by the destruction of some of the fairest of the vegetable tribes; and the Ship-worm, the dread of the mariner, appears an insignificant instrument to humble the glory and pride of Man, in demolishing, by its unseen labours, the noblest efforts of his ingenuity and skill.

The Cones are generally more esteemed by collectors than perhaps any other Shells. It is a very extensive Genus, as Lamarck describes 181 recent, and 9 fossil species, besides many varieties; yet the British Seas do not produce a single individual. This genus is confined to the warmer regions of the earth, increasing in numbers as we pass the equator. Many of the species are remarkable for the regularity and beauty of their markings, as well as for the fine colours which they exhibit. They are also prized on account of their elegant form, which is that of a reversed Cone, and turbinated.

Fig. 1. The MATCHLESS CONE. (*Conus Cedonulli*.) This Cone has always been highly esteemed by the curious collector. It was once exceedingly rare, and brought a very high price; as much as one hundred guineas have been paid for a single specimen of the *Cedonulli*. A single variety of this shell, which formerly belonged to the celebrated Naturalist Lyonnet, was valued at three hundred guineas. This shell is subject to considerable variety in the style and character of its markings;—nine are described by Lamarck. The Matchless Cone is a native of the seas of South America.

#### DESCRIPTION OF THE PLATE—THE WRENS.

Modern Naturalists have restricted this genus to such birds as have a slender, slightly compressed, curved, and marginated bill, with the nostrils basal, and half covered by a naked membrane; the wings are short and rounded, with the fourth

and fifth feathers of equal length, but longer than the others; the tail short, rounded, and erect, and the tarsus the same length as the middle toe.

The birds of this genus are subject to a wide geographical distribution; although there is but one species in Europe, which is common to all its kingdoms.

Fig. 1. The Winter Wren (*Troglodytes Hyemalis*).—This lively little bird is a native of North America, and visits the United States in the month of October, where it generally remains all winter, and migrates to the north in spring, to fulfil the important law of incubation. In its general appearance it has a strong resemblance to the European Wren; and some Naturalists have considered it as of the same species. It sings with great animation while mounted on the point of some branch of a tree. It is by no means a shy bird, as it is to be found in out-houses, yards, and gardens, in different cities of the Union.

Fig. 2. The European Wren (*T. Europæus*).—The Common Wren is a hardy bird, and braves the winter in almost every quarter of Europe, where it enlivens the natives with its sweet and sprightly notes. During this season, it is to be found close to the dwellings of men. It betakes itself to the woods in the summer. The nest is remarkable for its neatness, being of an oval shape, with a hole at the side for an entrance.

Fig. 3. The House Wren (*T. Oedon*).—This species is migratory; it arrives in Pennsylvania about the middle of April, and begins to construct its nest in the second week of May. It is customary for the natives to place a small box on the top of a pole in the garden for its reception; and if this be neglected, it will take possession of a hole in the roof or wall, and has even been known to breed in an old hat. The conjugal pair generally hatch two broods in a season,—the one in June, and the other in the end of July.

Fig. 4. Bewick's Wren (*T. Bewickii*).—This bird was discovered by Audubon, near St Francisville, Louisiana. It is also a migratory species; but the breeding station is unknown. It is not known whether it has any song.

Fig. 5. The Marsh Wren (*T. Palustris*).—The habits of this bird are retired; it arrives in Pennsylvania about the middle of May, or as soon as the water Nymphæ and reeds on the sides of rivers are sufficiently high to shelter it. To such localities it generally limits its excursions. It feeds on insects and their larvæ. Its notes consist of a curious crackling sound, like air bubbles forcing their way through mud or boggy ground when trod upon. Its nest is constructed with admirable neatness and apparent skill.

Fig. 6. The Brown Wren (*T. Furva*).—This species is a native of Brazil and Cayenne, and has sometimes been confounded with the House Wren of the United States. It constructs its nest in the low parts of woods. The total length of this bird is four inches.

Fig. 7. The Great Carolina Wren (*T. Ludovicianus*).—The general appearance of this bird at once conveys the idea that it is a Wren, although, on a minute examination, several characters present themselves which render it equivocal; its great size, and larger proportional bill, and other discrepant characters, render it necessary to form a sub-genus for its reception. It is found in Pennsylvania, Virginia, and other parts of the United States, where it is said to build. It is five inches and a quarter long.

Fig. 8. The Long-billed Wren (*T. Longirostris*) is remarkable for the length of its bill, and large size, measuring five inches and three quarters. It inhabits Brazil; but nothing is known of its habits.

A MONGREL DOG.—M. Joannon Navier, Mayor of Cuire, is possessed of a dog, the offspring of a Wolf-Dog and a Jackal. He is of a small size, not exceeding the ordinary dimensions of the Jackal, but so quarrelsome and fierce, that he is the terror of all the neighbouring dogs. He is very voracious, and devours all the ducklings and chickens which he meets with; and is consequently kept always tied up. He is most affectionate to his master, but is not considered a good watch-dog, as he seldom barks. Like all predatory animals, he frequently digs holes in the earth, and is very agile, bounding along the tops of walls with great dexterity when left at liberty. He is subject to frequent changes of his fur, and the last time he cast his coat the under hair was very short; that which covered the thighs was long, and streaked obliquely across, producing a wavy appearance; his tail was long, and finely formed. His ears are like those of his sire—the Wolf-Dog; the conch of which is firm, erect, and pointed backwards; his muzzle is provided with mustachoes, formed of numerous stiff hairs; his eyebrows are prominent, which, with a peculiar expression of the eyes, give him a look of suspicion and ferocity.

## BOTANY.

**EDIBLE SEA WEED.**—The Philippine Islands contribute a very large portion of those Edible Birds-Nests, which are consumed as food in immense quantities by the Chinese, and recently also in Europe. Our particular attention must now be directed to that Edible Sea Weed, which is encountered on the coast of the Philippines, as well as on those of the Bashees, the islands of the Japanese Empire, the Moluccas, and many others, where it serves either as an article of food or for exportation. In the markets of Macao and Canton, one meets with large chests of this dried Sea Weed, which is introduced from Japan. The marine plant constituting this branch of trade is the *Spharococcus cartilagineus*, variety *setaceus* of Agardh, which is found throughout India in extraordinary plenty. It is eaten by the Salangane or Esculent Swallow (*Hirundo esculenta* Lin., properly *Cypselus*), for the purpose of employing it in the construction of its nest. The mass, after being changed into a jelly in the stomach of the Bird, is again thrown up, and by its means the nest adheres together. This remarkable Indian Birds-nest comes to China in a raw state, besmeared with dirt and feathers, where it is cleansed in a large warehouse by instruments specially adapted for the purpose, and then consists of nothing else but well-soaked *S. cartilagineus*. On its being thus prepared, it is usual to add a very large quantity of seasoning, when it deserves to be placed in the first rank of Chinese delicacies. The Japanese have long since discovered the method of preparing the substance of this nest in an artificial manner. After having been pulverized, the Sea Weed is boiled down into a thick jelly, and is then drawn out into long threads in the same manner as Vermicelli or Macaroni. It is then brought for sale under the name of *Dschin-schan*. The Dutch call it *Ager-Ager*. These Birds-nests, whether genuine or counterfeit, are used by the Chinese for sauce, which are served up with their meat-dishes; but the Europeans resident in China prefer it in the form of jelly, for which use the *Dschin-schan*, or *Ager-Ager*, is well adapted. By means of a single boiling, they convert the dried substance into a jelly, which is served up in wine or the juice of fruit. The dried *Dschin-schan* is sometimes cut into large pieces, and put into thick gravy; it is dissolved in about a minute, and then assumes the form of transparent Vermicelli.

We have dwelt thus at length upon this substance, because there has been so much discussion as to the properties of *Carrageean*, which is nothing else than the dried *Spharococcus crispus*, found in large quantities on the western and northern coasts of England, and probably resembles the setaceous variety of the *S. cartilagineus*. But we can by no means believe that any other quality can be assigned to the jelly thence obtained, except one purely nutritive, and which does not overload the organs of digestion.—From the *German of Meyen*,—*Reise um die Erde*—(Meyen's Voyage round the Earth.) Bd. II. S. 276.

**RED SNOW PRODUCED BY A FUNGUS.**—Mr F. Bauer ascertained that the Red Snow of Baffin's Bay, observed by Captain Ross, was produced by a new species of *Uredo*, which he has termed *Nivalis*. The size of a globule of this fungus he found to be the 1600th part of an inch.

## GEOLOGY.

**ON THE FOOT-MARKS OF BIRDS, IN NEW RED SANDSTONE.**—It has been a matter of some surprise to geologists, how there should be an almost entire absence of Birds among organic remains found in rocks. Till lately, all that have been discovered are those mentioned by Cuvier, consisting of nine or ten specimens found in the tertiary gypsum beds near Paris. All the cases of fossil birds noticed by previous writers are regarded by Cuvier as unworthy of credit. Hence any new discoveries in this interesting branch of Oryctology are valuable to the geologist.

It was mentioned in our last Number, that Professor Hitchcock of Amherst College, North America, had discovered in the new red sandstone of the valley of the Connecticut, in five different places, the foot-prints of at least seven extinct species of birds, which, in all probability, may each represent a distinct genus. All these are imprinted, in regular succession, representing the continuous track of a biped, either walking or running, the right and left feet always appearing in their proper places alternately, as represented in the following figures:

The intervals between the foot-prints are subject to some variation, but not more than may be accounted for, by supposing the animal to have quickened its pace, or the reverse. These foot-prints resemble the tracks which may be seen left by that order of birds called *Grallæ* or Waders, on the muddy margin of a lake. Some have three toes distinctly impressed, as in figures 3, 4, and 5, while others have a fourth toe or hallux, as in figures 1 and 2.

Professor Hitchcock proposes to include all the different impressions discovered by him under the generic term *ORNITHICHRITES*, signifying *stony bird-tracks*. These he subdivides into 1. *Pachydactyli*, or thick-toed; 2. *Leptodactyli*, or slender-toed. In the former subdivision, the toes are of almost equal thickness through their whole extent, except that they are somewhat tuberosus; and they terminate rather abruptly; not, however, without a claw. In the latter, the toes are much narrower, and less thick, with an unequal span.

## SUBDIVISION I.—PACHYDACTYLI.

*O. Giganteus*.—The length of the foot, exclusive of the claws, is fifteen inches; it has three toes, and in one specimen the claw is at least two inches long, and even then a part of it appears to be wanting. In general, however, it is not more than one inch, but seems to be broken off. The whole foot, consequently, is sixteen or seventeen inches! The length of the successive steps, varying from four to six feet! The toes are somewhat tuberculated; the inner one, in some specimens, distinctly exhibiting two protuberances, and the middle one three, although less obviously. The average thickness of the toes, one inch and one fourth; and their breadth two inches.

The ordinary step is supposed to be four feet, as most of the foot-prints were that distance apart; six tracks in succession of this species being found in one spot of this average; and the greater distance of six feet, seems to indicate a rapid movement of the animal. From the length of step, indicated in the sandstone, the bird must have been about twice the size of an Ostrich, or its head elevated from 12 to 15 feet above the ground. The length of the leg of the African Ostrich is about four feet, and that of the foot ten inches. The Professor says, "Incredible almost as this description may seem, the specimens which I have obtained of this enormous species are, nevertheless, more satisfactory perhaps than any other species. The whole cavity made originally in the mud by the foot of the bird has been filled by a siliceous concretion, differing somewhat from the surrounding rock; so that the latter may be in a good measure detached, and the former be left standing out very naturally from the rock—presenting, in fact, a petrification of the entire foot." The foot-marks of four individuals all pointing in one direction, having been noticed here, shows that they must have moved along nearly together, rendering it probable that this species was gregarious. Found at Mount Tom Quarry.

The other species of this subdivision is the *O. tuberosus*, which is much smaller than the former, being only from seven to eight inches in length; the length of step measuring from twenty-four to thirty-three inches. Also from Mount Tom. In a quarry to the east of this locality, the prints of another individual were found, which measured only four inches. They agree with those of the *tuberosus*, and may be the young of that bird, but are in the meantime termed *O. dubius*.

## SUBDIVISION II.—LEPTODACTYLI.

*O. ingens*.—This bird has also been three-toed; the foot measuring from fifteen to sixteen inches, exclusive of the hairy appendage, attached to the heel, or hind part of the foot. No visible impressions of the plumlet have been noticed in any of the specimens which were found. The toes are much narrower than in the *O. giganteus*; they are quite divaricate, and gradually taper to a point, at a few inches behind the heel. The most perfect specimen exhibits a depression nearly an inch deep, and several inches across; the anterior slopes to which, in the rear, appear as if large bristles had been impressed upon the mud. This leads to the probability that the bird possessed a sort of knobbed heel covered with wiry feathers, which sunk into the mud when the track was deep. The impression of the bristles extends backwards from the heel at least eight or nine inches, so that the whole length of the foot-print is not less than two feet. The length of the step appears to have been six feet.

The rock on which this species of track appears is composed of a fine blue mud, such as is now common in ponds and estuaries; and where the bird trod upon it, in some cases, it seems that the mud was crowded upwards, forming a ridge round the track in front several inches in height. "Indeed," Professor Hitchcock remarks, "I hesitate not to say, that the impression made on the mud appears to have been nearly as deep, indicating a pressure nearly as great as if an Elephant had passed over it. I could not persuade myself, until evidence became perfectly irresistible, that I was examining merely the track of a bird."

In the quarry at Horse Race, impressions were discovered exactly similar to those of the *ingens*, but only twelve inches in the length of foot; and the step measuring from forty to forty-five inches. This the Professor inclines to consider a distinct species, but, in the meantime, has named it a variety of *ingens*.

*O. diversus*.—Three-toed, with a hairy appendage in the rear; length of the foot, exclusive of the hairy appendage, from two to six inches; length of the step varying from eight to twenty-one inches. A great variety of specimens are included under this specific character, from want of definite lines of demarcation. There is a variety named *clarus*, in which the foot-print, exclusive of the hairy appendage, is

from four to six inches; the appendage being from two to three inches long; the toes somewhat approximate, acuminate—the inner being shorter than the outer one. Step from eighteen to twenty-five inches. Found in the south-west part of Montague; also at Horse Race.

*O. tetradactylus*. Fig. 1.—Length of the foot, exclusive of the hind toe, from two and a half to three and a half inches. Toes divaricate; the hind one turned inward, so as to be nearly in the line of the outer toe, prolonged backward. A space, however, usually remains, between the heel and the hind toe, as if the insertion were higher on the leg than the other toes, and its direction obliquely downwards. Length of the step ten or twelve inches.

*O. palmatus*. Fig. 2.—Four-toed, all directed forward; the fourth toe being short, proceeding from the inner part of the foot; the heel is broad; foot from two and a half to three inches long. Length of step eight inches. Discovered at Horse Race.

*O. minimus*. Fig. 3.—With three widely-spreading toes, nearly of equal length; feet measuring from half an inch to an inch and a half long; step from three to five inches.

On comparing the descriptions which we have given of the species, it is interesting to observe how the length of the step increases in proportion to the size of the foot; from the *ingens*, having a foot sixteen inches in length, with a stride at least four feet, to the *minimus*, whose foot-print is but one inch long, and its step from three to five inches, which are indicated in the three specimens given in our first cut, drawn to a comparative scale. All these tracks appear to have been made on the margin of shallow water that was subject to changes of level, and in which sediments of sand and mud were alternately deposited. And the length of the legs, which must be inferred from the distance of the foot-prints from each other, was well adapted for wading in such situations.

The sandstone in this valley, where the *Ornithichnites* occur, extends nearly one hundred miles from New Haven, in Connecticut, to the north line of Massachusetts, varying in width from eight to twenty-four miles. It is divided by one or two ridges of greenstone, protruded through the sandstone, and running nearly north and south. The strata of the sandstone have a general easterly dip, varying from 5 to 30 degrees; so that the lowest or oldest portions of the sandstone lie along the western side of the valley. These lower strata consist, for the most part, of thick layers of red sandstone, not much diversified in appearance. But the upper strata, that is, those on the easterly side of the greenstone ranges, consist of slaty sandstones, red and gray conglomerated sandstones, very coarse conglomerates, shale, and perhaps red marl, with occasional beds of fetid limestone. Indeed, the red sandstone of Hartford is decidedly marly, as it effervesces with acids, and even contains numerous veins of calcspar.

The important discovery of the gigantic foot-prints of the *Ornithichnites*, which we have first described, is a further proof that there were animals inhabiting the former world of much larger dimensions than any existing races. The Mammoth may be mentioned as the largest of quadrupeds; and the *O. giganteus* seems to have been the largest of birds. In Professor Hitchcock's "Report on the Geology of Massachusetts," published some time ago, he shows that other organic beings, that must have been contemporaries with these immense birds, were their compeers in size; for we find in that work a description of a Sea-Fan (*Gorgonia Jacksoni*), found in the new red sandstone of West Springfield, that has been uncovered, without reaching its limits, eighteen feet in length, and four feet in width! Indeed, the colossal bulk of these birds is in accordance with the early history of organic life in every part of our globe. The much higher temperature that then prevailed seems to have been favourable to a gigantic development of every form of life.

## METEOROLOGY.

ON THE METEOROLOGY OF THE NEIGHBOURHOOD OF EDINBURGH.—The diffusion of heat and moisture over the surface of the earth is a subject full of interest; but it has not yet received that strict attention which its importance demands. We still require a great many local facts and observations to enable us to form general and correct conclusions. The regular prevalence of the equatorial currents, by which a stream of hot and moist air is constantly ascending from the earth's surface, and passing by various modifications to both poles, from whence a drier and colder current flows towards the equator, to occupy the place of the other, seems to be the grand agency employed by nature to warm, and refresh with moisture, every region of the globe. With our insular situation and temperate latitude, these currents are not so constant or so distinctly marked; yet even here we can trace them generally prevailing.

Thus, for eight months in the year, we have either south-west or west winds almost constantly prevailing; while, for the other four months, we have either east or north winds, alternating with north-west and south-west winds.

During our summer and autumn months, the tropical current blows very generally from the southwards: the great summer heat of the northern continent of Europe, by rarifying the air in that direction, causes a current to blow towards it.

This effect is sometimes retarded and interrupted by causes that diminish the heat of the continent—such as long and severe winter snows, and the late thawing of ice. Under these circumstances, we have moist and cold summer weather.

In winter, the low arctic current, blowing towards the tropics, occasionally has the ascendancy, especially when the sun is in the southern ecliptic. And, in spring, an easterly wind prevails generally for six or eight weeks, till the continental land becomes heated, and then the east wind yields to the supremacy of the south and south-west.

With these general principles the local phenomena in the atmosphere in this neighbourhood appear to coincide. And the differences of temperature and moisture between the east and west coasts of Scotland seem very marked.

To-day the summit of Arthur's Seat is enveloped in a dense cloud of vapour, the wind blowing from the southward. This cloud is stationary, and has been so for the last hour; nor does the vapour pass many yards beyond the mountain. The cause of this phenomenon is well understood: the current of wind is loaded with vapour, suspended in it by its high temperature. The temperature of Arthur's Seat is con-

siderably lower: whenever a portion of this current, then, comes in contact with the hill, it is suddenly cooled, deposits its vapour, and each successive portion of the current does the same. The mist does not extend beyond the hill, because the condensing cold is no longer present, and any remaining portions of deposited vapour carried along into the general mass are instantly redissolved.

Warm diffused fogs are not uncommon in this neighbourhood, especially in the spring months, when there happen to be two currents of air in the atmosphere. An east wind prevails annually here for the greater part of the months of April and May, usually setting in about the middle of April, and continuing, more or less, till the end of May. Blowing over the long tract of north-eastern continent, it is exceedingly chill and deficient in moisture. When it arrives on our insular shores, it gains an accession of temperature, and, with this, its capacity for absorbing moisture is prodigiously increased. This accounts for its chilling and arid effect on the whole vegetable and animal creation, and on the face of the soil generally; it greedily abstracts both their heat and moisture. A cold current of wind, thus sweeping along, and meeting with a warmer mass loaded with moisture, suddenly causes a deposition of vapour; but this cold current is so close to the surface of the earth as to prevent the usual formation of rain—a dense fog usually is the result.

These adverse currents were very perceptible in June 1832, and they appeared not only to cause fogs, but also several tremendous thunder-storms.

For some time previous to the 1st of June, the wind had prevailed from the east. On the 1st and 2d of June, an atmospheric current, passing from south-west to north east, was distinctly indicated by the rapid and continued motions of the clouds in that direction, at a moderate height in the air. On the 3d, the wind was still from the east—the atmosphere was remarkably transparent, and there was a dry scorching heat. In the evening, a dense fog from the eastward suddenly came on, which quickly passed into rain; and, on the morning of the 4th, at seven A.M., loud peals of thunder were heard, accompanied by vivid flashes of lightning. For eight days afterwards the weather continued chill, foggy, and rainy, with wind east-north-east. On the 13th, the weather became milder, the lower stratum of air blew from the eastward, while, above, dense masses of nimbi were seen rolling from south-west to north-east. At seven P.M., a tremendous thunder-storm came on, passing directly over the city from the south-east to north-east. In several cases the report followed the vivid flash instantaneously, with a sharp piercing sound. The electric fluid struck two different parts of the city, doing partial injury. We had then mild cloudy weather, with wind south-west, till the 20th. The morning of that day was clear and cloudless—wind unsteady, easterly; at twelve noon, a thunder-storm in the west passed distantly to the northward of the city. A dense thunder cloud appeared in the western horizon, arched, and tolerably well defined above, while below it was ragged, and constantly joined by numerous accessory clouds. A deep flame-coloured lurid light occupied the whole circular space, from the cloud to the horizon; and the dark accessory clouds shooting along this space, to join the main cloud, had a singular and highly interesting appearance. This lurid light frequently accompanies thunder clouds; whether it be caused by the electric matter, or is the effect of a modification of the sun's light falling on these clouds, is uncertain. A tortuous mass of clouds, something like a tornado, and producing similar effects, is said to have been witnessed to the westward of Edinburgh during this thunder-storm. After this storm, the weather continued throughout the month steady and genial. That these different currents of the atmosphere were connected with the electric phenomena just mentioned, there is every reason for supposing. Most probably, the higher current of heated air, moving from the south, and saturated with aqueous vapour, was positively electrified, and thus coming in contact with the cold, dry, and negatively electrified east wind, would be suddenly condensed, and an equilibrium of the electric fluid would be effected.

Thunder-storms, of any great magnitude, have been rather rare in this neighbourhood for the five years preceding 1831. In June of that year, two violent storms passed over this city. The night previous to the first great storm, flashes of diffused sheet lightning irradiated the heavens for upwards of an hour, accompanied by low peals of thunder. Next morning was calm and serene, but exceedingly sultry. About two P.M., thick masses of clouds began to rise from south-west, and float along the ridge of the Pentland Hills. Gradually the dense mass accumulated over the city—vivid flashes of forked lightning, succeeded instantaneously by a loud report, occurred at short intervals, and rain descended in torrents. The peculiar lurid glare was very conspicuous to the north-eastward, as the storm gradually passed in that direction. Although the lightning thus flashed almost close to the tall spires and houses of the city, yet no injury was done. A vessel, however, was struck in Leith Roads, a situation lower by several hundred feet, and her masts were shattered to pieces. That the lightning did not strike on the higher and exposed parts of the city is wonderful; and, indeed, it is remarkable how very rarely such accidents occur in large towns, while they are so frequent in the open country, and especially where there are trees and water. It, perhaps, may be accounted for thus—that the air overhanging cities is highly rarified from the numerous fires, is free from moisture, and, consequently, can act but as a very imperfect conductor of electricity.

Since 1831, we have annually, about May, June, and July, experienced several severe thunder-storms. In all of these which we have witnessed in this locality, the clouds first make their appearance in dense masses to the southwards, coming along either in the direction of the Lammermoor or Pentland Hills, while the sky to the east and north is generally cloudless and transparent. These electric clouds, becoming larger and denser as they proceed, pass onwards with a slow motion to the north or east.

The exposure of Edinburghshire, on the eastern coast of Scotland, renders it peculiarly subject to easterly winds. On the more inland parts of the country, and especially on the west coast, these winds are not so severely felt; for the space of country which they blow over in their progress serves to mitigate their severity. The climate on the eastern coast, however, is less liable to excess of humidity. The annual average fall of rain is, at Dalkeith, twenty-five inches—Edinburgh, twenty-three; while at Largs, near Glasgow, it is forty-three and a half inches; at Dumfries, thirty-six; at Castle Toward, Argyleshire, fifty inches. This, too, is easily accounted for

from local situation. The west wind, charged with moisture, and generally of elevated temperature, on coming to the colder land air, deposits its humidity very rapidly. The soil of Edinburghshire, too, is of a light porous nature, from the quality of the prevailing strata; and its level aspect, removed from the immediate contact of high mountain ranges, tends to preserve it from excess of humidity. The mean annual temperature is  $47^{\circ} 31'$ . Snow seldom lies for any length of time, from its proximity to the ocean. The winter temperature, then, like most parts of Scotland, is fully milder than that of England; while its summer heat is somewhat less. It has been calculated that the mean annual temperature of Edinburgh is  $3^{\circ}$  less than that of London.

That the nature of the prevailing strata, and the position of the country as regards mountain ranges, has a very material effect on the climate, is evinced from the country around Aberdeen, and the higher parts of Banffshire. In this part of Scotland the formation is primary, consisting of granite and its accompanying rocks. From the compact, impenetrable nature of this basis, the rain water cannot sink downwards by fissures and porosities, but remains on the surface till it again evaporates, or collects, by numerous superficial rills, into rivers. Thus, the soil is continually moist and cold, and so is the atmosphere around. The long range of Grampian mountains that intersect the north of Scotland also terminate in this quarter; and their summits continually conduct along the atmospheric vapour, so that an additional quantity is deposited on the soil. At Aberdeen, the annual fall of rain during the year 1829 was 28.66 inches, in 1830, 30.60 inches. The mean temperature of the same place, from 1823 to 1830, was  $47^{\circ} 61'$ .

The country immediately to the north (Morayshire) has a deep sandstone basis, which is light and porous. It is also removed from the line of mountain ridges; and, accordingly, its climate is found to be much drier and warmer. The annual average fall of rain at Fochabers, taking the mean of seven years, is twenty-six inches. Mean annual temperature, at same place,  $47^{\circ}$ ; at Inverness, mean temperature  $48^{\circ}$ . At Elgin, the mean temperature for 1835 was  $47^{\circ} 6'$ ; the mean fall of rain twenty-four inches.

The northern portion of Edinburghshire lies low, the general range being from one to two hundred feet above the sea level; to the south it gradually rises to five hundred and eight hundred feet. The extreme elevation of the Pentlands is 1879 feet.

The meridian, as calculated at the Observatory on the Calton Hill, is  $3^{\circ} 11' 4''$ . W. L.—*Rhind's Excursions, illustrative of the Geology and Natural History of the Environs of Edinburgh.*

FALLING OR SHOOTING STARS are appearances every where observed. They are probably the effect of hydrogen gas more or less sulphuretted, for phosphorus is too rapidly inflamed by the contact of the air to be capable of reaching so high an elevation. What seems to prove the hydro-sulphuretted origin of these meteors, is the nature of the circumstances by which they are accompanied. These fires, we are assured, often fall to the ground; and nothing is found at the place of their fall but a fetid glutinous matter of a whitish colour, bordering upon yellow. Now, we know that sulphuretted hydrogen gas holds sulphur in solution; that the hydrogen and the sulphur do not burn at the same moment; that, consequently, the sulphurous part may be precipitated to the earth, whilst the hydrogen, mixed with the oxygen of the air, is kindled by a slight electric spark.

#### MISCELLANEOUS.

THE HOT BLAST.—Lately there has been introduced into the great Iron Works of Carron, and other founderies of Scotland, a method of smelting iron by means of heated air, which has produced extraordinary changes in the manufacture of that useful metal, well worthy the attention of English iron smelters, and also the minor founderies which use iron. By the old method, for every ton of iron smelted, it required on an average about eight tons of coal, or a corresponding quantity of coke; while by the "hot blast" two tons are sufficient. If it shall be found that iron smelted by this system is not subject to greater deterioration or brittleness than that procured by the old process, the new mode will prove one of the greatest discoveries in modern science, and highly important in a national point of view; for it is said that the actual saving in the quantity of fuel required will be found in practice to be no less than three hundred per cent.

SUBTERRANEAN SOUNDS IN GRANITE ROCKS.—Humboldt was informed by credible evidences, that subterranean sounds, like those of an organ, are heard towards sunrise, by those who sleep upon granite rocks on the banks of the Oroonoko. He supposes them to arise from the difference of temperature between the external air, and the air in the narrow and deep crevices of the shelves of rocks. During the day, these crevices are heated to 43 or 50 degrees. The temperature of their surface was often 39 degrees, when that of the air was only 28 degrees. Now, as this difference of temperature will be a maximum about sunrise, the current of air issuing from the crevices will produce sounds which may be modified by its impulse against the elastic films of mica that may project into the crevices. MM. Jomard, Jollois, and Devilliers, heard at sunrise, in a monument of granite, placed at the centre of the spot on which the palace of Karak stands, a noise resembling that of a string breaking.

INFLAMMABLE GAS.—When Mr Hughes was travelling in Greece he found, not far from Pollina (the ancient Apollonia) in Albania, a desert place, from the fissures of whose surface an empyreumatic vapour arose, which took fire on the application of a taper, and burnt for some time. From ruins, which he noticed near this place, he inferred that they belonged to that oracle described by Dion Cassius, book xii. p. 45. Mineral pitch abounds in the vicinity. In other sacred places of Greece, as at Delphi and Dodona, where the ignorant were deceived by mineral vapours used in their oracular contrivances, these vapours have now totally disappeared. In the heights of Parnassus, where the remains of the Delphic oracles are found, the celebrated *foramina* (where carbonic acid rose from the fissure of the limestone) have been filled up: and in place of the springs with inflammable gas at Dodona, mentioned in Pliny's Natural History, vol. ii. p. 104, there is found at present near Joannina, along with the remains of the temple, simply a marsh.

PEAT MOSSES OF HOLLAND.—Destitute of coals, and without copse-wood, the Dutch have to depend on their *veen* or peat-mosses for fuel. There are two kinds of these, the higher and the lower. The high mosses afford a layer of what is called gray or dry peat. The upper bed of peat is generally about six feet in thickness; it seems to be composed rather of leaves and stems of reedy plants than of heath, or the plants which commonly accompany heath; and fragments of large branches of trees have sometimes been found in it. Beneath this peat a thin blue clay commonly appears, and which, on the peat being removed, forms arable land. The low mosses afford what are called mud-peats, and when these are taken from the inferior layer of such moss, the excavation speedily becomes covered with water. When the under stratum of moss is formed and contains wood, it is called *derry*. Many trunks of trees occur in it; and these uniformly lie with their heads pointing eastward, showing that the storm or debacle which overwhelmed them had come from the west. Some of the timber, oak in particular, remains sound, so that it can be used in carpentry; but it is of a dark colour, as if stained with ink: thus proving the amazing durability of oak. There is a law in Holland against digging through this derry in the lowest parts of the country, much water being found to ooze in the sand below, and to be repressed by the compact layer of wood moss.

IGNIS FATUI, arising from the development of phosphoretted hydrogen, are necessarily soon extinguished; a succession of these fires will therefore appear to the spectator to be one single flame, which moves with rapidity from place to place when we attempt to approach it. The air driven on before us forces the lambent flame to recede. There are other similar fires, which appear to be immoveable when viewed from a particular spot. There was one near Rettwick in Sweden, which was supposed to issue from the mouth of a dragon that kept watch over some hidden treasures. A simple miner ventured to sink a shaft, which discovered a cavern filled with sulphurous pyrites and petroleum, the combustion of which had occasioned the phenomenon.—(Memoires de l'Académie de Stockholm, 1740).

SINGULAR HEAT DEVELOPED IN THE FUSION OF TIN AND PLATINUM.—Mr Fox of Falmouth has found, that a very extraordinary degree of heat is developed by fusing together platinum and tin in the following manner:—If a small piece of Tin-foil be wrapped in a piece of Platinum-foil of the same size, and exposed upon charcoal to the action of the blowpipe, the union of the two metals is indicated by a rapid whirling, and by an extreme brilliancy in the light which is emitted. If the globule thus melted be allowed to drop into a basin of water, it remains for some time red-hot at the bottom; and such is the intensity of the heat, that it melts and carries off the glaze of the basin from the part on which it happens to fall.

DETONATING MUD IN SOUTH AMERICA.—Don Carlos del Pozo has discovered in the Llanos of Monac, at the bottom of the Onebrada de Moroturo, a stratum of clayey earth, which inflames spontaneously when slightly moistened, and exposed for a long time to the rays of the tropical sun. The detonation of this muddy substance is very violent. It is of a black colour, soils the fingers, and emits a strong smell of sulphur.

HOT SPRINGS OF LA TRINCHERA.—The hot springs of La Trinchera are situate three leagues from Valencia, and form a rivulet, which, in the seasons of the greatest drought, is two feet deep, and eighteen feet wide. Their temperature is  $93.3$  centigrade, from which it appears that they are the hottest in the world, excepting only those of Urijias in Japan, which are asserted to be pure water at the temperature of 100 degrees. Eggs plunged in the Trinchera springs are boiled in four minutes. At the distance of forty feet from them, other springs are found entirely cold. The hot and the cold streams run parallel to each other; and the natives obtain baths of any given temperature, by digging a hole between the two currents.

CORAL REEFS OF THE PACIFIC OCEAN.—These are sometimes very extensive. The inhabitants of Disappointment Islands and those of Duff's Group visit each other by passing over long lines of reefs from island to island, a distance of 600 miles. While on their route, they appear like troops marching upon the surface of the ocean.

#### LIST OF NEW BOOKS ON NATURAL HISTORY, AND THE PHYSICAL SCIENCES.

Rhind's Excursions, illustrative of the Geology and Natural History of the Environs of Edinburgh, royal 18mo, 3s. 6d. boards; Loudon's Encyclopædia of Plants, new edition, 8vo. half-bound, L.3, 13s. 6d.; Butterfly Collector's Vade-Mecum, 3d edition, 5s. boards; The Medico-Botanical Pocket-Book, by G. Spratt, 10s. 6d. cloth; Outlines of a Journey through Arabia-Petræa, the Edom of the Prophecies, by M. Leon De Laborde, 8vo. with 65 plates and map, 18s.; British Song Birds, by Neville Wood, Esq. foolscap 8vo, 7s.; The Ornithologist's Text-Book, being Reviews of Ornithological Works, published from A. D. 1678 to the present day, with an Appendix, discussing various topics of interest connected with Ornithology, by Neville Wood, Esq. 4s. 6d.; Paley's Natural Theology, with Illustrative Notes by Lord Brougham and Sir Charles Bell, 2 vols. post 8vo, with numerous wood cuts, L.1, 1s.; A Journey across the Andes and down the Amazon from Lima to Para, by Lieut. Wm. Smyth, R.N. with 11 plates and maps, 8vo, 12s.; The Horticultural Magazine and Miscellany of Gardening, by Robert Marnoch, No. 1. 6d.; Narrative of an Ascent to the Summit of Mont Blanc, with 3 illustrations by M. Barry, M.D. 8vo, 4s. cloth; Jacquemont's Journey in India, Thibet, Lahore, and Cashmere, No. 12, price 1s. completing the work; Captain Back's Narrative of the Arctic Land Expedition in 1833, 34, 35, 8vo, 30s. cloth; Loudon's Arboretum et Fruticetum Britannicum, No. 21, price 2s. 6d.; G. P. Deshayes Traité Élémentaire de la Conchyliologie, liv. 1, 15 fr. cold; Ad. Brongniart, Histoire des Végétaux Fossiles, 1836, liv. 10, 13 fr.

OCTOBER, 1836.

ZOOLOGY.

DESCRIPTION OF THE PLATE—THE HUMMING BIRDS.

Fig. 1. RIVOLI'S HUMMING BIRD (*Trochilus Rivolii*).—This beautiful species is a native of Mexico, and the specimen from which this drawing was made is in the collection of the Duke of Rivoli, who possesses one of the finest private cabinets of birds in Europe. Nothing can exceed the splendid display of colours exhibited by its head and throat, the beryl and ruby vying with each other in splendour; and these are beautifully set off by the strong black which surrounds the more brilliant hues.

Fig. 2. THE VIOLET-CROWNED HUMMING BIRD (*T. Stephaniodes*) inhabits Chili, and, according to Lesson, sips the nectar of the scarlet Loraanthus. It will probably be found hereafter, that this bird feeds upon the insects which prey upon the nectar, rather than upon the nectar itself. It penetrates to the North during winter.

Fig. 3. STOKES' HUMMING BIRD (*T. Stokesii*).—There are few Humming Birds which surpass this in beauty and elegance of form. The tuft of bright cobalt blue, which decorates its crown, adds great beauty to the bird. It was discovered by Captain King on the island of Juan Fernandez.

Fig. 4. THE NORTHERN HUMMING BIRD, MALE (*T. Colubris*). Fig. 5. FEMALE; and 6. the NEST.—This is the Humming Bird of the United States of America, and along with others lately described by Mr Audubon, are the only species of this numerous tribe which migrate so far north. This species arrives in Louisiana about the 10th of March, but is seldom found in the middle districts before the 15th of April. A person standing in a garden by the side of a common Althæa in bloom, will be surprised to hear the humming of their wings, and then see the birds themselves within a few feet of him; he will be astonished at the rapidity with which the little creatures rise into the air, and are out of sight and hearing the next moment.

When morning dawns, and the blest sun again  
Lifts his red glories from the eastern main,  
Then through our woodbines, wet with glittering dews,  
The flower-fed Humming Bird his round pursues;  
Sips, with inserted tube, the honey'd blooms,  
And chirps his gratitude, as round he roams;  
While richest roses, though in crimson drest,  
Shrink from the splendour of his gorgeous breast.  
What heavenly tints in mingling radiance fly!  
Each rapid movement gives a different dye;  
Like scales of burnish'd gold thy dazzling show,  
Now sink to shade—now like a furnace glow!

We are assured by Mr Audubon, that this species at least principally lives upon insects, which it seeks out diligently in the nectarium of the flowers, where a great number of insects are always to be found, attracted by the honey. These it rapidly abstracts with its tongue.

Fig. 7. THE CRESTED HUMMING BIRD, MALE (*T. Cristatus*). Fig. 8. FEMALE.—This pretty little species is a native of the islands of Martinique and Trinité. Its breast is emerald green with iridescent blue reflections. The female is devoid of a crest.

Fig. 9. THE PURPLE HUMMING BIRD (*T. Caligena*).—Mexico is the native country of this species, where it was first discovered by M. F. Prévost. It ranks among the larger species; and although having no great variety of colours in its plumage, is, however, a very beautiful bird.

Fig. 10. WAGLER'S HUMMING BIRD (*T. Waglerii*).—The remarkable form of the crest of this species distinguishes it from all others of its tribe; and its elegantly graduated tail gives it a very handsome aspect. It is a native of the warmer parts of Brazil.

Fig. 11. THE HORNED HUMMING BIRD, MALE (*T. Cornutus*).—This singularly beautiful bird is a native of the elevated Compos-Geraes of Brazil.

Fig. 12. THE HALF-TAILED HUMMING BIRD (*T. Enicurus*) is remarkable on account of having only six quill feathers in its tail. It inhabits Brazil.

DESCRIPTION OF THE PLATE—THE TITMICE.

This is a small but sprightly race of Birds, possessed of much courage and strength. Their food consists of seeds, fruit, and insects, and a few of them will eat flesh. Such are their pugnacious habits, that they will assault birds twice their own size; and it is said that they direct their aim chiefly at the eyes. They

are very prolific, laying about fifteen eggs at a time. Their voice is harsh and unpleasant.

Fig. 1. THE BLACK-CAPT TITMOUSE (*Parus atricapillus*).—This is a resident species of the United States of America. In summer they confine themselves to deep and woody recesses, and in winter approach the cultivated fields, and are even seen frequently in farm-yards. They are very sociable in their habits, and are to be met feeding along with the Nuthatch, Creeper, and small Woodpecker. Their principal food consists of the seeds of pines, and those of the sunflower. They also feed on insects.

Fig. 2. THE CANADIAN TITMOUSE (*P. Hudsonicus*) was discovered by Audubon; it extends its range from Canada to the southern limits of the United States. It is a nimble and lively bird, seeking insect food with great perseverance and adroitness.

Fig. 3. THE COLE TITMOUSE (*P. ater*).—This is a British species, about four inches in length, and its weight only two drachms and a quarter. It abounds in the pine forests of Scotland, feeding on insects and their larvæ.

Fig. 4. THE CRESTED TITMOUSE (*P. bicolor*).—This species is found widely diffused over the whole United States. It is a very noisy bird, and remarkable for the variety of its notes; sometimes uttering a squeak like that of a mouse, and at others whistling aloud as if calling a dog, which it will continue for half an hour at a time. It feeds on insects and their larvæ.

Fig. 5. THE AZURE TITMOUSE (*P. cyaneus*).—This beautiful bird is said by Latham to be a native of India, while Pallas asserts that it is to be found in the north of Europe, extending its range as far as Siberia.

Fig. 6. SMITH'S TITMOUSE (*P. Smithii*).—This bird was found by Dr Smith in Southern Africa, but nothing is known of its habits.

Figs. 7. and 8. THE PENDULINE TITMOUSE, MALE AND FEMALE (*P. pendulinus*).—It is an inhabitant of Europe, and is found in Italy, France, Poland, Russia, and Siberia; it frequents marshy grounds, and builds a pendulous nest.

Fig. 9. THE AFRICAN TITMOUSE (*P. Afer*).—This is one of the largest birds of its tribe, and lives almost exclusively on insect prey, which it searches for among moss and decayed bark of trees with much avidity, pulling off large pieces of bark and moss with apparent ease.

FALCULIA PALLIATA.—A new bird, belonging to the *Passeres*, and allied to the *Upupa*, has been found at Madagascar, by M. Goudot, and forms the type of a new and remarkable genus. The beak is very long, arched, compressed, or flattened, like a blade, and may be compared to that of a small scythe. The nostrils, placed at the base of the beak, and pierced laterally, are not covered by the anterior feathers of the head. The wings, which in length reach the middle of the tail, according to the nomenclature of M. Isidore Geoffroy, belong to the type called by him *sarobtus*—that is, having the fourth and fifth remiges the longest of all. The first, like that of the Hoopoes, is extremely short, and nearly useless in flight. The tail is square, and composed of twelve quills, the externals of which have their stems prolonged, in a very slight degree, beyond the barbs. The feet have three toes directed forwards, and a fourth backwards. All are long, thick, and furnished with curved talons, enlarged at the base by a thick membrane, which has some affinity with that of the Grallæ. The only species now known has the head, the neck, and the under part of the body, white; the back, wings, and tail, of a greenish black, with metallic lights. M. Isidore Geoffroy has named it *Falculia palliata*. It lives on the borders of streams, feeds on small aquatic insects, and the organic remains found in mud.

COCHINEAL.—In the Volume of the "Memoirs of the Academy of Sciences at St Petersburg," which has just appeared, there is an account given of the Cochineal of Armenia. The insect producing this dye has lately been found to exist in the marshy spots which are scattered through the Valley of Araxa, feeding on the root of the plant called *Poa Pungens*. It is said to differ from the Mexican Cochineal (*Coccus cacti*) in having a greater number of joints in the antennæ, and in its fore-feet being shorter, which are adapted for hollowing out the soil. On the termination of the abdomen are numerous filaments, while the Cacti has but two. M. Hamel, the principal author of the above paper, endeavours to establish, that the red colour so often spoken of in Scripture, and also by many ancient writers, was the produce of the Armenian Coccus.

ACCOUNT OF A PRETERNATURAL GROWTH OF THE INCISORY TEETH OF A RABBIT.—In the class RODENTIA of Cuvier, of which the Rabbit is a member, there not unfrequently occurs an extraordinary development of the incisory or cutting teeth. It is a well established point in physiology, that these teeth, like the tusks of the Elephant, are in a constant state of growth, and that they emanate from long roots nearly equal in length to the jaw; they curve backwards under the molar teeth, extending in some instances as far back as the coronoid process. Owing to this beautiful adaptation of Nature to the habits of the tribe, there is a constant, gradual advancement of the interior part of the teeth, to supply that portion worn down by friction, while the animal is feeding or gnawing substances—for which the Rodentia have a strong propensity. Under ordinary circumstances, this gradual increase is so admirably regulated, that the cutting edges of the two pair of incisory teeth uniformly preserve the same relative situation.

The above figure represents the head of a wild Rabbit, which is preserved in the private museum of Mr Robert Frazer, jeweller, 17, St Andrew's Street, Edinburgh; with an extraordinary elongation above the gums, of both the upper and under incisors, the former measuring an inch and five-eighths, and reaching considerably above the nostrils, while the latter is seven-eighths of an inch in length, and very much incurved, so much so, that their points would nearly reach the palate when the mouth is closed. The under incisors are also considerably bent, becoming gradually thinner and more depressed towards their points, where they are divergent, the inner sides being nearly a quarter of an inch apart at the tips. Their ordinary length in the wild Rabbit is about a quarter of an inch. Instances of the same kind have been noticed before, in Ploti's History of Staffordshire; in Morton's Natural History of Northamptonshire; and in London's Magazine, where an account of a lusus of this kind is given by the Rev. L. Jenyns, the object of which is preserved in the Museum of the Cambridge Philosophical Society.

Cuvier says, that the prismatic form of the cutting teeth occasions them to grow from the root as fast as they wear away at the edge; and this tendency to increase in length is so powerful, that if one of them be lost or broken, the opposite one in the other jaw having nothing to oppose or communicate, becomes developed to a monstrous extent. The elongation of the teeth in the specimen now before us, could not have been occasioned by any accident of this kind, as the development is excessive in both upper and under teeth, while none of them evince the slightest appearance of having been fractured. Therefore some other mode of accounting for this instance must be sought for, and we would rather attribute it to the unequal action of the jaws, in the under one not being exactly opposed to the upper.

Mr Jenyns supposes that this preternatural elongation may arise either from the food being too soft, or too rapid a secretion of the osseous matter which composes the teeth, or a derangement of the under jaw, produced from a dislocation or some other cause; and to one or other of these he attributes two of the cases which fell under his own observation. In the case of the rabbit's head preserved in the Cambridge Philosophical Society, which, so far as the length and disposition of the lower incisors are concerned, agrees very nearly with our case, he considers that it was occasioned by too rapid a secretion of the osseous matter; and in the second case, both upper and under incisors were preternaturally elongated; "but then," says he, "in this instance there was such an irregularity in their mode of growth, that we may perhaps find a better explanation of the anomaly in some derangement of the jaws, the result either of natural constitution or of accidental injury. Whatever this might have been (for I regret that this rabbit was not preserved, and an examination made of the jaws at the time), the effect was that of causing the lower pair of incisors, when viewed together, to assume the shape and appearance of the letter V, diverging from one another at the surface of the gum, and extending in opposite directions, to the length of nearly an inch and a half. The degree of divergency observed in the upper pair was nearly as great as this in the lower, and their length about the same; but their curvature very much greater; as indeed would naturally result from the greater bend of that portion of the jaw in which these incisors are formed. In this instance, the portion without the gums had completed three parts of an exact circle, and their cutting edges were in close contact with the roof of the mouth."

Both of the rabbits above referred to, when captured, were nearly starved to death from their incapacity to eat their usual feed. In that first noticed, the animal seemed to exist solely by means of the small quantity of food which it could nip by the lips

at the sides of the mouth, which exhibited marks of its having been used for that purpose. Our specimen has no such appearance. In the second case mentioned by Jenyns, the poor animal was unable to close its mouth, from the curve of the upper incisors pressing upon the tongue. These two were found in the neighbourhood of Cambridge.

Mr Jenyns mentions a third individual, from Lincolnshire, one of whose incisory teeth was still longer than any of the others mentioned, which had grown into the palate, and re-entered that portion of the jaw from whence it sprung, which appeared to have been produced by some local disease, affecting, in the first place, that single tooth, which was much twisted in its direction.

The specimen which has come under our notice was found dead from starvation in the rabbit-warren at Leven Links, Fifeshire, Scotland; and exhibited signs of great emaciation, from its inability to feed.

THE CROW AND RAT.—In the spring of the year 1834, while a person was crossing a field, in an elevated and retired situation, in the parish of Kirk-Marown, Isle of Man, he perceived a Crow flying at a short distance from him which attracted his attention. On account of the unusual noise which it made, and while watching its strange motions, he was able to perceive that it had some object suspended from its bill, which dropped in a few seconds, while the bird was almost flying over him. He immediately hastened towards it, and found it to be a young Rat more than half-grown. It was still alive, but somewhat stunned by the fall. This happened at the time that the young Crows were in the nest, and doubtless was intended for food to them. The particular noise made by the Crow must have been occasioned by the efforts of the Rat to disengage himself from his aerial foe.—(Communicated by a "Young Naturalist," Birmingham, August 1836).

## BOTANY.

ON THE SHAMROCK OF IRELAND.—Mr Bicheno has laid before the Linnean Society a paper "on the plant intended by the Shamrock of Ireland;" in which he attempted to prove, by botanical, historical, and etymological evidence, that the original plant was not the white clover which is now employed as the national emblem. He stated, that it would seem a condition at least suitable, if not necessary, to a national emblem, that it should be something familiar to the people—and familiar, too, at that season when the national feast is celebrated. Thus, the Welsh have given the *leek* to St David, being a favorite cleareaceous herb, and the only green thing they could find on the first of March;—the Scotch, on the other hand, whose feast is in November, have adopted the *thistle*. The white clover is not fully expanded on St Patrick's day, and wild specimens of it could hardly be obtained at this season. Besides, it was probably, nay, almost certainly, a plant of uncommon occurrence in Ireland during its early history, having been introduced into that country in the middle of the seventeenth century, and made common by cultivation. Several old authors affirm, that the *shamrock* was eaten by the Irish; one of which, who went over to Ireland in the sixteenth century, says it was eaten, and that it was a *sour* plant. The name Shamrock is common also to several trefoils, both in the Irish and Gaelic languages. Now, the clover could not have been eaten, and it is not sour. Taking, therefore, all the conditions requisite, they are only found in the Wood-sorrel, *oxalis acetosella*. It is an early spring plant; it was, and is, abundant in Ireland; it is a trefoil; it is called *Sham-roy* by the old herbalists, and it is *seur*; while its beauty might entitle it to the distinction of being the national emblem. The substitution of one for the other has been occasioned by cultivation, which made the Wood-sorrel less plentiful, and the Dutch clover abundant.

## MINERALOGY.

THE DIAMOND.—This precious Stone, in its natural state, is of the form of an octahedron. This may be defined a double four-sided pyramid, in which the lateral planes of the one are set on the lateral planes of the other, which will be better understood by the accompanying figure, being a regular octahedron, wherein the triangular faces are equilateral and equiangular, and, of course, the base of the two pyramids is a square. Diamonds are always found in detached crystals, and are more or less well shaped, as they are pure or otherwise; so that they occur in a variety of forms, of which their primitive one is the basis; the faces are frequently curvilinear; they are also subject to the

compound crystallization called the macle. The structure is perfectly lamellar, yielding readily to mechanical division parallel to all the planes of the regular octahedron, thus proving that this is the primitive form. Diamond is the hardest of all substances, and its specific gravity 3.5. When heated, it becomes phosphorescent. The general colour of the Diamond is white, but is found of various tints, red like the Ruby, orange like the Hyacinth, blue like the Sapphire, and green like the Emerald; the last of which is most rare, and of the greatest value when it is of a beautiful tint; the rose, blue, and yellow Diamonds are the next in value. Transparency and brilliancy are the natural and ordinary qualities of the Diamond, which exhibits but a single refraction of the rays of light; some, however, are quite opaque. Diamonds are divided into Oriental and Occidental or Brazilian, the former being the most valuable. Bœtius de Boot, in his "History of Gems," written in 1609, conjectured that the Diamond was inflammable. Mr Boyle discovered, in 1673, that when exposed to a high temperature, it gave out acrid vapours, in which a part of it was dissipated. Sir Isaac Newton, who composed his work on Optics in 1675, concluded, from its great refracting power, that it must be combustible, and that it might be an unctuous substance coagulated. But the celebrated Averani, in 1695, in presence of the Grand Duke of Tuscany, and several of the most philosophic men of that time, showed, by concentrating the rays of the sun upon it, that the Diamond was exhaled in vapour and disappeared entirely, while other precious Stones only

grew softer. Since that period, however, various chemists have burned Diamonds with as much facility as a piece of iron, wire, or wood, by exposing them on a piece of charcoal placed in the flame of a common lamp, or even a candle, and blown with a current of oxygen gas. At a heat less than the melting point of silver, it gradually dissipates, burns, and combines with nearly the same quantity of oxygen, and forms the same quantity of carbonic acid as charcoal.

Dr Murray of Edinburgh has invented the most simple apparatus which we have seen for exhibiting the combustion of the Diamond. The annexed cut gives a representation of it. A glass globe is filled with oxygen obtained from oxy muriate of potassa over mercury. A portion of the stem of a tobacco pipe, attached to the curved end of a wire fastened to the cork above, carries the Diamond, fixed in a nidus prepared for it. The Diamond is kindled by the oxy-hydrogen blow-pipe, or a stream of oxygen urged over the flame of a spirit-of-wine lamp, and then conveyed into the globe. When the combustion of the Diamond ceases, lime water is passed over the recipient, and the

weight of the carbonate of lime formed and precipitated, indicates the quantity of Diamond consumed. Dr Clark exposed a Diamond of six carats, of an amber colour, to the flame of the gas blow-pipe. It became colourless and transparent—after this it became white, and by continuing the heat, it was entirely volatilized in about three minutes. It has also been ascertained by Guyton, Davy, and others, that although Diamonds, whether Oriental or Occidental, are the hardest of all substances, they yet contain nothing more than pure charcoal or carbon. The extreme hardness and transparency of this carbon furnish a problem which has hitherto baffled the efforts of philosophers to solve satisfactorily. Nevertheless, the knowledge of the inflammability of Diamonds has very considerably reduced their mercantile value, and will probably bring it, like that of all other articles, to the common standard of comparative use.

Diamonds were first brought to Europe from the East Indies, where they are found in various parts. The first mine known there is that of Sumbulpour on the river Goual, which falls into the Ganges. A chain of mountains extending from Cape Comorio to Bengal are the most celebrated for producing Diamonds. But the chief of these are in the kingdom of Golconda, furnishing the greatest quantity and most esteemed Diamonds, especially those of Pastall, which are sent to Calcutta, where they are sorted, sealed up in bags, and conveyed to London. In 1770, there were fifty Diamond workings in the kingdom of Visapour; these furnished more than those of Golconda, but were abandoned, being smaller. They are also found in the Island of Borneo. The total annual value of the Diamonds so collected is said to amount to about L.142,500, exclusive of those which are smuggled. The largest Diamond which has hitherto been found, is that called the Mattan Diamond, from Borneo, and particularly described at page 31 of this Journal. The next largest Oriental Diamond is one, the size of a pigeon's egg, of the weight of 193 carats, equal to about one ounce two pennyweights Troy. The Empress Catharine II. of Russia offered L.104,166, 13s. 4d. besides an annuity for life of L.1041, 13s. 6d., which was refused; but was afterwards sold to Catharine's favourite, Count Orloff, for the above sum without the annuity, who presented it to the Empress on her birth-day, in 1772. This gem exceeds the famous Pitt Diamond in size, and is reckoned equal in water. It is now in the sceptre of Russia, and is considered the finest of the kind in Europe. The late Queen of Portugal possessed the next largest Diamond in Europe, but we are not aware whether it is still in the family. The Pitt Diamond weighs 136 carats, or nearly an ounce, it was purchased for 2,500,000 livres, and is now the finest of the crown jewels of France.

*Brazil Diamonds.*—In the year 1728 it was discovered that Diamonds were to be met with in some branches of the river Das Caravilas, at a considerable elevation, and at Serro de Trio, in the province of Mino Geraes, in the Brazils, belonging to Portugal. The Rio de Janeiro fleet brought home at once 1146 ounces of them. Such a considerable supply would have reduced the value of Diamonds, had not the Government of Portugal laid restrictions on the persons who searched for them. The Diamonds are found in such rivers, the courses of which have been more or less altered; and it seems probable that they are washed down by the torrents from the mountains, as they are found in the greatest plenty after violent storms of rain. They are not, however, confined to the beds of rivers alone, as they have been found in cavities and water-courses on some of the highest mountains in the district. The principal work in the present day is at Mandanga, or the Jigitonlona, a very shallow river, which admits of its waters being dammed out, or diverted from their course.

We learn from Mawe's Travels in the Interior of Brazil, that the Diamond mines of that country are situated due north of the mouth of the Rio de Janeiro. The capital of the district is called Tjuco. The face of the country exhibits in all directions a series of gritstone rocks alternating with micaceous schistus, in which numerous rounded quartzose pebbles are embedded, giving the whole the appearance of plum-pudding stone.

In the splendid collection of Mr Hewland, there is a Brazilian Diamond embedded in brown iron ore; another, also, in the same substance, is in the possession of M. Schuch, at Lisbon. Eschwege has, in his own Cabinet, a mass of brown iron ore, in which there is a Diamond in a drusy cavity of a green mineral, conjectured to be arseniate of iron. From these facts he infers that the matrix of Brazil Diamond is brown iron ore. The crust which envelopes the rough Diamond is found thicker on those from Brazil than those from the East Indies, and hence they are easily distinguished in their natural state; but as the most skilful lapidaries may be deceived in them after they are cut, they are accordingly of equal value in trade. This equality, however, is only to be understood as relating to small ones, as most of the Occidental Diamonds beyond four or five carats have blemishes, which are seldom found in the Oriental, and in that case the difference is great. Some Mineralogists are of opinion that the latter are harder and more brilliant than the former; but this opinion is not sanctioned by experiment.

*North American Diamonds.*—A Diamond weighing one carat and a half was found in the autumn of 1835 in the washings of a stream in North Carolina.

*Russian Diamond Mines.*—When, in the year 1826, Professor Engelhardt undertook a scientific journey into the Uralian Mountains, he remarked that the sands in the neighbourhood of Kouspra, and those of the Platina mines at Nigny-Toura, strikingly resemble the Brazilian sands in which Diamonds are found. Baron Humboldt, during his residence in that country in 1830, confirmed this resemblance; and examinations having been made according to his advice, a young countryman who was employed in washing the auriferous sand, on the grounds of the Countess Polier, discovered a Diamond on the 20th June 1830, which was nothing inferior to those of Brazil; soon after many others were found superior in weight to the first. Thus Russia has added this source of riches to those of which of late years it has obtained in the form of Gold and Platina Mines, from the Ural chain of mountains; and has proved, that what has hitherto been supposed to be the case is not correct, that Diamonds were only found near the line, and none beyond the tropics.

Professor Jameson is of opinion, that Diamonds continue to be formed even at the present day in some alluvial districts of India; as they have been discovered in alluvial beds of clay, not as a secondary deposit, but as an original one; and, says he, "nothing more seems necessary for the formation of the Diamond in such situations, than time, or other favorable circumstances, for allowing portions of the carbonaceous matter in the soil to be reduced to the adamantine state, and afterwards to coalesce, according to the laws of affinity, into the granular and crystallised form—in short, to form Diamond." The Professor also promulgates another theory for the formation of Diamonds; he says, "a direct appeal to the characters of some woods seems to countenance the idea I some years ago suggested to the Wernerian Society, that vegetables may contain carbonaceous matter approaching to the adamantine state. Certain woods which have not the gritty feel of those that contain silica are uncommonly hard, dark coloured, and take a high polish; these, I conjecture, may be somewhat of the adamantine nature. If this should prove to be the case, it would neither be surprising nor unexpected, that such trees may secrete carbon in the adamantine state, which, on being removed from the influence of the living principle of the plant, would, by the power of affinity, form into true Diamonds, just as the silica secreted from the Bamboo takes the form of opal, and that from teak wood the characters of hornstones."

In support of Professor Jameson's theory, we may mention that Dr Hamilton was informed by the workmen, when he visited the Diamond Mines of Parma, in Bengal, that the generation of Diamonds was always going forward, and that they had as much chance of success in searching earth that had been fourteen or fifteen years unexamined, as in digging what had never been disturbed; and, in fact, he saw them digging up earth which had evidently been before examined, as it was lying in irregular heaps as thrown out after examination. These men are so expert at discovering Diamonds, that they never overlook any during their search.

Sir David Brewster states, that Dr Voysey has shown that the matrix of the Diamonds produced in Southern India is the sandstone breccia of the dog slate formation; and that Captain Franklin has found, that in Bundel Kund, the rocky matrix of the Diamond is situated in sandstone, which he imagines to be the same as the new red sandstone of England; that there are at least four hundred feet of that rock below the lowest Diamond beds, and that there are strong indications of coal underlying the whole mass. Sir D. Brewster, from certain cavities observed in Diamond, and from their effects in polarizing light, is led to conjecture, "that the Diamond originates, like amber, from the consolidation of perhaps vegetable matter, which gradually acquires a crystalline form from the influence of time, and the slow action of corpuscular forces."

The usual method of seeking Diamonds is by throwing the stones and rubbish with which they are supposed to be associated into a cistern, full of water, having a cock and plug at the bottom. The lumps are then broken, and the muddy water drawn off till the stones are washed clean. When the sun shines bright, the sand and stones which remain in the cistern are carefully examined. In this business the workmen are so expert, that the smallest crystal cannot escape them.

The cutting and polishing of Diamonds are performed by first cleaving them in the direction of their lamellæ, and then rubbing them against each other, and the powder or dust thus disengaged serves to grind and polish them; these latter operations are performed by the aid of a mill, which turns a wheel of soft iron, sprinkled over with Diamond-dust, mixed with olive oil. The same dust, well ground and diluted with water and vinegar, is used for sawing Diamonds, which is effected by means of an iron or brass wire as fine as a hair.

## GEOLOGY.

*ON THE EXCAVATION OF VALLEYS.*—There is much diversity of opinion among Geologists on the subject of the excavation of valleys, and of the effects produced by river currents in modifying the form of the solid parts of the earth; and several distinguished men have lately turned their attention to this important and interesting subject. Professor Sedgwick seems to have formed opinions on this subject, which approach near to the true theory. Messrs Lyell and Murchison discussed this subject in a Memoir on certain portions of the volcanic regions of Central France. Their opinions accord with the views of Montrosier, Scrope, and some other writers, who conceive that the existing rivers have, by a long continued erosion, eaten out deep gorges, not only through currents of basaltic lava, which have flowed through the existing valleys, but also through solid rocks of subjacent gneiss. They further seem to prove, that no great denuding wave or mass of water, lifted by supernatural force above its ordinary level, could have assisted in forming such denudations; for the country is still studded with domes of incoherent matter, the remnants of former craters, from which may be traced continuously streams of lava, intersected in the course of the rivers by these deep gorges—the gauges and tests of the erosive power of running water during times comparatively recent.

Mr Conybeare proves that, within the records of history, the river Thames has had no erosive power on the valley, nor produced any effect on the general features of the country through which it flows, and that the propelling force of its waters is not now, and never could have been, adequate to the transport of the boulder stones,

which lie scattered on the sides and summits of the chains of hills through which it has found a passage; that much of the water-worn gravel, which has been drifted through the breaches opened in the sinuous line of its channel, is composed of rocks not found within the limits of its basin; and that the form of the country is often the very reverse of that which would have been produced by mere fluvial erosion, however long continued. Similar facts are supplied by nearly all the greater valleys of England; and on the whole, they point to one conclusion, that the fluvial erosion, as a mere solitary agent, has produced but small effects in modifying the prominent features of our island: at the same time, they leave untouched all the facts of an opposite kind supported by direct evidence, whether derived from the volcanic districts of Central France, or from any other physical region on the surface of the earth.

The power of mountain torrents in transporting heavy masses of stone is strikingly illustrated in a paper by Mr Culley. He states that a small rivulet descending from the Cheviot Hills along a moderate declivity, carried down, during a single flood, many thousand tons of gravel into the plains below; and that several blocks, from one-half to three quarters of a ton weight each, were propelled two miles in the direction of the stream. Facts similar in kind, but on a scale incomparably greater, must be in the recollection of every one who has seen the Alpine torrents descending into the plains of the north of Italy.

When mountain chains abut in the sea, the laws of degradation are not suspended. At each successive flood, fragments of rock are drifted in the direction of the descending torrents, and rolled beneath the waters. This kind of action is indeed casual and interrupted; but it is aided by another action which is liable to no intermission—the beating of the surf and the grinding of the tidal currents on all the projecting parts of a steep and rocky shore. Under such conditions there are now forming at the bottom of the sea, and at depths perhaps inaccessible, alternating masses of silt and sand, and gravel, which, if ever lifted above the waters, may rival in magnitude some of the conglomerates of our oldest formations.

Professor Sedgwick is of opinion, that the existing drainage of our physical region is a complex result, depending upon many conditions—the time when the region first became dry land—its external form at the time of its first elevation above the sea—and all the successive disturbing forces which have since acted upon its surface. But none of these elements are constant; no wonder, then, that results derived from distant parts of the earth should be so greatly in conflict with each other. In the formation of valleys there is, therefore, little wisdom in attributing every thing to the action of one modifying cause. We know by direct geological evidence, that nearly all the solid portions of the earth were once under the sea, and were lifted to their present elevation, not at one time, but during many distinct periods. This is proved beyond a doubt, by the various marine shells which are found in the strata of the different formations, all of them having existed in the ocean at different epochs of time, and varying in their structure according to the various eras when they existed; the most simply organized being buried in the most ancient beds, and the most complicated in the most recent. We know that elevating forces have not only acted in different places at different times, but with such variations of intensity, that the same formation is in one country horizontal, in another vertical; in one country occupies the plains, in another is only found at the tops of the highest mountains. Now every great irregular elevation of the land (independently of all other results) must have produced, not merely a rush of the retiring waters of the sea, but a destruction of equilibrium among the waters of inland drainage. Effects like these must have been followed by changes in the channels of rivers, by the bursting of lakes, by great debacles, and, in short, by all the vast phenomena of denudation. In comparing distant parts of the earth, we may therefore affirm that the periods of denudation do not belong to one, but to many successive epochs. And by parity of reasoning we may conclude, that the great masses of incoherent matter which lie scattered over so many parts of the surface of the earth, belong also to successive epochs, and partake of the same complexity of formation.

The excavation of valleys seems, therefore, to be a complex result, depending upon all the forces, which, acting on the surface of the earth since it rose above the waters, have fashioned it into its present form. We have old oceanic valleys which were formed at the bottom of the sea in times anterior to the elevation of our continents. Such is the great valley of the Caledonian Canal, which existed nearly in its present form at a period anterior to the conglomerates of the old red sandstone. We have longitudinal valleys formed along the line of junction of two contiguous formations, simply by the elevation of their beds. To this class belong some of the great longitudinal valleys of the Alps. We have other valleys of more complex origin, where the beds through which the waters now pass have been bent and fractured with an inverted dip at the period of their elevation. Such is the valley of Kingsclere described by Dr Buckland. We have valleys of disruption, marking the direction of cracks and fissures, produced by great upheaving forces. Such are some of the great transverse valleys of the Alps. Of valleys of denudation, our island offers a countless number. Some are of simple origin; for example, the dry valleys of the chalk formation, which appear to be swept out by one flood of retiring waters during some period of elevation. Others are of complex origin, and are referable to many periods, and to several independent causes. Lastly, we have valleys of simple erosion: such are some of the deep gorges and river channels in the high regions of Auvergne, excavated solely by the long continued attritions of the rivers which still flow through them.

**SOUTH AMERICAN GEOLOGY.**—M. Orbigny, who explored the countries of Buenos Ayres, Chili, and Peru, mentions some remarkable facts respecting fossil remains being found in those countries at a great height. He found primitive formations in the greater part of Brazil and of the Bande Oriental. The immense basin, which extends from the 25th to the 38th degree of south latitude, was the first place where he detected animal remains in strata, which he reckoned of the tertiary formation. The vegetable remains were below the bones of the Mammiferous animals, which were, in their turn, covered by banks of river shells. The sides of the rivers are high, presenting every facility for observing these superpositions. To the south a primitive chain of mountains separated this geological basin from that of Patagonia.

This last is analogous in a certain degree to the basin of Paris, in presenting alternating strata of oysters and freestone with osseous remains, gypsum, and river shells. M. Orbigny is decidedly of opinion that the higher plains of the Andes are volcanic at the height of 12,000 feet he discovered marine fossils.

## GENERAL SCIENCE.

**TRANSFORMATION OF VEGETABLE SUBSTANCES INTO A NEW PRINCIPLE.**—Braconot has discovered that vegetable substances produce, when heated with concentrated nitric acid, compounds very different from those afforded when diluted nitric acid is used. Saw-dust, cotton, linen, fecula from the potatoe gum, issoline and saponine, heated with concentrated nitric acid, are transformed into a peculiar mucilaginous substance, called by Braconot *Xiloidine*. It is transparent, and is reddened by tursole; cold water coagulates it, and boiling water softens without dissolving it. It is insoluble in alcohol and ammonia; and caustic potash dissolves it with great difficulty. On the other hand, the acids dissolve it in great quantities without altering it; the solutions leave upon bodies a brilliant varnish.

**PROSPECTS OF THE NEGRO POPULATION IN SOUTH AMERICA, AND OF THE GRADUAL EXTINCTION OF THE ORIGINAL INHABITANTS OF THE NEW WORLD.**—Dr Poeppig, in his account of Chili, has the following important observations on these interesting subjects:—"No country in America enjoys, to such a degree as Chili, the advantages which a state derives from an homogeneous population and the absence of Castes. If this young republic rose more speedily than any of the others, from the anarchy of the revolutionary struggle, and has attained a high degree of civilization and order, with a rapidity of which there is no other example in this continent, it is chiefly indebted for these advantages to the circumstance, that there are extremely few people of colour among its citizens. Those various transitions of one race into the other are here unknown, which strangers find it so difficult to distinguish, and which, in countries like Brazil, must lead, sooner or later, to a dreadful war of extermination, and in Peru and Columbia, will defer to a period indefinitely remote, the establishment of general civilization. \* \* \* If it is a great evil for a state to have two very different races of men for its citizens, the disorder becomes general, and the most dangerous collisions ensue, when, by an unavoidable mixture, races arise which belong to neither party, and in general inherit all the vices of their parents, but very rarely any of their virtues. If the population of Peru consisted of only whites and Indians, the situation of the country would be less hopeless than it must now appear to every calm observer. Destined as they seem by nature herself, to exist on the earth as a race, for a limited period only, the Indians, both in the north and south of this vast continent, in spite of all the measures which humanity dictates, are becoming extinct with equal rapidity, and in a few centuries will leave to the whites the undisputed possession of the country. With the Negroes the case is different; they have found in America a country which is even more congenial to their nature than the land of their origin, so that their numbers are almost every where increasing in a manner calculated to excite the most serious alarm. In the same proportion as they multiply, and the white population is no longer recruited by frequent supplies from the Spanish Peninsula, the people of colour likewise become more numerous. Hated by the dark mother, distrusted by the white father, they look on the former with contempt, on the latter with aversion, which circumstances only suppress, but which is insuperable, as it is founded on a high degree of innate pride. All measures suggested by experience and policy, if not to amalgamate the heterogeneous elements of the population, yet to order them so that they might subsist together without collision, and contribute in common to the preservation of the machine of the State, have proved fruitless \* \* \* The late revolutions have made no change in this respect. The hostility, the hatred of the many coloured classes, will continue a constant check to the advancement of the State, full of danger to the individual citizens, and perhaps the ground of the extinction of entire nations. The fate which must, sooner or later, befall the great part of tropical America which is filled with Negro Slaves, which will deluge the fairest provinces of Brazil with blood, and convert them into a desert, where the civilized white man will never again be able to establish himself, may not indeed afflict Peru and Columbia to the same extent, but these countries will always suffer from the evils resulting from the presence of an alien race. If such a country as the United States feels itself checked and impeded by its proportionably less predominant black population; and if there, where the wisdom and power of the government are supported by public spirit, remedial measures are sought in vain; how much greater must be the evil in countries like Peru, where the supine character of the whites favours incessant revolution, where the temporary rulers are not distinguished either for prudence or real patriotism; and the infinitely rude Negro possesses only brutal strength, which makes him doubly dangerous in such countries, where morality is at so low an ebb. He and his half descendant, the Mulatto, joined the White Peruvian to expel the Spaniards, but would soon turn against their former allies, were they not at present kept back by want of moral energy and education. But the Negro and the man of colour, far more energetic than the White Creole, will in time acquire knowledge, and a way of thinking that will place them on a level with the Whites, who do not advance in the same proportion so as to maintain superiority."

**EDUCATION.**—How greatly is Nature neglected in all our Schools! "Ten years," says Erasmus, "have I wasted in reading Cicero." *Decem annos consumpsi in legendo Cicero.* The Echo replied in Greek, "OË (Ass!)"

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE—THE ANTELOPES.

THE Antelopes are an elegant and active tribe of animals, inhabiting mountainous countries, where they bound among the rocks with so much lightness and elasticity, as to strike the spectator with astonishment. They browse like Goats, and frequently feed on the tender shoots of such trees as are found on their rocky fastnesses. In disposition they are timid and restless, and Nature has bestowed on them long and tendonous legs, peculiarly appropriate to their habits and manners of life. Almost the whole tribe are remarkable for the lively and fine expression of their eyes, and in the East they are considered as the standard of perfection;—a higher compliment cannot be paid to a female, than to say “She has the eyes of an Antelope.”

Fig. 1. THE CHAMOIS (*Antilope rupicapra*).—This extremely active animal is a native of the rocky and mountainous districts of Dauphiné, Piedmont, Savoy, Switzerland, and various parts of Germany. The flesh of this animal is well flavored, on which account it is hunted by the natives of Switzerland. This delicacy of its flesh may arise from its nicety in the choice of food, which consists of the best herbage, the most tender shoots of plants, the flowers, and young buds. It is also very fond of such aromatic herbs as are natives of mountainous districts. It runs along the rocks with great ease and seeming indifference, and leaps from one to another with unerring security.

Fig. 2. DUVAUCEL'S ANTELOPE (*A. Duvaucelii*).—This species is a native of Sumatra, and was discovered by M. Duvaucel. It is somewhat allied to the Cambing-Ootan, but its horns are more recumbent, with longer, larger, and more pointed hoofs; and it differs materially in point of colour, being of an ashy-gray, with a tinge of brown, whereas the former is black.

Fig. 3. THE FOUR-TUFTED ANTELOPE (*A. quadriscopa*) is one of the rarest of the tribe; one specimen only having been seen in Britain, and was exhibited in Exeter Change, London. It is a native of Senegal. This and the following species are nearly allied to the Goats.

Fig. 4. THE CAMBING-OOTAN (*A. Sumatrensis*).—The hair on the head, neck, and whole body, is longer and rougher than is common with Antelopes, which gives it much the appearance of an animal of the genus *Capra*; and the character of auulations of the horns adds still further to this peculiar aspect. It inhabits Sumatra.

Fig. 5. THE PRONG-HORNED ANTELOPE (*A. furcifer*) inhabits the New Continent, and its geographical range is further North by several degrees than any other species of its tribe. It is common on the fertile plains which border the Missouri in the United States, and has been observed by Dr Richardson as far North as the 53d parallel, on the north branch of the Saskatchewan. It is a beautifully-formed animal, somewhat larger than the Roebuck.

Fig. 6. THE VLACKE-STEENBOCK (*A. rufescens*).—This animal is found on the plains of Southern Africa, and was first noticed by Mr Burchell. It is one of the most elegant of the smaller Antelopes, and measures only two feet six inches from the muzzle to the insertion of the tail.

Fig. 7. THE FOUR-HORNED ANTELOPE (*A. quadricornis*).—This is a native of Nepal, and must not be confounded with the Chickara of Duvaucel. It is remarkable on account of its four horns, a character peculiar to it and the Chickara only, of all the numerous species of their tribe.

Figs. 8 & 9. THE BOMTEBOCK (*A. personata*).—An individual of this rare species belonged to Mr Cross, in whose possession it died. Its skin was purchased by Mr Morgan, and presented to the Museum of the Zoological Society. This was a young animal, and measured only two feet and a half in length; but when full grown it is said to be little inferior to the Red-Deer in magnitude. It is an inhabitant of the Cape of Good Hope, and has received the appellation of Bomtebock from the colonists.

#### DESCRIPTION OF THE PLATE—THE THRUSHES.

A striking peculiarity of the Merulidæ is their strong, sweet, mellow, and versatile voice, in which they are perhaps superior to all other Birds. Before the first rays of the sun have appeared above the horizon, this melodious tribe begin to pour forth their varied and delightful notes, which have delighted mankind in all ages, and

afforded a theme to many a bard. In this family is classed the Mocking Bird of America, whose extraordinary powers of voice exceed those of all other Birds.

The figures in our plate are all inhabitants of North America, and are represented the size of life.

Fig. 1. THE LITTLE TAWNY THRUSH (*Merula minor*) is found on the banks of the Saskatchewan. It leads a solitary life, and migrates to Pennsylvania in April, where it continues all the summer, employed in incubation and the rearing of its brood.

Fig. 2. THE GOLDEN-CROWNED THRUSH (*M. auricapilla*).—This is also a migratory species, arriving in Pennsylvania in April, and leaving it again late in September. It inhabits the woods, and is frequently to be seen on the ground running in the same manner as a Cock, and moving its tail like the Wagtails. It builds its nest on the ground.

Fig. 3. RICHARDSON'S THRUSH (*M. Richardsonii*).—This richly-coloured Bird was discovered in Nootka Sound, during Captain Cook's third voyage. Richardson found it at Fort Franklin, in latitude 65° 14', in April 1826, and it was also seen by him on the banks of the Saskatchewan. It builds its nest in a bush. Being never observed in the United States, its range to the East is probably bounded by the Rocky Mountains.

Fig. 4. AUDUBON'S THRUSH (*M. Ludoviciana*).—This bird was discovered by Audubon, who says it inhabits the States of Louisiana and Mississippi, where it is found at all seasons in deep and swampy cane brakes. He says its song is equal to that of the Nightingale. It “begins on the upper key, and progressively passes from one to another, until it reaches the bass note; this last frequently being lost when there is the least agitation in the air.” Its nest is built at the root of a tree.

Fig. 5. THE TAWNY THRUSH (*M. Wilsonii*).—This bird arrives at Pennsylvania from the South about the beginning of May, where it remains a week or two, and then passes northward to fulfil the business of incubation. It has also been observed by Richardson to pass as far to the North as the Saskatchewan. Nothing, however, is known of its nest. It frequents alder thickets and dense willow groves.

Fig. 6. THE WATER THRUSH (*M. aquaticus*).—This is a sly species, frequenting brooks and the shores of ponds and rivers, where it may be seen wading in search of aquatic insects. It also passes through Pennsylvania for the North early in May, and returns in August.

ASTRACAN SHEEP.—M. Leroux, of Franconville, has a flock of Sheep, presented to him by General Guilleminot, being the produce of a Ram and Ewe, which he brought from Constantinople, and originally introduced from Astracan. At present this small stock consists of two rams and a male lamb, some sheep of a pure race between the first pair, and a considerable number of a mixed breed, between the males and the native sheep of the country. The growth of the wool on these sheep is very rapid, so much so, that it is shorn twice a year, and yielding at each time a greater quantity than any variety of the European sheep, which is only shorn once a year. The wool is long and of a coarse texture, and fit only for the manufacture of common stuffs, the stuffing of mattresses, &c. Its colour is of a silvery gray, and consequently would dye all colours. Underneath the long wool is a thick coating of wool of fine silky or downy texture like that of Cashmere. These animals of the pure breed have the quality of attaining a greater height in a given time, than any other known variety of the sheep; while the flesh is of a good and pleasant flavour.

OBSTINACY OF A WEASEL (*Mustela vulgaris*).—The following anecdote is communicated by Lieut. John Brown:—“While fishing for Perch on Loch Fitty, a beautiful and picturesque sheet of water, about a mile broad and two long, situate about half way betwixt Kinross and Dunfermline, I observed near the centre of the lake a small object making its way for that part where I stood knee-deep in water. At first it struck me that it was a young Wild Duck (with which this lake abounds), but on its nearer approach, I discovered it to be a full grown Weasel, swimming with his head and back above water in the same manner as a Newfoundland Dog. I called to a friend who fished at some distance from me, and as soon as the Weasel neared us, we commenced an attack on him with our fishing-rods, and he in his turn gave us battle by biting at, and clinging to, the point of our rods, grinning and gnashing his teeth; and showed a determination to land at the very spot where we stood, in spite of our combined efforts to drive him off, by lashing him with the points of

our rods. It was of no avail, for our punishment only increased his ire, and he quitted hold of my friend's rod and made directly towards me, seemingly with an intention of coming to close quarters. He was now too near us to strike at him with our rods, and my friend ran to the shore, seized a piece of paling, and made two or three unsuccessful strokes at him, which served but to increase his fury; and he seemed determined not to relinquish his intentions, except with the loss of his life. As he stood so nobly to the contest, I thought it but humanity to call out "quarter, quarter—allow the brave animal to pass." He landed on *terra firma*, and seeing that hostilities had ceased, shook himself, and trotted quietly off. It was at the broadest part of the lake where he crossed; and from the time when I first saw him till the end of our attack, he must have been little short of three quarters of an hour in the water."

**EUPLERES GOUDOTTI.**—A new genus of Mammalia has been found in Madagascar, by M. Goudot, which M. Doyere, Professor at the College of Henri Quatre, proposes to call *Eupleres*. It is a lively, swift animal, with slender legs, and entirely plantigrade, the sole of the foot being the only part free from hair. It lives on the surface of the ground, is long and thin in the body, and its girth is that of most Insectivora. If any judgment can be formed from its anatomy, its hearing is equal to that of the other Insectivora, and the size of its orbits shows that its sight is likely to be good. The thumb is much the shortest of its five fingers, and all are armed with sharp, thin, and semi-retractile nails. The natives say, that it hollows out the sand, and lives in pits. Flacourt mentioned this animal under the name of Falanou, and thought it to be a Civet, which error has been continued in several works. The animal we now speak of was too young to have completed its dentition, but at present it has six incisors in the upper jaw, two canines, six pointed grinders, and four tuberculous grinders in the under jaw; eight incisors, two canines, with a double root, fitting behind those of the upper jaw like the Mole, four pointed grinders, and six with five tubercles in the lower jaw. M. Doyere gives the specific name in honour of M. Goudot, and calls it *Eupleres Goudotti*.

**INTRODUCTION OF FROGS INTO IRELAND.**—It is not generally known that the introduction of Frogs into Ireland is of comparatively recent date. In the 17th number of the Dublin University Magazine, there is a quotation from Donat, who was himself an Irishman, and Bishop of Fesula, near Florence, and who, about the year 820, wrote a brief description of Ireland, in which the following passage occurs:—

"Nulla veneta nocent, nec serpens serpit in herba;  
Nec conquesta canit garrula rana lacus."

"At this very hour," says the author of the article, "we have neither snakes nor venomous reptiles in this island; and we know, that, for the first time, *frog-spawn* was brought from England in the year 1696, by one of the Fellows of Trinity College, Dublin, and placed in a ditch in the University park, or pleasure ground, from which these very prolific colonists sent out their croaking detachments through the adjacent country, whence their progeny spread from field to field through the whole kingdom." In the Dublin Medical Journal, however, it is stated, "we have learned from good authority, that a recent importation of snakes has been made, and that they are at present multiplying rapidly within a few miles of the tomb of St Patrick."

## BOTANY AND HORTICULTURE.

### GENERAL REVIEW OF THE VEGETABLE KINGDOM.—NO. III.

North America, under the same degrees of latitude as France and England, and with a colder climate, presents a far richer vegetation. There large trees, such as the *Liriodendron* and *Magnolia*, bear the most superb flowers. Those of many other trees and shrubs vie in beauty with the flowers of the torrid zone; the light waving composite foliage of the *Robinias* and *Gleditschias* are the counterparts of the *Mimosas* of the tropics. The single genus of Oaks comprehends within the United States more species than Europe reckons within the whole amount of its trees.

In the Northern parts of Asia vegetation differs but slightly from that of our own country. We meet with nearly the same genera, and similar types prevail. But in the Southern parts the character of the country is changed. Without water, and swept by scorching winds, the drought is extreme. The carpet of soft verdure, and the refreshing shade of its Northern countries and of Europe, are looked for in vain. Most of the plants have thinly scattered long narrow arid leaves, unscalped and entire at the edge, and of a gloomy green; several have none at all, or at least such as, instead of leaves, may be truly termed thorns. Yet many of the trees and shrubs have a snowy blossom. Of the former, the largest in those parts belong to the Myrtle tribe, and have a punctured foliage, diffusing an aromatic scent when bruised. There are likewise many shrubs of the pulse tribe with a composite foliage; but the leaflets of the leaves are only evolved on the plants first rising from the seed. As they advance to maturity, the naked footstalks widen into simple lanceolate blades, or become transformed into acicular spines, resembling the leaves of some of the *Asparagi*. In New Holland the *Proteaceæ* abound; and also at the Cape of Good Hope; but the *Liliaceæ*, which decorate the African Promontory so profusely, are, on the contrary, rare in New Holland. It is a fact as notorious as surprising, that no one vegetable belonging to the countries towards the Southern pole produces a single fruit for the food of Man.

There are divers conditions without the performance of which the growth of the different species cannot proceed. An uninterrupted heat is requisite for some; a moment's decrease in it is fatal to them; some withstand a considerable degree of cold while their sap is quiescent, but want a high degree of heat when that is once in motion; some like a moderate temperature, and dread equally the excess of both heat and cold. It is upon the observation of such appearances that the cultivator grounds his practice; he knows that it would be in vain for him to attempt to grow, without shelter, either the Date or Orange beyond the 43d degree of Northern Latitude; that the Olive will do a little beyond; that the Vine is barren beyond the latitude of 50 degrees, or at least never brings its grape to perfection. He is cautious of exposing in a Southern aspect the species whose sap is readily set in motion by the first gleam of warmth; he knows that late frosts destroy them; as in the vineyards round Paris, the plantations there which escape the injuries of frost, are not those which look towards

the South, but those that look towards the North. The sap of the latter is set in motion late, and when the heat reaches them the season is already settled, and no risk is run from the inroad of cold.

Late frosts are peculiarly hurtful to the delicate American and Botany Bay plants, which we are attempting to naturalize in Europe. Many of these will bear a very sharp cold in the heart of winter; but no sooner does the spring advance, and a softer air prevail, than their roots begin to elaborate their juices underground, their bark to fill with moisture, their buds to swell and open, and a fall in the temperature, if but for one moment, destroys them.

Local circumstances, such as the elevation of the place, its aspect, the nature as well as dipping of its soil, the proximity of mountains, of forests, of the sea, &c. &c. are all causes of variation of temperature, and must each be attended to, in accounting for the vegetation of any particular district. For instance, the winter is less severe on the Northern coasts of France, than in the interior on the same level—an effect of the vicinity of the ocean. The sea preserves a far more even temperature than the atmosphere, and is constantly at work to maintain some degree of equilibrium in the warmth of the air. In the summer, it carries off a part of the caloric from it—in the winter it gives back a part of that which it contains. It is thus that the mass of water held in the vast basin of the ocean, tempers on its coasts the heat of summer and the cold of winter. For this reason, on the coast of Calvados, the Myrtle, the Fuchsia, the Magnolia, the Pomegranate, the Indian Rose, and many other exotic plants, grow in the open air; but in the department of the Seine, the same plants require shelter. This cause also permits the cultivation of many species in the open ground about London, that near Paris will not thrive without a green-house.

Local circumstances, however, have only a limited influence, and it may be laid down as a general principle, that the cold in the same or nearly the same longitudes is, during winter, in direct proportion to the distance from the Equator. We say during winter, because the length of the days in the summer of the Polar regions sometimes renders the heat even more intense than in our climates; and it is very probable that many of the herbaceous plants of the tropics would succeed in Sweden, Norway, Lapland, and even Spitzbergen, if the frost did not set in too early to admit of their completing the round of the vegetable career.

In proportion as we advance towards the Pole, we are sensible of the change in the appearance of the vegetation. Those species which require a mild and temperate climate, are supplanted by others which seem to delight in cold. The forests fill with Pines, Firs, and Birches—the natural decoration of a Northern land. The Birch of all trees is the one which bears the severity of the climate the longest; but as it approaches the Pole it grows smaller; its trunk dwindles and becomes stunted, and the branches knotty, till at last it ceases to grow at all towards the 70th degree of latitude—the point where Man gives up the cultivation of Corn. Beyond this, shrubs, bushes, and herbaceous plants alone are to be met with. The Wild Thyme, Daphnes, creeping Willows and Brambles, cover the face of the rocks. It is in these cold regions that the berries of the *Rubus arcticus* acquire their delicious flavour and perfume. The Shrubs disappear in their turn. They are succeeded by low herbs, furnished with leaves at the root, from the midst of which rises a short stalk surmounted by small flowers. Such are the Saxifrages, the Primroses, the *Androsaces*, *Arctias*, &c. These pretty plants take up their quarters in the clefts of the rocks, while the Grasses, with their numerous slender leaves, spread themselves over the soil, which they cover as with a rich verdant carpet. The Lichen, which feeds the Rein-deer, sometimes mixes in the turf, sometimes of itself covers vast tracts of country, its white tufts standing in clumps of various forms, looking like hillocks of snow which the sun has not yet dissolved. If we go farther, a naked land, sterile soil, rocks, and eternal snows, are all we find. The last vestiges of vegetation are some pulverulent *Byssi*, and some crustaceous Lichens, which cover the rocks in motley patches.

**ON THE RAPIDITY OF VEGETABLE ORGANIZATION.**—The vegetable kingdom presents us with innumerable instances, not only of the extraordinary divisibility of matter, but of its activity in the almost incredible rapid development of cellular structure in certain plants. Thus, the *Bovista giganteum* (a species of fungus) has been known to acquire the size of a gourd in one night. Now, supposing with Professor Lindley, that the cellules of this plant are not less than the one-two-hundredth part of an inch in diameter, a plant of the above size will contain no less than 47,000,000,000 cellules; so that, supposing it to have grown in the course of twelve hours, its cellules must have been developed at the rate of nearly 4,000,000,000 per hour, or of more than 96,000,000 in a minute! And, when we consider that every one of these cellules must be composed of innumerable molecules, each of which is composed of others, we are perfectly overwhelmed with the minuteness and number of parts employed in this single production of Nature.

**FIBRES OF THE ROSE OF SHARON.**—Mr S. Woodruff recently communicated to Professor Silliman that he had discovered, in the fibres of the bark of the Rose of Sharon, which were in a decayed state, a material very much resembling flax in its texture. The bark on the stalks appeared to be of the earliest growth, and it was separating from the wood; indeed, all of them were so much decayed that it was easy to divest them of the bark. The fibres are strong, and appear much like hemp, but may be divided into fibres as fine as flax. Mr Woodruff twisted a few small cords from this, without attempting any process of preparation, and it was found to be very durable and strong—even although it had not been macerated, and had, besides, the disadvantage of having been exposed to the vicissitudes of the weather, till a natural and gradual decay of its strength may have taken place.

The coat of the Rose of Sharon is much thicker, as well as softer and more silky, than that of hemp; but whether the fibres be sufficiently slender for fabrics of the finest texture remains to be ascertained. The plant is of a robust and healthy character, and is easily grown in a moderately good soil. It is also highly productive in seed, and being a perennial, might be raised with great facility in a long succession of crops on the same ground, and with much less labour and expense than flax or hemp. Professor Silliman, judging from the specimen sent him, thinks the plant is deserving of the attention of agriculturists.

## GEOLOGY.

ON THE PROOFS OF A GRADUAL RISING OF THE LAND IN CERTAIN PARTS OF SWEDEN.—It has been long imagined that the waters of the Baltic, and even the whole Northern Ocean, have been gradually sinking. In 1834, Mr Lyell investigated this interesting subject. On his way to Sweden, he examined the eastern shores of the Danish islands of Moën and Seeland, but neither there nor in Scania could he discover any indication of a recent rising of the land; nor was there any tradition giving support to such a supposition. The first place he visited, where any elevation of land had been suspected, was Calmar, the fortress of which, built in the year 1030, appeared, on examination, to have had its foundations originally below the level of the sea, although they are now situate nearly two feet above the level of the Baltic. Part of the moat on one side of the castle, which is believed to have been originally filled with water from the sea, is now dry, and the bottom covered with green turf. At Stockholm, the author found many striking geological proofs of a change in the relative level of the sea and land, since the period when the Baltic has been inhabited by the shells which it now contains. A great abundance of shells of the same species were met with in strata of loam, &c. at various heights, from 30 to 90 feet above the level of the Baltic. They consist chiefly of the Edible Cœkle (*Cardium edule*), the *Tellina Baltica*, and the common shore Nerite (*Littorina littoreus*), together with portions of the common Muscle (*Mytilus edule*), generally decomposed, but often recognisable by the violet colour which they have imparted to the whole mass. In cutting a canal from Södertelje to Lake Maelar, several buried vessels were found; some apparently of great antiquity, from the circumstance of their containing no iron, the planks being fixed together by wooden nails. In another place an anchor was dug up, as also in one spot, some iron nails. The remains of a square wooden house were also discovered at the bottom of an excavation made for the canal, nearly at a level with the sea, but at a depth of sixty-four feet from the surface of the ground. An irregular ring of stones was found on the floor of this hut, having the appearance of a rude fire-place, and within it was a heap of charcoal and charred wood. On the outside of the ring was a heap of unburnt fir wood broken up for fuel; the dried needles of the fir and the bark of the branches being still preserved. The whole building was enveloped in fine sand.

The author next notices several circumstances regarding buildings in Stockholm and its suburbs, from which he infers that the elevation of the land, during the last three or four centuries, has not exceeded certain narrow limits. At Upsala he met with the usual indications of a former elevation of the sea, from the presence of shells, which are now common on the shores of the Baltic. Certain plants, as the *Glauca maritima* and the *Triglochin maritimum*, which naturally inhabit salt marshes bordering the sea, flourish in a meadow to the south of Upsala; a fact that corroborates the supposition that the whole of Lake Maelar and the adjoining low lands have, at no very remote period of history, been covered with salt water.

The author examined minutely certain marks which had at different times been cut artificially in perpendicular rocks washed by the sea in various places, particularly near Oregrund, Gelle, Lüggrund, and Edskösund; all of which concur in showing that the level of the sea, when compared with the land, has very sensibly sunk. A similar conclusion was deduced from the observations made by the author on the opposite or western side of Sweden, between Uddevalale and Gettenburg, and especially from the indications presented by the islands of Orust, Gulholmen, and Marstrand.

Throughout the paper, a circumstantial account is given of the geological structure and physical features of those parts of the country which the author visited; and the general result of the comparison he draws of both the eastern and western coasts and their islands with the interior, is highly favorable to the hypothesis of a general rise of the land, every tract having in its turn been first a shoal in the sea, and then, for a time, a portion of the shore. This opinion is strongly corroborated by the testimony of the inhabitants (pilots and fishermen more especially), of the increased extension of the land, and the apparent sinking of the sea. The rate of elevation, however, appears to be very different in different places; no trace of such a change is found in the south of Scania. In those places where its amount was ascertained with greatest accuracy, it appears to be about three feet in a century. The phenomenon in question having excited increasing interest among the philosophers of Sweden, and especially in the mind of Professor Brezelius, it is to be hoped that the means of accurate determination will be greatly multiplied.

FOSSIL SHELLS ON THE SNOWY MOUNTAINS OF THIBET.—M. Gerard, while making a tour over the snowy mountains of Thibet, picked up some fossil shells on the crest of a pass, elevated 17,000 feet; and here also were fragments of rocks, bearing the impression of shells, which must have been detached from the contiguous peaks rising far above the elevated level. Generally, however, the rocks formed of these shells are at an altitude of 16,000 feet; and one cliff was a mile in perpendicular height above the nearest level. M. Gerard further states, "Just before crossing the boundary of Ludak into Bussalier, I was exceedingly gratified by the discovery of a bed of fossil oysters, clinging to the rock as if they had been alive." In whatever point of view we consider the subject, it is sublime to think of millions of organic remains lying at such an extraordinary altitude, and of vast cliffs of rocks formed out of them, frowning over the illimitable and desolate waters, where the ocean once rolled.

THE MOVING BOG OF RANDALSTOWN.—We have already alluded to this rather rare phenomenon, which has been lately witnessed on part of Lord O'Neil's estate in the neighbourhood of Randalstown, on the Ballymena road, and about two miles and a half from the former town. On the 17th September 1835, in the evening, the first movement occurred. A person who was near the ground was surprised to hear a rumbling noise as if under the earth; and immediately after, his surprise was not a little increased, on perceiving a part of the bog move rapidly forward, a distance of a few perches. It then halted, and exhibited a broken rugged appearance, with a soft peaty substance boiling up through the chinks. It remained in this state till the 22d, when it suddenly moved forward, at as quick a rate, covering corn-fields, potatoe-fields, turf-stacks, hay-ricks, &c.; not a vestige remained to be seen. So sudden and rapid was this movement, that the adjacent mail-coach-road was covered in a few minutes, or rather moments, to a depth of nearly twenty feet. It then

directed its course towards the river Maine, which lay below it; and so great was its force, and such the quantity of matter carried along, that the moving mass was forced a considerable way across the river. In consequence of heavy rains at the time, the river found its channel through the matter deposited in its bed, otherwise the water would have been forced back, and immense damage done to the land on the banks. The fish in the river were killed to a great distance. The damage done by the mossy inundation was very considerable. About 150 acres of excellent arable land have been covered and rendered totally useless. Down the middle of this projected matter a channel has been formed through which there is a continual flow of dark peaty substance, over ground which, but a fortnight before, the reapers were at work. A house close by the ground is so far overwhelmed, that only part of the roof is to be seen.

## METEOROLOGY.

REMARKABLE PARHELIA.—Lieutenant R. E. Clary, while at Fort Howard, Green Bay, Michigan Ter. in the United States, observed a very singular and interesting phenomenon, on the morning of the 27th of February 1835. It consisted of a large and brilliant halo around the sun, with two parhelia within the circumference, at the extremities of its horizontal diameter, but little inferior in brilliancy to the true sun; they were accompanied by luminous trains or tails opposite to the sun. Immediately above and beneath the sun, in the circumference of the same circle, there were bright luminous spots of an elliptical form, less intense in brilliancy than the first, but of much greater magnitude. From the superior or more elevated spot, rays, faintly coloured, and slightly curved downwards, appeared to emanate, forming a small portion of an arc of a circle, of less curvature than the halo. Another circle, the plane of which was horizontal, at right angles to, and of greater diameter than the first, with its centre apparently in the zenith, completely surrounded the heavens; its circumference passed through the sun and two mock suns, the latter being distinctly reflected in the opposite part of the heavens.

About 15° from the zenith, in the direction of the sun, there appeared two faintly luminous arcs of circles, nearly tangent to, and convex towards, each other; they were but a few degrees in extent.

Two well defined and tolerably brilliant rainbows, situated upon the right and left of the parhelia, with their convexity towards it, completed this rare and interesting appearance.

This phenomenon was first observed a little before 8 o'clock, the lower part of the halo being then about 2° above the horizon, its diameter descending as the altitude of the sun increased; arrived at its greatest degree of brilliancy and splendour 15 minutes before 10, when it began to decrease, and finally disappeared about 15 minutes before 11 o'clock, the duration of the phenomenon being about three hours.

The morning was extremely cold, the mercury standing at 16° below zero, and the atmosphere was uncommonly clear and serene. In the afternoon it became cloudy, and indicated snow.

The same phenomenon, with some modifications in its appearance, was observed at Fort Winnebago, 113 miles south-west from Fort Howard, which is in latitude 44° 30'.

In the above diagram, the position and appearance of the halo is represented; as also the horizontal circle, rainbow and parhelia, with their reflections, as they appeared 15 minutes before 10 o'clock;—greater number of reflections, perhaps, than were ever witnessed at one time before, all depending upon the same peculiar state of the atmosphere for their existence.

SHOWER OF FALLING STARS IN RUSSIA.—M. le Comte de Suchtelen communicated the following interesting fact to M. Feodorov, which he laid before the "Royal Academy of Sciences" at Paris. "On the 13th November 1832, between three and four o'clock in the morning, the weather calm and the sky serene, the thermometer indicating 55 degrees of Fahrenheit, the heavens appeared to be bespangled by a great number of meteors, which described an arch in the direction of from north-east to south-west. They burst like rockets into innumerable small stars, without producing any perceptible noise, and leaving in the sky a long continued, luminous belt, exhibiting all the varied colours of the rainbow. The light of the moon, however, then in her last quarter, considerably obscured this appearance. At times the heavens appeared as if cleft asunder, and, in the intervening space, there appeared long brilliant whitish bands. At other times flashes of lightning rapidly traversed the arch of heaven, eclipsing the light of the stars, and causing these long and luminous bands

of colour to appear. These phenomena continued in succession, without any noise. They were in their greatest splendour between five and six o'clock in the morning. During the same night, and nearly at the same hour, an appearance equally remarkable was witnessed at Hitzkaja-Saschtschita, about seventy-five miles to the south of Orenburg. Two white columns rose from the horizon equidistant from the moon, which at the time had not risen far; about the middle of their height they appeared very brilliant, and considerably curved. Several horizontal bands sprung from this point, the most brilliant of which extended towards the moon, in which they seemed to unite, so that in this way they appeared to form a great H. In the town of Ufa, the seat of the government of the same name, situate 360 miles to the north of Orenburg, a phenomenon similar to that which was observed at Hitzkaja-Saschtschita was noticed, which, however, according to the accounts which have been given, was less brilliant in its appearance."

**REMARKABLE SHOWER OF HAIL.**—After a violent storm at Clermont, MM. Bouillet and Lecoq found a number of hailstones as large as hens' eggs, and some others as large as those of turkeys. They were all of an ellipsoidal form, and seemed formed of a multitude of needles, united at the extremities of the great axis. They were from eight lines to two inches long. Those needles, on which the fusion had not made much impression, still showed traces of hexagonal prisms, terminated by prisms of six facets. In a second storm, others fell which were not larger than hazel nuts, and these were formed of concentric layers, more or less transparent, rounded, or slightly oval, and possessed a powerful horizontal motion; they were heard to hiss in the air, as if each hailstone rubbed against the other, and their rotation was extremely rapid.

Between the hours of one and two o'clock, on Saturday the 30th April 1836, a heavy shower of hail fell at Edinburgh. Professor Jameson and several members of the Wernerian Society examined the hailstones, and ascertained that they were crystallized in the form of double six-sided pyramids, and at the same time of larger size than usual.

**ON THE FORMATION OF AEROLITES, &c.**—M. J. L. Ideler has discussed, with great learning, the formation of Fire-balls, and of the Aurora Borealis; and the facts brought forward lead to the following conclusions:—

1. The fall of Aerolites generally takes place in summer, and at the period of the equinoxes; that is, in the season of the most abundant rains.

2. The frequency of this phenomenon diminishes from the equator to the poles, whilst in general the annual quantity of rain diminishes with the mean temperature of localities, allowance being made for the considerable influence of the direction of the winds.

3. The formation of Aerolites in a cloud, having their colour, is analogous to that of rain; as it rains with a clear sky, so in the same manner Aerolites descend unattended with the appearance of clouds.

4. The luminous appearance and the noise resembling thunder, are produced by electricity, which appears in all atmospheric phenomena. The different colours of fire-balls, during their descent, are the effect of the disengagement of different kinds of electricity. It is very likely that Aerolites may fall without being preceded by fire-balls, as it rains very powerfully, without lightning, when the temperature of the aeriform column is below the point of thawing.

5. Aerolites sometimes fall without noise, because the electric explosion has taken place in very elevated regions; there are analogous cases of lightning at the zenith without thunder.

The author, therefore, regards the formation of Aerolites in the atmosphere as the most plausible theory, and recurs to the same idea expressed by Aristotle and Seneca two thousand years ago.

Not satisfied with these observations, M. Ideler adds others in support of his theory. Thus, he quotes certain hail storms, in which the hailstones possessed a metallic nucleus resembling aerolites, is preceded by more or less glimmerings (*leceurs*) of light, and that the phenomena in question are connected with atmospheric changes, and these again with revolutions which take place within the interior of the earth. The simultaneous fall of meteoric stones in different countries is also in favor of their atmospheric origin, and it often takes place during storms.

M. F. G. Fisher has published in the Memoirs of the Academy of Berlin a Memoir upon the Origin of Aerolites, in which he adopts the foregoing ideas, and supposes that electricity performs an important part in the phenomenon.

Concerning Shooting Stars, M. Ideler endeavours to prove by facts, that they are merely precipitations of animal and vegetable matters disseminated through the atmosphere.

Finally, with respect to the Aurora Borealis, he supposes that the precipitation formed by the dry vapours in the elevated portions of the atmosphere take place in the regions of the magnetic poles, under the form of the Aurora Borealis, from the reason that the ferruginous particles arrange themselves about the pole, in an order similar to that of iron filings around a magnetic ear. Future observations upon terrestrial magnetism will aid in explaining the anomalies of this phenomenon.

The vaporization of all solid and fluid bodies goes on under every degree of temperature. When the maximum of density in the vapours is passed, a precipitate occurs, and clouds, cirri, or mists, are formed, which rest upon the earth, or a concretionary formation takes place. The latter case happens partly from the condensation of clouds, sometimes under a clear sky, sometimes without electric explosion (aerolites), or with the phenomena of electricity (fire-balls); finally, the fall of those bodies takes place in small particles, or agglomerated into masses of a larger size, and analogous to hail.

If such are the phenomena beyond the Polar regions, near the magnetic poles, the precipitates, being attracted, would continually be undergoing an arrangement in a circular series, and thus produce the Aurora Borealis. This kind of precipitation might take place contemporaneously with aqueous precipitation, in which case there would occur rains attended by foreign mixtures.

Professor Gruithuisen has lately been occupied with the origin of Aerolites and Shooting Stars; and supposes he has proved, by mathematical calculations, founded upon physics, that these bodies must necessarily be formed beyond our atmosphere, in the interplanetary space, where the metals and the metaloides, he says, are still held

in solution, by means of hydrogen, and where they exist continually for the formation of these opaque bodies.

According to Herschell, the observations of the shooting stars may be useful for the determination of longitude. The height of the meteors seen by M. Quetelet is estimated at from ten to eighteen leagues from the earth, and their motions at from five to eight leagues per second; results which correspond with those of Brandes and other German philosophers.

## MISCELLANEOUS.

**ACETIC ACID.**—A most important improvement has recently been introduced into the manufacture of vinegar, which is already extensively practised on the Continent. The introduction of this improvement is chiefly due, we believe, to Mitscherlich. It is founded upon the principle that alcohol, by absorbing oxygen, is changed into acetic acid and water. For, two alcohol + four oxygen = one acetic acid + three water ( $6\text{H} + 4\text{C} + 2\text{O}$ ) + 4 O = 3 H + 4 C + 3 O + 3 (H + O.)

This oxidation is promoted by the process of fermentation—and, when the fermentation has begun, is much accelerated by the pressure of acetic acid. The oxidation is effected entirely at the expense of the oxygen of the air; to accelerate the process, therefore, by producing as many points of contact as possible between the liquid and the air, the following arrangement is adopted:—A large cask is taken, placed upright, with a stop-cock at the bottom, and a series of holes, half an inch in diameter, bored one in each stave, a few inches above it. It is then nearly filled with chips or shavings of wood, previously steeped in strong vinegar till they are perfectly saturated. Within the upper end of the cask a shallow cylindrical vessel is placed, nearly in contact with the shavings, the bottom of which is perforated with many small holes, each partially stopped with a slender twig, which passes an inch or two beneath the perforated bottom of the cylinder. The alcohol, diluted with eight or nine parts of water, and mixed with the fermenting substances, is now poured into the cylinder, through the bottom of which it trickles, drop by drop, upon the shavings below, becomes oxidized in its passage, and runs out at the stop-cock beneath, *already converted almost entirely into vinegar*. The air rushes in by the holes beneath, and passes out by eight glass tubes, cemented for that purpose, into the bottom of the cylinder—and so rapidly is it deprived of its oxygen, when it escapes above, that it extinguishes a candle. During the process much heat is also developed; so that, from the temperature of 60° (that of the room), the interior cask rises as high as 86° of Fahr. In the proper regulation of this temperature much of the difficulty consists.

A second transmission of the acid, thus obtained, through another smaller cask, finishes the process. The whole is concluded in a few hours; four-and-twenty are considered amply sufficient to convert a given quantity of alcohol into vinegar.

**ORIGIN OF AMBER.**—M. T. Aessi says that amber is a resin of the Coniferae. He has examined particularly that of Castrogiovanni in Sicily, and he cites, though not with perfect confidence, a specimen of amber containing a land shell. M. Graffenauer has given to the Strasbourg Society of Sciences a monograph on amber, which he supposes to have originated in extinct species of trees.

**PURIFICATION OF WATER.**—In order to precipitate the earths mechanically suspended in water, it is recommended to employ the silicate of potash, gelatinous silica, or phosphoric acid. The last is an excellent reagent for throwing down the oxide of iron, without introducing any foreign principle into the water.

**TEMPERATURE OF AEROLITES.**—Most philosophers are of opinion that aerolites and meteoric iron are elevated to a high temperature while traversing the atmosphere; nevertheless, there is but little agreement concerning the degree of heat observed in them immediately after their fall. Recently, an experiment of M. Bierley, repeated by M. d'Arcet, has rendered this high temperature doubtful; a bar of iron, heated to whiteness, was held in the current of air from the blowing-machine of a forge—the metal did not cool, but burnt brilliantly, throwing off glowing particles in every direction. The temperature of the iron rather increased than diminished under the influence of the current of air.

**AFRICAN DIAMONDS.**—The Sardinian Consul at Algiers, M. Pelusa, lately purchased from a native three diamonds, which were found in the auriferous sand of the river Gumel, in the province of Constantine.

## OBITUARY.

**JOHN POND, Esq.**—This celebrated Astronomer died at his house in Greenwich, on Wednesday the 21st September 1836. He was a Fellow of the Royal Society, a Corresponding Member of the French Institute, and an Honorary Member of most of the Astronomical Societies in Europe. During the period of nearly twenty-five years, Mr Pond filled the high and important office of Astronomer Royal, from which a hopeless state of ill-health obliged him last autumn to retire; but his regret at quitting a situation, in the duties of which he had taken so great an interest, was lessened on finding himself succeeded by one of the greatest Mathematicians of the age, Professor Airy—a Philosopher eminently qualified to maintain the character and uphold the dignity of the appointment; to carry forward the improvements introduced by his predecessor, and to extend the boundaries of Astronomical Science.

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE—THE PTARMIGAN.

MODERN Naturalists have separated the Ptarmigan from the Grouse, under the new generic title of *LAGOPUS*, or Hairy-legged Grouse. They are wild birds, frequenting and incubating on high and precipitous mountain ranges, particularly in northern latitudes. They are susceptible of considerable variations in their summer and winter plumage, in the latter season being, with the exception of the tail feathers, quite white. They have a wide Geographical range, inhabiting all the islands which lie on the south of Baffin's Bay, and are pretty common on some of the loftiest mountains in the north of Scotland.

Figs. 1, 2, & 3. THE WILLOW PTARMIGAN (*Lagopus Saliceti*).—This is one of the most beautiful species which bear the designation of Game Birds. Its summer plumage is of rich and beautiful dark and pale chestnut, and its winter attire white, with a slight rosy hue. It inhabits the fur countries from the 50th to the 70th degrees of latitude, breeding in the valleys of the Rocky Mountains, and on the Arctic coasts, assembling in vast flocks on the shores of Hudson's Bay during winter. So numerous are these Birds, that Mr Hutchins mentions he has known *ten thousand* to be captured in a season. It is not yet ascertained whether this is identical with the Willow Grouse of Europe, and which is common to Greenland, Iceland, and Scandinavia.

Figs. 4 & 5. THE PTARMIGAN (*L. mutus*), in summer and winter plumage.—These were taken from specimens killed during the Arctic Expedition, under Captain Parry, and seem to differ from the European species, principally in their more diminutive size. The Ptarmigan always keeps near the snow line. It is considered an excellent food, many preferring it to Grouse.

#### DESCRIPTION OF THE PLATE—THE CHATS.

THIS genus belongs to the group of birds termed *Ampelide* by Swainson, and are distinguished by the shortness of the bill and excessive width of the mouth, which gives them the capacity of swallowing large berries, and even moderate-sized fruits. They alight very seldom on the ground, but may be seen constantly moving about among bushes and trees with great rapidity, to which the formation of their feet peculiarly adapts them. Their toes are rather short, more or less united at the base, and the soles broad. They are totally devoid of the nuchal bristles, which protect the mouth of insectivorous birds. This family is almost exclusively confined to America.

Fig. 1. THE YELLOW-THROATED CHAT (*Vireo flavifrons*).—This species is chiefly found in the woods during summer, and utters a slow and plaintive note with but little variation, which it repeats every ten or twelve seconds, and sounds like *preé, preé*, &c. It arrives in the Middle States from the south early in May, and returns with its young in the beginning of September.

Figs. 2 & 3. THE SOLITARY CHAT (*V. solitaria*), Male and Female.—This is a silent and solitary bird, found in Georgia and Philadelphia, and inhabits Louisiana during the spring and summer months, frequenting thick cane-brakes of the alluvial lands contiguous to the Mississippi. It hangs to branches of small berries, feeding upon them as a Titmouse does on buds of trees. The flight of this bird is rather peculiar, consisting of a continued tremor of the wings, as exhibited by birds when they are angry. It is about five inches and a half in length.

Fig. 4. THE PINE-SWAMP CHAT (*V. sphagnosa*).—The favourite haunts of this bird are the deepest and gloomiest pine and hemlock swamps in mountainous regions of the central states of North America. Its place of incubation is still unknown. Its habits are much akin to those of flycatchers, as it seeks after and feeds upon insects with great keenness. It has not been yet ascertained whether it is a bird of song.

Fig. 5. THE YELLOW-BREADED CHAT (*V. polyglotta*), frequents close thickets of hazel, brambles, and vines, and dense underwood; and when approached utters a scolding note, and seems offended at the intruder. The principal food of this Chat consists of large black beetles and other coleopterous insects. It arrives in Pennsylvania about the first week in May, where it incubates, and returns to the south about the middle of August, the males generally preceding the females by several days. It seems a bird of a wide geographical range, as it has been found in Mexico, Guiana, and Brazil.

Fig. 6. THE RED-EYED CHAT (*V. olivacea*).—This species, like most of its tribe, is a bird of passage, spending its summers in Pennsylvania and the neighbouring

States, and wintering in Jamaica. It builds a hanging nest between two twigs of a young dogwood or other small sapling, seldom more than four or five feet from the ground. Its notes are rapid and lively, consisting of three or four syllables.

Fig. 7. THE WHITE-EYED CHAT (*V. noveboracensis*), visits Pennsylvania and Georgia about the end of February, and is supposed to winter in Mexico. Its nest is frequently the shape of an inverted cone, suspended by the upper edge of the two sides on the circular bend of a prickly vine. It generally produces two broods in a season. It is five inches and a quarter long, and seven in extent of wing.

Fig. 8. THE WABLING CHAT (*V. melodia*), arrives in Pennsylvania about the middle of April, and frequents the thick foliage of orchards and high trees. Its voice is very soft and melodious. Its food consists principally of insects and caterpillars, and in its general manners is not unlike the Warblers. It is five inches long, and eight and a half in extent of wing.

ON THE HABITS OF LEECHES, AND TENDENCY OF THE REPTILES OF VALDIVIA AND CHILI TO BECOME VIVIPAROUS.—M. Gay, in a letter to M. de Blainville, dated 5th July 1835, says, "It is a remarkable circumstance, that here all the Leeches exist in the woods, and never in the water; and, indeed, I cannot botanize without having my legs severely punctured by them. They crawl on plants, trunks of trees, and shrubs, never approaching marshes or rivers; and the only one which I have been fortunate enough to discover in such localities is a very small species of 'Branchibelle,' which inhabits the pulmonary cavity of *Avicula Dombeii*; it was while dissecting this molluscous animal that I detected it. I have discovered another species in the neighbourhood of Santiago, which lives on the gills of the *Astacus*. An equally interesting fact, and which deserves your attention, is the tendency exhibited by reptiles to become viviparous in these southern regions. Almost all those which I have dissected presented this remarkable circumstance. Not only does the harmless adder of Valdivia give birth to a living progeny, but likewise all the beautiful Iguanas allied to the genus *Leposoma* of M. Spix, and which, on account of their beautiful colours, I have in the meantime termed *Chrysolaurus*. All the species which I have examined, including those which at Santiago deposit eggs, have without exception presented this phenomenon, and I may hence be allowed to generalize. The Batracians have also furnished me some examples of this description, although in general they are oviparous. Nevertheless, a genus resembling the *Rhinella* of Fitzinger, and of which several species, rather prettily marked, form part of my collection, is constantly viviparous, and therefore increases the proofs of a fact, which is rendered more remarkable by the circumstance that all the examples occur within a radius of two or three leagues only."

The habitat of Leeches, mentioned by M. Gay, is not, however, peculiar to South America, as he seems to imagine; for we find, by an account given in Percival's Ceylon, that they frequent similar localities. "One species of Leech, however," says he, "has left too deep an impression on my mind to be passed over unnoticed. It infests in immense numbers the woods and swampy grounds of Ceylon, particularly in the rainy season, to the great annoyance of every one who passes through them. The Leeches of this species are very small, not much larger than a pin, and are of a dark-red speckled colour. In their motions they do not crawl like a worm, or like Leeches we are accustomed to see in Europe, but keep constantly springing, by first fixing their head on a place, and bringing their tail up to it with a sudden jerk, while at the same time their head is thrown forwards for another hold. In this manner they move so exceeding quickly, that before they are perceived, they contrive to get upon one's clothes, when they immediately endeavour by some aperture to find an entrance to the skin. As soon as they reach it, they begin to draw blood; and as they can effect this even through the light clothing worn in this climate, it is almost impossible to pass through the woods and swamps in rainy weather without being covered with blood. On our way to Candy, in marching through the narrow paths among the woods, we were terribly annoyed by these Leeches; for whenever any of us sat down, or even halted for a moment, we were sure to be immediately attacked by multitudes of them; and before we could get rid of them, our gloves and boots were filled with blood. This was attended with no small danger, for if a soldier were from drunkenness or fatigue to fall asleep on the ground, he must have perished by bleeding to death. On rising in the morning, I have often found my bed-clothes and skin covered with blood in an alarming manner. The Dutch, in their marches into the interior, at different times, lost several of their men; and in our setting out, they told us we should hardly be able to make our way from them."

## MINERALOGY.

ON THE CHANGES WHICH THE STOMACH OF CRABS UNDERGO DURING THE PERIOD OF CASTING THEIR SHELLS.—Crabs, it is well known, change their shells at a certain season of the year; and it is a very old opinion that they change their stomachs at the same time, a new stomach being formed around the old, which is digested by the recently developed organ. Baer has proved that the Crab's stomach consists of two coats; one inner, which in every respect may be compared to a callos, horny epidermis, and which is destitute of vitality; and an outer or containing coat, transparent, but sufficiently strong and vascular. The inner coat, as it is well known, consists of various and very curious parts, some resembling bony plates, others compared to teeth. Now, at the period when the Crab changes its skin, it likewise casts the inner coat of the stomach, and on this account this process, analogous to the moulting of birds, and to the renewing of the hair in quadrupeds, is in the Crab attended with very great constitutional disturbance, and a total interruption of the digestive function. Baer relates very accurately the changes which the stomach undergoes preparatory to the casting of its inner coat. It would be beside our present purpose to follow him in this description, however interesting. Some things he mentions are, however, specially worthy of remark. In the first place, the softer parts of the old epidermis, or inner coat of the stomach, are very rapidly digested in the stomach, as soon as it has recovered its functions, and has— which it does quickly—formed a new lining on its inner surface. But there are other harder parts that cannot be readily digested and dissolved, and which are otherwise disposed of. The hard and hollow bones, popularly termed the teeth, are got rid of by being discharged through the external orifice corresponding to the mouth. There are other solid plates of the epidermic portion of the stomach, which are not of a shape calculated to irritate the new and tender epidermis, and consequently they can be retained with impunity, and are destined to perform a new and curious function; for, according to Baer, these plates, for some time preparatory to the act of casting the shells, rapidly increase in weight and in solidity, so as, at the period we are speaking, they may be considered as forming considerable reservoirs of earthy matter, to be gradually dissolved and digested in the newly lined stomach, at the very time earthy matter is required by the animal for the formation of its new shell. These plates are popularly called *Crab-stones*, and when submitted to the digestive process soon lose their roughness, and become smooth and polished before they are entirely dissolved. These Crab-stones are chiefly composed of carbonate of lime; and Baer has proved, by repeated analysis, that the fluid contents of a Crab's stomach contain (at the time these stones are in them) a considerable portion of lime, carbonic acid, and muriatic acid. It is interesting to observe, that the chemical investigations of Dulk render it highly probable, that the chief solvent in the Crab's stomach is the same acid which performs so important a part in human digestion and in dyspepsia, viz. free muriatic acid.—*Dublin Med. Jour.*

MOLLUSCOUS ANIMALS.—Animals of the Genera *Pneumoderma* and *Hyalea*, were only found in the great Ocean, to which they were hitherto supposed exclusively to belong; these have, however, been lately detected in the Mediterranean Sea by Dr Vanbenaden.

## BOTANY AND HORTICULTURE.

CAUSE OF THE FRAGRANCE ON APPROACHING TROPICAL LANDS FROM SEA.—When vessels begin to near the coasts between the tropics, a delightful fragrance is felt, of which even animals are so sensible, that they become restless, and, appearing to have an instinctive presentiment of the end of their long confinement, not unfrequently leap overboard to reach the shore, which they suppose to be close at hand. "Whoever," says Pæppig, "has made a voyage to the tropical countries of South America or the West Indies, will always remember with pleasure the sensation which he experienced on approaching the land. Perhaps no sense is then so strongly affected as that of smell, especially if the coast is approached in the early hours of a fine summer's morning. On the coast of Cuba, the first land I saw in America, on the 30th of June 1822, all on board were struck with the very strong smell like that of violets, which, as the day grew more warm, either ceased, or was lost amidst a variety of others, which were perceptible as we drew nearer the coast. During a long stay in the interior of this island, I became acquainted with the plant which emits such an intense perfume as to be perceived at the distance of two or three miles. It is of the species *Tetracera*, and remarkable for bearing leaves so hard, that they are used by the native cabinet-makers and other mechanics for various kinds of work. It is a climbing plant, which reaches the tops of the loftiest trees of the forest, then spreads far around, and in the rainy seasons is covered with innumerable bunches of sweet-smelling flowers, which, however, dispense their perfume during the night only, and are almost without scent in the day time."

ON THE DURATION OF THE GERMINATIVE POWER IN THE SEEDS OF PLANTS.—We gave an account of some experiments of this curious subject at page 35 of this Journal, and have now to record a still more extraordinary example of this power. In October 1834, a British tumulus was opened near Malden Castle, by Mr Maclean, who found therein a human skeleton, and a portion of the contents of the stomach, containing a mass of small seeds, which neither the operation of the gastric juice, nor the lapse of probably twenty centuries, had sufficed to destroy. Many of these seeds have been subjected to various careful experiments, to ascertain whether the vital principle was extinct; and we have the satisfaction of announcing, that Professor Lindley has succeeded in producing plants from several of these seeds. These plants have confirmed the opinion expressed by Professor Lindley, on a first inspection of the seeds, that they were those of the *Rubus Idaeus*, or common Raspberry. The plants are now very vigorous, have produced much fine fruit this season, and form an object of the greatest curiosity to horticulturists. This highly interesting circumstance proves the Raspberry to be an indigenous plant in this country, growing at a very early period, and then constituting an article of food.

ON A MASS OF GREEN MALACHITE OF EXTRAORDINARY SIZE.—A few months ago, there was met with in the mines at Nischne-Tagilsk, in Russia, a mass of Green Malachite measuring 16.2 French feet in length, 7.5 feet in breadth, and 8.6 feet in height, and weighing about 1300 Russian pounds.

TOPAZ.—In the vicinity of Villa Rica in Brazil, the Topaz Mines are situated in chlorite-slate, which rests on a sandstone of the primitive class. The Topaz occurs in regular crystals, or in angular masses, or rests on the mineral called Lithomarge, along with rock crystal.

VITREOUS QUARTZOSE TUBES.—In various parts of Europe, there have been found long quartzose tubes of a vitreous appearance, and of an inch and a half in diameter, but in length from twenty to thirty feet, and their interior is sluggy and vitreous-like. Several tubes of this description were found at Senner-Heath in Germany, and more recently E. L. Irton, Esq. of Irtonhall, Cumberland, has found on his estate in that county a number of these tubes, agreeing in every particular with those found in Germany. That gentleman presented to the Museum of the Edinburgh University a beautiful series of those found by him. The vitreous tubes of Senner-Heath were found in loose sand. The mottled appearance of the interior of these tubes, together with their form, and the situation in which they were found, favors the inference that they have been produced by lightning.

## GEOLOGY AND PHYSICAL GEOGRAPHY.

## CHRONOLOGICAL TABLE OF THE MOST IMPORTANT KNOWN ENCROACHMENTS MADE BY THE SEA SINCE THE EIGHTH CENTURY.

BY M. ADRIEN BALBI.

A.D. 800. About this period, the sea carried off a great part of the soil of the island of Heligoland, situate between the mouths of the Weser and the Elbe.

800—900. During the course of this century, many tempests made a considerable change in the coast of Brittany; valleys and villages were swallowed up.

800—950. Violent storms agitated the lakes of Venice, and destroyed the isles of Ammiano and Constanziaco, mentioned in the ancient chronicles.

1044—1309. Terrible irruptions of the Baltic Sea on the coasts of Pomerania, made great ravages, and gave rise to the popular tales of the submersion of the pretended town of Vineta, whose existence is chimerical, notwithstanding the imposing authority of Kant and other learned men.

1106. Old Malamocco, then a very considerable city on the lakes of Venice, was swallowed up by the sea.

1218. A great inundation formed the gulf of Jahde, so named from the little river which watered the fertile country destroyed by this catastrophe.

1219, 1220, 1221, 1246, and 1251. Terrible hurricanes separated from the continent the present isle of Wieringen, and prepared the rupture of the isthmus which united Northern Holland to the county of Staveren, in modern Friesland.

1277, 1278, 1280, 1287. Inundations overwhelmed the fertile canton of Reiderland, destroyed the city of Torum, 50 towns, villages, and monasteries, and formed the Dollart; the Tiam and the Eche, which watered this little country, disappeared.

1282. Violent storms burst the isthmus which joined Northern Holland to Friesland, and formed the Zuyderzee.

1240. An irruption of the sea changed considerably the west coast of Schleswig; many fertile districts were engulfed, and the arm of the sea which separates the isle of Nordstrand from the continent was much enlarged.

1300, 1500, 1649. Violent storms raised three-fourths of the island of Heligoland.

1300. In this year, according to Fortis, the town of Ciparum in Istria was destroyed by the sea.

1303. According to Kant, the sea raised a great part of the island of Rugen, and swallowed up many villages on the coasts of Pomerania.

1337. An inundation carried away 14 villages in the island of Kadzand in Zealand.

1421. An inundation covered the Bergseweld, destroyed 22 villages, and formed the Biesbosch, which extends from Gertruydenberg to the island of Dordrecht.

1475. The sea carried away a considerable tract of land situated at the mouth of the Humber; many villages were destroyed.

1510. The Baltic Sea forced the opening at Frisch-Haff near Pillau, about 3600 yards broad, and 12 to 15 fathoms deep.

1530—1532. The sea engulfed the town of Kortgene in the island of North Beveland in Zealand. In the latter year, it also raised the E. part of the isle of S. Beveland, with many villages, and the towns of Borselen and Remerswalde.

1570. A violent tempest carried off half of the village of Scheveningen, N.E. of the Hague.

1625. The sea detached a part of the peninsula of Dars in Pomerania, and formed the isle of Zingst, N. of Barth.

1634. An irruption of the sea submerged the whole island of Nordstrand; 1338 houses, churches, and towns were destroyed, 6408 persons and 50,000 head of cattle perished. There only remained of this island, previously so fertile and flourishing, three small islets, named Pelworm, Nordstrand, and Lütje-Moor.

1703—1746. In this period, the sea raised the island of Kadzand more than 100 fathoms from its dikes.

1726. A violent tempest changed the *saline* of Araya, in the province of Cumana, part of Colombia, into a gulf of many leagues in width.

1770—1785. Storms and currents hollowed out a canal between the high and low parts of the island of Heligoland, and transformed this island, so extensive before the eighth century, into two little isles.

1784. A violent tempest formed, according to M. Hoff, the lake of Aboukir in Lower Egypt.

1791—1793. New eruptions of the sea destroyed the dikes and carried away other parts of the island of Nordstrand, already so much reduced.

1803. The sea carried away the ruins of the Priory of Crail in Scotland.

ON THE CONJECTURED BUOYANCY OF BOULDERS AT GREAT DEPTHS IN THE OCEAN.—Travelled Boulder Stones are to be met with in all countries, and in situations where it is extremely difficult to account for their appearance. In addition to the observations which have already appeared in this Journal (see pages 51 and 55), we may remark that Lieutenant W. W. Baddeley, of the Royal Engineers, has communicated to Professor Silliman a curious paper on this interesting subject. He says, "Among the many phenomena which serve to interest and perplex geological students, none are more striking than the formation and position of Boulders, and it is highly probable that no cause, in the first instance, tends more to draw votaries into the labyrinths of this delightful science, than the silent eloquence of these mysterious masses. We who reside on this new and interesting continent (America), are particularly liable to have our conjectures kept alive respecting them, and it appears to me impossible to pass one of these travelled rocks, without feeling the momentary wish that it possessed the power of speech, and the inclination to gratify our curiosity concerning them.

"I wish to call your attention to the applicability of a fact, which, as far as I am aware, has not been pointed out before in any publication, although I doubt not it has occurred to many persons.

"As long as it was maintained that water was incompressible, an opinion originating in the well known Florentine experiment, an augmentation in the specific gravity of sea water, as the result of pressure, could not be rendered applicable to the inquiry. But the effect of experiments in recent times has been to overthrow the Florentine doctrine in this respect, and to render it probable that the density of water, owing to pressure, increases in a ratio proportionate to its depth.

"Now, if this be true, what is the amount of this ratio? Is it sufficient to give to the waters of the ocean, in their greatest depths, a density equal or superior to that of rock? For if this be conceivable, so is it that Pelagian Boulders are now floating about at great depths in all latitudes; and if now, then formerly, an admission which would much lessen the difficulty of accounting for their presence in all climes, and in almost all postures? Thus masses of rock, when once detached from, or reaching the depths of the ocean, might float to the antipodes of the spot where they first commenced their journey, and indeed continue to float until driven by upward currents, or other operative causes, upon the sides and summits of submarine hills and mountains, where they might become deposited, in consequence of their superior relative density compared with that of the water, and they are now in, after having undergone the rounding which they would be likely to meet with in the interim from erosion and attrition.

"This conjecture (for it is nothing more) will not be considered absurd, I think, when it is recollected that the compressibility of sea water has been proved by Perkins and others, and is now generally admitted; and that the depth of the ocean, although unknown, must be considerable, some writers making it between two and three miles, while one of them (La Place) considers it to be as high as twenty-five. Bakewell states it to be 'not exceeding ten miles, and more generally admitted not to be over five.' In short, it appears to me that although much is wanted in the way of experiment to determine this interesting question, what is positively known respecting it favors the conjecture now submitted." Lieut. Baddeley proposes the following question, and recommends those who have an opportunity of experimenting to ascertain the relative temperature, density, and saltness of the ocean at various measured depths.

"Given the specific gravity of a boulder (2.6) at the level of the ocean, what would be its specific gravity in relation to the water it is immediately surrounded by, five miles below the surface, and what its ratio of decrease?"

TRAVELLED STONES.—In our last Number, we gave an account of the Travelled Stone of Castle-Stuart. Captain Bayfield has lately laid before the Geological Society an account of the transporting power of the ice peaks framed every winter in extensive shoals on both sides of the River St Lawrence. These shoals are thickly strewed with massive boulder stones, round which the ice froze on all sides; and in the Spring, when the river rises from the melting of the snow, the masses of ice, with these stones still frozen to them, naturally float down the river, and frequently carry these boulders to great distances from their native beds, and are left in situations very remote from any rocks of the same nature. Captain Bayfield also affirms, that icebergs, in which large masses of stone are imbedded in gravel, are annually drifted down the coast of Labrador, through the Straits of Belleisle, and for several hundred miles up the Gulf of St Lawrence. These facts will, in a great measure, account for boulders which are found in situations far apart from formations of a similar kind.

TEMPERATURE OF THE INTERIOR OF THE EARTH.—On Wednesday the 17th August 1835, M. Arago, in delivering a lecture on the theory of the central heat of the earth, related an operation at this time carrying on in Paris, which may be of the highest importance not only to science but to public economy. The municipality have ordered an Artesian well to be pierced near the Barrière des Martyrs; but the men employed, after getting to a depth of 900 feet without finding water, came to a stratum of chalk, so thick, that the undertaking would have been abandoned but for the interference of men of science, who wished it to be continued, with a view to the elucidation of the above theory. According to observations made by means of a thermometer, no doubt remains as to a fact which hitherto it has not been possible to verify with any degree of precision—namely, that the temperature of the earth rises in regular proportion towards the centre; so that, at the 10th degree from the surface, all known matter must be in a state of fusion. At the point to which the perforation in question will have reached, M. Arago expects a spring of water will arise of a sufficient degree of heat to warm public establishments, supply baths, and serve for other purposes.

## METEOROLOGY.

EQUINOCTIAL RAINS.—Professor Arago remarks, that navigators occasionally mention rains which fall on their vessels while sailing in equinoctial seas, which led him to think that rain is much more abundant at sea than on land. But this subject still rests merely on conjecture, as it is but seldom that exact measurements are made. Measurements of this kind are not, however, difficult. For example, many measurements were made by Captain Tuckey, in his unfortunate expedition to the River Congo. We know that the discovery ship *Bonite* will be furnished with a small udometer. Its commander should have it placed on the stern of the vessel, in such a situation, that the rain collected by the sails and cordage cannot drop into it.

It would add greatly to the interest of those observations, if navigators would determine the temperature of the rain, and the height from which it falls.

To ascertain the temperature of the rain with precision, it is necessary that the mass of the water should be considerable, relatively to the size of the vessel in which it is contained. A metal udometer is unfavorable for this experiment. It would be greatly preferable to have a large pummel of sand, of some tight stuff, for this purpose, very close in its texture; and the water which runs from the under side of it ought to be received by a glass of small dimensions, containing a little thermometer. The only time at which the elevation of the rain clouds can be ascertained is during the storm; then the number of the seconds which elapse between the appearance of the flash and the time at which the sound reaches the observer, multiplied by 337 metres—the degree of rapidity with which the sound is propagated—indicates the lengths of the hypotenuse of a right-angled triangle, whose vertical side is precisely the height required. This height may be calculated if, by the aid of a reflecting instrument, we estimate the angle formed with the horizon, by the line which, taken from the eye of the observer, terminates in that quarter of the cloud where the lightning first showed itself.

If for an instant we suppose, that rain falls on the vessel whose temperature is lower than that which the clouds must possess, judging from their height and the known rapidity of the decrease of atmospheric heat, every person will understand the place which such a fact would occupy in Meteorology.

If, on the other hand, we imagine that, during a day of hail (for hail does fall in the open sea), the same system of observations had proved that the hailstones were formed in a region where the temperature of the atmosphere was higher than the point at which water congeals, and science would thus be enriched with a valuable result, to which every future theory of hail must necessarily be accommodated.

RAIN IN A PERFECTLY CLEAR SKY.—Some natural phenomena are so extraordinary and improbable in their nature, that many who have witnessed these eccentricities of nature forbear mentioning them, lest they should be ranked as mere visionaries. The rains of the equinoctial regions may be classed among such phenomena.

In intertropical climates rains have frequently been observed when the atmosphere was pure and serene, with the sky of the most beautiful azure! The rain-drops on such occasions do not fall thickly, but they are of much larger dimensions than rain-drops in European climates. The fact is certain; we have the assurance of Baron Humboldt, that he observed occurrences of this kind in the interior of countries; and Captain Beechey observed this phenomenon in the open sea. With respect to the circumstances on which such a singular precipitation of water can depend, we are entirely ignorant of them. In Europe, in calm and clear weather, during the day, sometimes, very small crystals of ice have been observed to fall gently from the atmosphere, their size increasing with every particle of humidity they congeal in their passage towards the earth. Does this approximation put us in the way of obtaining the desired explanation? Have not the large rain-drops of tropical climates been, while in the higher regions of the atmosphere, small particles of ice excessively cold—then in their descent become large pieces of ice by agglomeration; and when lower still, been melted into large drops of water? The object of these conjectures is to exhibit in what point of view the phenomenon may be studied, and to stimulate young travellers in particular, to observe carefully if, during these singular rains, the regions of the atmosphere from which they fall present any traces of halo. If such traces are noticed, however slight they may be, the existence of crystals of ice in the higher regions of the air will be demonstrated.

In almost every country meteorologists are to be met with, but their observations, in too many instances, are made at unsuitable hours, and with instruments which are either inaccurate in themselves, or improperly placed. It seems not to be difficult now to deduce the mean temperature of the day from observations made at any hour: thus a meteorological table, whatever may be the hours noted in it, will be of value by the mere condition that the instruments employed will admit of being compared with the student's barometers and thermometers.

Almost any thermometer will answer the ordinary purposes, but the most useful barometer which we have seen is Adie's sympiesometer, which is used to determine the pressure of the atmosphere, the altitude of any situation above another, or above the level of the sea. To obtain the altitudes from the common barometer, observation tables are required. The sympiesometer gives the altitudes without the use of tables, and only requires a single process of subtraction and multiplication.

DIRECTION OF THE WINDS.—W. C. Redfield, Esq. of New York, makes the following observations on this subject:—"It is deserving of notice, that during some of the coldest periods of winter, in this occasionally serene climate, the predominating winds blow from the south-western or southern quarters of the horizon. This fact appears to be established by the annual reports which have been made to the Regents of the University, and it is believed will become obvious in proportion to the accuracy of our observations. It sufficiently demonstrates, without resorting to other evidence, the fallacy of the notion commonly entertained, that winds are generally rectilinear in their progress, and blow for the most part in right lines over extensive portions of the earth's surface;—an error which appears to remain undisturbed in the minds of some meteorologists."

## GENERAL SCIENCE.

ON THE USE OF NICOL'S CALCAREOUS SPAR PRISM IN DISCOVERING SHOALS IN THE OCEAN.—It has been remarked by M. Arago, that the bottom of the sea, or the surface of a shoal at a given distance from a ship, is more distinctly seen from its mast-head, or, generally speaking, from a considerable height, than from the deck. He explains this phenomenon on the principle that the reflected light from the surface of the sea, which is always intermixed with that from the bottom, or the shoal, possesses a less and less degree of intensity in proportion as the angle of reflection, reckoned from the surface, is larger. That this reflected light may be entirely removed, when looking into the sea to discover cliffs or shoals, &c., he proposes to observe them by means of a Tourmaline, in which the axis is held horizontally, if possible under a polarizing angle of  $37^{\circ}$ , reckoning from the surface. The entire and absolute obstruction of the light reflected from the surface of the water cannot possibly take place under a smaller angle than  $70^{\circ}$ , because it is under this angle alone that it is completely polarized; but under angles of  $10^{\circ}$  or  $12^{\circ}$  greater or less than  $37^{\circ}$ , the number of polarized rays which the Tourmaline can arrest is still so considerable, that the same means of observation cannot fail to be attended with very advantageous results. Poggendorf proposes to use for this important purpose, instead of the Tourmaline, Nicol's Calc Spar Prism, because, from its being colourless, it is much better fitted for the purpose. By engaging in such experiments, Arago remarks, that "Mariners will throw a light on a curious question of Photometry; they will probably confer on navigation a means of observation which may prevent many shipwrecks; and by introducing Polarization into the nautical art, they will afford an additional proof of what those individuals expose themselves to, who unceasingly collect experiments and theories without any practical application of them, meeting every remonstrance with a contemptuous *cui bono*." Ere long, we doubt not, ships generally, at least all those vessels specially occupied in geographical and hydrographical researches, will, before leaving port, be provided with Nicol's valuable little instrument.

THE EFFECTS OF COMPRESSED AIR ON THE HUMAN BODY.—Dr Junod has communicated to the Academy of Sciences the results of his experiments with compressed air. In order to operate on the whole person, a large spherical copper receiver is employed, which is entered by an opening in the upper part, and which has a cover with three openings—the first for a thermometer, the second for a barometer or manometer, and a third for a tube of communication between the receiver and the pump. The air in the receiver is perpetually renewed by a cask. When the pressure of the atmosphere is increased one half, the membrane of the tympanum suffers inconvenient pressure, which ceases as gradually as the equilibrium is restored. Respiration is carried on with increased facility; the capacity of the lungs seems to increase; the inspirations are deeper and less frequent. In about eighteen minutes an agreeable warmth is felt in the interior of the thorax. The whole economy seems to acquire increased strength and vitality. The increased density of the air appears also to modify the circulation in a remarkable manner; the pulse is more frequent, it is full, and is reduced with difficulty; the dimensions of the superficial venous vessels diminish, and they are sometimes completely effaced, so that the blood in its return towards the heart follows the direction of the deep veins. The quantity of venous blood contained in the lungs ought then to diminish, and this explains the increased breathing of air. The blood there is then determined in a larger quantity to the arterial system, and especially to the brain. The imagination becomes active, the thoughts are accompanied with a peculiar charm, and some persons are affected with symptoms of intoxication. The power of the muscular system is increased. The weight of the body appears to diminish. When a person is placed in a receiver, and the pressure of the air is diminished one-fourth, the membrane of the tympanum is momentarily distended; the respiration is inconvenienced, the inspirations are short and frequent, and in about fifteen or twenty minutes there is a true dyspnoea. The pulse is full, compressible and frequent; the superficial vessels are turgid. The eyeballs and lips are distended with superabundant fluids, and hemorrhage and tendency to syncope are sometimes induced; the skin is inconveniently hot, and its functions increased in activity; the salivary and venal glands secrete their fluids less abundantly.

## REVIEWS.

*The Edinburgh New Philosophical Journal, exhibiting a view of the progressive Improvements in the Sciences and Arts, conducted by Professor Jameson, No. 42, July—octavo, 1836. Edinburgh: Adam and Charles Black.*

THE present Number of this Work contains a great variety of interesting articles, and none more so than that by M. Elie de Beaumont, "on the Temperature of the Earth's Surface during the Tertiary Period;" and also the article by Leopold Von Buch "on Volcanos and Craters of Elevation." The object of this paper is to show, that Craters of Elevation are not Volcanos; that there is a well grounded and important distinction between the two; and that even the cones of Volcanos can be formed only by a sudden elevation, and never by the building up of streams of lava. He considers that Volcanos are the constant chimneys, the canals uniting the interior of the earth with the atmosphere, which spread around themselves the phenomena of irruption from Craters that are of small extent, and are only once in operation; while Craters of Elevation, on the contrary, are the remains of a great display of powers from within, which are capable of, and actually have raised islands of several square miles in extent, to a considerable height. In a future Number we shall present in detail the views of Von Buch on this highly interesting subject.

The paper by M. Charpentier "on the Glaciers of the Canton of Vallais," contains some remarkable facts respecting the formation and decomposition of Glaciers. One of these we think deserving of notice; namely, that the mass of a Glacier consists of ice, or rather frozen snow, in a pure state, without any mixture of earth or stones. When blocks fall through a fissure to the bottom of the Glacier, they are rolled or pushed forward. If they remain hemmed in between the walls of the fissure, they

appear again after a lapse of a certain period of time on the surface of the Glacier, but at a point farther down the valley than where they fell in. When, however, a block falls quite near the lower end of a Glacier through a fissure to the bottom, and at a time when the Glacier is retiring, it remains nearly at the same point and in the same position which it occupied when it fell.

Bache's paper on the alleged influence of colour on the radiations of non-luminous heat contains a series of important experiments, the results of which are decidedly unfavorable to the specific effect of colour, in determining the radiating powers of bodies; and if the results be admitted as decisive of the radiating powers of the bodies used, they show, that each substance has a specific power not depending upon chemical composition nor upon colour.

Assistant-Surgeon Jameson's notes on the Natural History and Statistics of the Island of Cerigó, in the Mediterranean, are full of new and interesting information; and Dr Graham's Botanical Excursion acquaints us with a number of new localities, in which the rarer plants of our native Flora have been discovered.

This Number contains a very full account of the proceedings of the British Association at Bristol in August 1836; and the Miscellaneous information contained in the Scientific Intelligence is full and varied.

The Edinburgh Philosophical Journal was commenced in June 1819, and has been continued uninterruptedly, by Professor Jameson, up to the present time. It is but justice to say, that no European work, which has appeared during the same series of years, contains so full and varied accounts of the progress of the Sciences and Arts as it does. It is an indispensable companion to the Library of all who study the Physical Sciences, and the advancement of the useful arts.

## OBITUARY.

MR EDWARD TURNER BENNET.—Natural History has met with an incalculable loss by the death of Mr Bennet, who died on Sunday the 21st August, 1836, after a very short illness. He was Secretary to the Zoological Society, which office he filled with much credit to himself, and with great advantage to the Society. The scientific labours which this gentleman undertook, in addition to his official capacity, was to watch and detail the habits of the living Mammalia in the Gardens of the Society, Regent's Park. This task he performed with distinguished ability, which is borne out by his papers in the "Zoological Journal," brought out mainly by his able support and influence. He was also author of those excellent works the "Town Menagerie," and the "Gardens and Menagerie of the Zoological Society," of which we have spoken in high terms, in our notice at page 48 of this Journal.

MR DAVID DOUGLAS.—It is with extreme regret that we have to announce the death of this indefatigable and excellent young man; and more especially the melancholy accident which led to it. Mr Douglas was engaged by the Horticultural Society of London to travel in various countries as a Naturalist; and has in his journeys been very successful in discovering many new plants, and various Mammalia and Birds; especially on the Western territories of North America. He was engaged in his scientific pursuits when he met with the fatal accident, which took place on the 12th July 1834. The cause of his death is thus recorded in the Ke Kamu Hawaii, printed at Honolulu, of 26th Nov. 1834:—"From Edward Gurney, an Englishman, we received the following account of the tragical scene: About ten minutes before six o'clock in the morning, Mr Douglas arrived at his house in the Mountain, and wished him to point out the road to Hilo, and to go a short distance with him. Mr Douglas was then alone, but said that his man had gone out the day before (this was probably John, Mr Deill's coloured man). After taking breakfast, Edward accompanied Mr Douglas about three-fourths of a mile, and after directing him on the path, and warning him off the traps, went on about half a mile farther with him. Mr Douglas then dismissed him, after expressing an anxious wish to reach Hilo that evening, thinking that he could find out the way himself. Just before Edward left him, he warned him particularly of three Bullock traps, about two miles and a half a-head, two of them directly on the road, the other on the side. Edward then parted with Mr Douglas, and went back to skin some bullocks which he had previously killed. About eleven o'clock, two natives came in pursuit of him, and said that the European was dead, and that they had found him in a pit in which the bullock was. They mentioned that they were coming up to this pit; one of them observing some of the clothing on the side, exclaimed *lole*, but in a moment afterwards discovered Mr Douglas within the cave, trampled under the feet of the bullock. They went off immediately for Edward, who left his work, ran to the house for a musket and ball, and hide, and on coming up to the pit, found the bullock standing on Mr Douglas's body. Mr Douglas was lying upon his right side. He shot the animal, and after drawing him to the other end of the pit, succeeded in getting out the body. His cane was with him, but the bundle and dog were not. Edward knowing that he had a bundle, asked for it. After a few moments' search, the dog was heard to bark, at a short distance a-head, on the road leading to Hilo. On coming up to the place, he found the dog and the bundle. On further examination, it appeared that Mr Douglas had stopped for a moment and looked at the empty pit, and also at the one in which the bullock had been taken; that after passing up the hill some fifteen fathoms, he laid down his bundle, and went back to the pit in which the bullock was entrapped, and which lay on the side of the pond opposite to that along which the road runs; and that whilst looking in, by making a misstep, or by some other fatal means, he fell into the power of the infuriated animal, who speedily executed the work of death." Thus has perished a Naturalist who has travelled over a wide extent of country, and who, from his zeal, must have collected an immense number of facts which could not fail to have been of much use to science.

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE—THE WEASELS.

ALL the animals of this tribe are carnivorous. Their slender, lengthened, and cylindrical bodies, short legs, and the very free motion allowed in every direction by the loose articulations of their spine, well fit them for pursuing their prey into the deepest recesses. Constituted by Nature to subsist on animals, many of which have great strength and courage, the Weasels possess an undaunted and ferocious disposition. In their predatory character they are inferior to the Cats alone, to which they bear a striking resemblance in many points of their organization. Their disposition is very sanguinary, which frequently impels them to commit the most extensive devastation, simply for the sake of gratifying their excessive thirst for blood. Rats and Mice form a favorite article of their food, and they are very destructive to poultry. All the animals of the Weasel kind are nocturnal, usually remaining the greater part of the day in their retreats asleep, but on the approach of night, they begin to arouse themselves, and prow about in search of the victims on which they prey.

The Weasels belong to the genus *Mustela* of Linnaeus, retained by Cuvier, but from which he has discarded the Ichneumon, and other allied animals. He has formed the remainder into three subgenera, under the titles of *Putorius*, *Martes*, and *Mephitis*, the last of which embraces the Mephitic Weasel of South America and other fetid species.

Fig. 1. THE POLECAT (*Putorius maximus*).—In the winter season the Polecat or Foumart frequents houses, barns, &c. feeding on poultry, eggs, and sometimes milk. It also consumes fish. Bewick relates that one of these, during a severe storm, was traced in the snow from the side of a rivulet to its hole at some distance from it. As it was observed to have made several tries, and as other marks were seen in the snow which could not easily be accounted for, it was thought a matter worthy of some attention; its hole was accordingly examined, the Polecat taken, and eleven fine Beels were discovered to be the fruits of its nocturnal excursions. The Foumart is common all over Europe.

Fig. 2 is a white variety of this animal, commonly called the Ferret, and which many Naturalists have erroneously supposed to be a distinct species.

Fig. 3. HARDWICK'S WEASEL (*P. Hardwickii*).—This animal is a native of the mountains of Nepal, India. It is of a rapacious disposition, living in forests, and destroying small birds and quadrupeds. This is a large species, measuring from the point of the muzzle to the insertion of the tail two feet two inches, the length of the tail being one foot seven inches and six lines. Its native name is "Mull-Samprah," pronounced with a nasal sound.

Fig. 4. THE COMMON WEASEL (*P. vulgaris*).—This animal seldom exceeds nine inches in length from the nose to the tail, the latter being only about two inches and a half in length. It is a bold and active little creature, and makes no scruple of attacking a Hare, which, if it once seizes, it is sure to overcome and destroy: it is more than a match for the strongest Rat.

Fig. 5. THE ERMINE (*P. ermineus*), in its summer fur, and Fig. 6, in its full winter dress. The difference between the Ermine or Stoat and the Weasel is so small, that they have frequently been mistaken for each other when in their summer fur. The Ermine is, however, considerably larger than the Weasel, its length being fully ten inches, and the tail five inches and a half. During winter this animal is wholly of a yellowish white except the tail, which is invariably black at the point. It inhabits Britain, Norway, Lapland, and Russia.

Fig. 7. THE PINE MARTEN (*Martes pinus*) inhabits the North of Europe, Asia, and America, and is also found in some of the more extensive woods of this country. It is said that in its combats with the Wild Cat, it frequently comes off victorious, and instances are mentioned of its killing that animal, although so much larger.

Fig. 8. THE WHITE-CHEEKED MARTEN (*M. flavigula*).—This species is a native of India, and is one of the largest of its tribe. It is a beautiful animal, but partakes in a small degree of that unpleasant effluvia which is so strong in the Polecat.

Fig. 9. THE WHITE-EARED MARTEN (*M. leucotis*).—This animal is twenty inches long, but little is known of its habits, and zoologists are even unacquainted with its native country.

Fig. 10. THE SABLE (*M. Zibellina*).—This animal, so much in request on account of its valuable and fine fur, is a native of Siberia and Kamtschatka. It lives much in trees, and leaps with great activity from branch to branch in pursuit of Squirrels and Birds. In winter it feeds upon berries.

Fig. 11. THE VISON (*M. vison*).—America is the native abode of this animal; it is only about fifteen inches in length, exclusive of the tail.

#### DESCRIPTION OF THE PLATE—THE FINCHES AND BUNTINGS.

THE Finches are a numerous and active race, widely dispersed over the world, feeding principally on grain, seeds, and insects. Some of them are remarkable for the melody and variety of their notes, while others are destitute of song, and only utter a chirp.

Fig. 1. THE FIELD SPARROW (*F. pusilla*) is a native of Pennsylvania; it is a migratory species, arriving in that State early in April. It has no song, but a note not unlike the chirp of a cricket. It is the smallest of the American Finches.

Fig. 2. THE SWAMP SPARROW (*F. palustris*).—This is another summer visitant of Pennsylvania, where it arrives early in April, and frequents the low pine swamps. It rears from two to three broods in a season, returning to the south on the approach of cold weather. It has no song, but a simple cheep.

Fig. 3. THE TREE SPARROW (*F. arborea*).—This is a native of the northern parts of America, taking up its winter residence in Pennsylvania, and most of the northern states, where it arrives in the beginning of November, and departs in April. It frequents sheltered hollows, thickets, and hedge-rows. It has a low warbling note.

Fig. 4. THE SONG SPARROW (*F. melodia*).—This species is very generally diffused over the United States, and is only partially migratory. It commences its song early in the spring, and continues its sweet warblings during the whole summer, and is sometimes even heard in the depth of winter. It frequents the borders of rivers, meadows, and swamps. Its nest is built on the ground.

Fig. 5. THE CHIPPING SPARROW (*P. socialis*).—This is a social American species, inhabiting the city in common with Man in the summer season; but retires to the fields and hedges as the cold approaches, and takes its final departure for the south of America when the frost sets in.

Fig. 6. HENSLOW'S BUNTING (*Emberiza Henslowii*).—This new species was first discovered by Audubon, opposite Cincinnati, in the United States. Nothing is known of its history or habits.

Figs. 7 and 8. THE LAPLAND LONG-SPURRED BUNTING (*E. Lapponica*), male and female, inhabit the desolate arctic regions of Europe and America. They are common Birds in Lapland, and have been known to penetrate as far as some of the middle States of America. The Lapland Longspur only sings during its aerial flights, at which time it utters a few agreeable and melodious notes.

ON THE HABITS OF THE RINGDOVE (*Columba Palumbus*).—Sir—It is stated in Dr Fleming's History of British Animals, page 47, genus *Columba*, that the *Columba Palumbus*, or Ringdove of our woods, is easily tamed, but will not breed in confinement. Mr John Robertson, of Rosehall Tea Gardens, Glasgow, has in his aviary a pair of these beautiful Birds. A wooden box was put up in a corner of the aviary last spring, with the intention of giving these Birds an opportunity to breed. The box, however, was not securely fixed, and fell from its position in a short time after, containing a nest and one egg, which was broken to pieces by the fall. The box again being secured, the Cuckoos again built, and, pursuing the work of incubation, were successful in bringing out and rearing a pair of fine healthy young ones, and are to be seen in Mr Robertson's possession at this time. By inserting the above fact in your useful Journal, you will oblige, &c. (Signed) JOHN BLYTHE,

30, East Clyde Street,  
Glasgow, 28th Nov. 1836.  
To the Editor.

The above interesting fact serves to correct a mistake into which most naturalists have fallen, in supposing that the Ringdove will not breed in captivity. This Bird is the largest of the European Columbidae, and may form a valuable addition to our

domestic animals. The first brood should be carefully preserved; for if they can be induced to reproduce, their progeny will in all probability succeed, and be rendered completely domesticated, thus proving a valuable accession to the luxuries of the table. During our residence at Prinlows House, near Leslie, in Fife, a pair of Ringdoves built and incubated on a spruce fir-tree, in a plantation which bounded our garden, and not more than fifteen yards from the house. Their nest was not more than twenty-five feet from the ground, and close to a garden walk through which the family were constantly passing. Yet this seemed to give the connubial pair no uneasiness, as the female would sit on her nest, with her mate by her side, without attempting to quit the spot on the approach even of several individuals. The first young, which they brought up in the following spring, built a nest in a spruce fir within the garden, and reared their young. Both these nests were occupied every season afterwards during the four years which we remained there. These Birds very frequently alighted and fed in the garden, and even ate occasionally along with the domestic poultry; from which we are of opinion that, if unmolested, the Cusshat is not so shy a Bird as is generally imagined, and that it is only from persecution that it retires to the deep recesses of woods for shelter from its numerous enemies.

**SINGULAR TENACITY OF LIFE IN AN AQUATIC MOLLUSCOUS ANIMAL.**—M. Rang, Member of the Royal Academy of Sciences, Paris, received four young specimens of *Anodonta rubens*, of Lamarck, from Senegal, and although they had been enveloped in cotton for two months, they were still alive; he had learnt that these animals live eight months of the year out of water, upon the ground being suddenly abandoned by the river, and that they remain during six of these months exposed to the ardent heat of an almost vertical sun.

**MARINE AND RIVER MOLLUSCA IN THE GULF OF LIVONIA.**—So inconsiderable is the saltness of the sea-water in the Gulf of Livonia, that fresh and salt water conchiferous molluscos animals live together promiscuously on the same coasts. M. Freminville informed the Philomatic Society of Paris, that he collected from the same localities species of the fresh water genera, *Anodonta*, *Unio*, and *Cyclas*, which were intermixed with species of the Marine genera, *Tellina*, *Cardium*, and *Venus*.

**STEP OF THE CAMEL.**—What always struck me, as something extremely romantic and mysterious, was the noiseless step of the Camel, and the spongy nature of his foot. Whatever be the nature of the ground—sand or rock, turf or paved stones—you hear no foot-fall; you see an immense animal approaching you, stillly as a cloud floating on air, and unless he wear a bell, your sense of hearing, acute as it may be, will give you no intimation of his presence.—*Constantinople in 1828, by Charles Macfarlane*

#### SIVATHERIUM GIGANTEUM.

THIS very large animal forms an important accession to extinct Zoology. In size it greatly surpasses the Rhinoceros, and hence is larger than any known Ruminant in the Class Mammalia to which it belongs; at the same time the forms of structure which the Sivatherium exhibits, render it one of the most remarkable of fossil animals hitherto detected in the more recent strata of the globe.

Of the numerous fossil mammiferous genera previously discovered and established, all were confined to the Edentata and Pachydermata. The fossil species belonging to other orders have all their living analogues upon the earth; and among the Ruminantia, in particular, no remarkable deviation from the existing types has hitherto been discovered. However, the isolated position of the Giraffe and the Camels made it probable that certain genera had become extinct, which formed the connecting links between these and the other genera of the order, as well as between the Ruminantia and the Pachydermata. In the Sivatherium we have a Ruminant of this description, connecting that order with the Pachydermata, and at the same time so marked by individual peculiarities as to be without a living analogue in its own order.

The large cranium of the Sivatherium, of which the above are representations in profile and in front, is a remarkably perfect fossil. When discovered, it was fortunately so completely enveloped in a mass of stone, that although it had long been exposed to be acted upon as a boulder in a water-course, all the more important parts of structure had been preserved. The block might have been passed unnoticed, had not a projecting edge of the teeth, by jutting out in relief, given a promise of something additional concealed beneath. After much labour, the hard crystalline covering of stone was so successfully removed, that the huge head now stands out, with a couple of horns between the orbits, broken only near the tips, and the nasal bones projected in a free arch high above the chaffron. All the molars on both sides of the jaw are present, and singularly perfect. The only mutilation of the fossil is at

the vertex of the cranium, where the plane of the occipital meets that of the brow, and at the muzzle, which is truncated a little way in front of the first molar tooth. The only parts which are still concealed are a portion of the occipital, the zygomatic fossae on both sides, and the base of the cranium over the sphenoid bone.

The form of the head is so singular and grotesque, that the first glance strikes us with surprise. The prominent features are, 1st, The great size, approaching to that of the Elephant; 2d, The immense development and width of the cranium behind the orbits; 3d, The two divergent osseous cones for horns, starting out from the brow, between the orbits; 4th, The form and direction of the nasal bones, rising with great prominence out of the chaffron, and overhanging the external nostrils in a pointed arch; 5th, The great massiveness, width, and shortness of the face forward from the orbits; 6th, The great angle at which the grinding plane of the molars deviates upwards from the base of the skull.

Viewed in lateral profile, the form and direction of the horns, and the rise and sweep in the bones of the nose, give a character to the head widely differing from that of any other animal. The nose looks something like that of the Rhinoceros; but the resemblance is deceptive, and only owing to the muzzle being truncated. Seen from the front, the head is somewhat wedge-shaped, the greatest width being at the vertex, thence gradually compressed towards the muzzle; with contraction only at two points, behind the orbits and under the molars. The zygomatic arches are almost concealed, and nowise prominent; the brow is broad and flat, and swelling latterly into two convexities; the orbits are wide apart, and have the appearance of being thrown far forward, from the great production of the frontal upwards. There are no crests or ridges; the surface of the cranium is smooth; the lines are in curves, with no angularity. From the vertex to the root of the nose, the plane of the brow is in a straight line, with a slight rise between the horns.

There are six molars on each side of the upper jaw. The third of the series, or last milk molar, has given place to the corresponding prominent tooth, the direction of which, and of the last molar, is well advanced, and indicates the animal to have been more than adult.

The teeth are in every respect those of a Ruminant, with some slight individual peculiarities. The three posterior double molars are composed of two portions or semi-cylinders, each of which inclines, when partially worn down, a double crescent of enamel, the convexity of which is turned inwards. The last molar, which is normal in Ruminants, has no additional complication, like that in the corresponding tooth in the lower jaw. The plane of grinding slopes from the outer margin inwards. The general form is exactly that of an Ox or Camel, on a large scale. The ridges of enamel are unequally in relief, and the hollows between them equally scooped. Each semi-cylinder has its outer surface in horizontal sections, formed of three salient knuckles, with two intermediate sinuses, and its inner surface of a simple arch or curve. But there are certain peculiarities by which the teeth differ from those of other Ruminants.

Corresponding to the shortness of jaw, the width of the teeth is much greater in proportion to the length than is usual in this order, the width of the third and fourth molars being to the length as 2.24 and 2.2 to 1.55 and 1.68 inches respectively, and the average width of the whole series being to the length as 2.13 to 1.76 inches. Their form is less prismatic, the base of the shaft swelling out into a bulge or collar, from which the inner surface slopes outward as it rises, so that the coronal becomes somewhat contracted. In the third molar, the width at the coronal is 1.93, at the bulge of the shaft 2.24. The crescentic plates of enamel have a character which distinguishes them from all other known Ruminants; the inner crescent, instead of sweeping in a nearly simple curve, runs zig-zag-wise, in large sinuous flexures, somewhat resembling the form of the *Elosmatherium*. The space occupied by the line of the molars is 9.8 inches.

From the anterior margin of the foramina to the alveolus or first molar tooth, - - - - -	18.85 inches
From ditto to the truncated extremity of the muzzle, - - - - -	20.6
From the tip of the nasals to the upper fractured margin of the cranium, - - - - -	18.0
From ditto to ditto along the curve, - - - - -	19.0
Width of cranium at the vertex, - - - - -	22.0
Ditto between the orbits, upper borders, - - - - -	12.2
Ditto, ditto, lower borders, - - - - -	16.3
Ditto between the outer surfaces of the horns at their base, - - - - -	12.5

Among a quantity of bones collected in the neighbourhood of the spot in which the skull was found, there is a fragment of the lower jaw of a very large Ruminant, which is supposed to have belonged to the Sivatherium; and it is even not improbable that it came from the same individual with the head now described. It consists of the hind portion of the right jaw, broken off at the anterior margin of the last molar. The outline of the jaw, in vertical sections, is a compressed ellipse, and the outer surface more convex than the inner. The form and relative proportions of the jaw agree very closely with those of the corresponding parts of the Buffalo. The dimensions, compared with those of the Buffalo and Camel, are thus:

	<i>Sivotherium.</i>	<i>Buffalo.</i>	<i>Camel.</i>
Depth of the jaw from the alveolus, last molar, - - - - -	4.95	2.65	2.70 inches.
Greatest thickness of ditto, - - - - -	2.3	1.05	1.4
Width of middle of last molar, - - - - -	1.35	0.64	0.76
Length of posterior, $\frac{2}{3}$ of ditto, - - - - -	2.15	0.95	1.15

No known Ruminant fossil has a jaw of such large size,—the average dimensions above given being more than double those of a Buffalo, which measured in length of head 19.2 inches, and exceeding those of the corresponding parts of the Rhinoceros.

This gigantic fossil cranium, above described, was discovered near the Markenda river, in one of the small valleys which stretch between the Kyarda-dán and the valley of Pinjór, in the Siválik or sub-Himálayan belt of hills, associated with bones of the fossil Elephant, Mastodon, Rhinoceros, Hippopotamus, &c.

Among a quantity of bones collected from the same neighbourhood with the cranium of the Sivatherium, there are three singularly perfect specimens of the lower portions of the extremities, belonging to three legs of one individual. They greatly exceed the size of any known Ruminant, and there is no other ascertained animal of proportionate size excepting the Sivatherium.

## BOTANY.

### GENERAL REVIEW OF THE VEGETABLE KINGDOM.—NO. IV.

THE principal causes which induce this progression of changes are three; 1st, the excess of duration in the winters, a consequence of the obliquity and disappearance of the solar rays; 2d, the dryness of the air, a consequence of the decrease of heat; 3d, the prolonged action of the light, which illumines the horizon through the whole period of vegetation. It may be proper here briefly to trace the effects of each of these three causes.

1st, It is well known that too great a degree of cold, by congealing the sap, occasions the rupture of the vascular system in plants, and thereby destroys them; but the deleterious action of cold is not confined to purely mechanical results; it has been proved that heat is a stimulus that cannot be dispensed with in vegetation. Many species secrete juices in warmer regions, which are unknown in their economy in colder climates. The Ash yields manna in Calabria, but loses that faculty as it advances towards the north. The Grape, in the south of Europe, abounds in matter of a sweet quality; in the north, it contains an excess of acid. As long as the organic functions, which depend upon the degree or duration of heat, can be carried on, the Ash and the Vine continue to grow; they grow even when those functions are performed incompletely, but their growth is stunted. They finally disappear at that point where the portion of warmth in the atmosphere, though still equal to prevent the freezing of the sap, is no longer able to stimulate their organs or their frame into action. All other vegetables, whose duration and duration subject them to the full severity of the frost, share the same destiny, at a greater or less distance from the torrid zone, and in proportion as their constitutions require a greater or less degree of heat. So that nothing is found near the Pole but such dwarf shrubs as are sheltered under the snow in winter, or annuals and herbaceous species, endowed with so quick a principle of life, as to rise, flower, and fruit within the space of three months; or some agamous and cryptogamous species, which adapt themselves to all degrees of temperature, and are consequently the last organic forms under which vegetable life is to be desoried.

2d, Heat and moisture are highly favorable to the growth of plants. No countries are more abundant in herbaceous vegetables, or better wooded, than Senegal, Guinea, and Cayenne, where both these props of vegetation are in the plenitude of their force. Experiments made with the hygrometer prove that the moisture of the atmosphere increases as we approach the Equator. In hot climates, when the sun sinks below the horizon, the watery exhalations condensed are returned to the earth in the form of dew, that moistens the surface of the foliage, and feeds those vegetables in which the absorbing powers of the parts above ground suffice for their support. Of this number are the succulent plants; the Aloes, the *Cacti*, the *Mesembryanthemums*, some of the Spurges, &c. In these the fibrous root only serves to hold them in their places; and the moisture of the atmosphere is inhaled and retained by the spongy parts above. Thus, in the vast plains that receive the waters from the eastern declivity of the Andes, when the scorching heat of summer has consumed the grasses and other herbaceous kinds which the rainy season had brought forth, we still find some lingering *Cacti*, which, under their dry thorny coats, conceal a cellular system, by which an abundant sap has been imbibed and preserved. But in countries where the atmosphere holds but little moisture in evaporation, either because the soil is wholly destitute of water, or by reason of the coldness of the temperature, we find no plants at all, or such only as are of dry, hard texture. The sands of Africa, watered by no river, are found to be utterly barren. Spitzbergen, Nova-Zembla, Kamschatka, &c. where the influence of the sun is only felt for two months in the year at most, and where, consequently, the air is habitually dry, furnish a very scanty portion of herbaceous only, or some dwarf shrubs, with a narrow leathery foliage. It is true that drought is not in these instances the sole cause of the degenerated state of vegetation, but it would of itself be sufficient to produce it; for it is a fact, that plants acquire height of stem and breadth of foliage only in proportion to the abundance of nutriment which they meet with in the atmosphere, and that nutriment is water reduced into vapour, and held in suspension by the atmosphere.

3d, When vegetables are deprived of light, they extend in length, shoot up pale lank stalks, are of a lax fibre, and of no substance; in short, they spindle themselves out. The way that light acts upon this class of the creation is principally in separating the elementary parts of the water and carbonic acid contained in them, and in extricating the oxygen of the latter. The carbon of the acid, with the hydrogen and oxygen of the water, form the bases of the gums, resins, and oils, which flow in the vessels or fill the cells. These juices nourish the membranes, and induce the woody state in them; and they do this in proportion as the light is stronger, and its action more prolonged. Thus we see that darkness and light have effects directly opposite upon vegetables. Darkness favors the length of their growth, by keeping up the pliancy of their parts; light consolidates them, and stops growth by favoring nutrition. It should follow that a fine race of vegetables, one that unites in due proportion size and strength, depends in part upon the proper reciprocity of nights and days. Now, in the northernmost regions, plants go through all the stages of growth at a time when the sun no longer quits the horizon; and the light, of which they experience the unremitting effect, hardens them before they have time to lengthen. Their growth is quick, but of short duration; they are robust, but under-sized.

The same plants when transplanted into milder regions, where the atmosphere is moist, and light and darkness follow in regular succession, are seen to lengthen their stems, expand their branches, as well as multiply, dilate, and soften their leaves. They must, however, be endowed with a frame of sufficient pliancy to support their new mode of existence.

EFFECTS OF MOUNTAIN HEIGHTS ON PLANTS.—During the recent interesting tour made by M. Gay among the Cordilleras, he discovered many beautiful and rare specimens of *Baccharis*, *Loasa*, *Alstrœmeria*, and above all, those charming flowers, the *Mutisia*, which exhibit the most singular phenomena. As the tendrils with which these plants are usually furnished would become useless in these cold regions, unprovided with shrubs or bushes, they are changed into real leaves, organs of such great utility to mountain plants. He also remarked, that the plants which are herbaceous in the plains, become here entirely ligneous; and that several trees, especially the *Escalœonia*, instead of assuming that forked appearance which characterises it, becomes stunted, creeping along the rocks, and thus offering less surface to the cold with which the wind is charged in passing over the numerous and immense glaciers. But another observation, which he also made among these cold regions, is still more interesting; it is the form of imbricated leaves which the greater portion of the vegetables assume, among those generally even whose habitual form seems to be entirely contrary to this disposition; thus the leaves of the *Triptilion*, which are so lax and small in the lower regions, become here extremely hard and tough, closely imbricating the stalks, and even the flowers of these beautiful plants. The *Mutisia*, which is nearly devoid of leaves when at the side of mountains, produces at their summit a considerable number. The violets here have not that elegant form, which is observed in those flowers lower down, but possess a conformation altogether different; they have the appearance of a rosette, which may be compared to that of a *Sedum*, with this difference, that the leaves, instead of being almost vertical, are in these alpine violets entirely horizontal. These leaves, which are extremely hard and tough, are round, scabrous, strongly imbricated, and exhibit at the footstalk flowers which are sessile, and of a violet colour somewhat approaching to red. Although M. Gay was very familiar with the genera *Triptilion*, *Escalœonia*, *Mutisia*, and *Viola*, the particular aspect of these alpine species caused him to mistake them entirely, nor did he discover to what genus they belonged, until he studied them after his return.

ON THE BEDEGUAR OF THE ROSE.—Mr Jesse makes the following observations on this subject:—"I have often admired a small, round, mossy substance attached to a branch of the Dog-Rose growing in our hedges, and which I was unable to account for until the following circumstance was related to me by an ingenious florist and nurseryman in the King's Road, Chelsea, London, Mr Knight, who informed me, that, having been requested by one of his customers to endeavour to preserve a favorite mulberry tree, which for many years had flourished on her lawn, but which, with the exception of one very large branch, was either dead or decaying, he waited till the sap was ascended, and then barked the branch completely round near its junction with the trunk of the tree. Having filled three sacks with mould, he tied them round that part of the branch which had been barked, and by means of one or two old watering-pots, which were kept filled with water, and placed over the sacks, from which the water gradually distilled, the mould in the sacks was sufficiently moistened for his purpose. Towards the end of the year he examined the sacks, and found them filled with numerous small fibrous roots, which the sap, having no longer the bark for its conductor into the main roots of the tree, had thus expended itself in throwing out. A hole having been prepared near the spot, the branch was sawn off near the sacks, and planted with them, the branch being propped securely. The next summer it flourished and bore fruit, and is still in a thriving state.

"Having heard this fact, I examined the mossy substance on the Dog-Rose, and found that, in consequence of the bark on the branch on which it was found having been removed by some insect, the sap in receding had thrown out roots, which, from the exposure of the air, produced the mossy ball in question, and which was probably made the nest or hybernaculum of some insect. If this mossy substance be examined, the larva of an insect will be found belonging to the genus *Cynips*."

ON THE STRUCTURE OF THE RADISH ROOT.—It is well known to most observers, that at the summit of the root of the common radish, at the very base of the stem, or that place which the French call the *collet*, the English the *neck*, is an appendage at first resembling a membraneous sheath, enveloping the young root, and subsequently, as the root distends, becoming two loose straps hanging down on each side of the root. The nature of this appendage was unknown, until the late L. C. Richard discovered the existence of two modes of germination, called the *exo-rhizal* and *endo-rhizal*, and suggested that the radish was an example of the latter mode, a notion which has been generally admitted by recent writers, notwithstanding the circumstance, that if endo-rhizal, the radish would offer an exception to a very general law, that endo-rhizal germination goes along with the indigenous growth. M. Turpin has lately demonstrated that the supposed fleshy root of the radish belongs to the ascending axis, not to the descending one, and that consequently it belongs to the system of the stem, and not to that of the root. He further asserts, that the tumour, which ultimately becomes the radish, is in the beginning cylindrical, and that its cuticle loses at a very early period the power of distension; in short, that it dies, and separates from the subjacent living matter, just as dead bark separates from liber and young wood in old stems. Now this premature death of the cuticle is connected with the rapid lateral distension of the tumour, the cause of the existence of the two appendages in question, which are nothing more than two straps of dead cuticle, rent asunder by the gradual but rapid distension of the part that they originally ensheathed.

ON THE MATERIALS OF LEGHORN AND TUSCAN BONNETS.—There has been considerable controversy as to the plant from which these bonnets are manufactured. M. Merat, M.D. in a letter to the Editor of the Archives de Botanique, says, "This gramineous plant is a genuine Wheat (*Triticum*), and not a Rye (*Secale*), as M. Chaubard terms it. It is a summer corn, a sort of spelt. It is sown in the spring in barren ground, in a dry soil, and cut down before the expansion of the ear. The entire straw (*Sommites*) is employed, after having first bleached in the dew, and afterwards by a chemical process. There are lands which produce superior straw to others, and of which the middle boles (*centre nœuds*) are longer, a circumstance which is particularly desirable. The same fields in France do not produce such good straw, although the grain answers well."

## METEOROLOGY.

OBSERVATIONS ON LIGHTNING, BY M. ARAGO.

M. Fusinieri has been lately studying the effects of lightning under an entirely new point of view.

According to this philosopher, the electrical sparks, seen as they traverse the air from ordinary machines, contain brass in a state of fusion; and incandescent molecules of zinc, when they emanate from a brass conductor, if the sparks issue from a ball of silver, they contain impalpable particles of that metal. In the same way, a globe of gold gives rise to sparks, which contain, during their passage through the air, melted gold, &c. &c.

In the centre of all these sparks the molecules are melted only; but in the circumference, the metallic particles undergo a greater or less degree of combustion, in consequence of their contact with the oxygen of the atmosphere.

When a spark emanating from a globe of gold traverses a silver plate, even of considerable thickness, there is seen on the two surfaces of the plate, at the point where the electric spark entered and emerged, a circular layer of gold, the thickness of which must be very inconsiderable, since the natural volatilization is sufficient to cause it to disappear entirely after a short time. According to M. Fusinieri, these two metallic spots are formed at the expense of the fused gold which the electric spark contains. The deposit on the first face is nothing extraordinary; but by adopting the explanation of the Italian philosopher for the spot on the opposite surface, we are obliged to admit, that the gold disseminated through the spark has passed, at least in part, along with it through the whole thickness of the silver plate! It is unnecessary to add, that a spark issuing from a ball of copper gives rise to the same phenomena.

The spark which emanates from a certain metal, does not merely lose a portion of the molecules with which it was at first impregnated, when it traverses another metal; but it becomes charged with new molecules at the expense of that metal. It is even asserted by M. Fusinieri, that, at each passage of the spark, reciprocal changes are produced between the two metals; that when the spark, for example, quits the silver to pass to the copper, it not only transports a portion of the first metal to the copper, but it likewise transports the copper to the silver! I will not, however, longer insist on these phenomena, and have only now brought them forward with the view of showing that the sparks of our ordinary machines contain ponderable substances.

M. Fusinieri asserts that similar substances exist in lightning, and that in this case also they are in a state of great division, of ignition, and combustion. According to his views, these transported matters are the true cause of the transient smells which always accompany thunder, and also of the pulverulent deposits which remain round the fractures through which the electrical matter has forced a passage. In these deposits, which have been too much neglected by observers, M. Fusinieri has detected metallic iron, in different degrees of oxidation and sulphur. The ferruginous spots left on the walls of houses may be found, when strictly examined, to arise from the iron with which the lightning was charged, at the expense of that which occurs in almost every building; but how are we to explain the sulphurous spots on these same walls, and more especially the ferruginous marks which exhibit themselves in the open field, on trees struck with lightning? M. Fusinieri considers himself warranted to conclude from these experiments, that the atmosphere contains, at every height, or at all events as far as the region of stormy clouds, iron, sulphur, and other substances, on the nature of which chemical analysis has been hitherto silent; that the electrical spark is impregnated with them, and that it conveys them to the surface of the earth, where they form slight deposits round points that have been struck with lightning.

This new method of regarding electrical phenomena unquestionably deserves to be pursued with that accuracy which is suited to the existing state of science. Every one who witnesses the fall of a thunderbolt would render an essential service to science by carefully collecting the black or coloured matter which the electric fluid appears to have deposited at every stage of its progress, when it must have undergone sudden changes in rapidity. A careful chemical analysis of these deposits may lead to unexpected discoveries of very great importance.

**SPRING ON THE PEAK OF THE SARRANTINA.**—M. Dariou, who lately made a scientific tour in the kingdom of Asturias, mentions the following singular fact:—"A beautiful spring," says he, "flows from the highest point of the peak of the *Sarrantina*; but as this peak is not commanded by any neighbouring summit, we may necessarily suppose that the other branch of the syphon must be placed at a great distance to the east, to receive, on the flanks of the mountains covered by perpetual snow, and having a much greater elevation, the water which issues from the extremity of the shorter branch, and which an extraordinary accident, or a concealed natural cause, has forced to ascend to the top of a pointed peak."

**ANNUAL QUANTITY OF SALT RAISED FROM THE BOWELS OF THE EARTH IN EUROPE.**—From a careful examination of the most accurate returns, the European Salt Mines and Salt Springs afford annually from twenty-five to thirty millions of hundred weights of Salt!

**EFFECTS OF COLD UPON ICE.**—On Lake Champlain, and other American Lakes, and even in narrow rivers, fissures and rents of enormous magnitude are often made in the ice, and are always accompanied with loud reports, like those of cannon. The unwary traveller, who, with his sledge and horses, adventures by night, and sometimes even by day, across the great northern lakes, is frequently swallowed up in the openings which are thus unexpectedly made in the ice. When the weather grows warm again, before the ice melts, the fissures close, and sometimes the edges of them even overlap. At Plattsburg, in the winter of 1819-20, when the thermometer during the night was from 15° to 17° below 0° of Fahrenheit, and during the day from 10° to 12° below it, the reports of the rending of the ice were like that of a six-pounder, and the openings were from 10 to 15 feet wide.

**SEPIA COLOUR FROM PEAT.**—The stagnant water in Peat-bogs affords, on evaporation, a substance which equals the finest Sepia, and which, on being mixed with a proper proportion of gum or isinglass, may be used as a water colour. It requires no levigation.

**FILTRATION.**—When a powder saturated with a fluid, but not in the condition of a paste, is placed in the lower part of an open vase, and another liquid poured upon it, the last liquid permeates the powder, and completely replaces the first without mixing with it. This substitution is independent of the specific gravities of the fluids; thus water drives out alcohol and wine, and alcohol and wine drive out water.

## LEARNED SOCIETIES.

**LINNEAN SOCIETY, NOV. 1.**—A. Lambert, Esq. V.P., in the chair. Several donations were announced as having been received during the recess, amongst which were presents from the Academy of Sciences, Royal Society of Edinburgh, Asiatic and Geological Societies, &c. Amongst the specimens exhibited was the *Spartina polystachya*, a species new to the British Flora, discovered last summer growing abundantly on the muddy banks of the river at Southampton, by Dr Broomfield; a cone of the *Pinus Sabinensis*, by Mr Warden; and two stems of the true *Dahlia*, an indigenous plant in the interior of Mexico, which occasionally grows to the height of seventy feet—the present specimen being grown by the Chairman to the height of about seven feet. Mr Gould likewise exhibited a variety of birds from New South Wales, containing several *Meliffica*, Parrots, and Finches, and a new species of *Pteromorhynchus*, distinguished by a beautiful mural band. Mr Richard Taylor, the Secretary, read some remarks by Edward Foster, Esq., on the *Eaphorbia palustris*, a species which was supposed to be a new discovery, but which he proved to have been known in England above two hundred years ago, and described by Major Johnson in an edition of "Gerrard's Herbal;" as also some observations on the "wourale poison," by R. H. Seomburgh, Esq., illustrated by drawings and specimens of the plant, one of which was that seen by M. Martius on the Amazon, in the process of manufacture, and which was proved to be the *Strychnos toxicifera*. The meeting, which was numerously attended, adjourned to November 15th.

**BOTANICAL SOCIETY OF LONDON.**—The second meeting of the above Society was held on November 2d, at the Crown and Anchor Tavern, Strand; J. E. Gray, Esq. F.R.S., in the chair. The meeting was numerous, and comprised many noted botanists. After the laws as revised by the Council had been read, confirmed, and ordered to be printed, the Society determined to hold their anniversary meeting on 29th November, being the anniversary of the birth-day of the celebrated English botanist, John Ray. They then determined to hold their next meeting on Thursday, November 17th, at the rooms proposed by the Council at Adelphi Chambers, next door to the Society of Arts. A paper was then read by Mr Daniel Cooper, author of the "Flora Metropolitana," and Curator of the Society, on "The Influence of Light on Plants, and the effects produced by depriving them of it; also the effects of watering them with coloured vegetable infusions when grown in the dark," being a detail of some experiments instituted in the year 1835, together with coloured sketches of the plants after the conclusion of the experiments. Donations of books were received from J. E. Gray, Esq., F.R.S., from G. C. Dennes, from J. Reynolds, Esq. (the Treasurer), and from Dr McIntyre. Also presents to the Herbarium from D. Cooper, Esq., W. M. Chatterley, Esq., Honorary Secretary, and from Mrs Gawler. The meeting was then dissolved.

**WARWICKSHIRE SOCIETY OF NATURAL HISTORY AND ARCHÆOLOGY.**—At a recent meeting of this Society, Professor Puckland stated that he had discovered at Guy's Cliff the remains of an extinct species of animal, which had never before been found or mentioned by geologists. The learned Professor said, "He had commenced his studies by collecting fragments of Carisbrook Castle, Corfe Castle, and Warwick Castle; and little did he then dream that he should ever have an opportunity of saying that the stones of Carisbrook Castle contained a species of fresh water fish long extinct; or that, in the distant progress of time, he should have to assert that the Castle, the Collegiate Church, and the town of Warwick, were built upon a stratum utterly unknown to English geologists. Ten years ago he had obtained certain specimens from Guy's Cliff, which he had cherished up among his masses of ignorance, and stored amidst difficulties, in the hope that some ray of light might dissipate the darkness which enshrouded them, and enable him to acquire some accurate information respecting them. Within the last two hours that darkness had been dispelled, and he was able to say that at Guy's Cliff he had discovered an extinct species of animal never before found, and that those portions of rock which were before him on the table, were from a quarry, the name of which had never been uttered in England. Another discovery which he had made was, that the town of Leamington rested on the remains of animals which had existed in other times; and this fact was not hastily acquired, but was founded on strictly logical deductions. It was indeed true, that under the foundations of houses at Leamington (where there had been previously one immense lake) there were to be found the remains of elephants, hippopotamuses, hyænas, tigers, buffaloes, and a string of twenty other animals which he could enumerate."

**GEOLOGICAL SOCIETY, NOV. 2.**—Mr Lyell, President, in the chair. This Society commenced its meetings for the ensuing session. An elaborate paper (the first of a series) was read by Mr Hugh Edwin Strickland, F.G.S., who has recently returned from Asia Minor. The details of the paper were principally confined to the author's observations made during a winter's residence in Smyrna; and two excursions, one into the valleys of the Meander and Cayster, and the other from Constantinople to Smyrna.

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE.—THE ELEPHANTS.

THE Elephants constitute a genus belonging to the order *Pachydermata*, and are characterised by their vast size, in which they excel all the terrestrial Mammalia, their long flexible proboscis, forming an instrument of prehension as well as an organ of smell, and their large recurved tusks. Their most distinctive character, however, as Cuvier remarks, is to be found in their grinding teeth, of which the body is composed of a certain number of vertical plates, each formed of bony substance, enveloped with enamel, and connected by a third substance, named cortical. These grinders succeed each other, not vertically, as our second or permanent teeth succeed the first or milk teeth, but from behind forwards, so that in proportion as a tooth is worn down, it is pushed forwards by its successor. An Elephant may thus have one or two teeth on each side of each jaw, according to the period of growth. The first teeth have comparatively few plates. Some individuals are said to change or renew their grinders as many as eight times; but the tusks are not renewed more than once.

Two species only exist at the present day, one belonging to India, the other to Africa; but the bones of another occur, buried in diluvium in many parts of America, as well as the old continent.

Tooth of the Indian Elephant.

Tooth of the African Elephant.

Fig. 1.—THE INDIAN ELEPHANT, *Elephas Indicus*, is distinguished from the African species, by the following external characters:—The head is oblong, the forehead concave, the crown or face of the grinding teeth marked with transverse, parallel, undulating bands, the ears, although very large and pendulous, proportionally smaller than in the next. It has four nails or hoofs on the hind feet. The colour is generally dark brownish-grey, but varies considerably, and sometimes, although very rarely, albino individuals are met with. It inhabits India and the adjacent islands, where it has been domesticated from time immemorial. But it is remarkable that the species has never been propagated in captivity, and all the individuals subjected to man have been caught in the woods and jungles. The use of the ivory of the tusks for handles for knives, musical and mathematical instruments, plates for miniatures, billiard balls, and toys, gives rise to a great annual destruction of these animals, so that it is a matter of wonder that the race has not been exterminated. Although the docility and sagacity of the Elephant has been greatly exaggerated, they are yet probably superior to those of any other animal excepting the Dog.

Fig. 2. THE AFRICAN ELEPHANT, *Elephas Africanus*, has the head round, the forehead convex, the ears excessively large, so as sometimes entirely to cover the shoulder, and the crown of the grinding teeth marked by rhomboidal or diamond-shaped ridges, by which they are readily distinguished from those of the Indian species. It has frequently only three nails on the hind feet. The colour is lighter than that of the Indian Elephant, generally yellowish-brown, sometimes reddish. It inhabits Africa, from Senegal to the Cape of Good Hope. The tusks are larger than those of the Indian species, and in the female are nearly of the same size as in the male. Although it is probable that the African Elephant was the species subjected by the Carthaginians, it is not now any where domesticated.

#### DESCRIPTION OF THE PLATE.—THE TANAGERS.

THE Tanagers are a family of Birds peculiar to America, and belonging to the order *Passeres* of Cuvier, or *Insectores* of many other naturalists. They are in some respects nearly allied to the Finches and Buntings, although by the author just referred to placed among the Dentirostres. The bill is conical, short, pentagonal at the base, its dorsal outline arched. The wings are of moderate length, and sharp, the tail rather short, and even or slightly forked. Many of the species are remarkable for the brilliancy of their colours. In their manners they resemble the Finches, and live upon seeds and berries, as well as insects.

Figs. 1 and 2. THE SUMMER RED-BIRD.—*Tanagra aestiva*. The male of this species is of a rich vermilion hue, the female yellowish-brown above, yellow beneath. It inhabits South America and the United States, being found plentifully in the warm season in Florida and the Carolinas, although it seldom proceeds farther north than Boston. It feeds principally on insects, especially coleoptera, which it pursues on the wing, seldom alighting on the ground.

Figs. 3 and 4. THE SCARLET TANAGER.—*Tanagra rubra*. The male is equally distinguished for the brilliancy of its plumage as that of the preceding species, while the female is of a plain green tint above, and yellow beneath. It migrates from South America into the United States, proceeding as far as Canada, feeds on large winged insects and berries, lives chiefly in the depth of the woods, rarely approaching the habitations of man, and returns southward about the end of August.

Fig. 5. THE LOUISIANA TANAGER.—*Tanagra Columbiana* of Wilson, *T. Ludoviciana* of Bonaparte. This species was discovered in Louisiana by Lewis and Clark, in their expedition to the Pacific Ocean. Only a few imperfect skins were obtained by these travellers, and little more is known of its history than that it inhabits the extensive prairies between the territories of the Osage and Mandan Indians.

BATS.—Although not many years ago, the number of Bats known to occur in Britain amounted only to six, there are at present described in our more recent works on the Zoology of this country not fewer than sixteen species. The characters of these are briefly given in Jenyns' Manual of British Vertebrate Animals, and more fully in Mr Bell's beautiful work on the British Mammalia, of which six numbers have appeared. Many of the species have been found only in the southern counties of England; and it is somewhat remarkable, that hitherto the species observed in Scotland do not exceed three at most. The common bat of this country is the Pipistrelle, *Vespertilio Pipistrellus* of Gmelin and Desmarest, although, previous to Mr Jenyns' researches, it was considered as the *V. murinus* of Linnæus, a much larger species, which has also been found in England. The Pipistrelle we have determined from species obtained in various parts of the south of Scotland. The only other species which we have hitherto met with, north of the Tweed, is the *Plecotus auritus*, the Long-eared Bat, which in some places is nearly as plentiful as the Pipistrelle. Dr Fleming, besides these, mentions the *V. emarginatus* as having been found in Fife; but it is probable that the information is not to be depended upon, especially as the characters which he gives are vague, and equally applicable to the Pipistrelle, and as he considers the *V. murinus*, which is the Pipistrelle, to be the common Bat, although that has not been found in Scotland. The determination of our Scottish Bats is therefore a desideratum; and we shall feel obliged for the communication of specimens.

PECULIAR AFFECTION OF GALLINULES.—The Water Hen, *Gallinula Chloropus*, and the Corn Crane, *G. Crex*, are both subject to an affection, apparently resulting from terror, which some observers have attributed to epilepsy, and others to a feigned semblance of death. We remember once to have caught a Water Hen, which fell to the ground from fright induced by a shot, although it was not in the least injured, and after carrying it home and keeping it for a night, allowing it to escape next morning, when it flew off with great speed. On another occasion, having fired at and missed a Corn Crane, we were surprised to see it fly directly out to sea and alight in the water, where it floated buoyantly, and seemed indisposed to rise again. Unfortunately for it, a large black-billed Gull, *Larus marinus*, which happened to be flying along the shore, observed it, and descending with a scream, caught it in its bill, and carried it off. We have caught the Corn Crane alive, and have known the same feat performed more than once, in the Hebrides, where that bird is very common. In the sixth number of this Journal, a case of feigned death is related; but we are of opinion, judging from the timidity of this bird, that the phenomena there described could have resulted only from terror.

**THE CUCKOO.**—In a paper, by Mr E. Blyth, on the species of Birds observed near Tooting, Surrey, published in the Magazine of Natural History for December 1836, the following interesting particulars relative to the Cuckoo are given. It often arrives in the country several weeks before its well known cry is heard. Both its notes are common to the two sexes. The egg is found in a great variety of nests, both of granivorous and insectivorous birds; but, in the inclosed districts, it is most frequent in that of the hedge dunmuck, and not rare in the field lark's; whilst, on the open commons, the meadow pipits' and wagtails' nests most usually receive it, and not unfrequently that of the whinchat. Having spared no pains to investigate the economy of this interesting bird, I am now enabled to speak with confidence on most points on which I formerly was doubtful. The species both arrives and departs in flocks, though some of them migrate singly. The adults change the clothing plumage, and also the tail, during their stay with us; but retain the quills to bear them on their migratory journey, the barred markings on the sides of the neck are exhibited in the new feathers which the adult females put forth at the close of the summer, or rather a little after midsummer; and appear, therefore, to be a permanent characteristic of the sex; whereas Mr Selby states that "the female differs in no respect from the male." The young of the year do not change a feather till after they have left us. Unlike many other species with which I am acquainted, the females often continue to lay while in deep moult. They deposit, on the average, five eggs in the course of a season, rarely more; and these, judging from the result of numerous experiments which I have instituted, are not unfrequently ejected by the birds to whose fostering care they are entrusted; hence, I believe, the disproportionate scarcity of their occurrence. A considerable period intervenes between their successive deposition, during the lapse of which the female Cuckoo instinctively watches the proceedings of birds that are carrying about building materials; the time her egg requires to be matured for laying, being at least equal to that which the majority of smaller birds consume in the process of nidification. That she cannot, however, much protract the time of disburthening herself, as has been suggested, when the egg has been received into the oviduct, is sufficiently proved by the fact of her sometimes laying into an unfinished nest. There is no division of her eggs into separate lots, as in the case of birds which incubate their own; a fact which might, indeed, have been suspected *a priori*, seeing that no purpose could be effected by such an arrangement. In point of fact, each separate consecutive egg is analogous to a lot in other species. The remarkable deviation of the Cuckoo from the general habit of the feathered race in confiding its progeny to the care of strangers, is dependent on a peculiarity of the vascular system, and particularly on the maintenance of those blood-vessels which supply the parts concerned in the development of the eggs; in consequence of which, each successive egg requires so long a time to become fit for deposition, that they could not be incubated simultaneously. Even when developed, they are, from the same cause, remarkably small for the size of the bird; which, however, adapts them to that of the nests into which they are intruded. I cannot suppose that this peculiar conformation is intended merely for the purpose of retarding the growth of the egg, though this effect is unquestionably occasioned by it; it must rather have reference to some other peculiarity of the bird's habits which we have yet to discover. It is certain that the maternal feelings of the Cuckoo are not quenched, astonishing as this may appear. Mr John E. Gray, of the British Museum, informs us that he has himself seen a Cuckoo, day after day, visit the nest where one of its offspring was being reared, and which it finally enticed away from its foster parents! I had previously heard of analogous cases, but was disposed to regard them as fabulous, until corroborated by so paramount an authority. Since I have proceeded thus far with the Cuckoo's history, I may add that, although caterpillars form its principal subsistence, it feeds likewise on snails and various fruits, and that it is quite true that both sexes devour birds' eggs, as well as callow broods. Of the numerous cases I have now accumulated of the occurrence of the Cuckoo's egg, not one has been met with wherein it could not have been laid into the nest. The egg of the Cuckoo is most commonly found alone, or together with less than the average number of those of the species to which it is confided. I have one instance in which a young Cuckoo was found, half-fledged, in the same nest with two hedge dunmucks of equal age; which fact I can only account for by supposing that the interloper was weak and sickly at the time of its exclusion, and remained so till the instinctive propensity to oust its companions had entirely dissipated, as we know to be the case. It was, however, apparently quite healthy when discovered.

On this communication of Mr Blyth's we have a few remarks to offer. He alleges that in the Cuckoo there is no division of the eggs into separate lots, as in the case of birds which incubate their own; but neither is there such a division in these birds; and we are disposed to demand the facts on which Mr Blyth's results are founded, before we can give entire credence to the latter. The organs, moreover, are not smaller than in many other birds, nor differently supplied with blood-vessels. One of the most curious circumstances relative to the organization of the Cuckoo is seen in the stomach, of which the inner coat is generally found stuck full of the hairs of caterpillars, disposed in a circular manner, determined by the action of the muscular coat.

**MUSIC OF SNAILS.**—In the first number of the Naturalist is the following communication on this subject:—"There is a poetical notion that oysters, amongst other gentle qualities, love minstrelsy; and the fishermen, in some parts, 'sing to charm the spirits of the deep,' as they troll their dredging nets; for

"The Herring loves the merry moonlight;  
The Mackerel loves the wind;  
But the Oyster loves the dredging song;—  
For he comes of gentle kind."

These lines gave rise to a communication from a young lady, which I will send you. Perhaps some of your readers may confirm the supposition of the Snail's musical capabilities. She says.—"One evening I kneeled upon the window seat, when it was nearly dusk, and heard a soft musical sound; not a humming or murmuring, but a truly musical tone. I saw a snail, and, having a desire to annihilate those de-

stroyers of fruit and flowers, took it from the window. I had silenced the music! I recollected what I had heard, and felt a sort of pang." We have heard the same sort of sound emitted under similar circumstances, and believe it to be produced simply by the minute vibrations produced in the glass by the action of the muscular foot of the animal. A similar sound may be produced by bringing the wet finger along a pane. As to Snails, or other molluscous animals, having the faculty of emitting sounds in a manner analogous to that of the higher animals, it is entirely out of the question.

**LEPES ANATIFERA.**—The Rev. W. B. Clarke relates, that as one of the Poole pilot-boats was cruising, on the 22d October, in the Channel, the crew picked up, about four leagues from land, a bottle closely corked, on which three congregations of Lepades have rooted themselves. The pedicle or fleshy stalk was fastened to the bottle by a substance in appearance very like plaster of Paris. He conjectures that it was thrown overboard in the warm latitudes about the Gulf Stream, and that it has been floating across the Atlantic, in the set of the current, towards our shores.

**FISHES CAUGHT IN A WHEEL-BARROW.**—The same gentleman relates, that on coming out of Cherbourg, on Wednesday, September 21, when off Fort de Querqueville, about seven miles from land, he picked up a wheel-barrow, floating in the tideway, which, by the marks upon it, had evidently been washed from the breakwater, and had been in the water several days. "It was floating bottom upwards; and, on turning it to get it on deck, we found three John Dorys caught between the planks. They were, it is true, extremely small; but their position there showed that small fish are glad to get in (as Paddy said, when he fished under the ditch of Dublin Bridge) 'out of the wet,' and to shelter themselves from the violence of the surface waters."

**IRREGULAR GROWTH OF HORNS AND CLAWS.**—The horns of animals have a definite form and direction, according to the different species, and as they increase by the addition of matter to their bases, which is continually secreted, they enlarge indefinitely during the animal's life; but, in their regular state, preserve a direction which prevents them from impeding the actions necessary for the well-being of the individual. Thus, the horn of a ram may attain a very great size, but its curves being regular, it is of no inconvenience to the animal. Should any disturbing cause, however, alter the natural direction of the horn, it assumes an abnormal and frequently fantastic form, and sometimes runs into the face or neck, in which case it requires to be partially cut off. An accidental division of the horn of a young animal will also cause it to grow in a cleft form, which is the case with Sheep that are said to have three or four horns. In these cases there are never, in fact, more than two, but these being split, and running out in a divaricating manner, they seem to be multiplied. The claws of quadrupeds and birds grow in the same manner as horns. Indeed, they are precisely of the same nature. But their growth is checked by pressure and use, the latter of which also tends to wear them down. Thus, although in the natural state, the hoofs of a goat, however old it may be, do not acquire an inconvenient length, because they are constantly worn by being rubbed against the rocks and ground; yet, when the animal is kept in soft pasture ground, or in a house, where it cannot obtain its natural exercise, they often attain a great length, and curve upwards like a Turkish slipper. The claws of confined eagles, and of all cage birds, manifest the same tendency; and in birds of prey the point of the upper mandible sometimes elongates and curves so as to prevent the opening of the mouth. Examples of preternatural growth of the nails of the human subject are common in Medical Museums, but in these cases there is always disease of the secreting organs; yet one may easily imagine to what length the healthy nail would soon grow, when he may see that in a fortnight its free extremity attains a length of more than two-twelfths of an inch.

**HYBRID GROUSE.**—A bird, presenting characters intermediate between those of the Blackcock and Red Grouse, was lately obtained by Mr Fenton, Preserver of Animals in Edinburgh, and is now in the possession of Mr W. Smellie Watson, of that city. It was much emaciated, but in perfect plumage. The following description was taken from it in its recent state:—"In form and proportion it is similar to a female Black Grouse. The bill is of the same form as in that bird. The supra-ocular membrane resembles that of the Red Grouse, having a thin, free, fringed margin, which is not the case with that of the Blackcock. The feathers are generally oblong, broadly rounded, and have a large tufted plumule. The tail is complete, slightly forked, as in the female Black Grouse, but of only sixteen feathers, as in the Red Grouse. The quills are twenty-six. The tarsi are feathered all round, without a bare space behind. The toes are also feathered a third down, as are the interdigital membranes, and the plumage of these parts is as bushy as in the Red Grouse. They are margined with long linear scales, as in the Black Grouse. The claws are very long, arched, with thin parallel edges, like those of the Red Grouse and Ptarmigan. The bill is brownish-black; the supraocular membrane scarlet; the toes light brown; the claws brownish-black. The upper part of the head is minutely mottled with brownish-red, brownish-black, and grey; the hind neck with a larger proportion of grey. The rest of the neck is black, with a tinge of reddish-purple. On the throat the feathers are margined with white, on the sides of the neck obscurely barred with brownish-red. On the lower parts generally the feathers are black, tipped with white; those of the sides banded with red, of the lower part of the tail black, with a large terminal space. The lower surface of the wing and the axillary feathers are white. The upper parts generally are very minutely undulated with brownish-black and brownish-red, the feathers having very narrow terminal bands of white. The wing feathers and secondary quill-coverts are similar, as are the secondary quills, which are tipped with greyish white. The primary quills, the coverts, and alular feathers, greyish-brown; the outer edges of the primaries mottled with white. A white spot appears at the axilla, but there is not a white band on the wing as in the Black Grouse. The tail is black, the two middle feathers very obscurely mottled with reddish; the eight middle narrowly tipped with white. The tarsal feathers are greyish-white, those on the outer side mottled with red. The length 20½ inches; extent of wings 31. On inspecting the body, the cause of emaciation was obvious. The trachea and bronchi were much inflamed; the left

lung perfectly sound, but the right completely gorged with blood. The rectum was greatly dilated and filled with a substance resembling putty, being a deposition of uric acid, which completely obstructed the passage. In form and size this bird resembled a female or a young male Black Grouse, to which it was also similar in its internal organization. In plumage and colouring, it was as exactly intermediate between the two species as could be imagined. Hybrids are alleged to be occasionally produced between the Pheasant and Black Grouse; but we have not seen a specimen, and have reason to think that the birds supposed to be of this character were merely young Blackcocks.

ANECDOTE OF A PARROT.—A reviewer in the Naturalist relates the following anecdote:—"We feel confident that in various instances Parrots have intelligence enough to understand, if not the exact meaning of the words they utter, the *subject* to which they refer. We know an old lady, whose feet were so excessively tender as almost to preclude her from walking, and hence she always went abroad in her Bath chair. She had a favourite Parrot, who, when the tea equipage was placed upon the table, was invariably taken out of his cage by the footman, and placed on the board, as a proper accompaniment to the antiquated china. Poll, no doubt an attentive observer, had long perceived there was 'something rotten in the state of Denmark,' and hence, whenever his mistress failed to dole out what he considered his fair ration, he would, in a threatening manner, exclaim, 'Peck your toes, Madam.' As he sometimes flew from his position, to put his threat into execution, the old lady, to avoid the assault upon her toes, indulged him with a further allowance, which, of course, only led to increased insolence on his part, and the threat of 'Peck your toes, Madam,' was still oftener reiterated. At length, one day Poll having cried 'Wolf,' as he thought, without that attention being paid to the subject which it demanded, proceeded to suit the action to the word with such effect, that the old lady was compelled to scream loudly for help, Poll having administered a doze of toe-pecking that put her in dreadful pain for some days. This was too much to be borne, and the culprit received sentence of transportation. The footman was directed to sell or give him away. Now, though in this case we think it highly probable that the mischievous threat had been taught the bird by the servants, yet Poll must have seen the effect it produced in occasionally increasing his allowance, though doubtless, he did not calculate upon the final *dénouement*."

#### BOTANY.

RARE PLANTS FOUND IN JERSEY.—Mr William Christy, jun. F.L.S. &c. has communicated to the public, through the medium of London's Magazine of Natural History, a list of rare plants collected by him in the Island of Jersey, in October 1836. The greater part of the coast, he states, is composed of granite cliffs, too much washed by the sea to admit of much vegetation, except in some of the sheltered bays. The grassy slopes above them afford several very rare plants. The island is remarkably deficient in streams or pools, as well as in salt marshes; nor are there many inland rocks. The greatest number of rare species is afforded by the sandy parts of the shore, and by a great deposit of sand drift in the parish of St Brelade, nearly a mile distant from the sea.

*Allium sphaerocephalum*. By the road between Beaumont and La Haule.

*Asplenium lanceolatum*. Common.

*Asplenium marinum*. Cliffs at Plemont Point and Havre Giffard.

*Borago officinalis*. Roadsides and orchards.

*Carlina acaulis*. Common.

*Calystegia Soldanella*. Sands at Grève de Lecq.

*Centranthus rubra*. Rocks and walls of Fort Regent.

*Crithmum maritimum*. La Corbiere and Plemont Point.

*Cotyledon umbilicus*. Common.

*Cyperus longus*. St Peter's Valley, near St Brelade's Church.

*Dianthus prolifer*. Near St Ouen's, Quenvais.

*Echium violaceum*. Quenvais. Mont le Veau.

*Elymus arenarius*.

*Erodium cicutarium*, white-flowered. St Aubyn's Bay, Fort Quenvais.

*Erodium maritimum*. Grève de Lecq.

*Erodium moschatum*. St Aubyn's Bay, Fort Regent.

*Euphorbia Portlandica*. Sea shore, all round the island.

*Euphorbia paralias*. St Aubyn's Bay.

*Feniculum vulgare*. Near the sea; not rare.

*Glavicum flavum*. Quenvais, St Ouen's, Brelade's and St Aubyn's Bays.

*Gnaphalium luteo-album*. Near Petit Port.

*Helianthemum guttatum*. Between La Corbière and Noirmont Point.

*Hypochaeris glabra*. Grève de Lecq.

*Iris fatidissima*. Sea banks near La Haule.

*Juncus acutus*. Quenvais, St Ouen's Bay, and Petit Port.

*Linum angustifolium*. Common.

*Lotus angustissimus*. Between La Haule and Quenvais.

*Matthiola sinuata*. St Ouen's Bay, Petit Port, St Aubyn's Bay, Quenvais.

*Marrubium vulgare*. St Brelade's Churchyard, waste places.

*Mentha rotundifolia*. Above La Haule.

*Mespilus germanica*. Hedges between Roselle and Gorey.

*Neottia spiralis*. Quenvais.

*Polycarpon tetraphyllum*. Common in Gardens, &c.

*Petroselinum sativum*. Mont Orgeuil Castle.

*Scirpus Savi*. Between Quenvais and St Brelade's Bay.

*Scilla autumnalis*. Very common.

*Sedum Anglicum*. Common.

*Silene Anglica*. Common.

*Silene conica*. Quenvais.

*Silene nutans*. Near St Ouen's, St Aubyn's.

*Senebiera dily na*. St Helier's, St Aubyn's.

*Solanum nigrum*, with red berries. Quenvais, Petit Port.

*Scrophularia Scorodonia*. Common.

*Statice plantaginea*. Quenvais, St Brelade's Bay.

*Sibthorpia Europaea*. Above La Haule.

#### GEOLOGY.

ESTIMATE OF THE PROBABLE TEMPERATURE IN EUROPE DURING THE TERTIARY PERIODS.—M. G. P. Deshayes alleges that fossil conchology, studied in a logical manner in its various relations both as to zoology and geology, may become a powerful means of bringing this latter science to perfection. Very numerous observations, repeated upon more than eight thousand species of recent and fossil shells, and more than sixty thousand individuals of all regions, have enabled him to perceive important consequences with regard to an approximate estimate of the temperatures of the geological periods, concerning which man cannot cite his historical annals, since he then had no existence upon the surface of the earth. The animals best adapted to indicate temperature are those which, possessed of but small powers of motion, cannot withdraw themselves periodically from the changes of the seasons, and are obliged to sustain all their influence in the places which have given them birth. The greater number of the mollusca and zoophytes are of this kind. At the present day, certain species of the former are found to be peculiar to certain latitudes, some inhabiting the frozen ocean, others the tropical seas; and from the examination of these it is considered possible eventually to be able to reply to such questions as this: A series of species being given, to point out the climate of the spot from which they have been procured. From comparing all the known species of recent shells, with all those which are brought from the tertiary strata of Europe, the following results have been obtained:—

1. The tertiary strata of Europe contain no species which can be identified with the secondary strata lying beneath them.

2. The tertiary strata are the only ones which contain fossil specimens of existing species.

3. The fossil shells which can be identified with living species, are more numerous in proportion as the strata are more recent, and *vice versa*.

4. Constant proportions (3, 19, 52 per cent.) in the number of recent species determine the age of the tertiary strata.

5. The tertiary strata are superposed one upon another, and not parallel, as was at first imagined.

6. They ought to be divided into three groups or stages, according to their zoology, the shells which they contain indicating the temperature existing at the period of their deposition.

We are unable here to follow the author in the development of his ideas; but from what he states, it appears to him, that the following conclusions may be drawn:—

1. The first tertiary period took place under an equatorial temperature; and, according to all probability, one many degrees hotter than the present temperature of the equator.

2. During the second period, the beds of which occupy the centre of Europe, the temperature has been similar to that of Senegal and Guinea.

3. The temperature of the third period, at first a little more elevated than ours in the basin of the Mediterranean, has become similar to that which we experience. In the north, the species of the north are fossil; in the south, those of the south.

Thus, since the commencement of the tertiary strata, the temperature has been constantly diminishing. Passing, in our climates, from the equatorial to that which we now enjoy, it is easy to measure the difference. No doubt, naturalists have been able theoretically to conjecture *a priori* these changes of temperature; but it is curious to see their conjectures confirmed by a science which no one had thought of directing towards this end.

#### METEOROLOGY AND HYDROGRAPHY.

METEORIC STONES.—Several substances of this nature have recently been examined by Professor Berzelus, who has ascertained that meteoric stones are properly speaking minerals, and is of opinion that since they cannot be formed in the atmosphere, which does not contain their component parts, nor be ejected from volcanoes on the earth's surface, as they fall every where, they must be derived from some other body having volcanoes. The nearest to us is the moon, which has gigantic volcanoes, and is destitute of atmosphere to retard the masses ejected. The result of his investigations as to the composition of meteoric substances are the following: Two kinds fall on the earth. One of these is rare, for only three *aérolites* belonging to it have been remarked, viz. those of Stannern in Moravia, and of Jonzac and Juvenas in France. They contain no metallic iron; the minerals of which they consist are more decidedly crystalline, and magnesia does not form a prevailing component part in them. The second kind includes the other very numerous meteoric stones which have been examined, and which are frequently so similar in appearance, that they might be supposed to have been broken from one piece. They contain ductile metallic iron in variable quantity. It being assumed that these substances come from the moon, we may therefore say that meteoric stones come from only two different volcanoes, of which the one either ejects more abundant masses, or sends them forth in such a direction that they reach us more frequently. Such a state of things corresponds perfectly with the idea that a certain portion of the moon has the earth constantly in the zenith, and that all its ejected masses which are thrown out in a straight line are directed by it towards the earth, whither, however, they do not proceed in a straight direction, since they are also subjected to that motion which they previously possessed as part of the moon. If it is this portion of the moon that sends us meteoric blocks of iron, and if the other parts of the moon do not abound so much in iron, we see a reason why this point should be constantly turned towards the magnetic terrestrial globe. The mineral matter of meteoric stones is composed of the following substances:—

1. *Olivine*, containing magnesia and oxide of iron, and white or greyish, but seldom yellow or green. It is separated by being heated with acids, and dissolving the silica in boiling carbonate of soda. There then remain—2. *Silicates of magnesia, lime, oxide of iron, oxide of manganese, alumina, potash, and soda.* 3. *Chromate of iron*, which is always present in both kinds, and is the cause of their greyish-black colour. 4. *Oxide of tin*, containing traces of copper. 5. *Magnetic iron*, probably not contained in all. 6. *Sulphuret of iron*, which exists in all. 7. *Native iron*, not pure, although very ductile, but containing carbon, sulphur, phosphorus, magnesium, manganese, nickel, cobalt, tin, and copper.

TRANSPARENCY OF THE SEA ON THE COAST OF NORWAY.—Nothing, says Sir A. de Capell Brooke, in his *Travels in Norway*, can be more surprising and beautiful than the singular clearness of the water of the Northern seas. As we passed slowly over the surface, the bottom, which here was in general a white sand, was clearly visible, with its minutest objects, where the depth was from twenty to twenty-five fathoms. During the whole course of the tour I made, nothing appeared to me so extraordinary as the utmost recesses of the deep thus unveiled to the eye. The surface of the ocean was unruddled by the slightest breeze, and the gentle splashing of the oars scarcely disturbed it. Hanging over the gunwale of the boat, with wonder and delight I gazed on the slowly moving scene below. Where the bottom was sandy, the different kinds of asteriæ, echini, and even the smallest shells, appeared at that great depth conspicuous to the eye; and the water seemed, in some measure, to have the effect of a magnifier, by enlarging the objects like a telescope, and bringing them seemingly nearer. Now creeping along, we saw, far beneath, the rugged sides of a mountain rising towards our boat, the base of which was hidden some miles in the great deep below. Though moving on a level surface, it seemed almost as if it were ascending the height under us; and when we passed over its summit, which rose in appearance to within a few feet of our boat, and came again to the descent, which on this side was suddenly perpendicular, and overlooking a watery gulf; as we pushed gently over the last point of it, it seemed almost as if we had thrown ourselves down this precipice, the illusion, from the crystal clearness of the deep, actually producing a sudden start. Now we came again to a plain, and passed slowly over the submarine forests and meadows, which appeared in the expanse below, inhabited, doubtless, by thousands of animals, to which they afford both food and shelter,—animals unknown to Man; and I could sometimes observe large fishes, of singular shape, gliding softly through the watery thickets, unconscious of what was moving above them. As we proceeded, the bottom became no longer visible, its fairy scenes gradually faded to the view, and were lost in the dark green depths of the ocean.

#### MISCELLANEOUS.

MANUFACTURE OF GUN-FLINTS.—In the last number of the *Edinburgh New Philosophical Journal*, is a paper on this subject, communicated by Dr James Mitchell, of which the following is a condensed account:—Brandon, in Suffolk, is the only place in England in which gun-flints are made to any considerable extent, and it is said that none are now manufactured in France, or, in fact, in any part of Europe; yet the seventy or eighty men employed could barely make a living by their trade, so much had it been impaired by the cessation of war, and the invention of percussion caps. The masses of flint employed are obtained from a common about a mile south-east of the town, by sinking a shaft about six feet, then proceeding three feet horizontally, and thus alternately until they come to a floor of flint, sometimes going to the depth of about thirty feet. The blocks are handed up from stage to stage, a man being placed about half-way between each to receive them. It is not more than forty years since the present mode of making flints was introduced from France. The workman, called a cracker, who is seated on a chair, has a thick piece of leather strapped to his left thigh, and over it he straps a piece of iron. He takes a large piece of flint-stone, and breaks it into fragments of about two pound weight. Then taking a fragment in his left hand, and applying it to the iron plate on his thigh, he strikes out pieces at short distances from each other. He then strikes with his hammer on the parts of the edge of the flint, which are now separated from the rest, and the effect of the blow, together with the reaction on the plate of iron on his thigh, causes a flake of about three or four inches in length to come off, there being on each side a conchoidal fracture. Of the flakes thus obtained from the mass of flint, some are large and others small. The workman has before him three small casks with the upper end open; into one of them he drops the large flakes, into the second the flakes of a less size, and into the third the flakes of the smallest size. The refuse is thrown into a fourth cask, and is from time to time carried out of doors, and thrown into a heap of rubbish. The three casks with the flakes are intended each of them for a separate workman, who has to finish them into flints, single-barrel flints, double-barrel flints, and pistol flints. The workmen who divide the flakes into flints are called nappers, and one cracker suffices to keep three of them employed. A napper has before him a block, not unlike a butcher's block, upon which a piece of iron is nailed, from which rises a thin piece of iron three inches in length, and only a sixth of an inch in thickness, and brought to a coarse edge. He uses a hammer, which is merely a plate of steel, extending two inches on each side of the handle, and an inch in breadth, and not above a sixth of an inch in thickness. He takes into his left hand one of the flakes, lays it over the little anvil on the block, and with his hammer breaks it into three or four flints. All that he has to do after that, is to see which edge will be best for the flint, and from the other he breaks a little off, and the whole is complete. At Brandon, in the present depressed state of the trade, the best musket-flints, which at one time were sold for two guineas a thousand, now bring no more than from seven to eight shillings.

LUMINOUS APPEARANCE AT SEA OFF THE SHETLAND ISLANDS.—A curious luminous appearance at sea is mentioned in the following extract from a letter to Mr Stevenson, engineer, by the keeper of the Sumburgh Head Lighthouse:—“*Monday, September 19, 1836.*—The herring-boats went out through the night. There came on a severe gale of wind from the north-east, which drove them from their nets, and scarcely any one of them got into their own harbours. Mr Kay's

fishermen lost 180 nets, Mr Bruce of Whalsey lost 114, and a great many of the poor men lost the whole of their nets. The fishermen also informed me, that upon the same night, there appeared to them a light, which greatly annoyed them. It appeared to them like a furnace standing in the water, and the beams of the light stood to a great height. It became fainter on the approach of day, and at length vanished away by day-light. It continued for two nights. It stood so near some of the boats that the men thought of cutting from their lines to get out of its way.” *Edin. New Philos. Journal, January 1837.*

NEW METHOD OF DISENGAGING HEAT.—By projecting upon a fire a mixture of water and oily matters in a certain proportion a flame is produced, whose heat is extremely intense. If the water be in excess, the flame languishes; or, if in too small quantity, a smoke is produced. For 1 measure of tar it is necessary to employ  $1\frac{1}{2}$  of water. 15 lbs. of oil of turpentine mixed with 15 lbs. of water, and projected upon 25 lbs. of Newcastle coal, produce as much heat as 120 lbs. of this coal.

POISONING BY ARSENIC CURED BY HYDRATED TRITOXIDE OF IRON.—A remarkable case of this description is recorded in the *Gaz. Med. de Paris* (22d August 1835), by Monod. The subject of it was a hair-dresser, thirty-five years of age, who, in a paroxysm of delirium tremens, swallowed a drachm and a half of white oxide of arsenic. Half an hour afterwards the antidote was given to him, suspended in water, and he drank in twelve hours all the Tritoxide produced by the decomposition of five drachms of the Tritrosulphate of Iron. He had no violent colic, and twenty hours afterwards experienced scarcely any uneasiness.

#### REVIEWS.

*British Song Birds; being Popular Descriptions and Anecdotes of the Choristers of the Groves.* By Neville Wood, Esq., author of the *Ornithologist's Text-Book.* London: John W. Parker, West Strand. 1836.

THIS work contains, as its title announces, popular descriptions of the habits of seventy-three of our smaller birds, all of which, however, cannot with propriety be considered as choristers of the groves. The information afforded appears to be for the most part derived from the author's personal observation, and, although not in general new, is yet communicated in a pleasing style, and in a manner not calculated to mislead the student. In fact, we give full credit to the author when he asserts, that “no one fact is stated, which has not been observed with my own eyes, excepting where other authorities are referred to, which is, in every case, done openly and fully;” and we commend him for his candour, which is favorably contrasted with the disingenuousness of some celebrated ornithologists, who profess to give nothing but their own, while almost every page is full of unacknowledged borrowings. A remarkable difference, too, between the present generation and the last, is the decided preference now given to actual rational information respecting habits and structure, whereas formerly histories of animals were confined to mere technical characters, so brief and unsatisfactory, that in cases of doubt we seldom find them affording any assistance. We believe that our distinguished countryman, Sandy Wilson, the quondam Paisley weaver and packman, was the founder of this modern school of ornithologists, who combine glowing descriptions with accurate details. Mr Wood's “*Song Birds*,” we are happy in being enabled, from having paid considerable attention to the subject, to recommend to all who are interested in this most interesting department of zoology, and more especially to young persons, for the “old chroniclers” are generally too wise to learn, and too knowing to allow merit to any not disposed to flatter themselves. The nomenclature, although strange to those who commenced their studies twenty years ago, is as good as the old; and, in truth, seeing that both are defective, the more innovations that authors make the better, for it will ultimately render it necessary to select unobjectionable names.

*London's Magazine of Natural History. New Series. Conducted by Edward Charlesworth, F.G.S. Monthly, 2s. London: Longman, &c.*

THIS popular periodical, which has greatly contributed to the extension of the study of natural history, is particularly valuable as a depository of facts and observations. It is not our intention to offer a formal review of its contents, which are of a very diversified nature; but we take this opportunity of recommending it to those who are devoted to the study of natural history, or who find pleasure in occasionally perusing the remarks and observations made by the students of that science. The new series commences with considerable spirit, and its first number contains several interesting articles. Among others, there is one by Dr Edward Moore, Plymouth, describing a new British fish, the *Peristodion Marmorat* of Lacepede and Cuvier, the *Trigla Cataphracta* of Linnæus. The learned editor gives a description and figure of *Voluta Lamberti*, a fossil shell of the “*crag*.” Mr Bowman endeavours to ascertain the age of the Yew by referring to actual sections of its trunk; Mr Bree offers observations on *Trochilium Crabroniforme*, the Lunar Hornet Sphinx; and Mr Blyth makes some interesting remarks on the Psychological Distinctions between Man and all other animals. The most amusing paper, however, is a review of “*The Naturalist*,” in which that rival periodical is represented to be entirely destitute of all merit, the articles in the first number being, generally speaking, “extremely lame, and written in a style which unavoidably forces upon the reader's recollection the idea of their being got up for the occasion, instead of being the spontaneous productions of those who are engaged hand and heart in the advancement of that science of which they profess to treat.” Our opinion of “*The Naturalist*” is somewhat different; and although we cannot bestow upon it all the praise that we could wish, we must yet do it the justice to recommend it as a performance creditable to its conductors and useful to the public. We shall, however, take another opportunity of discussing the merits of this periodical.

ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE WOLVES AND FOXES.

THE Wolves of the American continent are generally supposed to be of the same species as those of Europe; and Dr Richardson, who has had ample opportunities of observing them, although appearing to consider them as probably distinct, yet, in our present state of knowledge, thinks it preferable to view them as races or varieties. They are very numerous on the sandy plains between the sources of the Saskatchewan and the Missouri, as well as in all the northern regions of America, burrowing like the Fox, and bringing forth their young under ground. So strong a resemblance do they bear to the domestic dogs of the Indians, that a band of them has often been mistaken for the latter, and the howl of both species is so similar, that even an Indian sometimes fails to distinguish the animal by it. Several varieties are met with, characterised by differences in size and colour; of these, two are represented on the Plate.

Fig. 1. The Dusky Wolf, *Canis lupus, occidentalis, nubilus*. This variety is of a greyish-black colour, more or less tinged with brown.

Fig. 2. The Prairie Wolf, *Canis lupus, occidentalis, latrans*, of a light grey colour, white beneath, may be considered as a variety of the common Wolf of America, although it differs considerably in voice, size, and manners. Dr Richardson states, that on the banks of the Saskatchewan, these animals start from the earth in great numbers, on hearing the report of a gun, and gather around the hunter, in expectation of getting the offal of the animal he has slaughtered. They associate in greater numbers than the grey Wolf, burrow in the open plains, hunt in packs, and excel the other kinds in speed.

Fig. 3. The European Wolf, *Canis lupus*, was formerly generally distributed over the continent of Europe, but, owing to the progress of cultivation, is now confined to the wilder, wooded, or mountainous regions. In Norway, Sweden, and Russia, where they are still plentiful, and hunt the deer and other large animals in packs, they are usually of a light grey colour, and have a woolly fur, like that of the American Wolves; but in Germany and other parts they are generally brown, with coarser and shorter hair; while in the Pyrenees, a variety occurs of a brownish-black colour. The Wolf is, in all probability, the original of the Domestic Dog, of which several races, especially those found with the wild tribes of our own species, so nearly agree with it, that no real distinction can be pointed out between them.

Fig. 4. The Common Fox of Europe, *Canis vulpes*, generally of a yellowish-red colour above, greyish-white beneath, also exhibits considerable diversity in size and colour. Even in Britain, which, from its small size, might not be expected to be favorable to the production of varieties, there may be distinguished the Mastiff Fox, the Hound Fox, of which the figure is a representation, and the Cur Fox, the smallest and darkest of the three. The Common Fox is so well known, on account of his proverbial character of cunning and sagacity, as well as for the amusement which his chase affords to the aristocratical part of the community, that it is unnecessary here to describe his manners.

Fig. 5. The American Foxes exhibit nearly as many varieties as the Wolves, but are generally considered as belonging to a species distinct from that of Europe, and named *Canis fulvus*. The variety represented is the Cross Fox, *C. fulvus, decussatus*, so denominated on account of having a dark line down the back of the neck, crossed by another on the shoulders. Individuals often occur, so similar on the one hand to the Red Fox, and on the other to the Black, that the hunters are in doubt how to name them.

Fig. 6. The Black or Silver Fox, *Canis fulvus, argentatus*, is the rarest and most prized of all the varieties; its fur, on account of its fineness and glossy black colour, more or less tinged with grey or white, fetching six times the price of any other fur produced in North America. It inhabits the same districts as the next variety.

Fig. 7. The Red Fox, *Canis fulvus*, may be considered as the principal, or most common representative of the species, of which the two preceding are varieties. Its size is somewhat less than that of the European Fox, its eyes nearer, its ears shorter, its fur closer and finer, and its colour lighter. It burrows in summer, takes shelter in winter under a fallen tree, preys on the smaller animals of the rat family, but re-

jects no kind of animal food that comes in its way. It hunts chiefly by night; but is much inferior in speed to the English Fox, and is soon overtaken by a wolf or a mounted horseman. The fur of all the varieties of this species is valuable as an article of commerce, but more especially that of the Black Fox.

DESCRIPTION OF THE PLATE.—THE GNAT-CATCHERS.

THE Gnat-catchers have been separated, by Mr Swainson, from the Fly-catchers, between which and the Warblers they seem to be intermediate. The group is peculiar to America, and is composed of small birds, generally bright yellow beneath, and green, blue, or dusky on the upper parts.

Fig. 1. The Hooded Gnat-catcher, *Setophaga mitrata*, is very abundant in the southern states of North America, where it prefers low situations covered with canes or thick underwood, feeding on small winged insects, and returning southwards after the breeding season.

Fig. 2. The Green Black-capt Gnat-catcher, *Setophaga pusilla*, is an inhabitant of the swamps of the southern states, whence it takes its departure early in October.

Fig. 3. The Yellow-tailed Gnat-catcher, *Setophaga ruticilla*, male; Fig. 4. the Female; and Fig. 5. the Young. This species is found in the interior of the forests, on the borders of swamps and meadows, and in deep wooded glens, in most parts of the United States, which it visits early in summer, to return southward in autumn. It bears a great resemblance to the Redstart of Europe, and exhibits nearly the same habits, feeding on insects, which it pursues in the air, retiring to a tree or bush, and frequently jerking out its tail.

Fig. 6. Selby's Gnat-catcher, *Setophaga selbii*. Male. This species was named in honour of Mr Selby by its discoverer Mr Audubon, who met with only three individuals, which occurred in Louisiana. Its habits are similar to those of the other species.

Fig. 7. Bonaparte's Gnat-catcher, *Setophaga bonapartii*. This also was discovered by Mr Audubon, and named in honour of the Prince of Musignano.

Fig. 8. The small Blue-grey Gnat-catcher, *Setophaga carulea*; and Fig. 9. the Female. The beautiful and diminutive species here represented is a very dexterous fly-catcher, and, moreover, somewhat resembles in its manners the Titmouse, with which it occasionally associates. Like all the rest, it is a summer visitant of the United States.

THE SISKIN FOUND BREEDING IN SCOTLAND.—Mr Weir of Boghead, a most zealous observer of the habits of birds, has recently favored us with the following account of the breeding of the Siskin in the neighbourhood of Bathgate, in the county of Linlithgow: "About the end of May 1834, as I was returning from Bathgate, I was astonished at seeing, on the parish road between it and my house, a pair of Siskins feeding very greedily on the ripe tops of the dandelion. The head of the male was very dark, and the yellow on its wings uncommonly rich. I followed them for several hundred yards, being exceedingly anxious to discover their nest. In this, however, I did not succeed, as they flew off to a considerable distance, when I lost sight of them. I again and again renewed my search, but without success. A few days after this, two persons who were catching linnets with bird-lime in a small field belonging to me, were struck with the unusual chirping of young birds in a spruce which was planted in the middle of a very strong hawthorn hedge. When they were looking into the tree, in their order to discover what kind of birds they were, they immediately flew out of their nest. They appeared to have a resemblance to the female Siskin; but as they were ripe, it was found impossible to secure any of them. The nest was small, built on two of the branches, one side of it resting upon the trunk of the tree, at the height of about five feet and a half from the ground, and within twelve yards of the North Glasgow road. It was one of the best concealed nests I recollect of ever having seen; indeed, had it not been so, it would not have so long eluded the notice of some of our most celebrated nest-hunting youths, who were almost in the daily habit of passing and re-passing the place in pursuit of their favorite amusement. The old Siskins, with their young, were seen for two or three weeks afterwards in the immediate neighbourhood. Mr

Macduff Carfrae, bird-preserver in Edinburgh, who came out to pay me a visit, saw the same birds hopping among the branches of some elder trees, about the distance of a quarter of a mile from the place where they were hatched."

**RARE BIRDS RECENTLY FOUND IN BRITAIN.**—In the last number of the Magazine of Zoology and Botany, it is stated, on the authority of P. W. MacLagan, that a Hoopoe, *Upupa Epops*, was shot near Coyton in Ayrshire, on the 16th of October 1836. In the same journal, Mr Albany Hancock gives intimation of the occurrence of the following species: *Falco rufipes*; a male, shot on the Durham coast, between South Shields and Marsden Rocks, in the middle of last October. *Motacilla neglecta*; a male, shot a little to the west of Newcastle, on the 1st of May last. *Larus minutus*; a specimen in first plumage; killed at the mouth of the river Tyne, in September last.

**RARE BIRDS RECENTLY FOUND IN IRELAND.**—In the same periodical is an account, by William Thompson, Esq., of Belfast, of two specimens of *Sterna stolidus*; which were killed in 1830, between the Tusker light-house, off the coast of Wexford, and Dublin bay: also of a specimen of *Larus Sabini*, in the plumage of the first year; shot in Belfast bay, on the 18th September 1822, by the late John Montgomery, Esq., of Locust Lodge: and of two others; one shot in Dublin bay, the other in Belfast bay, in September 1834. It appears from the statement given by Mr Thompson, that Bewick's Swan is of more frequent occurrence in Ireland than the common wild Swan; whereas the reverse is the case in England.

**SHOWER OF FROGS.**—M. Pontus, professor at Cahors, recently addressed to the Academie des Sciences a communication relative to a shower of Frogs. In August 1804, he was travelling in the diligence from Albi to Toulouse, the weather being fine, and the sky without clouds. About four in the afternoon the vehicle stopped a few minutes at La Conseillère, three leagues from Toulouse, to change horses. Just as it was about to set off again, a very thick cloud suddenly covered the horizon, and thunder was heard. The cloud must have been at a very small height, for the drops of rain that fell were very large. It broke upon the road at the distance of a hundred and twenty yards from where they were. Two horsemen, who were coming from Toulouse, and had been exposed to the storm, were obliged to wrap themselves in their cloaks; but were much surprised, and even frightened, at finding themselves assailed by a shower of Frogs. They hastened onwards, and on meeting the diligence, gave an account of their adventure to the passengers. M. Pontus saw that there were still some small Frogs on their cloaks, which they shook off in their presence. The diligence soon reached the place where the cloud had burst, when the passengers became witnesses of the extraordinary phenomenon: the road, and all the fields on both sides of it, were strewn with Frogs, of which the smallest were of the size of at least a cubic inch, the largest nearly two inches, so that they must have been upwards of a month or two old: there were as many as three or four layers of them, and many thousands were crushed by the wheels and the horses' feet. Some of the passengers would have closed the coach-windows to prevent their entering, as they suspected, from their leaps, that they would. The vehicle proceeded for at least a quarter of an hour over this mass of living creatures, the horses trotting all the while.

**GUACHARO OF THE CAVERN OF CARIBE.**—The Guacharo is a bird which flies abroad in the twilight, and remains concealed by day in some obscure retreat, and in particular, inhabits in great numbers a very deep cave in the Valley of Caripe, in the province of Cumana. Humboldt, who visited this cave in 1799, first made known this remarkable bird, to which he gave the name of *Steatornis Caripensis*, on account of the fat which abounds in it when young, and which the natives apply to the same uses as oil and butter. M. Humboldt's collections having been lost by shipwreck on the coast of Africa, no specimens existed in Europe until 1834, when the Academie des Sciences received from M. Lherminier, a physician at Guadaloupe, a Guacharo preserved in spirits, with a paper relative to its habits and zoological relations. Mess. de Blainville and Geoffroy-Saint-Hilaire drew up a report, which was read on the 6th October 1834, and of which a condensed account is here presented. The body of the Guacharo is not larger than that of a pigeon, its head broad, its mouth very wide, and furnished with long stiff hairs, its bill pretty strong, the upper mandible hooked, with a well-marked tooth on its margin, the lower truncated at the extremity. The nostrils are oval, the eyes of moderate size, the ears rather small, the tongue arrow-shaped and adherent. The wings are very large, the legs short and robust, the toes short, with strong, arched, rather pointed claws, that of the middle toe not toothed as in the Goat-suckers. The tail-feathers are ten. The colour is chestnut red, mixed with brown, and glossed with green, banded and dotted with black, and marked with white spots. M. Lherminier adds, that the sternum is like that of the Goat-suckers, and that, as in them, there is no crop, but only a proventriculus and a gizzard of moderate strength, with two longish caeca at the end of a rather wide and short intestine. He was led to suppose, that as it resembles the Goat-suckers in its nocturnal habits, its form, and the distribution of its colours, it was also similar in its mode of feeding; although Humboldt asserted that the adults are not seen to pursue insects, and that the gizzard of the young is often found filled with nuts. To ascertain this alleged fact, he endeavoured to procure specimens, and at length succeeded in obtaining many young birds, and two old individuals, one of which has been sent stuffed to the Academie, to be deposited in the Museum. The young Guacharos are of the same colour as the old. In most of the individuals examined, the stomach was empty, but in some it contained kernels of fruits, and in none were there any remains of insects; so that Humboldt's opinion has been confirmed by direct observation. M. Baupertuy, who procured the specimens for M. Lherminier, states that, of ten young birds which he attempted to rear, eight died in the course of the second month, and only two lived to the end of the third. The food which seemed to agree best with them was the fruit of the banana cut into small pieces; but although at first they digested it very well, it at length ceased to afford nutriment to them. In captivity the young birds are dull, and constantly keep their tail raised, and their bill on the ground. When approached they retreat in this position, and present somewhat of the appearance of a toad. When touched, they emit a sharp and very disagreeable cry. During the day, they seek the darkest places and remain quiet, but towards evening they seem to emerge from their usual apathy, and traverse their prison, crying and shaking their wings.

The flesh of the old birds is lean and tough, but that of the young fat, tender, and nearly the same in taste as that of a young pigeon. The fat which covers the abdomen is exceedingly abundant, and so fluid that it transudes when handled. When melted over a gentle fire, slightly salted, and then put into a calabash, and well closed, it remained clear and without smell for three months. In taste it is like sheep's fat, but rather more delicate. The seeds found in the gizzards of young birds taken from the nest belonged to various plants, but particularly to one named in the country Mataca. They are round, of the size of a nutmeg, with an aromatic smell, and are rejected entire when they have been deprived of their pericarp, or the fleshy part of the fruit. The Indians who accompanied M. Baupertuy told him, that the Cave of Caripe is not the only asylum of the Guacharos, but that they are also found in other caverns situated towards the north-east.

**THE TARANTULA.**—In a very interesting paper on the Tarantula, *Lycosa Tarentula*, by M. Leon Dufour, published in the Annales des Sciences Naturelles, and of which a translation is given in the number for February 1837 of Loudon's Magazine, are the following particulars relative to its habits:—The Tarantula inhabits dry, barren, uncultivated places, exposed to the sun. It hides itself in burrows of a cylindrical form, often an inch in diameter, sunk more than a foot in the soil, for four or five inches vertical, then horizontal, and again perpendicular. The orifice is ordinarily surmounted by a funnel, sometimes two inches in diameter, rising about an inch above the surface of the soil, composed of fragments of dry wood united by a little clay, and lined with a kind of tapestry, formed of the threads of the animal itself. This funnel not only protects its intrenchment from inundations, and fortifies it against the falling of external bodies, which, swept by the winds, would be likely to close it up, but it also serves as an ambush, by offering to flies and other insects an enticing resting-place. The months of May and June are the most favorable season for seeking it. After various fruitless attempts to procure specimens, M. Dufour succeeded in the following manner:—It occurred to him to take, by way of bait, a stalk surmounted by a spikelet, and to shake it and rub it gently against the opening of the hole. He was not long in perceiving that the attention and desire of the Tarantula were awakened. Tempted by this lure, he advanced, with a slow and irresolute step, towards the spikelet; and on its being drawn back a little, frequently used to throw himself, at one spring, out of his dwelling, the entrance of which was instantly closed. It sometimes happened that, suspecting the snare, or perhaps less pressed by hunger, he held back, immovable, at a little distance from his door, which he did not judge it advisable to pass. When this occurred, M. Dufour, after having observed the direction of the hole, and the position of the spider, drove in the blade of his knife, so as to surprise the creature behind, and cut off his retreat. By employing this mode of capture, he sometimes took so many as fifteen in an hour. We shall conclude our extract with an account of a combat between two Tarantulas.—“In the month of June, one day when I had been successful in the search after the Tarantulas, I chose two full-grown and very vigorous males, which I put together into a large vase, that I might witness the spectacle of a mortal combat. After having many times made the circuit of their arena, in the endeavour to shun each other, they hastened, as at a given signal, to set themselves in a warlike attitude. I saw them, with surprise, taking their distance, and gravely rising upon their hind legs, so as to present to each other the buckler formed by their chests. After looking each other in the face for about two minutes, and, without doubt, provoking each other by glances which I could not discern, I saw them throw themselves upon one another, entwine their legs, and endeavour, in an obstinate struggle, to wound each other with the hooks of their mandibles. Either from fatigue, or by mutual consent, the combat was for awhile suspended: there was a truce for some seconds; and each wrestler, retiring to a little distance, resumed his menacing posture. This circumstance reminded me that, in the singular encounters of cats, there were also suspensions of arms. But the struggle was not long in recommencing, with more fury than before, between our two Tarantulas. One of them, after victory had been a long time doubtful, was at length overthrown, and mortally wounded in the head: he became the prey of the vanquisher, who tore open his skull, and devoured him.”

**MODE OF TAKING QUAILS IN THE ISLAND OF CERIGO.**—The following notice is extracted from a very interesting account of the Natural History and Statistics of the Island of Cerigo, published in the *Edinburgh New Philosophical Journal*, by the late Robert Jameson, Esq., Assistant Surgeon, 10th Regiment of Foot. The flocks of Quails which appear here in spring and autumn are considerably reduced by various destructive means of the inhabitants; but the most singular is that of finding them by dogs, something similar to a lurcher, and then catching them with hand-nets. Two, or a party of three, go sporting in this way; each net has a mouth somewhat oval, stiffened by a rim of wood two or three feet long, attached to which is a net of a proportionate bulk; to this border is fastened at one end a pole, ten to fourteen feet long; and with such a weapon, a party of these will secure twenty or thirty couples during the day in the following manner:—When the dog makes a point, the party comes up towards the spot in different directions, holding their nets by the ends of the poles; and if the Quails lie so close, as they do in bushes, as to allow the party to touch each other's nets, then the dog is driven in to put them up. On rising, each man strikes at a bird with his extended oval-mouthed net, twisting it in the air to entangle his game, and, when expert, seldom misses.—On their first arrival, the Quails are often so much fatigued as to be taken by the hand, or nets of the simplest construction. In spring they are thin, and scarcely worth the trouble of procuring, while in autumn they are fat, and much prized as delicacies. Great numbers are preserved and fattened for the table, but unless great care is taken, they die quickly. Several experiments have been made here in autumn by private individuals, of several hundreds at a time, but they always died off before the cold weather had fairly commenced.

**THE ITCH INSECT, *Acarus scabiei*.**—M. A. Gras, an *élève interne* of the Hospital of St Louis, has recently made the following observations on this minute insect:—

The *Acarus scabiei*, or *Sarcoptes hominis*, generally exists on all persons affected with itch who have not commenced a course of medicine. It is almost entirely confined

to the hands, where it is found beneath the epidermis, but is also sometimes met with on the feet, in the arm-pits, and other places. It is never found on persons affected with any other cutaneous disease than itch. The insects are all destroyed after the sulfuro-alkaline ointment has been applied; but the patient may not be still cured, for the eruption may remain, unless it be properly treated.

Insects removed from an affected to a sound person, multiply on the skin of the latter, when presently the eruption appears. M. Gras several times communicated the disease in this manner; once, at the desire of Dr Pariset, secretary of the Academie de Medicie, when it produced a sanatory revulsion in a young girl who had fallen into a state of stupor. On the other hand, he several times tried to inoculate himself with the serum of the itch vesicles, but without success. He therefore concludes that the sarcoptes is the sole agent in producing the contagion of itch, which is not contracted unless that animal or its eggs adhere to the skin or clothes of persons coming into contact with those having the disease.

The number of insects on a person has no relation to the extent and intensity of the eruption; for sometimes not more than five or six are found on individuals covered with vesicles and pustules; and again, a hundred have been taken from the hands of a person, who yet had only a few vesicles.

## BOTANY.

ALLEGED IRRITABILITY EVINCED BY THE STEMS OF PLANTS WHEN SLIT.—Mr Golding Bird has endeavoured, in London's Magazine for February, to explain the retraction observed by the two portions of a slit stem or stalk, on the principle of endosmosis. If a portion of the stem of an herbaceous exogenous plant be divided longitudinally, the division extending to the length of about two inches, the divided portions will instantly separate from each other to the distance of an inch or even more. The same thing occurs if the young shoots of woody stems are slit. Dr H. Johnson of Shrewsbury, who first attempted to explain this phenomenon, attributed it to the vital irritability of the plants, in consequence of its absence in some which are very elastic, and in the woody parts of stems. Mr Bird, however, conceives that it may be explained in another manner. Dutrochet has shown, that when a fluid, as water, or a weak saline solution, is inclosed in an organized membrane, as a piece of bladder, or placed in a glass tube closed by a piece of membrane, and immersed in a solution of sugar, the bladder or glass tube is rapidly emptied; but if, on the contrary, the bladder or tube be filled with syrup, and immersed in distilled water, the reverse takes place, the bladder becoming completely turgid. From these facts he inferred, 1st, That when a fluid of low specific gravity, inclosed in an organic membrane, is immersed in one of greater density, the membrane becomes rapidly emptied, in consequence of a current being set up from the lighter to the denser fluid; and, 2d, That when a dense fluid is inclosed in a membranous reservoir, and immersed in a fluid of a lower specific gravity, a current is set up, whereby the membrane becomes distended by a supply of fluid from without. The current from within to without, Dutrochet named *endosmose*; that from without to within, *exosmose*. Now, on this principle, rather than on the irritability of the plants, Mr Bird accounts for the following facts observed by him.

1. A piece of the stem of *Lamium album*, on being longitudinally divided to the extent of three quarters of an inch, immediately exhibited a divergence of its segments, which separated to half an inch. 2. Another piece, similarly treated, showed the same result, fig. 1; and, on being immersed in distilled water, continued to curve in a still greater degree, fig. 2. 3. This piece was then immersed in a weak solution of sugar, when, in the course of an hour, the segments had approached so closely as to touch each other, fig. 3. When replaced in water, the segments again diverged; and so on repeatedly. 4. The upper part of the stem of a young plant, that had stood for twenty-four hours with its lower portion immersed in water mixed with hydrocyanic acid, showed no divergence on being slit. 5. The same piece was placed in distilled water, when, in six hours, the divided portions separated to the extent of half an inch. When removed, and immersed in syrup, it showed a still greater divergence. 6. A piece of the stem of *Stachys palustris*, removed from near the root, was left for some days exposed to the air, and when dry was slit, but did not exhibit the least appearance of divergence. 7. A portion of this dried piece, on being placed in weak syrup, nearly regained its natural stage of turgescence in about twelve hours; when, on being slit at its upper part, it immediately manifested divergence; and which increased on its being immersed in water.

Dr Bird's explanation is to the following effect:—That the property of divergence does not depend upon vital irritability, as Dr Johnson assumed, is shown by experiments 5 and 7, in which the property was restored, by artificial means, to stems deprived of vital influence, by being isolated from the plants bearing them, and submitted to the deleterious influence of a poison, or to desiccation. That it is not caused by elasticity is evident, seeing that the property of divergence is absent in the most elastic parts of plants, as true woody fibre, rattan cane, &c., and present in the most

delicate herbaceous plants, as well as in the most inelastic. Dutrochet has shown, that the valves of the pericarp of *Impatiens Balsamina*, which, when mature, separate from each other, and become considerably curved inwards, are composed of a vesicular tissue, of which the vesicles nearest the external are considerably larger than those nearest the internal face of the valves. The tissue being injected from an accumulation of sap, all the cellulose become turgid, and the larger ones occupy a greater space than before. Their complete distension being, however, prevented by the more compact tissue formed by the aggregation of the smaller cells, the whole valve assumes a tendency to curve in such a manner, that the external portion, or that composed of the larger cells, may occupy the convex part of the curve; and this tendency to curve is obeyed as soon as the resistance of the opposite valve is removed by a slight touch or otherwise. This explanation may be applied to the phenomenon in question. The vesicular tissue of the *Lamium* and other plants is more minute towards the circumference, the internal part being composed of much larger cellulose. When a stem possessing this structure is in perfect vigour, its vesicular tissue is injected with sap; the larger central cells become considerably distended, and press upon the smaller cells, which, resisting the pressure, give to the larger cells a tendency to separate, and occupy a greater space in consequence of this distension; their separation being, however, prevented by their intimate lateral organic connection. But when this bond of union is severed, by an incision or otherwise, the segments instantly separate, and curve in such a manner, that the internal portions, or those made up of the larger cellulose, form the convex part of the curve, and thus leave more room for their distension; whilst the external portions, formed of a more compact tissue, occupy the concave parts of the curve, in consequence of their not becoming distended so easily or readily as the tissue nearest the axis of the plant.

This explanation is considered to be in perfect accordance with the result of experiment; for, on immersing the piece of stem, when the segments have separated to a certain extent, in water, which is a fluid of lower specific gravity than the sap in the cells, endosmosis ensues, whereby a quantity of water is forced into the already turgid cells, which, consequently, become more turgid, and the curvature increases; and on removing the piece of stem into syrup, a much denser fluid than sap, exosmosis, for reasons already explained, ensues; the cells become emptied, and the separated portions recover their former rectitude; the elasticity of the woody fibre present, also, probably assisting. The reason why poisons prevent the divergence is, that as they destroy the vital energy of the plant, they prevent the cells from becoming distended with sap to an extent sufficient to cause their separation; but, on placing the piece of stem in water, endosmosis occurs, and the divergent property is developed. But when the piece of stem used had been previously dried, the cells were emptied of their sap, and it was necessary to fill them artificially with a tolerably dense fluid, as syrup, before they became sufficiently injected to cause the separation of the segment, on making a longitudinal incision.

Mr Bird, therefore, is decidedly of opinion, that the divergence is the result of a *purely physical action, independent of vitality*; and in this we agree with him, although it is obvious that a much simpler and equally satisfactory explanation of the phenomenon can be given.

The plants found to exhibit it are possessed of a vascular, a fibrous, and a vesicular tissue. The latter occupies the central parts exclusively; while the woody fibres occur towards the exterior, as do the vessels properly so called. This arrangement is represented by the diagram, fig. 4, in which *a, a*, indicate the surface of the stem, *b, b*, its axis. Now, the woody fibres near *a*, not being extensible, and the cellulose at *b*, being dilatible, it will necessarily follow, that when a section of the stem, such as that represented by the figure, is made, the cellulose being filled with fluid, or vapour, which readily passes from the one to the other, the larger inner cellulose, in consequence of the pressure caused by the unyielding cuticle and herbaceous tissue which compressed the interior when the stem was entire, being now allowed to expand to their full size, or in some degree, while the outer cellulose are bound together by the inextensible woody fibres, the curvature outwards of the section is a necessary result, so long as moisture is supplied by the unslit portion of the stem, or communicated from without, this fluid ascending on the principle of endosmosis. When, as in experiment 2, the slit stem is immersed in water, the divergence is increased on the same principle; but when, as in experiment 3, a denser fluid is substituted, exosmosis takes place in the vesicular tissue, in consequence of which, the pressure is removed from the larger vesicles, which, by their elasticity, regain their original size. In the plant, experiment 4, whose lower parts were destroyed by poison, the upper not having received a supply of fluid to replace the quantity evaporated in twenty-four hours, no divergence could ensue on slitting it; but, as in experiment 5, should it be filled with fluid, it diverges as explained above. For the reasons stated, a dried piece of stem, experiment 6, can of course undergo no change; but if restored to its natural state, as in experiment 7, it exhibits the usual phenomenon. In accordance with this explanation is the fact, that woody stems when slit do not diverge, because all their parts are equally bound together by firm longitudinal fibres, as well as that of purely cellular plants, such as *Fucus palmatus*, exhibiting no divergence.

Wherefore, we neither agree with Dr Johnson, in considering the divergence or curvature in question as a result of vital contractibility or irritability; nor with Mr Bird, in attributing it solely to the larger vesicles being more readily distended than the smaller.

## GEOLOGY.

Fossil Skull of *Dinotherium Giganteum*.—M. Kaup has addressed to M. Blainville a letter, giving intimation of the discovery of a perfectly-preserved head of *Dinotherium giganteum*, at Eppelstein, by a society, at the head of which is Dr Klippstein, who intends to prefix a geological introduction to the description and figure about to be published by the gentleman above-named. The expense of disengaging the head having been very considerable, the society intend to send it first to Paris, and afterwards to London, to be exhibited to the public. It is probable, however, that it will be purchased by the Academie des Sciences.

FOSSIL BONES DISCOVERED IN A NEW DEPOSIT CONNECTED WITH THE PLASTIC CLAY OF THE BASIN OF PARIS.—M. D'Orbigny, junior, has recently given an account of the discovery of a deposit of a peculiar marine limestone, between the tertiary formation and the chalk, and described numerous organic remains occurring in the lower part of the plastic clay. A trench that had been opened at Basmeudon, at the place called Les Montalets, and especially an opening made at the same point into one of the galleries of the chalk-work of M. Langlois, exposed immediately over the pisolitic limestone, several very interesting strata, of which no notice has until now been taken. The lowest bed is composed of plastic clay and marl, with numerous balls and fragments of chalk and pisolite, torn from the lower deposits, and forming a kind of conglomerate. At the base of this layer are balls, sometimes larger than the human head, of indurated pisolite, with milliolithes, and some fibrous nodules of sulphate of strontian. The organic remains found in this bed are:—1. Marine radiaria and shells torn from the chalk by the fresh water which flowed over its surface; viz. *Ananchytes ovata*, *Catillus Cuvieri*, *Ostrea vesicularis*, and *Belemnites mucronatus*. 2. Fresh water shells, *Planorbis*, *Cyclas*, *Paludina lenta*, and *Anodonta*, contemporaneous with the conglomerate. Until now, no species of *Anodonta* has been found in a fossil state; and M. D'Orbigny believes he has discovered two, which he intends to name *A. Cordieri* and *A. antiqua*. 3. Bones of fishes, which cannot be determined. 4. Reptiles, which no doubt lived in the fresh water which formed the conglomerate; bones of fresh water tortoises, *Trionyx* and *Emys*; several teeth of crocodiles, and of a kind of large saurian animal, nearly allied to the *Mososaurus* or *Monitor* of the Maestricht chalk; also a coprolite, containing small fragments of fishes, and probably belonging to one of the reptiles mentioned. 5. Land quadrupeds carried away by the fresh water. There is a considerable number of teeth, of which two belong to a carnivorous animal of the Otter kind, the rest to pachydermatous animals, viz. to a large species of *Anthracotherium*, to a small species of the same genus, and to *Lophiodons*.

“The presence of these numerous bones of mammifera beneath the plastic clay,” says M. D'Orbigny, “appears to me to be of very great interest, as it incontrovertibly demonstrates the existence of these animals at a much older period than is generally supposed. In fact, the only remains of mammifera hitherto found in the lower beds of the Paris deposits, were the jaw of a *Lophiodon*, discovered by M. Eugene Robert in the *calcaire grossier* of Nanterre, and two fragments of bones, probably also of the *Lophiodon*, which Cuvier has mentioned as having been taken from the lignite of Laonnais, the age of which is uncertain. These latter facts had already modified the opinion formed by Cuvier as to the depth at which the remains of mammifera might be found in the Paris deposits, and which, he presumed, never went below the gypsum. Now, however, it must be conceded that these animals lived at the period when the first layers of the plastic clay, which is the lowest deposit of the Paris basin, began to be formed. This fact once admitted, it will no longer be difficult to admit, in like manner, some cases which have given rise to much discussion, and which tend to carry still farther back the existence of these animals. One of these is the occurrence of the remains of *Didelphis Bucklandi*, in the oolitic limestone of Stonesfield; another, that of impressions of animals recently observed in the variegated sandstone of Hildburghausen in Saxony, and which some naturalists consider as foot-marks of mammifera or reptiles, while others assert that they are nothing but vegetable impressions; the third and most important refers to the bones of pachydermata, lately found by Professor Hugi in the Portland oolite of Soleure in Switzerland.

From these observations, in connection with those made by myself, may we not conclude, not only that mammiferous animals existed at the commencement of the tertiary period, but even before it, and that further researches will lead to the discovery of a much greater number?

In conclusion, it must be admitted, 1st, That the plastic clay of the neighbourhood of Paris is separated from the chalk by a distinct deposit, which may henceforth bear the name of pisolitic limestone, and which, from its containing only tertiary shells, appears very clearly to be connected with the paleotherian or tertiary epoch, and not with that of the chalk; and, 2dly, That in the lower part of the plastic clay deposit new characters have been found, demonstrating especially that various kinds of mammifera lived at the period when that deposit was formed, and that these mammifera differed greatly from those found in all the upper parts of the Paris formation.

FOSSIL BONES OF THE CAMEL.—M. de Blainville has announced to the Academic des Sciences of Paris, that he has been informed by an individual who has recently arrived from India, that the fossil remains of the Camel have been found in the deposits of the lower ranges of the Himalayan mountains. The remains alluded to consist of a cranium, which was discovered in a very hard sandstone, about two miles from Ramghur, and six from Pingon. This skull, almost entire, appears to have belonged to the single-humped Camel, *Camelus Dromedarius*. There was also found in the same place, the anterior part of the head of an animal intermediate between the *Acroplotherium* and *Paleotherium* of the Paris Basin; together with the tooth of a species of Mastodon, allied to *M. angustidens*.

#### MISCELLANEOUS.

EXPEDITION FOR EXPLORING CENTRAL AFRICA.—An expedition, under the superintendence of Dr Andrew Smith, fitted out by some individuals resident at the Cape of Good Hope, for the purposes of promoting the objects of science, and of benefiting the commerce of the colonists, has recently penetrated as far as lat 23° 28'. Dr Smith, in concluding his Report, states that the following are the principal results obtained:—

“1. It has put us in possession of much information respecting many tribes even hitherto unknown to us by name; and has enabled us also to extend very considerably our knowledge of those which had previously been visited, by having brought us in immediate connection either with them, or with persons who could furnish information regarding them.

“2. It has enabled us to ascertain the geographical position of many places previously doubtful—to lay down the sources and courses of various rivers which run to the eastward—and otherwise obtain what will considerably add to the utility of our maps of South Africa.

“3. It has enabled us to extend considerably our knowledge of natural history, not only by the discovery of many new and interesting forms in the animal kingdom, but also by additional information in regard to several previously known; and has put us in possession of a splendid collection, which, if disposed of, will in all probability realise a sum more than equal to the expenses which have been incurred.

“4. It has enabled us to ascertain that the Hottentot race is much more extended than has been hitherto believed; and that parties or communities belonging to it inhabit the interior, as far, at least, as the inland lake, which we were told is not less than three weeks' journey to the north of the Tropic of Capricorn.

“5. It has made us aware of the existence of an infinity of misery in the interior, with which we were previously unacquainted—a circumstance, which, in all probability, will lead eventually to the benefit of thousands, who, without some such opportunity of making known their sufferings, might have lived and died even without commiseration.

“6. It has enabled us to establish a good understanding with Umsligas (a chief), and insure his services and support in the farther attempts which may be made to extend our knowledge of South Africa, which, without his concurrence, could never be well effected from the Cape of Good Hope.”

About sixty birds and thirteen quadrupeds, supposed to be new, are characterized in an appendix to the Report. The number of specimens collected is as follows:—180 skins of new or rare Quadrupeds; 3379 skins of new or rare Birds; 3 bands of Snakes, Lizards, &c.; 1 box of Insects; 1 box of Skeletons, &c.; 3 Crocodiles; 2 skeletons of Crocodiles; 23 Tortoises, new or rare; 799 Geological specimens; and 1 package of dried Plants. In botany, however, very little has been done by the party, there having been no person attached to it for the express purpose of collecting and drying plants. It is intended to dispose of the duplicates, and send the most valuable part of the collection to Europe, to be exhibited for the purpose of raising funds to enable the Association to send out other expeditions.

#### REVIEWS.

*The Northern Flora; containing the Wild Plants of the North of Scotland.* By Alexander Murray, M. D. Part I. 1836. Edinburgh: Adam and Charles Black.

THE object of this work is, to present an account of the native vegetation of the north-eastern parts of Scotland, “which might afford to those resident there the means of acquiring a knowledge of the native plants they may expect to find, without the evident and well-known inconvenience, arising from the extraneous matter, occurring, of necessity, in works of a more general character; while, at the same time, a knowledge of our indigenous species might be imparted to others at a distance, who may be interested in such matters.” The principal objection which we have to the Northern Flora is, that the limits of the district or region, whose vegetable productions are described, have not been pointed out, and the range of the Forfarshire hills having been included, apparently for the purpose of taking in Mr Don's discoveries there. We have had occasion, in describing several plants for a projected Flora of Scotland, to refer to Dr Murray's descriptions, which we have invariably found to be accurate and judiciously drawn up. The characters of the genera and species are not elaborated in the usual manner; and yet, in our opinion, they are exceedingly well adapted to the wants of the student, whose aim is to determine a plant unknown to him expeditiously and with certainty. This is certainly the most original of all our local Floras, and indicates much patient research and discriminative acumen. The descriptions are not always so full as we could desire, but the distinctive characters are generally so accurately traced, that the young botanist can scarcely ever be in doubt as to the species in hand, provided his intellect be of ordinary acuteness, although he will find his examinations somewhat laborious from the want of a synopsis of the genera usually prefixed to the classes. We object to the frequently tedious accounts of the real and reputed virtues of the plants, which are quite unnecessary in the present state of science; and it is obvious enough that few people would apply to a Flora for information on this subject, the proper place for which is a treatise on the *Materia Medica*. The part published does not extend beyond the thirtieth genus of the fifth class. In an appendix are “Notes from the Ancients,” by Francis Adams, Esq., more curious than valuable; and “Observations on the agricultural properties of native plants,” by the Rev. J. Farquharson, better adapted for the Journal of Agriculture than for the Northern Flora.

*The Ornithologist's Guide to Orkney and Shetland.* By Robert Dunn, Animal-Preserver, Hull. London. 1837.

WE are much pleased with this amusing and useful little work, which, besides an interesting account of the northern islanders, and of the author's wanderings among them, contains an enumeration of the different species of birds found in Orkney and Shetland, and affords to the intending visitor precise information on subjects of importance to him, such as the expense of boating, lodging, food, and other matters of a like nature. Independently of its interest to the collector, it will also be found useful to the student of British Ornithology, as indicating with certainty the species that occur in these islands.

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE.—THE BULLS.

OF the numberless varieties of the Domestic Ox, those peculiar to India and the East coast of Africa, forming a race generally known by the name of Zebu or Indian Ox, are among the most remarkable. They are more especially distinguished by having a large tumour or hump, chiefly composed of fat, on the back between the shoulders. Of this race there are numerous breeds, varying in size from that of our largest Bulls to that of a Mastiff, and dispersed over Southern Asia, the islands of the Indian Archipelago, and the coast of Africa from Abyssinia to the Cape of Good Hope, in which countries it supplies the place of the common Ox, being used as an article of food, as a lactiferous animal, and as a beast of burden. In some parts of India it is also employed for riding, as well as for drawing carriages, and is said to perform a journey of thirty miles a-day. Its flesh, although good, is inferior to that of the European races; but the hump is reckoned a great delicacy. It varies in colour like the other domesticated breeds, the most common tints being ash-grey, cream-colour, or white, but it is often red or brown, and occasionally black. Some of the breeds are horned, others have pendulous or flexible horns, destitute of the core or bony part, and some are entirely hornless.

Fig. 1. Represents an individual of the largest kind.

Fig. 2. One of the smaller horned breeds.

Fig. 3. The smallest race.

Fig. 4. An individual of the hornless variety.

Fig. 5. The American Bison (*Bos Americanus*). This animal attains a much larger size than our domestic breeds, and is peculiar to the American continent, where it occurs in vast herds in the great plains or prairies extending along the Mississippi, Missouri, Arkansas, and Saskatchewan rivers. It has a savage and ferocious aspect, owing partly to the enormous size of its head, which it carries low, and partly to the long shaggy hair with which its neck and the fore part of its body are clothed. The shoulders are very high, but the protuberance formed by them does not consist merely of flesh and fat, as in the Zebu, but also of the elongated spinous processes of the dorsal vertebrae. Its flesh is excellent, and affords the principal subsistence of many tribes of Indians. The Bisons are extremely fleet, and although possessed of enormous strength, generally take to flight on the appearance of an enemy, seeking shelter in the forests and swamps. But when wounded they manifest great ferocity, so that it is dangerous for the hunter to show himself, as they are capable of easily overtaking him. Dr Richardson mentions an accident of this kind which occurred while he was residing at Carlton House, one of the Hudson's Bay Company's Stations. "Mr Finnan McDonald, one of the Company's clerks, was descending the Saskatchewan in a boat, and one evening having pitched his tent for the night, he went out in the dusk to look for game. It had become nearly dark, when he fired at a Bison-bull, which was galloping over a small eminence, and as he was hastening forward to see if his shot had taken effect, the wounded beast made a rush at him. He had the presence of mind to seize the animal by the long hair on its forehead as it struck him on the side with its horn, and being a remarkably tall and powerful man, a struggle ensued, which continued until his wrist was severely sprained, and his arm was rendered powerless; he then fell, and after receiving two or three blows became senseless. Shortly afterwards he was found by his companions lying bathed in blood, being gored in several places, and the Bison was couched beside him, apparently waiting to renew the attack had he shown any signs of life. Mr McDonald recovered from the immediate effects of the injuries he received, but died a few months afterwards." Individuals of this species are sometimes seen in collections in this country, being exhibited under the classical name of *Bonassus*, to which, of course, they have no title. The weight of an old male is from twelve to fifteen hundred weight. The hair, being remarkably fine and woolly, has been manufactured into coarse cloth, and the dressed skin with the wool adhering forms an excellent blanket, and in Canada often sells for three or four pounds, being there used as a wrapper by persons travelling over the snow in carriols.

#### DESCRIPTION OF THE PLATE.—THE HUMMING BIRDS.

Fig. 1. The Modest Humming Bird, *Trochilus modestus*, variety. The species of which a variety, partially affected with albinism, is here represented, has obtained

its name from the plainness of its colours, which are dull greenish-brown on the upper, and dark grey mixed with green on the lower parts. It lives in the forests of Brazil, but nothing is known of its habits. The variety figured is remarkable for the white patch on the occiput, indicating a tendency to albinism, which is of very rare occurrence in this family of birds.

Fig. 2. The Mango Humming Bird (*Trochilus Mango*). Male. This beautiful species varies exceedingly in colour, according to age and other circumstances. In the adult state, the general tint is a bright green, the throat and middle of the breast black, part of the abdomen pure white. It inhabits Jamaica and other West India Islands, and is said to occur on the Spanish Main, and in Brazil and Guiana.

Fig. 3. The Mango Humming Bird. Young Male. With the upper parts glossed with yellowish-brown.

Fig. 4. The Mango Humming Bird. Young. In this state, although considerably different in colour, and having a large portion of the lower surface white, it is equally beautiful.

Fig. 5. The White-eared Humming Bird (*Trochilus leucotis*). The delicate and beautiful bird to which the name of "white-eared" was somewhat erroneously applied by M. Vieillot, seeing the region of the ears is deep blue, although a white line passes over it, is one of the most common species in Guiana and Brazil, where it is frequently met with in thickets near houses.

Fig. 6. The Blue-throated Humming Bird (*Trochilus Lucifer*). This diminutive species is characterised chiefly by a tuft of scale-like feathers, coloured with the iridescent tints of the Elba iron ore, on the throat. The female is not known. It is a native of Mexico.

Fig. 7. Swainson's Humming Bird (*Trochilus Swainsonii*). M. Lesson, who named this species in honour of a well-known English Naturalist, states that it is extremely rare, and that its native country is Brazil.

ORGANIZATION OF THE ORAN-OUTAN.—M. Geoffroy-St-Hilaire has recently presented to the Académie des Sciences the following observations on this subject:—If we compare the Oran-Outan with Man, we perceive the most remarkable conformity in all their parts. There is not a vessel, nor a nerve, nor a muscular fibre, more or less; but, at the same time, each organic element presents modifications in the length and thickness of the parts. The vertebral axis is comparatively shorter, not from the absence of any of its parts, but on account of their vertical compression. The head is generally larger, but this more in appearance than in reality. The neck seems wanting, the parts which form it appearing to belong to the hind-head, and to prolong it to the shoulders. This is produced by the following mechanism. In the Oran as in the Bat, the clavicles are extremely long; and to be kept beneath the integuments without occupying too much room, they are directed obliquely, so that their outer extremity has, as it were, ascended towards the skull, and drawn with it a certain number of muscles, which, adding to their thickness, that of the muscles peculiar to the posterior region of the neck, fill up the wide groove formed by the series of spinous processes, which are themselves very large. The action of this strong layer of cervical muscles tends to throw the head backwards. The animal, in consequence of this general modification, must keep its body and head parallel to the trunk of the tree on which it resides, clinging to it by the extremities, and also fixing itself by the hands to the branches which are small enough to be laid hold of. The brain of the young Oran-outan bears a great resemblance to that of a child. The skull might in fact be taken, at an early age, for that of the latter, and the illusion would be almost perfect, were it not for the development of the bones of the face. But it happens, in consequence of its advance in age, that the brain ceases to enlarge, while its case continually increases. The latter becomes thickened, but in an unequal degree, enormous bony ridges appear, and the animal assumes a frightful aspect. When we compare the effects of age in Man and the Oran-outan, the difference is seen to be, that, in the latter, there is a super-development of the osseous, muscular, and tegumentary systems more towards the upper than the lower parts, while the development of the brain is entirely arrested.

QUANTITY OF SEEDS EATEN BY WILD BIRDS.—Rock Pigeons, which are very abundant in the Hebrides, Shetland, and Orkney Islands, live chiefly on grain and the seeds of various plants. We had the curiosity to count the number of seeds con-

tained in the crops of two individuals recently obtained from Shetland. In that of one were 510 grains of barley, while the other contained 1000 grains of the grey oat, besides a few small seeds. Now, supposing there may be 5000 Wild Pigeons in Shetland, or perhaps in Fetlar alone, which feed on grain for six months every year, and fill their crops once a-day, half of them with barley, and half with oats, the number of seeds picked up by them would be 229,500,000 grains of barley, and 450,000,000 grains of oats;—a quantity for which the poor Shetlanders would be very thankful in a season of scarcity like the present. What is the number of Pigeons, wild and tame, in Britain, and how much grain do they pick from the fields and corn-yards? It is probable, that were the quantity of seeds of the cereal plants, which all the granivorous birds in the country devour annually, accurately known, it would prove much higher than could be imagined; yet by far the greater part could be of no use to Man, were all the birds destroyed, it being irrecoverably dispersed over the fields.

**STERNUM OF BIRDS.**—M. F. Lherminier, a French physician, settled at Gaudaloupe, has recently made extensive observations on the development of the sternum in Birds. Before giving a brief account of his discoveries, we shall shortly describe the bone to which they refer, with the aid of a figure of that of the Black Grouse, *Tetrao Tetrix*.

The letters *a, b, c, d, e*, mark the limits of the sternum itself; *h*, indicates the coracoid bones, or clavicles of many authors; *i, i*, the furcula, or anterior clavicles; and *j, j*, the scapulae. The sternum varies greatly in form in different tribes of birds; the body, *b, c, d, e, f, g*, being sometimes complete, often, as here, with deep vacancies or sinuses, by which it is broken up; and often with holes or notches in its posterior margin. The crest or ridge, *a, e*, is more or less prominent according to the size of the pectoral muscles, which depress the wings, and is therefore, in some degree, indicative of the power of flight of the species. It is wanting in the Ostrich, which is destitute of wings properly so called, that is, organs of flight, and is very highly developed in Eagles, and other birds that fly with great speed.

From the observation hitherto made, only two modes of ossification of the sternum have been admitted; namely, five pieces in the Gallinaceous birds, and two in the Ducks and Ostrich. M. Lherminier, however, considering the diversified forms under which that bone exists in birds, found it difficult to believe that there are only two types for the arrangement of the pieces which enter into its composition; and on extending his researches, came to the conclusion that the number of original pieces is nine; at least, that there are nine distinct bones in the sternum of birds, considered in a general sense, although in no species does the whole number occur at any period of development.

These nine pieces may be considered as belonging to three transverse series, an anterior or *prosternal*, a middle or *mesosternal*, a posterior or *metasternal*. The first row comprehends a median piece, the *prosternum*, and two lateral pieces, the *prosternals*; the second is composed of a *mesosternum* and two *mesosternals*; the third of a *metosternum* and two *metasternals*. It is to be remarked, however, that the number of the pieces of each series may sometimes be more than three, and in certain groups of birds, M. Lherminier has seen it amount to six.

The first series, when it exists, is generally confined to a much smaller space than the rest. It is sometimes complete, sometimes reduced to two lateral pieces, and sometimes to the middle piece alone. It serves to support the coracoid bones, *h*, and affords a fixed insertion to the sterno-coraco-clavicular aponeurosis. It is that part denoted by the letters *b, c*.

The second series may, in like manner, be complete, or formed only of the two lateral pieces, but it is never reduced to a single central piece. When the three pieces exist, sometimes the mesosternum forms part of the body of the bone, and is seen at its upper surface; sometimes it belongs to the keel, *a, e*, and occupies its upper part. In the former case, it may be double or single; in the other, it is always a single nucleus. The use of this series is to afford a point of support to the sternal ribs, and to contribute to the development of the crest and body of the sternum. When the first series is absent, the second occupies its place opposite the coracoid bones, which then rest on the mesosternum, or, in its absence, on the mesosternals.

The third series belongs entirely to the body of the bone, and is sometimes complete, sometimes reduced to the two lateral pieces, or to the middle piece alone, which it is sometimes rather difficult to distinguish from the two other central pieces. When these are wanting, the metasternum directly supports the coracoid bones. The metasternals, like the mesosternals, contribute to the support of the ribs, and maintain in a state of tension the fibrous membranes of the sternum, so as to favour the action of the muscles inserted into them.

These pieces exhibit great diversity in their mode of development. Their relative importance, estimated according to the frequency of their occurrence, is as follows:—1. The mesosternals, which are never wanting; 2. the mesosternum; 3. the prosternals; 4. the metasternum; 5. the prosternum and metasternals.

In the Gallinaceous Birds, of which the figure represents the sternum, that bone results from the union of five pieces, there being originally in the chicken five centres of ossification, viz. two lateral pieces of the middle series, and three of the posterior series. The two lateral pieces of the middle row form the part included between *b, c*, and *f*; the middle posterior piece is marked by *a, d, e*; and the two lateral posterior pieces are denoted by *g*.

By researches of this kind, that is, by comparing the parts in Birds of different genera and families, it may be expected that much light will ultimately be thrown on the natural arrangement of Birds, which at present is left in the hands of persons who can do little more than compare skins and stuffed specimens, and who, ludicrously enough, perpetually talk of the "strict analysis" by which they have absolutely fixed the order of Nature

#### BRITISH BIRDS.—NO. I.

**THE RAVEN.**—The habits of many of the most remarkable of our native Birds being very imperfectly described by our most accredited authors, we propose to present those of the species, which, on account of their great size, beauty, utility, or injurious agency, are especially worthy of notice, in a series of papers, commencing with that most sagacious of all birds, the Raven.

This species, which is the largest of the Crow family resident in Britain, with a grave and dignified air, combines much cunning, and in courage is little inferior even to some of the Rapacious Birds. Its body is of an ovate form, rather bulky; the neck strong, and of a moderate length; the head large and oblong; the bill rather long, deep, and nearly straight; the feet of moderate length and ordinary strength. The plumage is compact and highly glossed; the wings long and much rounded; as is the tail. The bill and feet are black; the plumage deep black, with splendid reflections of rich purplish-blue. The length of the male is twenty-six inches, and its extended wings measure fifty-two.

The Raven is a remarkably grave and sedate bird, and, unlike many men who assume an aspect of dignity, is equally noted for sagacity and prudence. It is crafty, vigilant, and shy, so as to be with great difficulty approached, unless in the breeding season, when its affectionate concern for its young, in a great measure, overcomes its habitual dislike to the proximity of Man; a dislike which is the result of prudence more than of mere timidity; for, under particular circumstances, it will not hesitate to make advances which a timorous bird would, no doubt, deem extremely hazardous. It eats from off the same carcase as a Dog, and takes its station close to an Otter devouring its prey, doubtless, because its vigilance and activity suffice to enable it to elude their efforts to inflict injury upon it; and while it yields to the Eagle, it drives away the Hooded Crow and the Gull. It knows the distance, too, at which it is safe from a man armed with a gun, and allows the shepherd and his dogs to come much nearer than the sportsman. It never ventures to attack a man plundering its nest, and rarely pretends to be crippled, in order to draw him away from it, but stands at a distance, looking extremely dejected, or flies over and around him, uttering now and then a stifled croak indicative of anger and anxiety.

When searching for food on the ground, it generally walks with a steady and measured pace; but under excitement, it occasionally leaps, using its wings at the same time, as when driven from carrion by a dog, or when escaping from its fellows with a fragment of flesh or intestine. Its flight is commonly steady and rather slow, and is performed by regularly timed beats of its extended wings; but it can urge its speed to a great degree of rapidity, so as to overtake an Eagle, or even a Hawk, when passing near its nest. In fine weather it often soars to a vast height, in the manner of the birds just mentioned, and floats, as it were, at ease, high over the mountain tops. Some Naturalists having observed Birds thus engaged, have imagined them to be searching for food, and have consequently amused their readers with marvellous accounts of the distances at which the Eagle can spy its prey; but had they patiently watched, they might have found that the quiet soarings of the Raven and the rapacious species have no reference to prey. On the other hand, it may sometimes be observed gliding along, and every now and then shifting its course, in the heaviest gales, when scarcely another bird can be seen abroad. Although there is not much reason for calling it "the tempest-loving Raven," it would be a severe storm indeed that would keep it at home, when a carcase was in view.

In the Hebrides, where this bird is much more abundant than in any other part of Britain, it may be seen either singly or in pairs, searching for food, along the rocky shores, on the sandfords, the sides of the hills, the inland moors, and the mountain tops. It flies at a moderate height, proceeding rather slowly, deviating to either side, sailing at intervals, and seldom uttering any sound. When it has discovered a dead sheep, it alights on a stone, a peat bank, or other eminence, folds up its wings, looks around, and croaks. It then advances nearer, eyes its prey with attention, leaps upon it, and, in a half crouching attitude, examines it. Finding matters as it wished, it croaks aloud, picks out an eye, devours part of the tongue, if that organ be protruded; and, lastly, attacks the abdomen. By this time another Raven has usually come up. They perforate the skin, drag out and swallow portions of the intestines, and continue to feast until satiated or disturbed. Sometimes, especially should it be winter, they are joined by a Black-backed Gull, or even a Herring Gull, which, although at first shy, are allowed to come in for a share of the plunder; but should an Eagle arrive, both they and the Gulls retire to a short distance, the former waiting patiently, the latter walking backwards and forwards, uttering plaintive cries, until the intruder departs. When the carcase is that of a larger animal than a sheep, they do not, however, fly off, although an Eagle, or even a Dog, should arrive. These observations were made by the writer, when lying in wait in little huts constructed for the purpose of shooting Eagles and Ravens from them. The latter were allowed to remain unmolested for hours, that they might attract the former to the carrion; and in this manner, he was enabled to watch their actions when they were perfectly unrestrained.

Although the Raven is omnivorous, its chief food is carrion, by which is here meant, the carcasses of Sheep, Horses, Cattle, Deer, and other quadrupeds; Dolphins and Cetaceous animals in general, as well as fishes that have been cast ashore. In autumn it sometimes commits great havoc among barley, and in spring occasionally destroys young lambs. It has also been accused of killing diseased sheep by pecking out their eyes. It annoys the housewives by sometimes flying off with young poultry, and especially by breaking and sucking, or rather gobbling eggs, which the ducks or hens may have deposited, as they frequently do, among the herbage.

In these islands, should a Horse or a Cow die, as is not unfrequently the case in the beginning of summer, after a severe winter or spring, or should a Grampus or other large Cetaceous animal be cast on the shore, the Ravens speedily assemble, and remain in the neighbourhood until they have devoured it. Whatever may be said by closet-naturalists as to the unrivalled adaptation of the point of the upper mandible of the Rapacious birds for tearing flesh, the bill of the Raven is in practice quite as efficient an instrument. That bird can not only with great ease tear off morsels of flesh, but can pick the smallest shreds from the bones, and rend the intestines in pieces. When engaged upon a large carcase, they conduct themselves very much in the manner of the North American Vultures, as described by Wilson and Audubon. We have seen them thus occupied with a Cow. Some were tearing up the flesh from the external parts, others dragging out the intestines, and two or three had made their way into the cavity of the abdomen.

The Raven sometimes nestles at no great distance from the Eagle, in which case these birds do not molest each other; but in general the former is a determined enemy to the latter, and may often be seen harassing it. Two Ravens attack the Eagle, one hovering above, the other beneath; but without ever coming into contact with the object of their dislike, which seems to regard them as more disagreeable than dangerous, and appears to hurry on to avoid being pestered by them. Although they keenly pursue all intruders that seem in any way formidable, they on the other hand allow the Cormorant, the Rock-pigeon, and the black Guillemot, to nestle in their immediate vicinity.

The voice of the Raven is a hoarse croak, resembling the syllables *crook*, *cruck*, or *chroo*; but it also emits a note not unlike the sound of a sudden gulp, or the syllable *cluck*, which it seems to utter when in a sportive mood; for, although ordinarily grave, the Raven sometimes indulges in a frolic, performing somersets and various evolutions in the air, much in the manner of the Rook.

The character of this Bird accords well with the desolate aspect of the rugged glens of the Hebridian moors. He and the Eagle are the fit inhabitants of those grim rocks; the Red Grouse, the Plover, and its page, of those brown and scarred heaths; the Ptarmigan of those craggy and tempest-beaten summits. The red-throated Diver and Merganser, beautiful as they are, fail to give beauty to those pools of dark-brown water, edged with peat banks, and unadorned with silvan verdure. Even the water-lily, with its splendid white flowers, floating on the deep bog, reflects no glory on the surrounding scenery, but selfishly draws all your regards to itself.

The species is also very abundant in the Orkney and Shetland islands. In Sutherland, Ross-shire, and many parts of the county of Inverness, it is also not uncommon. In most of the Highland districts, we have met with it here and there. In the lower parts of the middle division of Scotland, it is of much rarer occurrence; nor is it plentiful even in the higher and more central portions of the southern division, although we have seen it in many places there. In England it is much less frequently met with than in Scotland, although it seems to be generally distributed there also. If we take the whole range of the island as its residence, we must add to its bill of fare many articles not mentioned above, so as to include young Hares and Rabbits; other small quadrupeds, as Rats, Moles, and Mice, young poultry, and the young of other birds, as Pheasants, Grouse, Ducks, and Geese; eggs of all kinds, echini, mollusca, fruit, barley, wheat, and oats; insects, crustacea, grubs, worms, and probably many other articles, besides fish and carrion of all sorts.

In the northern parts of Scotland, the Raven constructs its nest on high cliffs, especially those on the sea-shore; but in the southern parts of the island, where rocks are not so common as tall trees, it is said frequently to nestle in the latter. According to the locality, it begins to repair its nest, or collect materials for forming a new one, as early as from the beginning to the end of February. In the maritime districts, it is generally composed of twigs of heath, dry sea-weeds, grass, wool, and feathers. It is of irregular construction, and very bulky. The eggs are from four to seven, pale-green, with small spots and blotches of greenish-brown and grey, and are about two inches in length. The young are at first of a blackish colour scantily covered with soft, loose, greyish-black down. They are generally abroad by the middle of May. It has been remarked, that when, during incubation, or even when the young have left the nest, one of the old Birds is killed, the survivor soon finds a mate. Ravens, if unmolested, breed in the same spot year after year.

Few Birds are possessed of more estimable qualities than the Raven. His constitution is such as to enable him to brave the fury of the most violent tempests, and to subsist amidst the most intense cold; he is strong enough to repel any bird of his own size, and his spirit is such as to induce him to attack even the Eagle; his affection towards his mate and young is great, although not superior to that manifested by many other birds; in sagacity he is not excelled by any other species; and his power of vision is at least equal to that of most others, not excepting the Birds of prey, for he is generally the first to discover a carcase. To Man, however, he seems to be more injurious than useful, as he is accused of killing weakly sheep, sometimes destroys lambs, and frequently carries off the young and eggs of domestic poultry. For this reason he is generally proscribed, and in many districts a price is set upon his head; but his instinct and reason suffice to keep his race from materially diminishing. He seems to have fewer feathered enemies than most other Birds, for although he may often be seen pursuing Gulls, Hawks, and Eagles, we have never seen any species attacking him, with the exception of the Domestic Cock. It has been alleged, however, that Rooks assail him in defence of their young, and there is nothing incredible in this, for the weakest bird will often in such a case attack the most powerful and rapacious.

Numberless anecdotes are told of the Raven in the domestic state, but as our space is limited, we are unable to present any of them; and have only further to state, that young birds are easily reared, become perfectly tame, may be taught to pronounce words, and form amusing, though occasionally mischievous pets. The species is very widely distributed over the globe, being more or less common in Europe, Asia, and America, but more abundant towards the Arctic regions.

**EAGLES' NESTS.**—"An Old Correspondent" of London's Magazine states, that not many years ago, the Eagle had its nest annually in two places on the borders of the counties of Dumfries and Selkirk. One was on a precipice in Eskdale; "the other situation was chosen with much of that touch of reflection that we sometimes observe among birds, as well as others of the lower animals. There is a small rocky islet, almost even with the water, in Loch Skene, which is surrounded with the highest mountains south of the Forth; and, although the side of one of these mountains, that overhangs the lake, is rocky and seemingly inaccessible, the Eagles chose to have their nests on the islet in the loch, because, forsooth, the loch-erag could be approached by ropes from above, while it is almost impossible to convey a boat to the loch, and there never was one there." Now, we would have naturalists to think a little before they state a fact, and be sparing of the theory. A boat has been conveyed to the loch, and the Eagles of the district are extinct. The side of the mountain "that overhangs the lake" is a rocky slope of less than forty degrees, and certainly does not afford a spot to which a person without a rope might not approach to within ten yards. Eagles often make their nests in very insecure places. We have seen several that could easily be got at by a steady person. One was in a rock not thirty feet high, on the edge of a lake in Harris; another on a smaller rock among the hills of that island; a third at the height of sixty feet in the island of Shelly; a fourth about thirty feet from the top of a rock on the west coast of Harris; a fifth at least five hundred feet of perpendicular height from the sea, but not ten feet from the brink of the precipice, which, however, was surmounted by a very steep and slippery slope; a sixth was on a small island in a lake, in the pass of Mliavag, surrounded by precipices, compared with which the rocks of the south of Scotland are contemptible, and on which were many utterly inaccessible spots. The Eagle seems, in fact, to have no precise notions as to either ropes or boats; and it is unnecessary to attribute to her more sagacity than she possesses. She certainly selects what she considers the safest spot, but without regard to its altitude; and, accordingly, her nest may be seen on the gravelly beach of a small lake, or on the summit of a precipice five hundred feet high. In this respect she resembles the Starling, whose nests we have seen in high precipices, on grassy slopes, and in deserted rats' holes, close to the tide-mark.

**RUMP GLAND OF BIRDS.**—The uropygial gland of Birds, being one of the few organs accessible to the external-character Ornithologists, has been the subject of much discussion. Its uses are still unknown; although it was at one time confidently asserted to be a reservoir of oil, to be employed by the Bird for anointing its feathers. It is a remarkable fact, however, that the rumpless race of the domestic fowl, which is destitute of this organ, has its feathers not less perfect than those races which are complete in all its parts; and therefore it has been maintained, that the contents of the gland are not applied to the purpose alleged. No person has actually seen a Bird squeeze the oil from the gland, and apply it to the plumage; and it seems quite impossible that many species, whose bills are of great length, or of a form ill-adapted for the purpose, could thus besmear their feathers: the Curlew, for example, the Spoonbill, the Pelican, and the Gannet, whose head and neck, although beyond reach of their bill, is always in as good condition as any other part of their body. It is a well-known fact, that in Birds, when moulting, this gland is greatly enlarged, and in eagle-birds often inflames and suppurates in consequence of the increased action which takes place in it. But it has not hitherto been known, that when the moult is completed, or rather, when the feathers of the tail are fully developed, the organ diminishes to such a degree, that frequently little of it can be seen besides its nipple-like prominence. We were led to make this observation by finding it much reduced in a fine Peregrine Falcon, shot in the beginning of winter, and of which the tail seemed complete, while in a Pigeon which had been killed when several of the tail feathers were sprouting, it was extremely large. Since then, we have inspected a multitude of birds, and in almost every case where the tail was full grown, have found the rump-gland very small. It therefore, in all probability, has reference to the development of the caudal quills in a manner which we shall explain on a future occasion, and in this respect is analogous to certain other organs in Birds which undergo periodical changes.

**IRREGULAR GROWTH OF THE TEETH OF RODENTIA.**—Professor Meisner of Basle has recently given some account of the prodigious growth of incisor teeth in some of the *Rodentia*, which he thus accounts for. These teeth, in their normal state, are continually growing in length, slowly rising in height from the alveola, in such proportions as become requisite to compensate for the daily wearing away of their chisel-formed edges. This growth not ceasing during life, he remarks that all such teeth are invariably tubular at their base; and that the same effect is produced not only in the incisor teeth, but in all others whose roots remain unclosed. In animals, such as the Elephant, Babroussa, Hippopotamus, and Narwhal, where these bony productions serve as a defence, the same observation seems fully to apply; and they sometimes attain an enormous length, no given measure having been ascribed to them for the full period of their maturity, that depending solely upon the duration of the animal's life. In the molar teeth of Hares, Rabbits, the Beaver, and some other Rodentia, this fact holds equally good; but it is not so in the domestic Rat, Mouse, and others, in which the alveola is always closed. He cites the observations of Blumenbach on the monstrous growth of the molar teeth of a Hare, examined by him, and also those of Rudolphi on a similar Jusus in a Guinea Pig. We have fully confirmed these observations by an examination of several extraordinary examples of this phenomenon in the matchless Museum of the College of Surgeons. In a Rabbit, we observed the incisor teeth to have grown in a spiral form; in a Hare, also, in which,

from their position, they must have occasioned the animal's death, by entering the head, or pressing so firmly upon it, at either side, as to wound the flesh and penetrate in. It thus appears clear, that a beautiful provision of Nature is exhibited in the formation of these teeth; their continual increase enables them to preserve a fine, even, cutting edge, always set to a particular angle with each other, so long as they remain truly in opposition; the motion of gnawing or cutting their food having also the effect of keeping the teeth sharp, by means of their constantly slipping over each other. If, however, by any accident, or malformation of parts, these teeth cease to act against each other, their growth still going on, they form a curved line, extending to an indefinite length during the animal's life, and occasioning, no doubt, in many instances, premature disease and death. So perfect is Nature in all her mechanism, that the slightest deviation from it, by accident or other causes, produces fatal effects.—*The Naturalist.*

### BOTANY.

NOTES RESPECTING THE VALUE OF SPECIFIC CHARACTERS.—M. Wiegmann, in a letter addressed to the Editor of the *Flora* (1835, p. 106), communicates some observations made by him on this subject. The results obtained by him give little countenance to those authors who raise the slightest deviation of form to the rank of a species. Certain genera, of which numerous species are cultivated in the gardens, such as *Veronica*, *Verbascum*, *Delphinium*, and *Thalictrum*, are rich in species of which the native country is unknown. The origin of multitudes of nominal species in our catalogues may easily be accounted for by the changes caused by cultivation, and the numerous hybrid forms whose production is favoured by the proximity in which species of the same genus are placed in Botanic gardens. In 1833, the author saw a plant of the onion, *Allium Cepa*, bear a bulb in place of seeds. In the following spring, he put this bulb in the ground, and was astonished to find, that from it sprung up the *Allium proliferum* of Schrader, with a nearly naked, flexuous, and feeble stem, supporting a proliferous umbel, having sterile flowers on long pedicles. He refers to the numerous forms of *Iris* produced by M. Berg, and to the multiplicity of the *Calceolaria* and other ornamental plants. *Taraxacum palustre* he has found, under cultivation, to assume the appearance of the common species; and seeds of *Myosotis sylvatica* of Ehrhart, on being sown in the same spot, furnished five different forms, which authors consider as so many distinct species. Seeds of *Veronica agrestis* gave rise to six different forms. He is of opinion, that the numerous species into which the genus *Rubus* has been divided by Weisse, have been produced in the same manner.

PLANTS OF THE NORTH OF CHINA.—M. A. Bunge, who resided in China, during 1831, with the Russian missionaries, brought with him on his return a valuable botanical collection, the principal species of which he briefly described in a small work, at the same time communicating specimens to the Botanists, and especially to the herbarium of the Paris Museum. But as among these plants there were several very interesting species, he has thought proper to give more detailed descriptions, and to illustrate some of them by figures. As this work, which was printed at Casan, is not easily procurable, the Editors of the *Annales des Sciences Naturelles* have given an abstract of it in their number for July 1836.

### GEOLOGY AND MINERALOGY.

MICROSCOPIC FOSSIL ANIMALS IN TRIPOLI SLATE.—M. Ehrenberg has discovered that the friable siliceous slate, commonly called Tripoli, or polishing slate, is entirely composed of remains of Infusory animalcules of the family of Bacillariae. These remains retain their form so that they can be very distinctly seen with the microscope, and compared with living species. Bog iron-ore is also almost entirely composed of the species named *Gallionella ferruginea*. If a piece of one of these substances be rubbed a little on a glass plate, and the powder thus obtained mixed with water, thousands of animalcules may be seen with a good microscope.

OXIDULOUS COPPER.—Mr G. B. Sowerby, in Loudon's Magazine for March 1837, gives an account of the occurrence of detached cubes of this mineral in Cornwall.—“They vary in dimensions from a quarter to nearly three quarters of an inch: they are of a very dark colour; many of them are nearly complete at all their angles, more particularly the smaller ones. Occasionally two or three are grouped together; some of them are accompanied by a small quantity of green carbonate of copper. Very few are slightly modified, having some of the planes which tend to the rhombic dodecahedron; and one very large crystal, being exactly half an inch long, which is adhering to a like quality, has the planes of the octohedron as its solid angles.”

### METEOROLOGY.

LUMINOUS METEOR.—Mr Couch, in a paper on Shooting Stars, published in Loudon's Magazine, mentions the following singular phenomenon, which he states to be incapable of explanation on any principle “of our philosophy.”—“On July 1, 1832, riding homeward in the evening, whilst the lightning was vivid, and thunder loud and frequent, a ball of light, of about the size of a large orange, met my view on the right, towards the north-west, distant about twenty yards. As if projected from a cannon, it passed straight and rapidly across the lane, close before me, and was instantly lost sight of on the other side. The whole was the work of an instant; the ball, of a steel blue, passing but at the elevation of my head, unattended by any noise or explosion, and evidently unconnected with the lightning that glared around.”

STORM OF THE 29TH NOVEMBER 1836.—Mr W. H. White, in his Meteorological Retrospect for 1836, in Loudon's Magazine, gives the following account of this memorable hurricane:—“The violent gusts of wind, chiefly from the N.W., did much damage, leaving many a sad memento behind, both by land and sea. From

the most authentic accounts of this gale which have reached me, it appears that it commenced on the 23d, on the eastern shores of North America, off St Lawrence. A ship from Poole fell in with it on the 26th, in lat. 47° N., long. 32° 20' W., and was thrown on her beam ends. It continued its progress across the Atlantic, and reached the Land's End about 7 $\frac{3}{4}$  A.M.; Plymouth, 8 $\frac{1}{2}$  A.M.; Exeter, 9 $\frac{1}{2}$  A.M.; Weymouth, 10 A.M.; Poole, 10 $\frac{1}{2}$  A.M.; Farnham, 12 noon; London, 1 $\frac{1}{2}$  P.M.; Suffolk coast, 2 $\frac{1}{2}$  P.M.; and Hamburg, at 6 P.M. Thus the storm travelled at the rate of about 50 miles per hour; but the circular motion of the wind had a velocity of from 120 to 150 miles per hour. The fury of the gale was most felt on the coast of France and Belgium. At Ostend there was scarcely a house which was not unroofed; and so great was the demand for tiles, that they arose from 16 to 30 florins per 1000. The motion of the mercury in the barometer, during the most violent part of the hurricane, attracted great attention. On the morning of the 29th, at 9, the mercury stood at 29.30 in.; it soon afterwards began to sink very rapidly, exhibiting much agitation during the violent gusts of wind for which this hurricane was particularly remarkable, till 12 at noon, when it stood at 28.82 in. At 2 P.M., the barometer had risen to 29.35, soon after which the wind lulled into almost a calm.

### MISCELLANEOUS.

FIDELITY OF THE DOG, A PATTERN TO MAN.—In the Rev. Dr Duncan's Sacred Philosophy of the Seasons, recently published, is the following interesting anecdote of Burns: “While yet a school-boy, I enjoyed an opportunity of hearing, in my father's manse, a conversation between the poet Burns and another poet, my near relation, the amiable Blacklock. The subject was, the fidelity of the Dog. Burns took up the question with all the ardour and kindly feeling with which the conversation of that extraordinary man was so remarkably imbued. The anecdotes by which it was illustrated have long escaped my memory; but there was one sentiment expressed by Burns, with his own characteristic enthusiasm, which, as it threw a new light into my mind, I shall never forget. ‘Man,’ said he, ‘is the god of the Dog: he knows no other; he can understand no other. And see how he worships him!—with what reverence he crouches at his feet—with what love he fawns upon him—with what dependence he looks up to him—and with what cheerful alacrity he obeys him. His whole soul is wrapt up in his god; all the powers and faculties of his nature are devoted to his service: and these powers and faculties are ennobled by the intercourse. Divines tell us that it ought just to be so with the Christian; but the Dog puts the Christian to shame!’ The truth of these remarks, which forcibly struck me at the time, have since been verified by experience; and often have events occurred, which, while they reminded me that ‘Man is the god of the Dog,’ have forced from me the humiliating confession, that ‘the Dog puts the Christian to shame!’”

USES OF THE SALIVA.—M. Alp Donné has recently published a pamphlet on the saliva, very little light on the nature of which, he remarks, has been thrown since the time of Haller, physiologists being satisfied with attributing to it two uses: 1st, that of moistening the mouth, favouring the motion of the tongue, and facilitating speech and deglutition; 2d, that of penetrating the food, altering its condition, and aiding the solvent action of the gastric juice. M. Donné adds to these uses that of neutralising, by means of the free alkali which it contains, the excess of acid of the gastric juice, in the intervals between digestion. This fact serves to explain a difficulty respecting the gastric juice, which, although examined by the best chemists, has been found to vary much in its composition, being sometimes acid and sometimes alkaline. These differences M. Donné shows to be owing to the circumstances under which it is obtained. Thus, when procured in the morning, it must be but slightly acid or even alkaline, in consequence of being mixed with the saliva which has been swallowed through the night; whereas, when obtained by exciting the stomach of Dogs, it must contain a large proportion of acid, being then pure and unmixed.

MODE OF PREVENTING BEER FROM BECOMING ACID.—A patent has been taken out in America, for preserving beer from acidity in hot weather, by Mr Storewell, who gives the following statement:—“To every 174 gallons of liquor add one pound of raisins, which are put into it inclosed in a bag, previous to fermentation. The liquor may then be let down at 65°, or as high as 70°. The bag must remain in the vat until the process of fermentation has so far advanced as to produce a white appearance or scum all over the surface of the liquor, which will probably take place in about twenty-four hours. It must then be taken out, and the liquor left until fermentation ceases. The degree of heat in the place where the working vat is situated should not exceed 66°, nor be less than 60°.—*Journ. of Franklin Institut.*”

GREATEST WATERFALL IN EUROPE.—In the mineralogical report of Lapland presented to the Swedish Government, amongst other curious facts, the discovery of a great Waterfall in the River Lulea is particularly mentioned. It is said to be one-eighth of a mile broad, and at its greatest height to fall four hundred feet. It is probable, that the measurements in this document are according to the German standard, a mile being equal to four and a half English miles.

GAS FROM RESIN.—It has been ascertained by experiments, that five cubic feet of gas from resin gave as much light as nine of oil-gas. Respecting the products of combustion, or the purity of the gases, the advantages in favour of gas from resin are incontestable.

EFFECTS OF MAGNETISM ON CHRONOMETERS.—When Harrison's timekeeper was under trial at Richmond, it did not go as was expected. No one suspected the cause, till Geo. III., who interested himself much about the machine, suggested that it was affected by a magnet which was lying near it. The magnet was removed, and the timekeeper recovered its rate.

ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE CERCOPITHECI, OR GUENONS.

THE Long-tailed Apes, to which the French give the name of *Guenons*, have been separated from the rest of the very extensive family of Monkeys, and constitute a genus to which the appellation of *Cercopithecus* is applied. They are of moderate size, have a rather prominent muzzle, with a facial angle of about 60°, cheek-pouches, callosities or bare spaces behind, and a tail of moderate length, or sometimes longer than the body. The species are numerous, live in flocks, and are of a lively disposition. They are easily domesticated, and although petulant, do not manifest the vicious propensities of the Baboons, which are the most intractable and disgusting animals of the family.

Fig. 1. THE GREEN MONKEY OR GUENON (*Cercopithecus Sabaeus*).—This species, which inhabits Senegal and the Cape de Verd Islands, is one of those most frequently imported into Europe. They live in large flocks, ascend the tallest trees with the greatest agility, spring from one branch to another with unerring dexterity, and are at first little frightened by the report of a gun, so that, according to Adanson, specimens may easily be procured, although, on account of their colour, they are not always readily perceived.

Fig. 2. represents a variety of the same species, which some, however, have considered distinct. It is the *Malbrouc* of Buffon, the *Simia Faunus* of Gmelin.

Fig. 3. DIANA MONKEY (*C. Diana*).—This handsome species, distinguished by the dark colour of its upper parts, which are dotted with white, is also an inhabitant of Senegal, and other parts of Africa.

Fig. 4. THE MONA (*C. Mona*).—Of a brown colour, with the limbs black, the breast and a great part of the head white, the tail longer than the body. It inhabits various parts of Africa, as well as Arabia, India, and Persia, and is one of the species that agree best with the temperature of our climates. It is easily tamed, and being naturally timid, is rendered obedient by threats, while it is also capable of considerable attachment, and is not so mischievous as most Monkeys.

Fig. 5. ATYS, OR WHITE MONKEY (*C. Atys*).—The bare parts being flesh-coloured, and the fur white, this has by some been supposed to be merely an albino variety of some other species.

Fig. 6. SOOTY OR COLLARLESS MANGABEY (*C. fuliginosus*).—Of a chocolate brown on the upper parts, and said by Buffon to inhabit Madagascar.

Fig. 7. COLLARED MANGABEY (*C. Æthiops*).—Somewhat similar to the last, but having a white band between the eyes, and another on each side of the head. It is said to inhabit Madagascar and Abyssinia.

DESCRIPTION OF THE PLATE.—THE AGATE-SHELLS.

THE genus *Achatina* belongs to the Trachelipodous order of Lamarck, and to the family of *Colinaces*, or Snails. It is composed of species generally of large or moderate size, of which the ovate or oblong shell, which is usually thin, with an entire, thin-lipped mouth, is for the most part marked with various colours. These shells, in fact, are very beautiful, and several, being also rare, are of comparatively high price. Lamarck supposes them to be terrestrial, but to live in the vicinity of water.

Fig. 1. THE ZEBRA AGATE-SHELL (*Achatina Zebra*).—Longitudinally striped with red and brown on a white ground, this shell, which is one of the largest of the family, is also one of the most beautiful. It attains a length of six or seven inches, and inhabits Madagascar.

Figs. 2, 3. WHITE-LINED AGATE-SHELL (*A. albo-lineata*).—This species, which is seldom more than an inch and a half in length, differs in form from the preceding, by having the last turn compressed so as to narrow the mouth. It is found in Martinique.

Fig. 4. ACUTE OR SHARP-POINTED AGATE-SHELL (*A. acuta*).—Somewhat similar in form and markings to the Zebra-shell. It is found near Sierra Leone.

Fig. 5. PURPLE-MOUTHED AGATE-SHELL (*A. purpurea*).—This species, which, according to Lister, inhabits Africa and Jamaica, is in much request, on account of the beautiful purple tint with which the inner surface of its mouth is ornamented.

Fig. 6. represents a variety of the same shell, having the spire more variegated, and its turns following an opposite direction, so that the mouth is placed on the other side, an anomaly which sometimes presents itself in shells of this order, as well as in many others, which are then said to be *reversed*.

Fig. 7. CHESTNUT AGATE-SHELL (*A. castanea*).—The individual represented is paler than usual, the colour being generally reddish-brown. The native country unknown.

Fig. 8. THE FIERY AGATE-SHELL (*A. fulminea*).—Of an elongated spiral form with red longitudinal bands on a whitish ground. It inhabits St Domingo.

Fig. 9. VARIEGATED AGATE-SHELL (*A. variegata*).—From the West Indies.

Fig. 10. VIRGIN AGATE-SHELL (*A. virginica*).—Although common in collections, one of the most beautiful species of the genus, being girt with black and red bands on a white ground, and with the inner lip rose-red. It comes from the West India Islands.

BRITISH BIRDS, NO. II.

THE GOLDEN EAGLE.—Of the various Birds that inhabit this country, perhaps none have attracted more attention than the Eagles, of which two species are indigenous. The Golden or Ring-tailed Eagle (*Aquila Chrysaetus*), although formerly not uncommon in various parts of Britain, is now chiefly met with in the mountainous districts of the middle and northern divisions of Scotland, and in the larger Hebrides, where the species still maintains a rather precarious existence. Excepting the White-tailed Sea Eagle, *Haliaeetus Albicilla*, it is the largest of our rapacious birds. As is generally the case among the Raptores, the male is much inferior in size to the female. Several individuals were about two feet nine inches in length, their expanded wings measuring about six feet; the body robust; the neck of moderate length; the head rather large; the wings when closed reaching nearly to the end of the tail, which is rather long, broad, and rounded; the bill is rather short, very deep, compressed with a curved acute tip; and the feet, which are feathered to the lower tarsal joint, are very muscular; the toes strong, united at the base by a short web, and furnished with large, curved, tapering, acute claws, rounded on the sides, and flat beneath; those of the first and second toes being largest. The bill is greyish blue at the base, black at the end, as are the claws; the cere and toes yellow. The general colour of the plumage is dark brown; the hind head and neck light yellowish-brown; the inner and fore sides of the legs and tarsi reddish-brown. The quills are brownish-black, their inner webs irregularly barred with greyish-white; the tail brownish-black towards the end, its proximal part lighter, and irregularly barred or mottled with greyish. The female is generally about three feet two inches in length, with the extended wings measuring about seven feet; the weight varying from ten to twelve pounds. The colours are similar to those of the male, but generally lighter. Young birds have the basal portion of the tail white, that colour being gradually encroached upon by the brown, until the fifth or sixth year, when it entirely disappears.

This beautiful, powerful, and rapacious bird, having very frequently come under our observation both in the wild and captive states, we are enabled to present to our readers a somewhat detailed account of its habits. All Eagles when at rest have a peculiarly clumsy appearance, owing chiefly to the great size of their wings, which they seem to find it difficult to dispose of in a neat and compact manner; but when roused they assume a bold and lively attitude, rendered more imposing by the glare of their full and bright eyes, which are partially overshadowed by the projecting lachrymal bones or eyebrows. The Golden Eagle is more lively than the Sea Eagle, and of more destructive habits; for, although a carrion bird, it frequently seizes grouse, hares, and other small animals, and sometimes attacks even deer and sheep. Great havoc is occasionally made by it among the lambs, before they have attained the age of six weeks; and in consequence of the injury thus inflicted, various methods have been employed for reducing its numbers. Sometimes its nest is assailed from above, by letting down a person upon a rope, who generally succeeds in destroying its contents, whether by removing them, or by lowering among them a bundle of combustible matter with a live coal enclosed. The old birds are shot, by being enticed, by means of a dead Sheep or Horse, to a spot in the immediate vicinity of which a person is concealed under ground, or in a small hut, so covered with heath that it cannot be distinguished from the surrounding surface. More commonly, however, Eagles are trapped, at least on the mainland of Scotland.

The flight of the Golden Eagle is very beautiful. Owing to the great size of its wings, it finds some difficulty in rising from the ground, although it is considerably more active in this respect than the white-tailed Eagle; but when fairly on wing, it proceeds with great ease, and on occasion is capable of urging its speed so as to equal that of most large birds. However, even at its utmost stretch, it is certainly much inferior to that of the Rock Pigeon, the Merlin, and many other species; and the Raven, during the breeding season, finds no difficulty in overtaking an Eagle that may happen to fly near his nest. When searching the hills for food, it flies low, with a motion of the wings resembling that of the Raven, but with occasional sailings and curves, in the manner of many hawks. At times it ascends high into the air,

and floats in a circling course over the mountains, until it has discovered some large object; but in tracing grouse and other animals concealed among the herbage, or in hunting for sea-fowls and their young, it does not indulge in those aerial gyrations, which many closet and some field naturalists have supposed to be performed solely for the purpose of enabling it to spy out its prey from afar. In its ordinary flight, it draws its legs close to the body, contracts its neck, and advances by regular flap-pings of the wings; but when sailing, it extends these organs nearly to their full stretch, curving them at the same time a little upwards at the tips. An Eagle sweeping past in this manner is a most imposing object, the more especially if in the vicinity of its rocky haunts, and still more if the observer be groping his way along the face of a crag, anxiously seeking a point or crevice on which to rest his foot.

Both our native Eagles sometimes ascend to an immense height in fine weather, and float high over the mountain tops for hours together; but certainly not for the purpose of descrying the objects beneath, for no person has ever observed their sudden descent from this sublime station. It is a popular notion, countenanced even by many anatomists and others, who ought to know better, that the Eagle mounts towards the sun in order to enjoy unrestrained the sight of that glorious luminary. They tell us that its eye is peculiarly fitted for this purpose by having a strong semi-opaque nyctitant membrane, by means of which the rays are blunted; but they forget that the common duck, the domestic fowl, and the sparrow, which are not addicted to astronomical investigation, have eyes organized precisely in the same manner.

On the ground, the Golden Eagle, like all others, is extremely awkward; for, owing to its large wings, its great weight, and the form of its toes, which are encumbered with very large curved and pointed claws, it can only walk in a very deliberate manner, or move from place to place by repeated leaps, in performing which it calls in the aid of its wings. Its feet in fact are not adapted for walking; they are most powerful organs of prehension, capable of inflicting mortal injury on any animal not exceeding a Sheep in size. It is with them that it deprives its prey of life, and carries it off to its nest or to some convenient place of retreat. With its curved bill it tears off the feathers and hair; separates morsels of the flesh, and even crunches the bones of small animals.

It is seldom that the Golden Eagle ventures under any circumstances to attack a human being. A respectable person in Sutherland relates that two sons of a man of the name of Murray, having robbed an Eagle's nest, were retreating with the young, when one of the parent birds, having returned, made a most determined attack upon them. Although each had a stick, it was with great difficulty that they at length effected their escape, when almost ready to sink under fatigue. The Rev. Mr Inglis, Lochlee, has furnished us with a similar anecdote. The farmer of Glenmark, whose name was Miln, had been out one day with his gun, and coming upon an Eagle's nest, he made a noise, to start her, and have a shot. She was not at home, however, and so Miln, taking off his shoes, began to ascend gun in hand. When about half way up, and in a very critical situation, the Eagle made her appearance, bringing a plentiful supply to the young which she had in her nest. Quick as thought she darted upon the intruder, with a terrific scream. He was clinging to the rock by one hand, with scarcely any footing. Making a desperate effort, however, he reached a ledge, while the Eagle was now so close that he could not shoot at her. A lucky thought struck him: he took off his bonnet and threw it at the Eagle, which immediately flew after it to the foot of the rock. As she was returning to the attack, finding an opportunity of taking a steady aim, he shot her; and, no doubt glad that he had escaped so imminent a danger, made the best of his way down.

The male and the female keep together all the year round, and very probably remain attached for life; but should one of them be killed in the breeding season, the survivor is not long in repairing his loss. This circumstance is not peculiar to Eagles, but has been frequently observed in other birds, more especially those of the Crow family. The Golden Eagle prepares its nest about the beginning of March, choosing a place for it as nearly inaccessible as possible. Although it is often met with on the maritime cliffs of the Hebrides, yet the species has a greater predilection for inland precipices than the Sea Eagle. It is of great size, flat, and formed of sticks, twigs, grass, and other materials. The eggs are generally two, sometimes single, yellowish white, with irregular, pale, purplish dots. The young are fledged about the end of July, and soon after coming abroad, are left to shift for themselves, or are driven off from the haunts of their parents.

The cry of this species is clear and loud, and may be heard in calm weather to the distance of a mile. It resembles the syllable *cleek* or *qweek*, several times repeated; but although in captivity the bird frequently utters it, in the wild state it is less loquacious. When kept a prisoner it is more ferocious than the Sea Eagle, and can scarcely be trusted even by the person who supplies it with food. The capability of existing under long-continued privation has sometimes been exhibited in a wonderful degree by captive Eagles, which have been accidentally neglected for days or even weeks.

Many marvellous tales are told of Eagles, and there is scarcely a parish in Scotland, in which, if tradition be correct, they have not carried off a child. According to popular belief, an Eagle transported one from the island of Harris to Skye, over a space of about twenty miles; but as even more wonderful events are as firmly believed, no confidence can be reposed in such accounts. Although individuals of the species sometimes appear in various parts of England, it is probable that they seldom or never breed in any district of that country. The species has been extirpated from the South of Scotland, as has very nearly been the case with the Sea Eagle; and it is only in the central ranges of the Grampians, or in the wild glens of the northern division, and among the hills of Skye, Rum, Harris, and other islands on the north-west coast, that the Ornithologist has much chance of meeting with it. How few of those who have given detailed histories of this bird have ever seen it, but how much more few they who have enjoyed opportunities of studying its manners! A single fact is of course worth more than a volume of idle imaginings; and however much the above account may yield in interest to those of others, it has the merit of being entirely derived from personal observation.

REMARKS ON THE DIGESTIVE ORGANS OF BIRDS.—Whether the intestinal canal may be employed, in preference to the sternal apparatus, the bill, the feet, or the nervous or respiratory organs, as a basis for the classification of animals, is a question which we do not intend here to discuss; but of its importance in the animal economy, and of the superior facility with which it may be examined, no one having any acquaintance with Comparative Anatomy will entertain a doubt. The accompanying figures represent the digestive organs of the Red Grouse or Ptarmigan (*Lagopus Scoticus*), which being common in our markets during the autumn and winter, can be readily procured for inspection. Its bill is short, somewhat conical, strong, with sharp edges, and a rather rounded point.

The Tongue, Fig. 1, *a*, is short, triangular, pointed, flat above, sagittate and papillate at the base. The Oesophagus, *b, c, d, e, f, g, h*, is six and a half inches long, narrow, and having a distinct muscular coat composed of transverse or circular fibres, with an internal mucous coat, studded with glandules or crypts, which pour out the clammy fluid with which it is constantly moistened. On the lower part of the neck, it is expanded, or opens into a large membranous sac, of a roundish form, the crop, *d, e*. On entering the thorax, at *f*, it is narrowed; but at *g* appears enlarged, which, however, is owing solely to the thickness of its walls there. This part, named the *proventriculus*, has, between the outer muscular and inner mucous coat, a great number of oblong hollow glandules, that secrete a peculiar fluid, which is copiously poured out into the cavity of the organ. Here the Oesophagus terminates, and is succeeded by the stomach or gizzard, *h, i, j, k*. This organ is of a roundish or somewhat rhomboidal, lobulated form. Its outer coat is composed of two very powerful lateral muscles, *i, j*, of which the fibres converge, become tendinous, and are inserted into a roundish tendinous space on each side; of a lower muscle, *k*, of the same nature, but less powerful; and of a belt of superior transverse fibres, *h*. Within this muscular coat is another, of a dense texture, thin, and having a semicartilaginous appearance. The inner coat is a very rough, hard, rugous sac, of which the portions opposite the two lateral muscles, *i, j*, are thicker and harder than the rest. The intestine comes off on the right side at *l*, forms a curve, *l, m*, which returns upon itself, *m, n*, enclosing the pancreas, and receiving its ducts, together with those bringing the bile from the liver and gall-bladder. The intestine, *n, o, p*, is then convoluted in the abdomen, and before terminating at *q*, sends off two processes, or caeca, which are represented by Fig. 2, in which *a, b*, is a portion of the intestine, *c, d, e, f*, the two caeca. The intestine has beneath its external or peritoneal filmy covering, a distinct muscular coat, composed of circular fibres, and an internal coat, having its surface villous, or raised into very delicate filamen-

tary processes. The cæca have a similar structure, and are internally villous, but are also marked internally with about seven longitudinal, prominent, white bands. This description, brief and superficial as it is, will afford a more precise idea than a laboured account to the tyro, to whom alone it is addressed, and who, with this beginning, may easily perfect his knowledge by examining the organs of such birds as he can readily procure.

The physiology of the matter, also briefly sketched, is this:—The Red Grouse feeds on the tops of heath, *Calluna vulgaris*, and *Erica cinerea*, the leaves and twigs of *Vaccinium Myrtillus*, and *Empetrum nigrum*, with young heads of cotton-grass, shoots of *Galium saxatile*, carices, grasses, willows, and other plants, as well as berries. While feeding, it walks among the heath, selecting the fresh tips of the twigs, which it breaks off nearly of a size, the largest pieces not exceeding half-an-inch in length. Along with these substances it occasionally picks up a small fragment of white quartz. Before it ceases it has filled the œsophagus and crop—the latter holding a very considerable quantity, as its diameter is nearly three inches. It then reposes among the heath. The crude food is propelled downwards by the successive contraction of the muscular fibres of the œsophagus, until the stomach is filled, when the lateral muscles of that organ, *i, j*, alternately contract and relax, and thus agitate the mass of food, pressing it against the horny rugæ of the inner coat, and causing the numerous particles of quartz, a substance harder than glass, to cut or lacerate the fibres, which have been moistened with the copious clammy fluid of the proventriculus, *g*. The crop, *d, e*, it must be understood, is merely a recipient, and is destitute of mucous glandules excepting near its mouth; nor do its fluids, which are scanty, exert any solvent power upon the food. But the fluid of the proventriculus, *g*, operates both as a solvent and a diluent. The mass contained in the stomach, being reduced to a coarse pulp, is forced, by the general contraction of the muscles, into the intestines, through the pyloric opening at *l*. In the upper part, or duodenal fold of the intestine, *l, m, n*, it is further diluted by the pancreatic fluid, and mixed with the bile; and as it gradually passes along the intestine, its nutritious parts are separated, adhere to the surface, and are taken up by the absorbents to be carried into the mass of the blood. As it advances, the woody fibres and fragments of leaves become more perceptible; and as the mass passes the mouth of the cæca, the finer particles are taken up by them, until their entire cavity is filled with a brownish pulpy fluid, which seems to undergo there a second elaboration, and to be absorbed, the residue being returned into the intestine, where it accumulates in the rectum, and is voided in concrete cylindrical fragments.

All the Gallinaceous Birds have a crop, a powerful gizzard, and cæca of which the capacity is about equal to that of the intestine; but these cæcal appendages vary greatly in form and length, being cylindrical in Grouse and Ptarmigans, and oblong towards the end in Pheasants and other species. In the Pigeons there is also a large crop, and a strong gizzard; but the cæca are merely rudimentary, seldom exceeding a third of an inch in length, with a diameter of about two lines. In many Birds the œsophagus has no dilatation or crop, and the stomach exhibits all the gradations, from the powerfully muscular kind or gizzard of the Gallinaceous Birds and Pigeons, to the fibro-membraneous sac of Owls and Hawks. In Birds that feed on fish, the œsophagus is extremely dilated, and the stomach reduced to small size;—in short, the variations exhibited are at least as great in this class as in any other, and the organs in question none but those who are unacquainted with them can possibly consider as of less importance to the scientific Ornithologist than the feathers, or other appendages of the dermal system. If the intestinal canal of any bird be laid before a person who has examined that series of organs, he can instantly determine the group or family of the species to which it belonged.

**THE BRENT GOOSE.**—Having recently had occasion to examine the Cromarty Frith, one of the estuaries of the north-eastern coast of Scotland, we were delighted to find upon it vast flocks of Brent Geese, *Anser Bernicla*. These birds arrive there in the beginning of winter, and remain until the end of spring, keeping generally in the expanded part of the frith, between Invergordon and Cromarty Ferry. On the northern side of that portion of the estuary are very extensive flats of sand and mud, which are exposed when the tide recedes, and then present in many places the appearance of large meadows, being covered with Sea Grass, *Zostera marina*, of which the long, creeping, cylindrical, saccharine roots afford them an abundant supply of food. We have seen probably ten thousand of these Geese on the shoals, together with nearly an equal number of Gulls of various species, but chiefly *Larus canus*, and *Larus ridibundus*. The Brent Geese also frequent the Beaulie Frith, but in much smaller numbers. The best account of this species is that by Mr Selby, in his Illustrations of British Ornithology, in which it is mentioned that the gizzard is frequently found “filled with the leaves and stems of a species of grass that grows abundantly in the shallow pools left by the tide,” and which may possibly be the *Zostera*. Mr Selby states that they leave the Northumbrian coast between the end of February and that of March. According to the reports of the “natives,” they remain much later in Cromarty Bay; and, on the 22d March, when we saw them there, the flocks had not begun to break up.

**MATERNAL SOLICITUDE OF THE PARTRIDGE.**—In the county of Linlithgow, for three years past, the Partridges have been rapidly disappearing. During the month of July in these years, there were several successive days of uncommonly wet weather, in which a vast number of the young lost their lives. Their attachment to their brood is truly astonishing. I have known them, day after day, sitting on their young, until, on account of the rain, they all died; but I never heard or saw such striking instances of their care and tenderness as those which took place last season. I knew of two broods in my neighbourhood, in protecting which both father and mother sacrificed their lives. The one consisted of twelve birds. The male and the female were found sitting close together, with their wings spread out, and six chickens under each. The other consisted of ten birds. The male and the female were found in the same situation, with five birds under each, and all of them dead. So anxious had they been to protect their tender offspring from the rain, that they starved themselves to death, rather than suffer them to run any risk. Mr Mellis, gamekeeper to Sir William Baillie of Polkemmet, told me that he knew several instances of the same

kind last season, an occurrence which he never before had observed. How beautifully does it illustrate our Saviour's lamentation over Jerusalem, once the holy and beloved city of God, and the joy of the whole earth, but so soon, alas! to be devoted to irretrievable destruction!—*Boghead*, 21st March 1837.—T. D. WEIR.

## BOTANY.

**PINE FORESTS OF SCOTLAND.**—The aboriginal woods of Britain have been so much destroyed in consequence of the increase of population, that few remains of them are now to be found beyond the limits of the Highlands of Scotland, and even there it is only in some of the more remote valleys that continuous tracts of sylvan vegetation are met with. The species which are most abundant in those remains of our ancient woods are the Oak, the Birch, and the Pine. Oak-woods, however, are generally reduced to the state of copses, which are periodically cut down for their bark, and for hoops and other articles of domestic and rural economy. Birch forests are still to be seen in many places, especially the glens of the Grampians, and the mountains of the northern division, and as they are not so useful as those of oak and pine, they have a chance of remaining for a much longer period. The pine forests are almost entirely confined to the valleys of the Dee and the Spey, where, however, they have of late years suffered extensively from the axe. In Braemar, trees having a girth of from ten to twelve feet are not uncommon, but most of the larger trunks near the Dee have been cut down, and floated to Aberdeen. In Badenoch and Strathspey, the long ranges of native pine, sombre as they may be in the eyes of the Lowlander or Englishman, afford a delightful feeling to the lover of wild nature, and to the Celt revisiting his native home, after years of absence in a foreign land, must impart a joy more intense than that experienced on contemplating the palm groves of the most sunny climes. In those woods once roamed the wolf and the wild ox, while the stately stag betook itself to the grassy valleys, and the graceful roe browsed among the thickets of alder and willow that skirted the streams. The wild pine of the Highlands has a very different appearance from the trimmed and formal trees of the plantations; its trunk is thicker, shorter, and less rugged; its branches more spreading and covered with a redder bark undisfigured by lichens, and its wood is more resinous and of a redder tint.

**ON THE WAKE AND SLEEP OF PLANTS,** by M. DUTROCHET.—There are flowers that have only a single wake, which is their expansion, and a single sleep, which immediately precedes the death of the corolla. Of this kind are the flowers of *Mirabilis* and *Convolvulus*. Other flowers present alternations of sleep and waking for several days, such as that of the Dandelion, *Leontodon Taraxacum*.

The flower of *Mirabilis Jalapa* and *M. longiflora* opens its funnel-shaped corolla in the evening, and closes it in the following morning. This flower may be considered as formed by the union of five petals, each of which has its middle nerve. The five nerves which sustain the membranous tissue of the corolla, in the same manner as the whalebone slips support the cloth of an umbrella, are the sole agents of the movements by which are produced the opening of the corolla, or its state of waking, and its closing or sleep. In the former case, the five nerves curve so as to direct their concavity outwards; in the latter, they bend so as to direct their concavity towards the interior of the flower, and they thus carry with them the membranous tissue of the corolla as far as the orifice of its tubular canal.

Thus the same nerves, at two different periods, successively perform two opposite motions of incurvation. I have observed, with the microscope, the internal organization of these nerves. They present, at their outer side, a cellular tissue, of which the cells, disposed in longitudinal series, chiefly diminish in size from the inner towards the outer side, so that, during the turgescence of these cells, the tissue which they form must curve in such a manner as to direct its concavity outwards. It is by it, therefore, that the expansion of the corolla, or what is named its wake, must be operated. On the inner side of each nerve there is a fibrous tissue, composed of transparent fibres extremely slender, and intermingled with globules arranged in longitudinal series. This fibrous tissue is situate between a layer of tracheæ or spiral vessels on the one hand, and a layer of superficial cellules filled with air on the other; so that it is placed between two laminæ of pneumatic organs.

On separating, by a longitudinal section, the cellular tissue and the fibrous tissue, of which the nerve is composed, and then immersing it in water, I found that the cellular tissue curved outwards, while the fibrous tissue curved towards the interior of the corolla. These two inverse curvings invariably took place. Thus it is without any doubt the cellular tissue of each nerve that, by its incurvation, produces the wake or opening of the corolla, and the fibrous tissue that, by its incurvation in the opposite direction, effects its sleep or closing.

I separated a nerve from a corolla of *Mirabilis* which was yet in bud, but near the period of expansion, and on immersing it in water, observed that it curved strongly outwards, thus instantly taking the curve which produces the expansion or wake of the corolla. I then removed it into syrup, when it curved in the opposite direction, or inwards. This proves that, in the second case, there was turgescence of the cellules, the external water then, from the effect of endosmosis, directing itself towards the organic liquid that existed in these cellules; and that, in the second case, there was depletion of the cellules, because their organic liquid, being less dense than the external syrup, then directed itself towards it. It might be thought from this experiment, that the spreading or wake of the corolla being owing to the turgescence of the cellular tissue of its nerves, its shutting or sleep must be owing to the depletion of the same tissue; but it is proved by experiment, that this is not the cause of the shutting or sleep of the corolla. I separated a nerve from a corolla near the period of opening, and immersed it in water. This nerve, which was curved slightly inwards, as is the case in the corolla, when in bud, curved strongly outwards, or in the direction which produces expansion or the state of waking. Endosmosis then determined the turgescence of the cellular tissue, which is the organ of this incurvation. When it had been immersed about six hours, the nerve gave up its outward bend, began to curve inwards, and was soon entirely rolled up.

This succession of phenomena is entirely independent upon the action of light. Thus, the nerve of a corolla of *Mirabilis* assumes in water the curve which effects

the opening of the flower; and again, at the end of some time, takes the bend that produces sleep. If, therefore, as cannot be doubted, it is the turgescence of the cellular tissue of the nerves that produces the incurvation on which depends the wake of the corolla or its expansion, it is to quite a different cause that we must refer the incurvation to which is owing the sleep of the corolla or its closing; for it cannot be admitted that cellular tissue, immersed in water, is emptied. The experiment mentioned above proves that it is the fibrous tissue contained in each nerve of the corolla that is the agent of the inward curvature, or that to which the sleep, or shutting of the corolla, is due. We must, therefore, perceive, that in the nerves of the flower of *Mirabilis*, the incurvation of waking, or that of which the concavity is directed outwards, and which is owing to the turgescence of the cellular tissue, at first predominates over the incurvation of sleep, or that whose concavity is directed towards the interior of the flower, and which is due to the action of the fibrous tissue; and that afterwards the incurvation of sleep, which depends upon this latter tissue, ultimately proves victorious. The outward incurvation which the cellular tissue affects when the nerve is immersed in water, changes to inward curvature when the nerve is immersed in syrup; which proves that it is endosmosis that acts here. Now, when the nerve, on being placed in water for some hours, has then taken the second curvature, or that of sleep, it does not lose it when removed into syrup. It is not then endosmosis that has occasioned this second incurvation, or that of sleep.—(To be continued.)

### MISCELLANEOUS.

#### DESCRIPTION OF THE FRITH OF CROMARTY, AND REMARKS ON ESTUARIES.

THE subject of Estuaries being one of great importance, not merely in a geological, but also in an economical point of view, and more especially with relation to the salmon fisheries, we have thought that an account of one of the most remarkable of those of our Eastern coast might prove interesting to our readers.

The Cromarty Frith is an Estuary or Inlet, extending from the northern coast of the Moray Frith, in a slightly curved direction, to the town of Dingwall in the county of Ross, having a length of about 21 miles, a breadth varying from 4 miles in its widest part, to about 4000 feet at Cromarty and Invergordon Ferries; and having an average breadth of a mile and three-fifths, so that its entire superficial area is about 34 square miles. The whole extent of its southern coast is low, the land rising from it gently to form the peninsula of the Black Isle, but having a bank, in several places abrupt, and with an elevation of about 30 feet, excepting at its mouth, where it rises to a greater height. At its upper extremity the shores are nearly flat. Along its northern side, for about a third of its length, they are low, with a bank of small elevation, and not continuous. It is then succeeded by rather steep acclivities, forming the slopes of rounded hills of moderate height, which are themselves the flanks of higher mountains placed farther back. Along the middle third, the mountains recede to the distance of from one to three miles, leaving a gradual slope, which becomes more or less level as it approaches the shores. The ground along the remaining third is very low, but undulated; and the shores are nearly flat, excepting at the mouth of the Frith. There, on both sides, from Cromarty Ferry to the coast line of the open sea, the banks gradually rise, then become rocky and precipitous, and at length are formed of cliffs from one to two hundred feet in height, of a harder nature than those on any other part of its shores. Here, on either side, is a rounded hill or ridge, several hundred feet high. On the south side, the ridge continues some way along the coast of the Moray Frith; but on the north side it soon terminates, by sloping gradually into a nearly level space, extending obliquely from the eastern angle of the bay of Nigg to the sea coast at Shandwick. This elevated ground may have been at one time continuous, as is perhaps indicated by the exact similarity of the rocks on both sides of the very deep channel formed by their disruption. If this were the case, the lake of fresh water, formed by the Conon and other streams, in the basin marked by the steep banks along the present Frith, would no doubt have emptied itself into the sea by the nearly level and very low tract mentioned above as extending from the bay of Nigg to the coast.

A distinct channel, increasing in breadth and depth from the bridge over the Conon to the Moray Frith, exists in the whole length of the basin; while on either side are shoals composed of mud and sand. The depth of this channel, in the lower parts of the Frith, is unusually great, it being at Invergordon Ferry from 60 to 80 feet at low water of spring tides, and at the entrance from 110 to 184. The most remarkable shoals or sand banks are those extending along the bay of Nigg, and at low water filling nearly half the breadth of the space from Invergordon Ferry to Cromarty Ferry, which forms the widest part of the Frith, or that usually called Cromarty Bay. Similar mud-flats occupy a great portion of the other bays on the Frith, and nearly the whole of its upper part. The deposits which thus narrow the channel of the waters, when the tide is out, are formed of sand intermixed with mud, and frequently have fragments of primitive rocks scattered over their surface, together with decayed shells of various kinds. Along the north shore of Cromarty Ferry is a deposit of pure quartz sand, forming downs or sand hillocks, covered with sea-bent. Many parts of the shoals in the upper portion of the Frith are composed chiefly of gravel and stones, covered with sea-weeds, while others consist of sand and mud.

The precipitous rocks along the coast of the Moray Frith, and a portion of the narrow channel, extending from it to near the town of Cromarty, are formed of a rock of a very different nature from those on the other parts of the shores of the Cromarty Frith, being of gneiss, and composed of quartz, felspar, mica, chlorite, and hornblende, the quartz and felspar generally predominating. These cliffs and the eminences bounded by them are commonly named the Sutors, although that appellation is applied more particularly to certain fragments or detached masses at their base, projecting from the water, and bearing a fanciful resemblance to cobbles at work. The rocks here are composed of strata, generally thin, which are vertical, or inclined from fifteen to twenty degrees on either side, that is, to the east and west, and often extremely contorted. Their colour is generally red, owing to the predominance of felspar in their composition. At their base are numerous fissures and small caves,

some of which are inhabited by Rock Pigeons and Cormorants. Farther up the channel the rocks become of a duller red, having a less crystalline texture, and are chiefly composed of felspar; their stratification is gradually obscured, and the mass at length presents irregular fissures resembling those of an igneous deposit. This rock is succeeded by vertical beds of red conglomerate and sandstone; the former composed of fragments of primitive rocks, chiefly quartz and gneiss; the latter of grains of quartz, cemented by argillaceous matter and oxide of iron, and intermixed with scales of mica. Near the junction of the primitive and secondary rocks, imbedded in the sandstone, and about twelve yards distant from the edge of the conglomerate, is a bed of grey limestone, in thin parallel layers, from one to three or four inches thick, with thinner layers of sandstone interposed. The rocks on the south side are similar; and the limestone bed, which is ten feet thick, runs nearly north and south, and inclines about fifteen degrees to the west, is seen there also. Beyond this the rocks are covered with sand on the north side, and with clay and gravel on the south; but where exposed by quarrying, are found to be sandstone of the old red series, or of that kind named by some primitive sandstone, on account of its resting upon and being formed of the detritus of primitive rocks.

From Invergordon Ferry to Conon bridge the rocks continue of the same nature. The sandstone is generally red, sometimes grey, whitish, or greenish, rather coarse-grained, in some places firm, in others friable, composed of particles of quartz, mica, and chloritic or argillaceous matter, very frequently having pebbles of quartz, gneiss, and granitic rocks interspersed. The conglomerate is composed of pebbles of gneiss, granite, quartz, hornblende-rock, mica slate, and fragments of other primitive rocks, often little rounded, and cemented by argillaceous and arenaceous matter, generally of a deep red colour. Towards Dingwall, on the north side of the Frith, are beds of dark-grey or blackish rocks of the same nature. The strata are nearly horizontal, or incline to the south-west at an angle varying from fifteen to twenty degrees, and, along the shore-line of the southern side, where they sometimes present a fractured face of twenty feet or more in height, have their seams of stratification parallel to the water-line. The same rocks are seen in the bed of the Frith at its margin, but rarely, being almost everywhere covered with sand or mud, and the shores near high-water mark composed of pebbles of quartz, gneiss, and other primitive rocks.

The soil of the surrounding country is a mixture of clay and sand, generally having a large proportion of pebbles; and the subsoil is of a similar nature, with fragments and blocks of primitive rocks.

The vegetation along the shores is composed of the plants common to pasture lands in all parts of Scotland, intermixed with those which are peculiar to maritime stations. There is very little natural wood, excepting on the north side, towards the upper part. In the natural state, the vegetation of the southern side is heathy; but the parts near the northern shores have either been cultivated or are covered with pasture plants. *Anemophila arundinacea* and *Triticum junceum*, which are peculiar to sand, cover the downs above mentioned near the mouth of the Frith. In short, it may be generally observed, without specifying particular plants, that the vegetation is of that mixed nature observed on the sea-coast, along estuaries, or by the mouths of rivers to which the tides have access.

The vegetation of the bed of the Frith is composed of marine Algæ, which, it is well known, are not peculiar to pure salt water, but occur also in the mixed salt and fresh water of estuaries. In the Bay of Nigg, the extensive banks or flats are covered to a great extent with *Zostera marina*, of which the fleshy, saccharine stems, and long grassy leaves, afford abundant food to the vast flocks of Brent Geese, which frequent the Frith in winter. This plant forms submersed meadows, and in winter remains undecayed, although it assumes a duller green. It grows on sand and mud banks and shoals, chiefly in sheltered places, sometimes in salt marshes or ditches along the shore, but is not peculiar to estuaries, as it occurs abundantly on the coasts of the Hebrides and Shetland Islands, in places where there is no intermixture of fresh water. On the Nigg sands, attached to the stones and shells, are also considerable quantities of algæ, of which may be mentioned *Fucus serratus*, *Fucus nodosus*, *Fucus vesiculosus*, *Laminaria saccharina*, *Laminaria digitata*, and *Scytosiphon filum*.

The quantity of algæ in an estuary, or along the shores of the sea, is determined by that of the rocky or stony ground, for these plants adhere only to a solid basis, and do not grow out of mere sand and mud, although a very small point of support, such as a dead shell or a pebble, is sufficient for them. Thus, in the mouth of the Frith of Tay up to Broughty Castle, there are very few sea-weeds, because the bottom and shores are sandy. On the sand and mud flats from thence, several miles above Dundee, scarcely any are to be seen. But wherever rocks or stones occur, either in the bed of the estuary or along its shores, they are found in profusion, and the piers of the harbour of Dundee are densely covered with them nearly up to high-water mark. In the Cromarty Frith these plants are in many places abundant, and some of them are met with to a considerable distance above the mouth of the Conon. On the flats of the Bay of Nigg they are very luxuriant, adhering in large tufts to the stones; along the shores, above Invergordon Ferry, they attain a moderate size; but towards the top of the Frith they gradually diminish, until, in the river itself, they become dwarfish, and at length cease far below Conon Bridge. The predominant species above Invergordon are *Fucus vesiculosus*, *F. nodosus*, and *F. serratus*, which are the plants chiefly used in the manufacture of kelp; but besides these are found *F. canaliculatus*, *Laminaria digitata*, *Ulva umbilicalis*, *U. lactuca*, and many others. Although these and other Algæ are peculiar to salt water, they are yet frequently found in places where fresh water predominates for at least twelve out of every twenty-four hours.—(To be continued.)

ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE MARMOSETS AND TAMARINS.

THESE generally beautiful and gentle little animals are all inhabitants of South America, where they reside in the midst of the forests, living on vegetable substances. They seldom much exceed a common squirrel in size, and are easily tamed, but being peculiarly delicate, are unable, without much care being bestowed upon them, to withstand the effects of our variable and severe climate. The Marmosets differ very little from the Tamarins, one of the principal external distinctions being derived from the tail, which, although very long in both, is bushy and ringed in the former, while it is slender and uniformly coloured in the latter. The species of both genera have the head of a roundish form, the face flat, the nostrils lateral, the hips clothed with hair; they have no cheek-pouches, and their tail is not prehensile; all their claws are compressed and pointed, excepting those of their great-toes, which toes are however so small, and so little separated from the rest, or capable of being put into opposition to them, that these animals are more bipedal than quadrumanous.

Fig. 1. THE COMMON MARMOSET (*Jacchus vulgaris*).—This delicate little creature is characterized by having two large tufts of white hair before the ears, the body grey, transversely banded with dusky, the tail bushy, and ringed in its whole length with blackish-brown and greyish-white. It is pretty generally distributed over South America.

Fig. 2. THE GREAT-EARED TAMARIN (*Midas rufimanus*).—Of a dusky colour, the hind parts barred with grey, the hands and feet reddish. It inhabits Guiana and other parts of South America.

Fig. 3. THE RED-TAILED TAMARIN (*Midas Edipus*).—The head and lower parts of this species are white, the upper parts brown, the tail reddish, tipped with dusky.

Fig. 4. THE FAIR OR SILVERY TAMARIN (*Midas argentatus*).—The face is red, the hair over the whole body of a greyish or silvery white, excepting that of the tail, which is dusky. It inhabits the countries along the Amazons River.

Fig. 5. THE SILKY TAMARIN (*Midas Rosalia*).—This species, of which the fur is of a reddish colour, the tail with two bands of dusky, is further characterized by the great length of the hair of the head and neck. It occurs in Brazil and Guiana.

Fig. 6. THE NEGRO TAMARIN (*Midas Ursulus*).—The fur is black, the back and sides undulated with reddish, the hands and feet black. In other respects it resembles the *M. rufimanus*. Like the other species, it is a native of South America.

DESCRIPTION OF THE PLATE.—THE CROSSBILLS.

THE CROSSBILLS constitute a genus of small birds of the Conirostral division of the Insectores, characterized by the peculiar form of their bill, of which the curved and attenuated points of the mandibles are laterally deflected, so as to present the appearance of crossing each other. In other respects, these birds agree with the Bullfinches and Buntings, between which they are in a manner intermediate. They inhabit the pine and larch forests of the northern parts of the European and American Continents, and derive the principal part of their food from the seeds of the cones, the scales of which they separate by a lateral motion of their mandibles. It is in fact probable that this habit, commenced at an early period, when the bill is yet comparatively soft, is the cause of the lateral divarication of the tips of the mandibles. They are irregularly migratory, shifting about in flocks from place to place, according to the abundance or scarcity of food. The plumage varies greatly in colour, that of the young birds being dull, of the females generally not much brighter, and of the males remarkable for its conspicuous, but not generally vivid tints. Only four species are known: The Parrot Crossbill, *Loxia pytiopsittacus*; the Common European Crossbill, *L. Europaea*; the American Crossbill, *L. Americana*; and the White-winged Crossbill, *L. leucoptera*. The first is common to Europe and America; the second peculiar to Europe; the third confined to America; the fourth common to both continents. In the plate are represented the American and White-winged species.

Fig. 1. THE AMERICAN CROSSBILL (*Loxia Americana*). Adult male.—This species is in all respects similar to the Common European Crossbill, excepting in being considerably smaller, and in having the bill more slender, with the tips of the

mandibles much more elongated. The old male has the greater part of the plumage of a dull vermilion tint, more or less mixed with yellow, the wings and tail dusky, their feathers edged with lighter, the back of a darker red, the rump much brighter. It inhabits the woods of Canada, Nova Scotia, and the Northern United States, feeding on the seeds of the pines, larches, and junipers.

Fig. 2. THE AMERICAN CROSSBILL. Female.—The female is destitute of red, the upper part of the head, the hind neck, and the back, being dull greenish-grey, spotted with dusky, the rump wax-yellow, the lower parts greyish-yellow, the neck, breast, and sides, spotted with dusky.

Fig. 3. THE WHITE-WINGED CROSSBILL (*L. leucoptera*).—This species is about the same size, and has the same general form, but is differently coloured, its principal specific distinction being derived from two white bands crossing the wings, which, as well as the tail, are otherwise deep black. The upper parts are of a light reddish ochre. Its habits are the same as those of the other species.

Fig. 4. THE WHITE-WINGED CROSSBILL. Young male.—In its second plumage, the male has the upper parts deep-red, largely spotted with black, the rump rose-red, the wings black, with transverse white bands, the tail also black, the lower parts greyish-white.

Fig. 5. THE WHITE-WINGED CROSSBILL. Female.—The female is greenish-grey, spotted with dusky, above, pale grey, also spotted, beneath, the wings and tail black, but the former with conspicuous white bands.

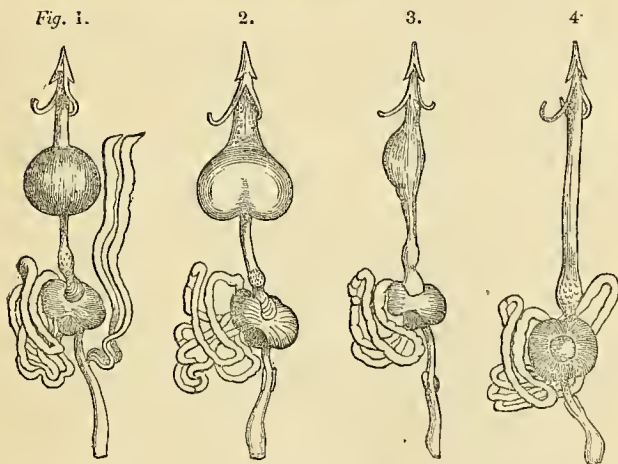

THE SISKIN.—Our esteemed correspondent, Mr William Drew, of Paisley, has favored us with the following notice respecting this bird:—"I have remarked the account of the Siskin contained in your Journal of this month. Undoubted as the circumstance of its breeding in Scotland must now be, from the respectable authority of Mr Weir, yet I do not think it amiss so far to corroborate his observations. Early in June 1833, at which time I resided at Inveraray, I went out one morning to fish, and, according to my usual practice, I carried a light gun with me. I was rather surprised, at that season, to see a pair of Siskins among some furze bushes, on the shore of Luchfane, and the birds being close together, I killed both. On dissecting the female, an egg was found ready for exclusion, and I never had any doubt but that the birds were breeding in the neighbourhood, though I did not look for or see the nest. It is very likely that it was on some of the spruces, which were the predominant trees in the place. I subsequently saw and secured a pair of Siskins in the same locality.—Paisley, 26, Causeway Street, 3d March 1837."

VENTRILOQUISM OF THE ROBIN.—The bird endowed with this singular control over his vocal powers, is our favorite and pugnacious little Robin, whom I discovered to be as complete an adept in this art as any human ventriloquist could possibly be. While in my garden a few weeks ago, the notes of this bird fell deliciously on my ear, being mellowed, as I believed, by distance. I expected to descry my musician on some distant tree; but, to my great surprise, I perceived him within a few yards of the spot I occupied. I was near enough to observe the alternate contractions and expansions of the breast; but I could not see any motion of the bill.—*Mr Edmunds, in Loudon's Magazine.*

PRESERVATION OF ZOOLOGICAL SPECIMENS.—Various substances have been employed in preparing skins of animals to be stuffed as specimens, and with various success. Arsenical soap has of late years been very generally substituted for the powders and solutions formerly used; but this substance, being applied exclusively to the inner surface of the skin, has no other effect than to preserve it; while the hair, the feathers, and especially the down, are left without protection. Now, of what value is a well-preserved skin, from which the feathers have been eaten by moths? We have seen such skins in abundance. The arsenical lathering which they had received did not act in the slightest degree as a preservative from vermin. Others, prepared with alum, corrosive sublimate, and powdered spices, we have seen similarly affected. In short, it is our firm conviction, founded on observation, that nothing applied to the inside of the skin can prevent the hair and plumage from being eaten. As to solutions applied to the outer surface, we have found none that has a permanent effect. Alcohol quickly destroys moths, and so does solution of corrosive sublimate; but neither has a lasting effect. Rectified oil of turpentine acts still more speedily, and even its vapour in a close case destroys insects, but although its action is thus powerful, it is not permanent. Still, we are convinced, it is the best preservative; but, not to injure the plumage, it must be of the best quality, for, if

bad, it remains long moist, clogs the feathers, and gathers dust. Preserved birds ought to be kept in close cases, cleaned at least twice a-year, carefully searched for vermin; if much infected, baked in an oven, then slightly impregnated with pure rectified oil of turpentine. Under this treatment skins last long enough; but, judging from appearances, the keepers of museums are a lazy race, the more so if paid by the public; and all naturalists who have visited such places have seen quadrupeds in rags; birds, under which lay small heaps of dust and dead moths, and eggs, of which the membrane had been devoured, and the colours gone; while the minerals, shells, and other comparatively imperishable articles, were carefully laid on cotton, kept perfectly clean, and tended with unusual care. Oil of turpentine we have also found to be the best preservative for dry anatomical preparations, and under its detergent influence, we have seen a collection of muscular and vascular articles, that literally swarmed with Acari and Tineæ, reduced to a state of perfect sanity, although not until they had been repeatedly soaked in it. In short, this oil is invaluable, and greatly surpasses all other substances in use, for where they have failed, we have found it invariably to succeed. To preserve collections of birds' skins in drawers, it is enough to moisten the latter now and then with a little of it by means of a bit of sponge. After a few days, its smell will not nauseate the most delicately organized or clean-fingered inspector of bills, feathers, and claws.

**DIGESTIVE ORGANS OF BIRDS.**—Having, in a former Number, given a short description of the digestive organs of Birds, illustrated by a sketch of those of the Red Grouse, we now present four figures intended to exhibit the differences on which characters, designative of the various orders, may be founded. These figures are from "A History of British Birds," by W. Macgillivray, newly published, and in which will be found, besides the ordinary technical characters, and an account of the habits, distribution, and relations of the species, various anatomical details, especially with reference to the digestive organs. These figures are representative of the orders Rasores or Gallinaceous Birds, Gemitores or Pigeons, Deglubitores or Conirostral Birds, and Vagatores or Crows and Starlings. It will at once be perceived, that they differ from each other in several particulars.

In the *Rasores*, Fig. 1, the œsophagus is narrow, with a very large globular crop, having a small aperture; the proventriculus is bulbiform, with oblong, generally sacculated glandules; the stomach is a powerful gizzard, with very thick lateral muscles, a prominent distinct inferior muscle, and thick rugous epithelium, or inner coat; the intestine of moderate length, and nearly uniform diameter, but having appended two cœca of extreme size, being together of equal capacity with the intestine.

In the *Gemitores*, Fig. 2, the œsophagus dilates immediately with an extremely large transverse crop, internally reticularly rugous in the breeding season, and having a small aperture; the proventriculus is bulbiform, with oblong simple glandules; the stomach a powerful gizzard, with very thick lateral muscles; a prominent distinct inferior muscle, and thick rugous epithelium; the intestine is long and narrow; the cœca reduced to very small cylindrical adnate tubes.

In the *Deglubitores*, Fig. 3, the œsophagus gradually dilates into a membranous sac of moderate size, lying on the right side, and sometimes curving round the back of the neck; the proventriculus is oblong, with cylindrical glandules; the stomach a powerful gizzard, with very thick lateral muscles, a prominent inferior muscle, and thick rugous epithelium; the intestine short and rather wide; the cœca minute, oblong, adnate.

In the *Vagatores*, Fig. 4, the œsophagus is rather wide, without crop or dilatation; the proventriculus bulbiform, with oblong or cylindrical glandules; the stomach rather large, roundish, more or less compressed, its muscular coat of moderate thickness, not separated into distinct muscles, but composed of uniform fasciculi, inserted into circular tendinous spaces; the epithelium thin, and slightly rugous; the intestine of moderate length and diameter; the cœca very small, cylindrical, and adnate.

All the other orders possess equally distinctive characters, which, when clearly pointed out, will throw considerable light upon the affinities of the different species, and effect changes in classification which will prove utterly subversive of some of our most approved systems.

**THE GREEN WAGTAIL (*Motucilla flaveola*), IN NORFOLK.**—Mr Salmon, in the May number of the *Naturalist*, gives the following notes respecting this bird:—"The few pairs of spring Oatears, or Green Wagtails, that visit this neighbourhood, resort to the immediate sides of the river, which is bordered by grass lands and uncultivated wastes; it is only in this locality that they are to be seen. I have repeatedly noticed them running upon the weeds on the surface of the water, catching insects, &c. I have found its nest among the ling which grows close to the water.

The old birds express considerable anxiety when you approach within the vicinity of their nest, hovering with their peculiar undulating motion whilst on the wing over your head, or alighting upon a bank or any other convenience on the ground, at the same time uttering their note of alarm."

**THE GREEN WAGTAIL, IN MID-LOTHIAN.**—In July and the beginning of August, very large flocks of this species are seen in the irrigated meadows to the west of Edinburgh. They are composed of young and old birds, which search for insects and worms on the newly mown grass, as well as on the taller leafy weeds, such as docks. Their flight is similar to that of the Grey Wagtail, that is, performed in long undulations, and they perch occasionally on trees and bushes. A few individuals may be seen in the same place early in summer, but certainly not a fiftieth part of the number that may sometimes be seen in July. None of them remain after the middle of August.

#### BRITISH BIRDS.—NO. III.

**THE WHITE-TAILED SEA EAGLE.**—Of this magnificent bird, which is still not uncommon in the North of Scotland, and especially in the Hebrides, the principal distinctive characters are the following:—Its form is robust, the neck of moderate length, the head rather large, the wings very long, the feet strong, the toes stout, the claws large, curved, tapering, acute, rounded above, flat beneath. The bill is nearly as long as the head, very deep, compressed, with a long, curved, acute tip. The plumage is compact and imbricated; the space between the bill and the eye sparsely covered with very small, narrow feathers; those of the neck narrow and pointed, of the back broad, of the belly very soft and downy, of the outer part of the tibiae elongated. The fourth and fifth quills are longest, and the wings when closed are of equal length with the tail, which is rather short, broad, and rounded. The cere and bill are pale yellow, the iris bright yellow, the tarsi and toes gamboge, the claws blueish black. The general colour of the head, neck, breast, back, and upper wing-coverts, is pale greyish-brown; the lower parts and legs are chocolate-brown; the primary quills blackish-brown, their base and the greater part of the secondaries tinged with ash-grey; the tail white. The length of the male is three feet, of the female three feet two inches, the extent of the wings of the latter seven feet. The colouring varies considerably, young birds being darker. For the first three years, the bill is black or dusky, the iris brown, the feet yellow. The colour of the plumage is dark-brown, mottled with white and light-brown, the tail blackish.

This bird is not remarkable for courage, although its strength is great, and its flight powerful. Its principal nutriment is derived not so much from the produce of its own industry, as from carrion of all kinds; and it is frequently seen sweeping along the sides of the mountains, and hovering over the shores, in search of dead sheep, fish, young birds, and such animals generally as are large enough to furnish a meal, so weak as to make no formidable opposition, or so heavy as to be incapable of very rapid or protracted flight. It sometimes carries off poultry that have straggled to a distance from the house, clutches up young lambs, and, when hard pressed by hunger, is said to attack sheep and even deer; but a fox, an otter, or a seal, it scarcely ever ventures to molest, and a man may carry off its young before its face with little danger of even a scratch. Yet instances have occurred of its manifesting some spirit in defence of its nest.

Being a heavy bird, with very large wings, it finds some difficulty in raising itself on wing, and therefore seldom alights on plain ground for the purpose of resting but usually settles on a large stone or block, the pinnacle of a rock, or the edge of a precipice. The case is different, however, on an extensive sand, for there it can escape from its enemies without experiencing any danger. When it is fairly on wing, its motions are beautiful in the highest degree. Its wings are extended to their full length, forming an obtuse angle with the back, and as it sweeps along in wide curves, it seems to glide through the air without the least effort, and with very little motion of the wings or tail. The feet are drawn close to the abdomen, and the neck is retracted to such a degree, that the head seems stuck upon the shoulders—a character common to all our rapacious birds. In this manner it searches the hill sides, the moors, and the shores; but in proceeding to a distance, without regarding the intermediate space, it flies in a straight line, always at a great height, and with regular flaps, somewhat in the manner of the Raven. It utters a loud, shrill scream, which in calm weather may be heard at the distance of more than a mile, and emits a noise somewhat resembling the yelping of a Dog, which may be imitated by the syllables *queak, queak*, uttered repeatedly in rapid succession.

It sometimes seizes fishes when they swim close upon the surface, and has frequently been observed watching by a lake or stream for salmon or trouts. When it has young, it provides abundantly for them, and instances have occurred of people obtaining a supply of food, in times of scarcity, by climbing to its nest. On observing a person walking near it, they fly around him at a safe distance, occasionally uttering a savage scream, and allowing their legs to dangle, with outspread talons, as if to intimidate him.

The Raven frequently harasses it, and the Skua and Peregrine Falcon have been seen to pursue it; but it is perfectly safe from the attacks of any bird excepting the Golden Eagle. Like that species, it is often shot from a concealed hole or pit, and deprived of its eggs or young by letting down a person by means of a rope to the nest, which is generally placed in the most inaccessible part of a precipice, although sometimes in no very secure place, and occasionally on the island of a lake.

There seems to be no reason for believing that this Eagle has a very acute sense of smell, especially as it is not aware of the presence of a person lying in wait within fifteen yards of it; but its vision must be very penetrating, otherwise it could not so readily fall upon a carcase on the hills, or a dead fish on the shores, from the great height at which it often soars. In searching for food it usually, however, sweeps along the mountain's sides, at no great height.

In almost every district in the Highlands, stories are told of Eagles that have carried off infants, and it is probable that such an occurrence may have taken place, although the evidence is usually imperfect. Many absurd notions have been enter-

tained respecting their powers and courage; but there is good reason to believe, that the Sea Eagle does not often subject itself to much danger from temerity.

It begins to construct its nest sometime in March, and the young are abroad about the middle of August. The diameter of the nest is about five feet, and it consists of twigs, heath, sea-weed, dry grass, and other materials of a like nature, arranged in a slovenly manner. There are generally two eggs, sometimes only one. They are about the size of those of a goose, but shorter, and of a yellowish-white colour, with a few reddish dots at the large end. The young are fed with fish, carrion, grouse, and young sea birds.

Great numbers of Eagles are annually destroyed in Scotland, on account of the depredations which they commit among the lambs; yet there is little probability of their being extirpated in the northern parts of that country, although very few remain in the south. Dr Bushnan, writing in 1834, doubts whether a pair is to be found wild in Dumfriesshire, or more than a dozen in Galloway. This species is less frequently seen in captivity than the Golden Eagle, probably because its haunts are more remote from the densely peopled parts of the country. An interesting account is given of a captive Eagle, in Macgillivray's *Rapacious Birds of Great Britain*, by its owner, Dr Neill, who has kept it since the autumn of 1827.

**HABITS OF THE BLUE-BACKED DOVE (*Columba Enas*).**—In "The Naturalist" for May, Mr Salmon gives the following interesting notice on this subject:—"I have lately been asked if I can suggest a better name than *Stock* or *Wood Pigeon* for the *Columba Enas* of authors. The provincial name in this district is *Sand Pigeon*, which I cannot but consider fully as appropriate as *Bank Swallow*, applied in consequence of the situation the bird selects for nidification. Those who live in woody districts, however, might object to this specific designation, as the bird would then, in all probability, breed in woods; but of this I am not certain. I am inclined to suspect that the species is very local in its distribution in this country during the breeding season, and that it is only towards its autumnal migration that it is seen in very great numbers in the woodlands. I have known an instance of its breeding in the topmost branches of the Scotch Fir, in a similar manner to the Ring Pigeon (*Columba Palumbus*), which is a true arboreal species, and might, with great propriety, be called *Wood Pigeon*. Indeed, the latter is given by Selby as a provincial name, by which also it is always known in this country. If it be found necessary to make any alteration in the nomenclature of the British Pigeons, I should be disposed to name them thus:—*Wood Pigeon*, *Columba Palumbus*; *Sand Pigeon*, *C. arenea*; *Rock Pigeon*, *C. Livia*." Our mode of nomenclature differs, and we should prefer naming them thus:—*Columba Palumbus*, *Ringed Dove*, or *Wood Pigeon*; *C. Livia*, *Rock Dove*, or *White-backed Pigeon*; *C. Enas*, *Blue-backed Pigeon*; *C. Turtur*, *Ring-necked Turtle Dove*. But there is no end to alterations of this kind, chiefly because names are imposed at first without consideration, and altered by persons destitute of judgment, or, if possessing that quality, deficient in the necessary knowledge of species.

**ARRIVAL OF BIRDS IN THE PRESENT SPRING.**—Notwithstanding the severity of the weather, the Wheatear was seen in the King's Park, early in April, and by the end of the month was common. *Hirundo rustica* was seen at Newton on the 29th April. *Cypselus murarius*, *Hirundo rustica*, *Hirundo urtica*, and *Hirundo riparia*, were observed at Caonmills on the 1st May. *Sylvia Trochilus* was shot at Roslyn on the 29th April. *Turdus torquatus* was observed near Swanston on the Pentland Hills on the 4th May; and on the same day, two Cuckoos were seen on Dalmahoy Hill. *Totanus hypoleucos* occurred at Roslyn on the 29th April, but had probably arrived several weeks before.

## BOTANY.

M. DUTROCHET'S OBSERVATIONS ON THE SLEEP OF PLANTS.—Continued from last Number.

THE flowers above described expand and close only once, after which the death of the corolla takes place. I shall now examine the flowers which alternately open and shut for several days in succession, taking the Dandelion, *Leontodon Taraxacum*, as an example. The flower of this plant generally lives ten days and a half, having during that period its expansion in the morning, and its sleep in the evening. Its last sleep takes place in the middle of the day, and is followed by the death of the corollas. In the state of waking, the semiflorets of which this flower is composed curve outwards, producing its expansion; and in sleep curve inwards, effecting its closing. Although these semiflorets are very thin, I have with the microscope observed the internal organization of their nerves, which are very small, and four in number in each. At the inner or upper surface of each of its nerves there is a cellular tissue disposed in lines, of which the cellules are covered with globules, and which is exactly similar to that which I have observed in the nerves of the corolla of *Mirabilis*. At the outer or lower surface of the nerves of the semifloret is a very thin layer of fibrous tissue situate between a layer of tracheæ and a layer of cellules filled with air, and placed superficially. This fibrous tissue, in all respects similar to that which exists in the nerves of the corolla of *Mirabilis*, is in like manner included between two layers of pneumatic orgaos. It is therefore probable that this fibrous tissue is incurvable by oxygenation, and that the cellular tissue is incurvable by endosmosis, just as is the case with the nerves of the corolla of *Mirabilis*. And in fact, observation shows that the incurvation which produces the wake of the semiflorets of the Dandelion is owing to the impletion of the cellules with fluid to excess; in other words, to endosmosis, and that the incurvation which produces sleep is owing to oxygenation. The semiflorets of the flower of the Dandelion being gathered early in the morning, while they are still in the state of sleep or curved inwards, and being immersed in aerated water, assume the opposite incurvation, or curve outwards. This takes place in darkness as well as in light. If they are immersed in unaerated water, they curve outwards to excess, and so remain. If these semiflorets, thus curved, are placed in syrup, they assume the opposite curvature; and, on being placed in pure water, resume the outward

curve. Thus, there can be no doubt that endosmosis produces this action. If semiflorets, in the state of waking, are left for some hours in aerated water, they then assume an inward curve, or that of sleep; and this curve is not altered by transporting them into syrup, which proves that the incurvation of sleep is owing to oxygenation. Thus, the wake and sleep of the semiflorets of the flower of the Dandelion result from the alternately predominating incurvation of an organic tissue incurvable by endosmosis, and of an organic tissue incurvable by oxygenation. The first is undoubtedly the cellular tissue, and the last the fibrous tissue, both contained in the nerves of the semifloret. These two incurvable tissues, according as the one prevails over the other, expand or close the flower.

The causes which render predominant the morning incurvation of the cellular tissue, or agent of waking, are, on the one hand, a more powerful ascent of the sap under the influence of light, which increases the turgescence of this tissue; and, on the other hand, the diminution of the antagonist force of incurvation of the fibrous tissue, which is the agent of sleep, and which takes place at night. In fact, if the semiflorets are gathered in the evening when they have assumed the incurvation of sleep, and immersed in oxygenated water, they there retain without change their incurvation; but if, next morning, there be plucked from the same flower other semiflorets which still retain the incurvation of sleep, and if they be immersed in aerated water, they instantly assume the incurvation outwards, even in the dark. Now, by immersing the semiflorets in water, endosmosis of their cellular tissue is excited, and so its incurvation is effected, producing the state of waking or expansion. If this result does not take place in the evening, it is because the incurvation by oxygenation of the antagonist fibrous tissue is too strong, and cannot be overcome by the incurvation of the cellular tissue. If by immersing next morning in water the semiflorets which have passed the night on the plant, their outward incurvation is produced, this proves that the force of incurvation of the fibrous tissue has diminished, and that, in consequence, this fibrous tissue has lost in the course of the night a part of its oxygenation; so that the cellular tissue, incurvable by endosmosis, which is its antagonist, and which is the agent of the wake or expansion of the flower, then predominates.

Thus the flower which during several days presents the alternations of waking and sleep, is that in which the fibrous tissue, the agent of sleep, loses during the night a part of the oxygen which has been fixed in its interior in the course of the day, and which is the cause of its incurvation; so that this latter having in the morning lost its strength, the cellular tissue, which is incurvable by endosmosis, and is the agent of expansion or waking, becomes again predominant. The sleep of this flower takes place anew in the evening, because the oxygenation of the fibrous tissue, the agent of sleep, gradually increases during the day, and at length renders its incurvation victorious; at the same time, the diminution of the light occasions a diminution of the ascent of the sap, which weakens the turgescence, and consequently the incurvation of the cellular tissue, which is the agent of expansion or waking. These alternations cease only with the death of the corolla. The flowers which have only a single expansion and a single closing, or which wake and sleep only once, are those whose single sleep is immediately followed by the death of the corolla.

The entire flower of the Dandelion, if immersed when expanded in unaerated water, deprived of communication with the atmosphere, remains in the same state without change. If the water is in contact with the atmosphere, it takes up air in solution, and the flower immersed in it assumes the state of sleep in two or three hours.

It may with propriety be remarked, that these experiments confirm what I have said in my *Essay on the Respiration of Plants*, namely, that vegetables respire like animals, by assimilating oxygen, of which the presence in the organic tissue is as necessary in the one as in the other order of beings.

**PINES OF NORTH CALIFORNIA.**—The following note is extracted from the "Companion to the Botanical Register," in which a biographical account of the late Mr Douglas is given:—"About an hour's walk from my camp, I met an Indian, who, on perceiving me, instantly strung his bow, placed on his left arm a sleeve of Raccoon skin, and stood on the defensive. Being quite satisfied that this conduct was prompted by fear, and not by hostile intentions, the poor fellow having probably never seen such a being as myself before, I laid my gun at my feet on the ground, and waved my hand for him to come to me, which he did slowly, and with great caution. I then made him place his bow and quiver of arrows beside my gun, and striking a light, gave him a smoke out of my own pipe, and a present of a few beads. With my pencil I made a rough sketch of the Cone and Pine-tree which I wanted to obtain, and drew his attention to it, when he instantly pointed to the hills fifteen or twenty miles distant towards the south; and when I expressed my intention of going thither, cheerfully set about accompanying me. At mid-day I reached my long-wished-for Pines, and lost no time in examining them, and endeavouring to collect specimens and seeds. New and strange things seldom fail to make strong impressions, and are therefore frequently overrated; so that, lest I should never again see my friends in England, to inform them verbally of this most beautiful and immensely grand tree, I shall here state the dimensions of the largest I could find among several that had been blown down by the wind. At three feet from the ground its circumference is 57 feet 9 inches; and at 134 feet, 17 feet 5 inches: the extreme length 245 feet. The trunks are uncommonly straight, and the bark remarkably smooth for such large timber, of a whitish or light-brown colour, and yielding a great quantity of bright amber gum. The tallest stems are generally unbranched for two-thirds of the height of the tree; the branches rather pendulous, with cones hanging from their points like sugar loaves in a grocer's shop. These cones, however, are seen only on the loftiest trees, and the putting myself in possession of three of them (all I could obtain), nearly brought my life to a close. As it was impossible either to climb the tree or hew it down, I endeavoured to knock off the cones by firing at them with ball, when the report of my gun brought eight Indians, all of them painted with red earth, armed with bows, arrows, bone-tipped spears, and flint-knives. They appeared any thing but friendly. I endeavoured to explain to them what I wanted, and they seemed satisfied, and sat down to smoke,

but presently I perceived one of them string his bow, and another sharpen his flint-knife with a pair of wooden pincers, and suspend it on the wrist of his right hand. Farther testimony of their intention was unnecessary. To save myself by flight was impossible; so, without hesitation, I stepped back about five paces, cocked my gun, drew one of the pistols out of my belt, and holding it in my left hand, and the gun in my right, showed myself determined to fight for my life. As much as possible I endeavoured to preserve my coolness; and thus we stood looking at one another without making any movement or uttering a word for perhaps ten minutes, when at last one, who seemed the leader, gave a sign that they wished for some tobacco. This I signified they should have if they fetched me a quantity of cones. They went off immediately in search of them; and no sooner were they all out of sight, than I picked up my three cones and some twigs of the trees, and made the quickest possible retreat, hurrying back to my camp, which I reached before dusk. Of my three cones, one measures  $1\frac{1}{2}$  inches, and the two others are respectively half an inch and an inch shorter, all full of fine seed."

#### MISCELLANEOUS.

##### DESCRIPTION OF THE FRITH OF CROMARTY.—NO. II.

ON the flats of the Bay of Nigg are extensive beds of the common mussel, *Mytilus edulis*, which the fishers use for bait, together with various other shells, as *Venus pullastra*, *Solen siliqua*, *Mya truncata*, *Lucina radula*, *Cardium edule*, *Mactra subtruncata*, *Fusus antiquus*, *Buccinum undatum*, *Purpura lapillus*, *Trochus cinerarius*, *Turritella terebra*, *Turbo littoreus*, and *T. retusus*. Besides these are observed numerous dead shells of the Great Clam, *Pecten maximus*, the Common Clam, *Pecten opercularis*, as well as most of the above. It is a somewhat curious circumstance, that although shells of the former species occur in the Frith of Forth, as well as in that of Cromarty, living specimens are not found there, while on many parts of the north-western coasts of Scotland they are not uncommon. There is an oyster scalp or bed below Invergordon, near the north shore, and another above it, among the shells found in the upper half of the Frith, are *Buccinum undatum*, *Purpura lapillus*, *Turritella terebra*, *Trochus cinerarius*, *Potella vulgata*, *Turbo littoreus*, *T. retusus*, *T. rudis*, *Mytilus edulis*, *Pecten opercularis*, *Venus pullastra*, *F. decussata*, *Solen siliqua*, *Mya truncata*, *Mya arenaria*, *Cardium edule*, and *Mactra truncata*; but they are not generally found in great numbers, the welks and limpets, in particular, being rare and diminutive.

The fishermen at Cromarty set their lines in the open sea, and do not fish in any part of the Frith, although a few large, generally sickly Cod appear there, with a good number of Codlings, occasionally Haddock, Skate, and Flounders. Herrings sometimes enter; Sand-eels, *Anmodytes tobianus*, are found in the sands; and Cuddies, the fry of *Gadus carbonarius*, are plentiful in many parts. Fresh-water Trouts are sometimes caught more than half-way down; Eels occur in the upper part, and the Ocellated Blenny is plentiful on the shoals.

*Echinus esculentus* and *Spalangus cordatus* occur below Invergordon; as do the Spider Crab, the Hermit Crab, and Common Shrimp; but the Lobster and Common Crab are not met with. Several *Asteria*, *Alcyonia*, and *Sertularia*, are not uncommon, and the Lug, or Sea-worm, *Lumbricus marinus*, is plentiful in most parts of the Frith.

Seals are numerous at times, and frequently ascend the river as far as the bridge, near which they are sometimes caught by the salmon-fishers. Porpoises also enter the Frith, but are said not to enter the river.

The birds to be seen on the waters, or along the shores in winter, are very numerous. Vast flocks of Brent Geese, *Anser Bernicla*, frequent the shoals of the Bay of Nigg, as already mentioned, and at high-water are seen floating in detached parties over the basin below Invergordon. Long-tailed Ducks, *Heredia glacialis*, are also very abundant there. The Mallard, *Anas boschas*, and the Golden-eyed Duck, *Clangula chrysophthalma*, are seen in great numbers feeding along the edge of the water, when the tide is out. The other species of common occurrence are, the Common Gull, *Larus canus*; the Black-headed Gull, *L. ridibundus*; the great Black-backed Gull, *L. marinus*; the Guillemot, *Uria Troile*; the Auk, *Alca Torda*; the Red-throated Diver, *Colymbus septentrionalis*; the Cormorant, *Phalacrocorax Carbo*. The Feaser, *Lestris parasiticus*, is of rare occurrence. Along the shores are seen the Redshank, *Totanus Calidris*; the Curlew, *Numenius arquata*; flocks of Ringed Plovers, *Charadrius hiaticula*, and Lapwings, *Vanellus cristatus*, together with the common Heron, *Ardea cinerea*. All these are, properly speaking, sea-birds, excepting the Brent Goose, the wild Duck, the Curlew, the Lapwing, and the Heron, which, however, are as frequently found on or by the sea as on land; while, on the other hand, several of the others are often seen on the land, and on fresh waters, and the Gulls often, and the Red-throated Diver always, breed on the latter.

The general considerations respecting estuaries, a subject of great importance with reference to the salmon-fisheries, which form the second part of this paper, must be deferred till another opportunity. In the meantime, it may be remarked, that the greater number of our estuaries present characters similar to that of the Cromarty Frith, being inlets of the sea entered by a river, and having the same vegetable and animal productions as those enumerated; each, however, having peculiarities of form, depth, and other circumstances. The Beaulieu Frith, or upper part of the Moray Frith, and the Frith of Tay, in particular, are very analogous to the Cromarty Frith, as will be shown in the sequel.

#### METEOROLOGY.

DR ALLNAT of Wallingford has transmitted, for insertion in this Journal, the following account of a Western Aurora, which appeared on the night of Saturday 18th February last, between the hours of ten and eleven.

From the horizon almost due west a blood-red glow of light arose, shooting upwards to the zenith, where it was joined by another broad sheet of lurid light, which dipped far down into the east, thus forming an irregular arch extending almost continuously across the face of the heavens, from the western to the eastern horizon.

The moon, which was high at the time, and the stars, were shining with unusual lustre, and a bitter wind was blowing from the south. There was a kind of nucleus of a brighter hue in the centre of the western or principal aurora, from which emanated streams of light. This nucleus was surrounded by external bands of a deeper and less vivid colour. In the north were also broad insulated patches of dense luminous matter of the same lurid aspect, which occasionally extended themselves so that the moon at one period was overshadowed by them, which caused a halo faintly exhibiting the prismatic colours. There was not a cloud to be seen.

Shortly after eleven these remarkable appearances vanished, when a strong wind sprung up from the south, and the succeeding day was wet and gusty.

A circumstance occurred during the continuance of these phenomena (which fact I do not find noticed in the records of Meteorology), namely, the sudden rise of the barometer. It had been sinking on the previous day, and it also rapidly sank after the disappearance of the aurora. This might have been merely the transient effect of natural causes in simultaneous operation; but if it were not, and the barometrical indication on similar occasions be hereafter fully established, it will, I conceive (as do the vibrations of the magnetic needle), lend a collateral and an important aid in determining the real nature of the aurora.—*Wallingford, 12th March 1837.*

#### REVIEWS.

*The Naturalist; illustrative of the Animal, Vegetable, and Mineral Kingdoms.*

Edited by Neville Wood, Esq.

THIS useful and entertaining monthly journal, which, after the appearance of its sixth number, underwent what we were apprehensive was nothing less than an entire demolition, has, to our great pleasure, reappeared under a somewhat altered form, under the auspices of the accomplished author of "British Song Birds," and joint editor of the Analyst, a quarterly publication of great merit. The number for April contains, among other papers, an excellent account of the Lemuridæ; A Catalogue of Medicinal Plants found in the neighbourhood of York; Remarks on the sense of Smell in Carrion Birds, by the Rev. F. O. Morris; Observations on the habits of the Fitchet Weasel, by W. R. Scott; together with a variety of interesting miscellaneous notices. The number for May is at least of equal interest. The first paper, by Thomas Allis, on the impropriety of placing the Columbidae in the order of Rasores, is in all respects to our mind; and the views entertained by that intelligent writer will be found to be similar to those expressed at greater length in Macgillivray's History of British Birds, vol. I. recently published. The Pigeons certainly differ from the Phasianinæ, Pavoninæ, Perdiciinæ, and other families of the Rasores, as much in external as in internal characters and habits, and the only point in which they agree is their feeding on vegetable substances. If this were sufficient to induce an intelligent ornithologist to class them together, why is not the Goose permitted to join the group? In conclusion, Mr Allis remarks:—"To make the order Rasores consist of these five families (Pavonidæ, Tetraonidæ, Cracidæ, Struthionidæ, and Columbidae), appears to me very incongruous, and to arise more from a desire of adapting them to the exigencies of a preconceived theory, than from any natural affinities observable between them. A circle composed of families differing so greatly in the amount of their aberrations, presents, according to my ideas, chasms so extensive and frightful between the different families of which it is composed, as not at all to accord with the beautiful order of Nature; whereas, if placed in separate orders, we find the extreme species running into each other, and forming one harmonious whole, which cannot be contemplated without feelings of admiration and delight." Right:—"The vagaries of these people" are so absurd, their jargon so ludicrous, their self-sufficiency so amusing, that a reasonable creature, who studies Nature as she is, cannot refrain from associating the most comical ideas with the system advocated by them. "The Naturalist Abroad," by Edwin Lees, is a delightful paper, and Mr Morris's Explanation of the Latin names of British Birds, a very useful one, not to the tyro alone, but to the system-makers, who rarely can spell their names. Various interesting papers follow, in perusing which, we promise the reader much amusement as well as instruction. This eighth number, in fact, is a capital one; and we trust that those which are to come will not disappoint us in fulfilling the expectations to which it gives rise.

*London's Magazine of Natural History.* New Series. Conducted by Edward Charlesworth, F.G.S.

THIS long-established, entertaining, and most useful monthly periodical, continues to support its well-earned reputation under the management of its new editor, who has published in it several very interesting papers on Geological subjects. The information which it conveys, although generally of a popular character—that is, intelligible to the reading public at large—is occasionally more strictly scientific or technical, and subjects requiring illustration are very beautifully represented by engravings on wood. The number for May contains a notice of the Teeth of *Carcharias megalodon*, occurring in the Red Crag of Suffolk, by the editor; A continuation of a Catalogue of the Birds of Devonshire, by Dr E. Moore; Natural Phenomena observed in 1833, by the Rev. W. B. Clarke; On the errors which may arise in computing the relative antiquity of Deposits from the characters of their imbedded Fossils, by H. E. Strickland, Esq.; Observations on the existence of Electric Currents in vegetable structures, by Golding Bird, Esq.; On the enlargement of the Eggs of some marine Mollusca during the period of their hatching, by J. E. Gray, Esq.; Remarks on Generic Nomenclature, by Mr Shuckard; Description of a new genus of British Parasitic Hymenoptera, by Mr Westwood; Observations on the changes of colour in the Fur of Mammalia and in Feathers, by Mr Blyth; besides Reviews, and short Notices on various subjects.

EDINBURGH: Published for the PROPRIETOR, at the Office, No. 13, Hill Street.  
LONDON: SMITH, ELDER, and Co., 65, Cornhill. GLASGOW and the West of Scotland: JOHN SMITH and SON; and JOHN MACLEOD. DUBLIN: GEORGE YOUNG. PARIS: J. B. BALLIERE, Rue de l'Ecole de Médecine, No. 13 bis.

# THE EDINBURGH JOURNAL OF NATURAL HISTORY,

AND OF

## THE PHYSICAL SCIENCES.

JULY, 1837.

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE.—THE MAKIS.

THE Lemurs or Makis are quadrumanous animals, which differ from most of the other families of this extensive group in having a pointed muzzle, whence they have been called Fox-monkeys, small ears, and a long unprehensile tail. They have four incisors above, six below, edged canine teeth, and six grinders on each side of either jaw. There is little diversity in their form, and they are said to be very limited in their geographical distribution, being supposed to be peculiar to Madagascar, where they reside in the woods, moving with great agility much in the manner of squirrels, and living on fruit.

Fig. 1. THE WOOLLY MAKI (*Lemur Mongoz*).—As little can be said of the manners of the different species, we shall confine our notices to their characteristic colours. The present is of a brownish-grey colour, with the lower parts lighter, and the throat and sides of the head light red.

Fig. 2. THE RED MAKI (*L. rufus*), of a brownish-red colour, with the muzzle black, and the sides of the head pale greyish-yellow.

Fig. 3. THE WHITE-FRONTED MAKI (*L. albifrons*).—Yellowish-grey, the head whitish, the muzzle black, the hands brownish-red.

Fig. 4. THE RUFFED MAKI (*L. Macaco*).—Variegated with black and white, in large patches.

Fig. 5. THE RUFFED MAKI (*L. Macaco*).—A variety having the body all black, excepting a band across the back, the cheeks and part of the limbs white.

Fig. 6. THE GREY MAKI (*L. griseus*).—This species scarcely differs from the Woolly Maki in colour, but is smaller and has a shorter muzzle.

Fig. 7. THE RING-TAILED LEMUR (*L. Catta*).—Ash-grey, with the tail ringed with black, the head white, the muzzle, a space about the eyes, and a collar black.

#### DESCRIPTION OF THE PLATE.—THE HUMMING BIRDS.

OF the Humming Birds represented in this plate, little is known beyond their external characters, which present some diversity as to colouring, but with respect to form, proportions, and texture of plumage, are pretty similar.

Fig. 1. THE AZURE-CROWNED HUMMING BIRD (*Trochilus cyanocephalus*).—So named on account of the rich blue of the upper part of its head, is not remarkable for brilliancy of colour. It is a native of Brazil, but its peculiar history is unknown.

Fig. 2. Represents the young of the same species, differing from the adult in having the bill darker, and the green colour of the upper parts more extended over the sides.

Fig. 3. THE BLUE-FRONTED HUMMING BIRD (*T. glaucopsis*).—Nearly four and a half inches long, with the top of the head indigo-blue changing to green, the back of a deep gold-green, the wings brown, and the tail steel-blue. It inhabits Brazil.

Fig. 4. TEMMINCK'S HUMMING BIRD (*T. Temminckii*).—Was first described by the celebrated ornithologist, to whom it has since been dedicated by M. Lesson, who states that it "belongs to Brazil, that rich country which yields the diamond, and nourishes the most beautiful birds."

Fig. 5. SAPPHIRE AND EMERALD HUMMING BIRD (*T. bicolor*). Male.—This species nearly three and a half inches long, and distinguished by blue and emerald-green colours, is said, by Buffon, to be a native of Guadeloupe, by Sonnini, to occur also in Martinique, and, by Lesson, to have been received from French Guiana.

Fig. 6. The young of this species, nearly of the same colour as the adult.

Fig. 7. CLEMENCE'S HUMMING BIRD (*T. Clemencia*).—This beautiful species, which is about five inches in length, and of a bright green colour above, is a native of Mexico.

#### DESCRIPTION OF THE PLATE.—THE GROUSE.

THE Grouse which inhabit the cold and temperate regions of both continents are characterised by their robust form, full plumage, short, slightly curved, convex bill, concave, rounded wings, and short, stout feet, of which the tarsi are usually entirely or partially covered with feathers, but sometimes bare, and the toes are furnished with lateral pectinated scales, by which especially these birds are distinguished from the Ptarmigans. They exhibit considerable diversity of plumage, some having tufts on the head or neck, and the tail varying in length, as well as in the proportion and form of its feathers. They live upon vegetable substances of various kinds, leaves, twigs, and berries, and afford a generally esteemed article of food. They all nestle on the

ground, laying numerous spotted eggs, and their young run about immediately after exclusion.

Fig. 1. THE ROCKY MOUNTAIN SPOTTED GROUSE (*Tetrao Franklinii*).—This bird is by some considered as a variety of *Tetrao Canadensis*, while others hold it to be a distinct species. A certain writer, finding the tail feathers of specimens of the one kind to be emarginate and mucronate, and those of the other plain, looks upon this difference as decisive; but a little practical knowledge is sufficient to convince us that no dependence can be had on such a circumstance, for feathers which are mucronate when new are often rounded when old, and in other cases the reverse happens. It is plentiful in the Rocky Mountains near the sources of the Columbia River.

Fig. 2. Female.

Fig. 3. THE DUSKY GROUSE (*T. obscurus*). Male.—This species has also been named *T. Richardsonii*, and is stated to be plentiful in the subalpine regions of the Rocky Mountains. The male is greyish-brown above, undulated with dusky, the abdomen whitish.

Fig. 4. Female. The female is more spotted and variegated than the male.

Fig. 5. THE RUFFED GROUSE (*T. Umbellus*). Male.—The beautiful species here represented has a tuft of feathers on the head, and a large ruff on the neck, whence its specific name. It occurs in the British Colonies of North America, and in most parts of the United States, where it is common in the markets.

#### DESCRIPTION OF THE PLATE.—THE INDRIS, LORIS, GALAGOS, AND TARSIERS.

THESE animals, generally of small size, constitute the last families of the great division of the Quadrumana.

Fig. 1. THE SHORT-TAILED INDRI (*Lichanotus brevicaudatus*).—This is the only authenticated species of the genus, which differs from the Lemurs in having four instead of six lower incisors, and a very short tail. It is of a blackish colour, with the face grey; has the hind limbs proportionally longer than those of any species of Monkey; and, according to Sonnerat, is tamed by the natives of Madagascar, and employed in hunting, although in the natural state it is strictly frugivorous.

Fig. 2. THE SLOW LORI (*Stenops tardigradus*).—The Lorises have teeth similar to those of the Makis, but with the points of the grinders more acute; their muzzle is less elongated, and they are destitute of tail. Their eyes are large and approximated, and their tongue is rough. They are nocturnal animals, live upon insects and other small animals, and are said to be very slow in their motions. The present species is of a yellowish-brown colour, with a dusky band along the middle of the back, and is a native of Bengal.

Fig. 3. THE SLENDER LORI (*Stenops gracilis*).—This species is smaller and of a more slender form, with the nose a little raised, the colour nearly similar to that of the last, but without the dorsal line.

Fig. 4. THE SENEGAL GALAGO (*Otolocnus Senegalensis*).—The Galagos have the same kind of teeth as the Lorises, and are also insectivorous; but their tail is very long, and their eyes and ears large. They are natives of Africa, reside on trees, in the holes of which they nestle, and are very active. The present species is about six inches in length, exclusive of the tail, and of a yellowish-brown colour.

Fig. 5. THE LITTLE GALAGO (*Otolocnus Madagascariensis*).—The colour is similar, but the ears are shorter, and the size considerably smaller.

Fig. 6. THE PODGE TARSIER (*Tarsius Spectrum*).—The Tarsiers, so named on account of the great length of their tarsi, are very similar to the Galagos, from which they differ in having the interval between the grinders and incisors filled with several shorter teeth, a shorter muzzle, and still larger eyes. They are equally of nocturnal habits, and live on insects. The present species has the body about six inches long, its tail considerably longer, and terminated by a tuft of hairs. It is said to be a native of Madagascar.

#### DESCRIPTION OF THE PLATE.—THE SWALLOWS.

THE Swallows constitute an extensive family of birds, remarkable for the elegance of their form, their adaptation for rapid and protracted flight, and their extended migrations. From the liveliness of their manners, their attachment to the habitations of man, and the circumstance of their announcing the return of summer, they are general favourites. This group has been divided into several genera, of which it is

unnecessary to speak at present, as the species in the plate, which represent three of these sections, have been referred to the single genus *Hirundo*. These birds are extensively distributed, some species occurring in all the warm and temperate parts of the globe, or, during the summer, extending their migrations to the confines of the frozen regions. Those represented in the plate are all natives of America.

Fig. 1. THE BARN SWALLOW (*Hirundo rufa*.) Male.—This species so closely resembles the *H. rustica* of Europe, that some ornithologists have considered it absolutely the same. It is about seven inches in length, with long pointed wings, and a very deeply forked tail; the forehead and throat reddish-brown, a dusky bar across the fore neck, the upper parts glossy bluish black, and the tail-feathers with a white spot on the inner web. It visits all parts of the United States in the end of spring, nestles in the same manner as our Chimney Swallow, lays five white eggs spotted with reddish-brown, and generally rears two broods in the season.

Fig. 2. THE BARN SWALLOW. Female.—The female has the tail less elongated, the upper parts tinged with green, the rufous colour on the throat and forehead paler.

Fig. 3. THE BANK SWALLOW (*H. riparia*.)—This species, which is much smaller than the last, and of a greyish-brown colour on the upper parts, is common to both continents, its habits in America being precisely similar to those which it exhibits with us. It receives its specific name from its burrowing in sandy banks.

Fig. 4. THE WHITE-BELLIED SWALLOW (*H. bicolor*.)—The upper parts are of a glossy greenish-blue, the lower white. It has been ascertained by Mr Audubon to winter in Louisiana, and in summer to extend over all parts of the United States.

Fig. 5. THE CLIFF SWALLOW (*H. fulva*.)—This species, which is named from its habit of building on the face of rocks, is more variegated in its colours than the preceding, and has the tail abrupt or truncate. It inhabits the southern and western parts of the United States, from whence it returns southward in August.

Fig. 6. THE WHITE-COLLARED SWALLOW (*H. albicollis*.)—Of this species little seems to be known. It is of a uniform blackish colour, with a band of white across the hind part of the neck, and a patch of the same colour on the fore neck; and is said to inhabit Brazil.

RAVAGES OF FIELD MICE.—The following interesting account of the destructive effects of Field Mice is extracted from Mr Jesse's Gleanings:—"An extraordinary instance of the rapid increase of Mice, and of the injury they sometimes do, occurred a few years ago in the new plantations made by order of the crown in Dean Forest, Gloucestershire, and in the New Forest, Hampshire. Soon after the formation of these plantations, a sudden and rapid increase of Mice took place in them, which threatened destruction to the whole of the young plants. Vast numbers of these were killed; the Mice having eaten through the roots of five-year-old oaks and chestnuts, generally just below the surface of the ground. Hollies also, which were five or six feet high, were barked round the bottom; and in some instances the Mice had crawled up the tree, and were seen feeding on the bark of the upper branches. In the report made to government on the subject, it appeared that the roots had been eaten through wherever they obstructed the runs of the Mice. Various plans were devised for their destruction; traps were set, poison laid, and cats turned out; but nothing appeared to lessen their number. It was at last suggested, that if holes were dug, into which the Mice might be enticed to fall, their destruction might be effected. Holes, therefore, were made, about twenty yards asunder, in some of the Dean Forest plantations, being about twelve in each acre of ground. These holes were from eighteen to twenty inches in depth, and two feet one way by one and a half the other; and they were much wider at the bottom than at the top, being excavated or hollowed under, so that the animals when once in could not easily get out again. In these holes at least thirty thousand were caught in the course of three or four months, that number having been counted out and paid for by the proper officers of the forest. It was, however, calculated that a much greater number than these were taken out of the holes, after being caught, by Stoats, Weasels, Kites, Hawks, and Owls; and also by Crows, Magpies, Jays, &c. The Cats, also, which had been turned out, resorted to these to feed upon the Mice; and, in one instance, a Dog was seen greedily eating them. In addition to the quantity above mentioned, a great many Mice were destroyed in traps, by poison, and by animals and birds of prey; so that in Dean Forest alone, the number of those which were killed in various ways could not be calculated at much less than one hundred thousand. In the New Forest, from the weekly reports of the deputy-surveyor of the forest, about the same number were destroyed, allowing the same calculation for those eaten by vermin, &c.; in addition to which, it should be mentioned, that these Mice were found to eat each other when their food fell short in winter. Putting these circumstances together, the total destruction of Mice in the two forests in question would probably amount to more than two hundred thousand."

MATRIMONIAL UNION BETWEEN A BLACKBIRD AND A THRUSH.—We are indebted to Mr Weir of Boghead for the following notice:—"That birds in a state of confinement should be induced, by the solicitations of love, to form matrimonial alliances with other species of the same genus, or such as resemble them most closely in size and habits, when they have not an opportunity of making a choice, is not wonderful; but that they should do so when left at liberty, is of very rare occurrence. Mr Russell of Mossie, my next neighbouring proprietor, and his brother, informed me, that they were surprised at the attention which a male Blackbird paid to a female Thrush about the end of the winter of 1836. They were always in company, and fed together. As the spring approached, their attachment appeared more decided, and they carried on a course of regular flirtation, which ended in matrimony. After a good deal of consultation, they at length determined to build their nest in a bush of heath which hung over what is here called a "farret brae." They had four young ones before the nest was discovered, so cunningly had they concealed it. When they were about half fledged, they were unfortunately carried off by some boys, notwithstanding all the care that had been taken to preserve them.

SNOWY OWL SHOT IN ENGLAND.—On the 13th of February last, a fine male Snowy Owl was shot three miles below Selby-on-the-Moor, where it had been ob-

served by the miller at a mill adjoining, for a day or two previous. The moor is well stocked with Rabbits, and the Owl was most probably preying upon them. It appeared very shy, and when pinioned by the shot was extremely fierce. It was ultimately got into a sac and killed by pressure, when it came into the possession of A. Clapham, Esq. of Potternewton, near Leeds.—*H. Denny, in the Magazine of Zoology and Botany.*

ATTACHMENT OF THE LARK TO ITS YOUNG.—Some mowers shaved off the upper part of the nest of a Sky Lark without injuring the female, which was sitting on its young; still she did not fly away, and the mowers levelled the grass all round without her taking further notice of their proceedings. A young friend of mine, son of the owner of the crop, witnessed all this, and about an hour afterwards went to see if she was safe, when, to his great surprise, he found that she had actually constructed a dome of dry grass over the nest during the interval, leaving an aperture on one side for ingress and egress. My friend immediately hastened to inform me of the circumstance, and I was about to follow him to the spot, but, on his return, he found that some ruffian had, in the meantime, torn open the nest, and made off with the young ones. How disheartening it is for the Naturalist to be so continually annoyed by these callous bird-nesters! I was in hopes, when the brood had left the nest, to have preserved the latter as a most interesting specimen; but, alas! all is, as usual, frustrated. I should add, that the intention of the parents was, obviously, to have preserved their young from the scorching heat of the sun.—*Mr Blyth, in The Naturalist.*

## BOTANY.

### GENERAL REVIEW OF THE VEGETABLE KINGDOM.—NO. V

VEGETATION, in ascending above the level of the sea, undergoes modifications analogous to those which attend its progress from the line to either pole, with this distinction, that in the last case the phenomena succeed by almost imperceptible gradations, while they crowd upon and follow each other in rapid succession on the ascent of mountains. The height of 4000 or 5000 yards in the hottest parts of the globe produces changes as distinct as the 2000 leagues, or more, which lie between the Equator and the polar regions. The three causes of the influence of which we have just spoken, all reappear within this space, viz. a diminution of heat; dryness of air; and protracted duration of light. To these we must add two others, a decrease of depth in the volume of the air, and a scarcity of those substances which abound in carbon, and are produced by the decomposition of organic bodies.

The higher we ascend, the shallower the upper stratum of air becomes; whence the excessive cold at great heights; for it is the action of the atmosphere upon the rays of light which extracts the caloric from them, and we know that the extraction of caloric diminishes in proportion as the mass of air traversed by the rays is shallower; but, on the other hand, the light is purer and more active, just as if caloric were really a simple transmutation of light, as some naturalists have conceived it to be.

The weight of the atmosphere, which at the level of the sea supports a column of mercury 28 inches high, diminishes as we ascend; so that at the elevation of 6000 yards it will only support a column of 13 inches and some lines high. A consequence of this fact is, that the vaporisation of fluids takes place on high mountains at a very low degree of heat. Notwithstanding this, however, the decrease of heat is so great, that the ambient air is very slightly impregnated with moisture.

It is true that heights have not the long days of the polar regions; but they receive the rays of the sun earlier than the plains, and are quitted later by them, so that their nights are shorter than in levels.

In fine, substances containing carbon, the wrecks of organised bodies, are rare on mountains, the rains as well as the waters of the springs dissolving them, and carrying them away as they run off into the valleys.

It cannot be doubted, but these causes united must act powerfully upon vegetation. The slightest degree of heat will cause the plants on mountains to transpire copiously; the severity of the cold, the dryness of the atmosphere, the shortness of the nights, the scarcity of carbon, will impede the enlargement of their leaves, and the growth of their stems; the strength of the light, and the protracted duration of the day, will accelerate the induration of all the parts of their frame.

The course of vegetation on mountains had not escaped the penetration of Tournefort. At the foot of Mount Ararat he had observed the plants which grow in Armenia; a little higher, those of Italy and France; above, those of Sweden; and upon the summits, those of Lapland. Observations of the same kind had been subsequently made on Mount Caucasus, the Alps, the Pyrenees, and other mountains of the old Continent. Every botanist had learned that many of the Alpine plants, that is to say, plants which grow on the various high lands of Europe and Asia, are likewise met with at Spitsbergen, in Nova Zembla, Lapland, and Kamschatka. Swartz had discovered on the mountains of Jamaica, under a still hotter sky, if not plants exactly of the same species with those of our Alpine Phanogamous ones, at least some that were analogous to them; and a great many of the Cryptogamous species precisely the same as our own: For example, *Funaria hygrometrica*, *Bryum serpyllifolium* and *cespitiolum*, *Sphagnum palustre*, *Dicranum glaucum*, &c. Linnaeus, in his own way, had summed up these facts in an axiom. "The different kinds of plants," says he, "show by their stations the perpendicular height of the earth." Yet it was not till lately that any exact survey had been taken of this interesting department of botanical geography.

The first connected series of researches made with the direct intention of ascertaining the progressive succession of plants on mountains, was instituted by M. Ramond. That celebrated individual devoted ten years to the investigation of the entire chain of the Pyrenean mountains; and studied it not only as a geometrician, natural philosopher, and mineralogist, but also as one of the most skilful of botanists; he discovered, with the sagacity that distinguishes him, the stations to which the different species of vegetables belong, and the special circumstances which sometimes cause a derangement in the natural order of their succession. We shall here shortly point out some of the results of his observations.

The Common Oak (*Quercus Robur*) grows in the plains, on a level with the sea;

reaches the slopes of the mountains, and ascends to the height of 1600 yards. It degenerates in proportion as it approaches the point where it ceases to vegetate.

The Beech (*Fagus sylvatica*) makes its first appearance at the height of 600 yards above the sea, and its last at 200 yards above the Oak. The Silver-Fir (*Pinus picea*), and the Yew (*Taxus communis*), show themselves at 1400 yards, and go on to about 2000. The Scotch-Fir (*Pinus sylvestris*), and Mugho Pine (*Pinus pumilio*), take their stations between the heights of 2000 and 2400 yards.

There the trees stop, and shrubs, with a juiceless foliage, and low or creeping stems, present themselves; these lie hid beneath the snow in the winter. Among them are some of the *Rhododendrons*, *Daphnes*, *Passerinas*, the *Globularia repens*, the two species of *Salix*, *herbacea*, *reticulata*, &c.

Soon after we meet only small herbs with perennial roots, spreading radical leaves, and a naked stalk. These, with the lichens and *Byssi*, arrive at the height of 3000, and even 3400 yards. The first that occur are the *Gentiana campestris*, *Primula villosa*, *Saxifraga longifolia*, and *Aizoon*, &c.; then *Ranunculus alpestris*, *nivalis*, *parnassifolius*, *Arctia alpina*, and finally, *Ranunculus glacialis*, *Saxifraga cespitosa*, *oppositifolia*, *Androsacea*, and *Groenlandica*. The last brings us to the borders of eternal snow.

Botanists who have explored the Alps, have remarked phenomena perfectly corresponding with those observed by M. Ramond in the Pyrenees. But it was reserved for Messrs Humboldt and Bonpland to demonstrate the succession of modifications in the vegetable structure on the highest mountains yet known, and in one of the hottest and most fertile regions of our globe.

In the equinoctial countries of America, vegetation displays itself to the view of the observer as on the gradually rising steps of an immense amphitheatre, the base of which sinks below the waters of the ocean, while its summit reaches to the foot of the glaciers which crown the Andes, 5000 yards above the level of the sea; showing that in America there are vegetables which grow at the height of 1600 or 1800 yards beyond the point where vegetation ceases in the Pyrenees and Alps; a difference that does not depend solely upon latitude, but likewise, according to M. Ramond, upon the breadth, or, if you will, the thickness of the chain of mountains. In chains of but little breadth, such as those of Europe, the air and temperature of the plains have an influence, which is constantly tending to confound the limits of the different kinds of vegetables; but this is not the case in the chain of the Andes, which is from 48 to 60 leagues in breadth. Messieurs Humboldt and Bonpland have had also this advantage in their researches, that as these were made under the Equator, they have been enabled to trace the whole series of modifications which are to be met with between the two extremes of temperature found at the surface of the globe; while other botanists, having explored none but the northern mountains of the old Continent, could only trace the modifications between a mean temperature and extreme cold.

The Plants which belong to dark and humid abodes, such as *Boletus ceratophorus*, and *botrytes*, *Lichen verticillatus*, *Gymnoderma sinuata*, and *Byssus speciosa*, are found on the vaults of caverns and the woodwork of mines, as well in Mexico as in Germany, England, and Italy. Concealed within the bowels of the earth, these less perfect species constitute the last zone of vegetation.

Next come the Plants which belong to fresh-water and salt-water. Of these, a great portion grow without preference in every degree of latitude; the medium in which they exist preserving a more equable temperature than the atmosphere. Duck-weed (*Lemna minor*), and the Greater Reed-mace or Cat's-tail (*Typha latifolia*), grow in the marshes both of Asia, Europe, and America. The *Typha latifolia* belongs in common to Jamaica, China, and Bengal. Probably there is no region on the globe where the Gray Bog-Moss (*Sphagnum palustre*) is not to be found. This indifference to climate is still more remarkable in the Sea-plants, such as the *Fuci*, *Lavers*, and *Ceramia*. The Gulf-weed (*Fucus natans*), detaching itself from the rocks on which it grew, and forming shoals of an immense extent at the surface of the water, obstructs the way of the ships as well towards the poles as under the line. On a level with the sea to the height of 1000 yards, we find the palms, the liliaceous plants, the plantain trees, the *Scitamineæ*, the genera *Theophrasta*, *Mussenda*, *Plumeria*, *Casalpinia*, *Hymenaea*, the *Cecropia peltata*, the Balsam of Tolu, the Cusparé or Cinchona of Carony, with crowds of other species which grow only in a very hot temperature. This is the zone of the palms; a tribe conspicuous for the elegance and grandeur of part of its species, and forming one of the chief ornaments of the scorching plains that lie between the Tropics. Some of them thrive, however, in more temperate regions. The *Ceroxylon andicola*, a fine palm, rising 60 yards in height, grows in the Andes at Tolima and Quindiu, in the 4° 25' of northern latitude, setting off at 1860 yards above the sea, and continuing to the height of 2870, an elevation where the atmosphere is at a moderate degree of warmth. Another species has been discovered at the Straits of Magellan, towards the 53° of southern latitude. Two sorts, the fan-palm (*Chamarops humilis*) and date-tree, are even seen to grow on our side of Europe, upon the coasts of the Mediterranean, and not far from the foot of the Pyrenees, thus advancing their tribe to beneath the 43d degree of northern latitude. But these are the exceptions; the palms in general confining themselves to the hottest parts of the globe, and none being met with towards the polar regions.

The zone of the arboresecent ferns and the cinchonas succeeds to that of the Palms and Scitamineæ. The ferns begin at 400 yards, and end at 1600. The cinchonas grow to about 2900 yards high. The oaks begin to appear at 1700 yards. These are deciduous, and by their periodical evolutions from the bud, remind the European, while wandering in these distant regions, of the mild springs of his native land.

Trees cease to grow at the elevation of 3500 yards, where the shrubs, which before had formed but a small part of the vegetation, take their place, and cover the whole soil.

A good deal lower, at about 2000 yards, the Gentians, *Lobelias*, Crowfoots, or Ranunculuses, &c. which answer to our Alpine plants, have already begun to show themselves, and keep on from thence to 4100 yards.

At this point, where snow occasionally falls, the grasses, whose numerous species were mingled in the vegetation of the lower steps of the amphitheatre, begin to reign

alone. The oat-grasses (*Avena*), bent-grasses (*Agrostis*), cock's-foot-grasses (*Dactylis*), panic-grasses (*Panicum*), feather-grasses (*Stipa*), *Jarava*, &c. here cover the face of the mountains, and continue their career up to 4600 yards, the point at which Phanogamous vegetation ceases.

#### THE COFFEE-TREE.

THE COFFEE-TREE (*Coffea Arabica*) seldom exceeds twelve feet in height, and has a slender trunk, sending off long trailing branches at its upper part. The leaves are elliptical, undulated, pointed, smooth, and opposite. The flowers are axillar, sessile, or on very short peduncles, two or three together; the calyx very small, tubular, with five teeth; the corolla funnel-shaped, its limb deeply cut into five elliptico-lanceolate, reflexed segments; the stamens five, their filaments short, and attached to the tube, their anthers linear; the germen roundish, the style simple, the stigma cleft, its segments reflexed. The fruit is a round fleshy red berry, which contains two seeds, commonly called coffee-beans. The plant thus belongs to *Pentandria monogynia* of the Linnæan system, and is referred to the natural order of *Cinchonaceæ*.

It is a native of Arabia and Ethiopia, but is cultivated in various parts of the world. It was first described by Alpinus in 1591, and was planted by the Dutch in Java in 1690, and by the English in Jamaica in 1732. The Mocha coffee, however, is considered superior to all others. It is raised from seedlings, planted out in moist shady places, and watered by artificial rills. When the fruit is mature, cloths are spread under the trees, which are shaken. The berries are afterwards spread on mats, and exposed to the sun until perfectly dry, when the husk is broken with heavy rollers of wood or stone; the kernels are again dried in the sun, and winnowed. It is scarcely necessary to say, that coffee, as used by us, is an infusion of the powdered seeds after they have been roasted.

As an article of food, coffee owes its nutritious quality chiefly to the milk and sugar used in preparing it. Considered medicinally, it counteracts the narcotic effects of opium and spirituous liquors. On strong healthy constitutions it seems to have little effect; but on debilitated or nervous persons it acts injuriously, inducing, when used to excess, headaches, giddiness, dimness of sight, and aggravating hysterical affections. It is, therefore, less adapted for sedentary people than for those employed in the open air; but used moderately, as to strength and quantity, along with substantial food, it produces no injurious action. Its effects in promoting digestion and obviating drowsiness are well known; but while, to persons in ordinary health, it forms a wholesome diluent, or a grateful stimulant, neither it nor tea, especially when used in large quantities, ought to be indulged in by those of a nervous temperament, or who are debilitated by disease.

LAMUM ALBUM AND L. MACULATUM NOT DISTINCT.—At a recent meeting of the Botanical Society of London, Mr Thomas Hancock read a paper on these plants, which he considered as forming only one species, to which he proposed giving Dr Lindley's name, *L. vulgatum*. He had been led to investigate the subject from having seen many specimens of *L. maculatum* entirely destitute of the longitudinal white patches on the leaves, so particularly insisted on by most authors as its most important specific character, as well as from having several with white flowers, and approaching so closely to *L. album* as to be scarcely distinguishable from it. He stated that Reichenbach, in his figure and description of what he considered to be the true *maculatum*, and Dr Hooker, in his adoption of the same as such, had fallen into an error, and that their plant was doubtless a variety of *L. purpurcum*.

## MISCELLANEOUS.

## ACCOUNT OF AN OSSIFEROUS CAVERN AT YEALMTON BRIDGE, NEAR YEALMTON, DEVONSHIRE.

In the summer of 1835, having casually heard of certain bones having been met with, in the progress of working a limestone quarry at Yealnton Bridge, we undertook to investigate their value, and the circumstances under which they occurred; the results of which inquiry we soon afterwards published, with a feigned signature. The present account regards only the bare facts which obtruded themselves, and is a condensed and corrected relation of what has been before made public in this neighbourhood.

Lime-rock abounds at Yealnton Bridge, and caverns and fissures of various sizes are not unfrequently disclosed to view during its removal for economical purposes. That, on the southern side of the river, at this spot rises to a great height; and before its consumption commenced, its bed projected to the banks of the river. It was in the upright surface of the rock, that the opening or openings of the cave probably formerly existed; but the memory of man can render no account concerning these original entrances. I say entrances, for as there were certain chambers to the cave, each pursuing different directions to the surface, it is reasonable to suppose there were an equal number of apertures; besides which, the fact of the remains of the predatory beasts here discovered, being disposed so that each kind was, generally speaking, separate from the others, seems to point out independent and unconnected movements of these creatures.

A great part of the cavern had been destroyed, and a large quantity of the bones removed, and irrecoverable, at the time we commenced the investigation. The relative positions, directions, and measurements of the remaining cavities, are stated by Captain Mudge as follows:—"Portions of only the eastern and western chambers remained. The former consisted of a descending shaft to the depth of ten feet, which turned at right angles, and again ascended to the surface, both the descent and the ascent being at an angle of 45°. Of the western chamber, a portion remained uninjured. From the present opening, it takes a northerly direction for forty-three feet, the height varying from five to six feet, and the breadth from four to five. It then turns westerly for twenty-five feet, the height varying from five to twelve feet, and the breadth from three and a half to five."

Several deposits, arranged as superimposed strata, occurred in this cavern. The lowest stratum consisted of compact red clay, three feet six inches deep. Above this was found a layer of argillaceous sand in the eastern chamber, and of coarse gravel in the western chamber, the former varying in depth from six to eighteen inches, and becoming broader towards its limit; the latter not exceeding six inches in depth. Over these respectively a bed of stiff white clay, since become red, presented itself, being in depth about two feet six inches. Lastly, above the whole was an accumulation of diluvial clay, three feet six inches, containing pebbles, and the osseous remains. A stalagmitic crust of variable thickness formed an almost general covering to these strata and animal remains. Such were the appearances, and number of deposits, where the space was sufficient and circumstances favorable.

In one direction, where the cave had communication with the surface by means of numerous small, circular, lengthened apertures, an alternation of thin beds of clay and stalagmite was observable; and, contained in the substance of this stalagmite, we discovered the bones of three or four species of *Mus*, which, however, we have not been able to identify as the remains of existing kinds. One of them is certainly allied to the Water-rat, and another to the common Field-mouse. These facts are mentioned, because we imagine these said alternate deposits of clay and stalagmite to be modern comparatively with those before named, originating in accidental fallings-in of recent soil; and pointing out, at the same time, a difference in the age of these, and of the other animal remains. Besides these, there were other recent exuvie found in connection with the diluvial clay, namely, certain snail shells, and the bones of a bat, both of which creatures are known to hibernate, and not unfrequently to experience death in such places. There were likewise other relics, of the antiquity of which we are not clearly satisfied, since it is the habit of very many animals to appropriate such cavities for dwellings, to betake themselves during night, during sickness, during winter, or as a resource when pursued, to the hollows and crevices of rocks; and since, by a variety of causes, their bodies, after death, are liable to be found blended with such as are the genuine productions of a former epoch.

The pebbles found in the uppermost stratum are certainly granite, and were, therefore, most likely derived from Dartmoor, where granite universally abounds. Breccia, or conglomerates of clay, fragments of rock, bones, pebbles, and stalagmite, coprolitic masses, bodies resembling indurated adipocere, portions of rich spongy fibrous clay, and particles of black mould, were also distributed through the same bed. No hair was found. The bones were in great number and variety, and for the most part it appeared, that besides the separate occurrence of those species which are predaceous, such as the Fox and Hyena, there was, moreover, a separation of the herbivorous from the other kinds; but this may have been accidental, and it must be recollected that this account refers only to such portions of the cavern as remained for our examination. It is, for the same reason, difficult, or impossible, to state the proportions borne by the different kinds to each other; but, if the facts presented by these remaining portions of the cave could be allowed to furnish such a statement, it would be, that the rapacious exceeded in number the other creatures. Very many dozens of Hyenas' teeth were collected; and in one small spot, having an area not greater than four feet, we extracted seven dozens of canine teeth of this animal. Next in frequency of occurrence to the bones of the Hyena and Fox were those of the Horse, Ox, Deer, and Rabbit. After these ranks the Rhinoceros, whilst the bones of the Elephant, Wolf, Pig, Glutton, and Bear, were extremely rare. Phalangeal bones, and a very few others, were all that we found perfect, the rest being in a broken state. The long bones had generally lost their epiphyses, and very many, not excepting those of the Hyena, were marked by teeth of some predatory beast, and evidently show that they had been clipped and gnawed. One or two fragments display on their surfaces scratches resembling those made by the teeth of a Weasel,

or animal of that kind. Teeth of very aged animals were found, and there were also bones of young individuals belonging, with the exception of a few of the Hyena, to the herbivorous kinds. The remains of the Elephant are indeed confined to two teeth of a young animal. Some of the bones have been attacked by inflammatory disease, and this occurs among the larger kinds of teeth, which, also, in some instances, are fractured as if they had been submitted to great violence. Some pieces of bone are on one side highly polished, as if they had been subjected to great friction; and Captain Mudge observed a part of the roof of the cavern, which is lower than usual, perfectly smooth and glossy, as though it had been rendered so by the frequent transits of the tenants of the cave.

It is very difficult to determine on the precise number of species of animals found in this cave, since, besides that a very great quantity of the bones had been originally destroyed, our knowledge of fossil osteology is as yet very imperfect, and the broken condition they were found in precludes the possibility of identifying a great many of them, even with the greatest facilities of comparison with other specimens. Add to this, also, that not unfrequently fragments, and even teeth, are met with, which baffle the keenest discrimination, that a degree of uncertainty with respect to date often attaches to some of the animal remains deposited in ossiferous caverns, and that sometimes from a disparity in size, conjoined with a similarity in shape and figure, of some series of teeth, a doubt arises whether there may not have existed several analogous species of such animals. This kind of doubt has unavoidably arisen in the present investigation; but it seems most reasonable to conclude, that there were two or even three species both of Deer and Horse, since there are series of teeth of these genera greatly differing in size.

With regard to the composition of these fossil bones, we ascertained, by means of chemical experiments, that they contained a much less quantity of animal matter than ordinary bones, such as have lain exposed to the atmosphere and rain for some time. They likewise were found to have received into their texture a portion of carbonate of lime, where they had been so situated as to have derived it from the drippings of the cave. These circumstances render them so extremely dry, that they imbibe moisture with great rapidity, and to a great extent, so that if the lips are applied to them, they adhere tenaciously.

Besides the present, there were and are other caverns of a like kind near Plymouth, some of them adjoining this place. The Oreston Caves were well known to the scientific world; another, similar in its nature to that of Yealm Bridge, was discovered near Yealnton, by some workmen, a few years since, and its contents thoroughly destroyed; a third instance is that of a small cavity investigated very recently by a gentleman, on whose property it occurs. It is not far distant from Yealm Bridge, and its contents were precisely similar, except in variety and quantity, to those mentioned in this paper. The bones of the Hyena and Deer were chiefly remarked. A fourth example is Kitley Cave, amongst the pebbles and rubbish of which we found a tooth of the Hyena, and a portion of the head of a Rabbit or Hare, evidently an extinct kind; and there is also a bone of some quadruped firmly fixed among the diluvial pebbles in that part of the cavern which seems to have been choked up with these bodies:—facts which are at variance with the account of the subject of this memoir given by Captain Mudge, in his paper read before the Geological Society, though we are not prepared to say that this cavern had been submitted to the same circumstances as that at Yealm Bridge. Lastly, there is another cavity of small dimensions, occurring, as do all the others, in lime-rock, situated midway between this village and Yealm Bridge, in which, among the pebbles, breccia, and mould, we found, after a long search, a single tooth of a Pig, cemented to a portion of indurated clay.

Yealnton, 23d August 1836.

JOHN C. BELLAMY.

**INFLUENCE OF LIGHT AND DARKNESS ON THE HUMAN BODY.**—Dr Allen, in his work on the influence of the atmosphere on the human frame, mentions the following instances:—Baron Humboldt was acquainted with a lady who, at sunset, invariably lost her voice, and did not again receive it till sunrise. Aristotle mentions the case of an innkeeper, who lost her understanding every evening at sunset, but recovered it next morning. When a person has taken too much wine, he becomes much more conscious of the influence of the wine on his brain when the light is removed. He is then no longer able to stand, and the chair or bed on which he may be seems to him to be revolving with rapidity. When he is again placed under the influence of light, all these phenomena cease. In early life, says a German physician, I made a curious experiment of this kind on myself. At a merry breakfast party, I drank a few glasses too many of Malaga wine. It was not until about twelve hours after that, when, in bed, I extinguished my candle, the effect of the wine on my brain became perceptible. Every thing then seemed to move round me in a circle; heat and a feeling of uneasiness came on, and I found it necessary to spring out of my bed. As soon as light was brought every thing became again stationary, and the disagreeable sensations vanished. During the whole day, while under the influence of light, I had been able to follow my usual avocations, without perceiving the slightest symptoms of an unhealthy over-excitement.

**ASPIDIUM DUMETORUM.**—Professor Don finds that the *Aspidium dumetorum* of Smith is merely an accidental state or variety of *Aspidium dilatatum*, and states that the distinctions derived from the fructification in the English Flora are fallacious, being dependent partly on the age of the frond, and partly on that of the individual plant described.

ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE WEEPERS.

THE Weeping Monkeys form a section of the *Quadrumana* characterized by having four incisors above and below, and a canine tooth and six grinders on each side of either jaw; the head round, the forehead somewhat prominent, the muzzle short, the occiput projecting, the ears rounded; and the tail prehensile, but entirely covered with hair. The species greatly resemble each other in their external form, so as to render it difficult to characterize them; and, accordingly, authors have differed as to what ought to be considered as species or varieties. They live in troops in the forests of South America, residing on the trees, and feeding on fruits and insects.

Fig. 1. THE COMMON WEEPER (*Cebus Apella*). This species, which is found in French Guiana, has the upper parts of a dusky-brown, the lower paler, the top of the head, the feet, and the tail, blackish-brown; the outer side of the arms yellowish-brown.

Fig. 2. THE FEARFUL WEEPER, here represented, is generally considered a dark coloured variety of the Common Weeper.

Fig. 3. THE CAPUCHIN WEEPER (*C. Capucinus*) is characterized by having the body of an olivaceous grey, subject, however, to great variation; the top of the head and the hands black; the forehead, cheeks, and outer side of the arms, yellowish-grey. It inhabits Guiana.

Fig. 4. THE WHITE-THROATED WEEPER is nearly a variety of the Capuchin, of a darker colour, but with the forehead, throat, and shoulders, greyish-white.

Fig. 5. THE BEARDED WEEPER (*C. barbatus*) is so named on account of a circle of long whitish hairs surrounding the face. The general colour is a dull greyish-red, varying, however, to brown or grey.

Fig. 6. THE HORNED WEEPER (*C. fatuellus*) is distinguished by two tufts of long hair on the forehead. Its colour is brown, paler beneath; the extremities blackish-brown. It inhabits Guiana.

DESCRIPTION OF THE PLATE.—THE OWLS.

THE Owls are nocturnal predaceous birds, easily recognised by their peculiar form, although closely allied to the falconine family. They are characterized by the enormous size of their beak; their flattened face; their very large eyes, which are directed forwards, so as to enable them to see an object at once with both; their hooked bill and claws; and their peculiarly soft and tufty plumage. Their ears are generally extremely large, and furnished with a flap or operculum, but differ greatly in form and extent, sometimes extending from over the eyes to the throat in a semi-circle, and sometimes of a roundish form, as in the Falcons. Many species have tufts on the head, which, although vulgarly called ears or horns, have no relation whatever to these organs. Some Owls are diurnal, pursuing their prey in open day; but by far the greater number are nocturnal or crepuscular. The larger species prey on quadrupeds, birds, and fishes; the smaller chiefly on insects. Squirrels, Rats, Mice, and small birds, are favorite articles of food with those of medium size. Their flight is peculiarly noiseless, buoyant, and wavering; and they are extremely light for their size, the great bulk of their body being made up chiefly of feathers, while that of the head is partly owing to the same cause, and partly to the separation of the two tables of the skull by very large cells, which communicate with the organ of hearing. Owls are found in all parts of the globe. They inhabit forests, woods, and rocky places; breed in rocks, towers, old buildings, out-houses, or trees, according to the species. Their eggs are always white, and more rounded than those of any other birds. This great family has been divided into several genera or sections, respecting the limits of which, however, no two authors are agreed. Cuvier considers them as forming only a single genus, which he divides into groups according to their tufts, the size of their ears, the extent of the circle of feathers surrounding their eyes, and other characters. Those represented in the plate belong to his *Chevèches*, which have no tufts on the head, and are further characterized by having the ears comparatively small.

Fig. 1. TENGMALM'S OWL (*Strix Tengmalmi*). This species is about twelve inches in length; its upper parts are liver-brown, spotted with white, the tail barred with the same colour, the lower parts yellowish-white. It is common to Europe and North America; is strictly nocturnal; builds in trees, laying two white eggs, and feeds on mice and insects.

Fig. 2. THE GREAT CINEREOUS OWL (*S. cinerea*). This is the largest of the American species; and, according to Dr Richardson, inhabits the woody districts of the fur countries; hunts by day, preys on hares and other animals, and nestles on high trees.

Fig. 3. DALHOUSIE'S OWL (*S. Dalhousiana*). This species, one of the smallest with which we are acquainted, is named in honour of Lady Dalhousie, who presented a specimen of it, along with many other birds, to the Museum of the Edinburgh University. It is a native of Canada.

Fig. 4. THE LITTLE or PASSERINE OWL (*S. passerina*) is nearly of the same size as Tengmalm's Owl, from which it is distinguished by having the lower parts marked with longitudinal brown spots, as well as by other circumstances. It is common to Europe and North America.

REMARKABLE INSTANCE OF SAGACITY IN A DOG.—M. Alphonse De Candolle being last October in the neighbourhood of Aiguesmortes, had occasion to observe a remarkable instance of sagacity in a Dog. The day was hot, and the season unfavorable, on account of the trade winds, which are productive of so much inconvenience on the shores of the Mediterranean. After walking several hours in the desert which separates the town of Aiguesmortes from Carmagne, he arrived with his companions at a plain, where they found some remains of a shipwreck. Of three Dogs which had followed their guide, two accompanied them to this spot. Their black hair imbibed the heat from the sun's rays, and they seemed to find the sand very unpleasant. M. De Candolle sat down on a mat half buried in the sand. One of the Dogs nestled close to a horizontal plank, by way of procuring a little shade, but finding this insufficient, scraped up the sand until it came to the part moistened by the sea-water. It then stretched itself with delight in this fresh and shady bed. The other Dog, however, though of the same breed, knew not what to do, and writhed in the hot sand.

HAIRS IN THE INTESTINES OF HORSES.—M. Maillet of Alfort has proved by numerous dissections, that hairs exist in some parts of the digestive canal in almost all horses. They are found especially in the pylorus and stomach, and are also frequently seen in the colon and cæcum.

BRITISH BIRDS.—NO. IV.

THE SWIFT, *Cypselus murarius*, arrives in Britain from the 20th of April to the beginning of May. It has been stated by Mr Selby, that "it is seldom seen in the northern parts of England before the end of May, or the beginning of June;" but this appears to be a mistake, for in Edinburgh it always comes before the 5th of May, and even in the very severe weather of 1837, it was seen at Newington and Canonmills on the 3d of that month. It is not in general, however, until after the different species of swallow have made their appearance that it presents itself, a few individuals only being seen at first, and the number gradually increasing until at length they become in many places plentiful, and attract attention by their extremely rapid flight and loud screams. The plumage is perfect at the period of its arrival, and it does not moult during its sojourn in this country.

The general form of the Swift is rather full; the body somewhat depressed, the neck very short; the head broad; the bill extremely small, but expanded at the base; the feet remarkably short, but strong; the tarsus anteriorly feathered; the four toes nearly of equal length, and all directed forwards; the claws very strong and curved; the wings are exceedingly long and sickle-shaped; the tail forked. The bill, feet, and eyes, are black; the colour of the plumage is blackish-brown, generally glossed with greenish, the throat whitish. The length of the male is seven and a half inches; the extent of its wings sixteen and a half.

The Swift betakes itself to steeples, high towers, ruinous castles, and abrupt rocks, where it nestles in the holes and crevices. At early dawn, in fine weather, it is to be seen shooting through the air in all directions, with a rapidity scarcely equalled by that of any other bird. Its flight is performed by quick flaps of its long narrow wings, alternating with long glidings or sailings, during which these organs seem motionless, but extended at a moderately open angle. If you watch an individual, you observe it speeding away with quick motions of its wings, which, being raised and depressed over a great range, seem to alternate with each other, although this is not in reality the case, all birds moving their wings synchronously. There it shoots along, turns to the right and left, flutters for a moment, ascends, comes down abruptly, curves and winds in various directions, darts in among its fellows, and is lost to your view. The ease with which it rises, falls, bends to either side, glides in short or long

curves, or stops in the midst of its full career, is less astonishing than it ought to be, familiarity in this, as in other instances, producing a disposition to regard as simple what is the result of elaborate mechanism.

It continues searching the air in this manner all day long, when the weather is good; nor does a shower, however heavy, usually induce it to relinquish its pursuit. Even in the midst of heavy thunder-rains, it may often be seen wheeling and diving with unremitted vigour, and in drizzly weather, when the swallows have disappeared, it pursues its avocations, heedless of the damps. On the day on which the accession of her Majesty was proclaimed in Edinburgh, the weather was extremely sultry and oppressive, and a very heavy rain fell in the afternoon, during which I was a little surprised to see the Swifts wheeling joyously over the town at a considerable height. How the insects, of which they were in pursuit, could exist in such a rain, is not less astonishing. In dry and sunny weather, however, it generally rests in the middle of the day, and towards evening is extremely active, filling the air with its shrill and joyous screams.

Its food consists entirely of insects, which it seizes exclusively on wing. Several curious circumstances may be noted with reference to its pursuit of these animals. In rainy or damp coldish weather, the Swifts are to be found flying, at no great height, generally from ten to fifty or sixty yards, frequently in bands of twenty or more, often shooting along the sides of the hedges, descending in curves, and skimming the surface of the grass, wheeling, circling, and performing all sorts of evolutions. On such occasions, they are easily shot, for they often come quite close to the gunner, being altogether heedless of his presence, so intent are they on capturing their prey.

In fine weather, they fly low in the mornings and evenings, and are among the first birds that come abroad, and the latest in retiring to their places of repose; but during the greater part of the day they are to be seen chiefly at a great elevation, apparently that of several hundred yards. Yet I have seen them flying high in rainy weather, when the clouds were separated by long intervals; and, from long observation, I am satisfied that no prognostication of the weather can be based on the flight of Swifts and Swallows. These birds fly high or low, according as their prey is abundant in the higher parts of the air, or near the surface of the ground or woods; and as insects fly lower in the evening and morning, or in damp weather, so the Swifts then descend.

In dry sunny weather they frequently utter a long loud shrill scream, as they pursue their prey; but not in such weather only, for you often hear it before or during rain, especially in the evening. Some have fancied this scream to be an intimation given by the male to his mate that he is at hand, and others that it is caused by the excitement of electricity; but these conjectures are destitute alike of ingenuity and truth. It is not in thundery weather alone that Swifts scream, but often in the clear, dry, and sunny skies, that exhibit no phenomena indicative of a want of electric equilibrium. And, as to the other theory, it suffices to reflect that Swifts scream as frequently over the open fields, at the distance of a mile or more from their resting places, as when wheeling near steeples or towers. The cry of Jackals, Wolves, and Hounds, when in full chase, seems to be analogous to the scream of Swifts under similar circumstances, but the cause and use of either is not satisfactorily ascertained. I have observed, however, that single birds very seldom scream, and that the loudest and most frequent cries are heard when birds are evidently in active and successful pursuit. It is so with Terns, Gulls, and even Gannets; and when you see these birds hovering over the sea, and hear their mingling cries, you may be sure that they have discovered a shoal of fishes, and are enjoying their good fortune. They seem to scream or cry out from pleasure, and thus give intimation to their fellows of the plentiful existence of food. As to the organ of this loud and shrill scream in the Swift, namely, the trachea, it is short, remarkably flattened, and gradually diminishes in diameter to the bifurcation. It has no song or twitter, like the Swallows.

If we suppose that the Swift is destined to feed exclusively on insects as they flutter in air, which is in fact the case, we can be at no loss to trace the reason of its peculiar form. Its body is light, but moderately stout, and its pectoral muscles are large, otherwise it could not move its wings with the requisite strength and rapidity. The wings are extremely elongated and narrow, because great rapidity of flight is required in the pursuit of animals which themselves fly with speed, and because sudden turns require to be executed in seizing them. A short, broad, concave wing, as that of a Partridge, on being rapidly moved, produces considerable velocity, but is not fitted for either buoyant gliding or quick evolution. For the latter, the surface of the wing must be extended in length and narrowed, and instead of presenting a concavity, must be straight in the horizontal direction. Accordingly, in the Swift, the wing has its humeral articulation peculiarly free, insomuch that, holding one alive in your hand, you at first imagine that its wings have been broken. At the same time, their muscular apparatus is remarkably strong. Then the secondary quills are very short, and the primaries gradually and rapidly elongated, and furnished with very strong, but highly elastic shafts. The tail, although not so long, is similarly constructed, being deeply forked, and so in a manner divided into two pointed and elongated laminae, similar in some degree to the wings, and aiding their action in executing turns. In seizing its prey, while gliding or fluttering in the air, the bird would be incommoded by any length of neck; that part is, therefore, extremely abbreviated, so that the head seems as if stuck upon the shoulders, as is the case, for a similar reason, in the Cetacea and fishes. A long pointed bill would be of use on y to a bird that has objects to pick from the ground or any other surface, or from among soil or foliage. In the present case, the bird, carried with rapidity to its tiny prey, merely requires to open its mouth, which is extremely enlarged, and supplied with an abundant viscid secretion, which immediately entangles the fly that has been caught, and prevents its escape, should the mouth be opened the next instant. A bird so living has no need of walking, and there being nothing superfluous in nature, its feet are reduced to cramping organs, by which it can cling to any kind of surface when entering its nest, and its gait is merely a hobbling motion, aided by the wings. It cannot rise from a flat surface, as I have ascertained by experiment, but it launches from any little eminence, and if it can spring out horizontally is en-

abled to fly off, although its usual mode of launching is, like that of the Gannet, by a deep curve.

These two birds are very similar in some points of their organization. Their wings are long and narrow, and their flight is rapid and buoyant; they seize their prey by throwing themselves with velocity upon it; they launch from the rocks in the same manner; and exhibit other points of mutual resemblance; as do the Terns more especially, which, on account of their form and buoyant flight, have received the vulgar appellation of Sea Swallows.

The want of walking feet might be supposed to be somewhat inconvenient on many occasions. Thus, when the bird has its nest to make, it must gather straws and feathers; but so great is its dexterity on wing, that it picks them up with ease as it sweeps along. The nest is placed in the crevice of a wall or rock, in a steeples or tower, in holes under the eaves, or in some such place, at as great a height as possible, and is composed of twigs, straws, and feathers, being bulky, but shallow, and not neatly arranged. The eggs are two or three, of an elongated form, pure white, their average length one inch, their greatest breadth seven and a half twelfths. They are deposited from the beginning to the middle of June, and the young are abroad by the end of July. Only one brood is reared in the season. The Swifts take their departure from the middle to the end of August, thus residing with us only three months and a half.

As the insects on which they live are generally very small, they do not swallow each as it is caught, but collect a number previously to the act of deglutition, for at whatever period they are shot, one generally finds insects in their mouth. When collecting food for their young, they do not return to the nest so frequently as the Swallows, but accumulate a considerable quantity at a time. I have never found any particles of gravel or sand in their gizzards, of which the hard cuticular lining is of a reddish-brown colour, as in most birds that feed on insects, such as Wagtails, Pipits, and Warblers. The insects on which they feed are numerous species of Coleoptera, Ephemerae, Phryganeae, and occasionally Libellulae and Muscae.

It has been conjectured by some that the visceous saliva of the Swallows is used for agglutinating the pellets of which the outer crust of their nests is composed. I have carefully examined these mud crusts of the Chimney and Window Swallows, and can find in them no appearance of cement. The Sand Swallow, which has no such crust to its nest, has an equally copious viscid saliva. The same is the case with the Swift. But the absurd fancies of ornithological writers are so numerous and so palpable, that it is tiresome to refute them.

The young Swifts are of a dusky colour, at first blind, and almost naked, having merely a few straggling tufts of down. When fully fledged, they are of the same colour as the adults, but of a lighter tint, with the edges of the feathers of the head paler.

Previous to their departure, the Swifts do not collect into large flocks, like the Swallows, but disappear gradually, setting out apparently in small parties, in the same manner as that in which they arrived.

**MORTALITY AMONG BIRDS.**—The following curious statement rests upon the authority of a Lausanne Journal. During the last fortnight great numbers of sick and dead Birds, particularly Thrushes, have been found in the fields of Soleure. An inflammation of the spleen is the cause, and the disease is attributed to some acid exhalations from the earth. All the Sparrows and Finches, it is added, have deserted the infected districts, and in several parts of Switzerland domestic animals have been attacked in a similar way.—*Literary Gazette.*

## BOTANY.

*Remarks on the Mountain-Ash, or Rowan, and the Apple Tree of Russia, by William Howison, M.D., Lecturer on Botany, Edinburgh.*

**THE MOUNTAIN-ASH, or ROWAN** (*Pyrus Aucuparia*), is distributed over the greater part of the Russian Empire, and towards the northern parts attains great perfection, exhibiting a luxuriant display of blossoms and fruit. It occurs in abundance on the outskirts of the forests, as also around noblemen's and gentlemen's parks or policies, where the tree acquires great size. An open situation appears to be absolutely necessary to its prosperity and increase; for when found in the midst of the forests, which, however, is rarely the case, it is always stunted, and falls into the state of brushwood. In all parts of Russia where I have seen it, it is a natural production, propagating itself by the seeds which are accidentally blown about, and is very seldom artificially planted. During the summer and autumn, it enhances the beauty of the forests by its flowers and fruit, and on that account is esteemed by all classes of Russians, as well as foreigners, in the neighbourhood of their habitations. On the summer holidays or fasts, its branches in full flower are used to ornament the windows of the village Isbac. In a country like Russia, where timber of the finest kinds can be procured in such abundance, and at a trifling price, the wood of the Mountain-Ash, on account of its softness and want of durability, is not applied to any particular use. At times it presents itself amongst the billets of birch and fir sent down from the interior, when, of course, it is consumed along with them as firewood. This tree, however, is by no means destitute of value; for besides affording food to man, it furnishes subsistence, during a considerable part of the year, to the feathered inhabitants of the forests.

The ripe fruit of the Mountain-Ash is used extensively, in a variety of ways, as an article of food. The first application of it to this purpose, which I shall mention, is to form a liquor, which is much esteemed as a stomachic, an agreeable bitter, and for diffusing a glow over the system during the winter months. To make this, take a small cask, two-thirds full of the ripe berries, picked and cleaned; fill it with strong spirits, and allow it to stand in a cold cellar for twelve months. Then run off the spirit, which has become completely impregnated with the colour and flavour of the fruit, and comes away perfectly pure, the macerated berries remaining at the bottom. The spirit or tincture is then bottled. The boors or lower class make use of the Watky, or common fermented spirits of the country, for the above purpose.

while the nobility, the higher orders of the people, and foreigners, employ gin, brandy, rum, or other spirits. A glass or two of this liquor is taken each forenoon during the winter months, and it generally makes its appearance at lunch.

The second application of the fruit of the Rowan Tree as an article of food, is in the form of jelly, jam, or preserve. To make the jelly, put the berries, when ripe and cleanly picked, into a large jar, which is to be placed either in an oven, or in a saucepan of boiling water, until they part with their juice. Strain through a fine sieve, but do not press the berries; weigh the juice, and add to it an equal weight of loaf sugar; boil them together until they acquire a proper consistence. Rowan jelly thus made has a pleasant, slightly bitter taste, and in appearance resembles that made from red currants. It is eaten in considerable quantity with partridges, the different varieties of wild fowl, &c., which are to be had in any quantity at a trifling price, and constitute a daily dish. The jam is made in the same manner as that of the gooseberry, or any other species of fruit, and forms a good remedy in stomach complaints and sore throats. Lastly, the berries, towards the end of the season, when ripe, are collected in great quantities by the boors, for their own consumption, and for that of the nobles on whose estate they live; and are salted, along with various sorts of wild berries, and preserved amongst their winter store in the ice-cellars. During the winter the berries thus kept form a part of their daily meals, and are reckoned antiscorbutic. Far distant, I am afraid, is the period when the fruit of the Mountain-Ash will be applied to any useful purpose by the peasantry of Great Britain, although thus relished and sought after by the more opulent and better fed boors of the interior of Russia.

THE APPLE TREE, *Pyrus Malus*, in all its varieties, attains a state of great perfection, and is found in abundance in the Russian Empire, particularly towards the southern parts, the Crimea and the Ukraine. It presents a healthy and luxuriant appearance, and yields abundant crops. The fruit markets in the great towns, during the autumnal months, are amply supplied with the finest apples of every description; they are handed in abundance through the streets by the itinerant fruit-dealers, and are sold at a cheap rate. They generally attain a great size, and ripen perfectly, as is indicated by the richness of their colour and odour. During the course of the winter they may be had to purchase in the grocery shops in their preserved state.

When the apples are intended to be preserved in their fresh state, those which are in the best condition are carefully picked out and well cleaned by means of a dry cloth. They are then put up in small heaps, or are arranged in regular rows, on the wooden floor of the ice-cellar, with which every Isbac is supplied, for keeping their various sorts of provisions in a fresh state, during the winter and summer months. At regular intervals, any moisture that may have collected upon them is carefully rubbed off; they are frequently turned; those which present the slightest appearance of spoiling are removed for immediate use; and the rest are found to keep in good condition from November until the next crop is ready for use.

I was informed while in Russia that apples may be preserved fresh for a considerable period by another method, which, although it has not been my good fortune to see it practised, I shall now describe, being convinced that it is worthy of a fair trial. A quantity of tight well-made casks or barrels, sufficient to contain the fruit to be preserved, must first be procured. The apples, after being picked out and carefully rubbed with a dry cloth, are to be placed in layers, alternating with others of cranberries, until the casks are completely filled. Cold spring water is then poured in so as to fill up every interval, and, when the process is completed, each cask is secured in a perfect manner by fixing its top on.

Whether the cranberry possesses any preservative power, whether any other kind of small fruit would answer the same purpose, or whether their use might be omitted, I cannot take upon me to determine. I feel inclined, however, to think that it does not exert any such power, and that the preservative or antiseptic quality evinced depends entirely on the water and the consequent exclusion of the air. It is a well known circumstance, that apples which have fallen from the trees in orchards or gardens, and have accidentally got buried under the surface of the earth during the autumn months, have been dug up the following spring or summer in a fresh state; and this, of course, arises from their submersion and consequent protection from the air.

Apples are preserved in great quantity throughout the Russian Empire by another method; they are kept in a dry state. For this purpose, the inferior sorts are generally made use of. They are cut through the centre from top to bottom, into four, six, or eight divisions, according to their size; the seeds with the capsule being generally removed, as is done in this country in preparing apples for pies. The various pieces collected together are dried in the sun, if the heat of the season is sufficient for the purpose; if not, by means of fires; after which they are strung upon twine, formed into bunches, and will remain in good condition for any reasonable length of time. When apples dried in this way are moistened by putting them in warm water at any after period, they regain their natural spongy appearance, and are used by the peasants to make pies during the winter months, and to form a particular kind of drink much consumed in Little Russia.

Preserved in the manner here described, apples brought from the Crimea, Ukraine, or south of Russia, may be had to purchase all the year in the shops of the great towns. In the Island of Mohn, situated at the head of the Baltic, and belonging to Russia, the crab apple only abounds, and of it the boors make a tolerably well-tasted cyder.

NEW ESCULENT SEA-WEED.—At a recent meeting of the Medico-Botanical Society, a paper was read by Dr Sigmond, respecting a new esculent sea-weed, which possesses nutritious properties to a much greater extent than Iceland moss, without any of the bitter principle which renders that plant so disagreeable to many. This fucus, of which specimens have lately been brought from Calcutta, is said to contain 54 parts of starch in 100, and to be employed in large quantities by the Chinese, who form with it an agreeable and refreshing jelly. It is abundant in the neighbourhood of Ceylon, and has been much employed by the medical profession in Calcutta. The jelly is said to be quite equal to *blanc nange*.

## THE TOBACCO PLANT.

THE TOBACCO PLANT, *Nicotiana Tabacum*, belongs to *Pentandria Monogynia* of the Linnæan system, and to the natural family of *Solanææ*, or Nightshade Tribe, which are generally narcotic or poisonous, although the Potato, *Solanum tuberosum*, whose farinaceous tubers now afford so important an article of food, ranks among them. The root of the common Tobacco is large, fibrous, and of annual duration; the stem erect, round, hairy towards the upper part, branched, and attains a height of from four to six feet; the leaves alternate, large, ovate, pointed, veined, and clammy; the flowers are disposed in terminal panicles; the calyx is monosepalous, bell-shaped, with five deep-pointed segments; the corolla monopetalous, somewhat funnel-shaped, with a long cylindrical tube, and five acute revolute segments; the stamens five, with in-curved tapering filaments and oblong anthers; the germen oval, with a long slender style, and a round cleft stigma; and the capsule oval, two-celled, containing numerous small roundish seeds.

Tobacco, which is the dried leaf of *Nicotiana Tabacum*, as well as of several other species of the same genus, was first imported from America into Europe, about the middle of the sixteenth century, by Hernandez de Toledo, who, however, had not the honour of giving it its scientific appellation, which was derived from a Frenchman, Jean Nicot, Lord of Villeda, who being ambassador from Francis II. at the court of Lisbon, sent some to his queen, Catherine de Medicis. The custom of smoking is said to have been introduced into England by Sir Walter Raleigh, who found tobacco cultivated in Trinidad on his first visit to it in 1593. It is believed that the first time the Spaniards saw it smoked was in 1518, at an interview between Grijalva and a cacique of Tabasco, or Tabaco, from which place the plant received its popular name. In spite of the strenuous opposition which was made to its introduction by the princes of Europe, it gradually gained ground, and is now in general use, being extensively cultivated in both hemispheres. The importation of tobacco and snuff into Great Britain, in the course of a recent year, amounted to nearly 17,000 hogsheads. It is related of M. Fagon, physician to Louis XIV., that in the midst of a most energetic speech on the pernicious effects of tobacco, he paused, and deliberately taking his snuff-box from his pocket, refreshed himself with a pinch, to enable him to resume the argument; it may be imagined with how little effect. Another curious fact is related with reference to its cultivation in Virginia, where it was introduced in 1616, under the government of Sir Thomas Dale. The planters at that time being all bachelors, regarded themselves as merely temporary sojourners; but the London Company for the colonization of Virginia sent out a number of respectable young women as wives to the settlers. These ladies were actually sold for a hundred and twenty pounds of tobacco each, that quantity being equivalent to the expenses of the voyage.

Tobacco is extensively cultivated in Cuba, St Domingo, Trinidad, Brazil, Virginia, the Cape of Good Hope, and India. In the United States of America it is raised in the following manner:—The seed is sown in February and March, in beds carefully prepared. In April the young plants are laid out in the fields in rows, at the distance of three feet from each other. Besides being hoed and weeded, they are deprived of the lateral shoots and the tops in order to increase the size of the leaves. When the plants have attained their full size, and the leaves begin to assume a brownish hue, they are cut close to the ground, and left in heaps exposed to the sun for one day. They are then carried to a shed and hung up in pairs on ropes, where they remain until dry, when the leaves are separated and made up into small bundles, which are laid in heaps and covered with a cloth, to favor a slight fermentation, care being taken by occasional exposure to prevent too great heat. They are finally packed in casks for exportation, and undergo a second fermentation, which gives them a dark colour and soft texture.

Along with its narcotic properties, tobacco has a lightly stimulant action, more especially with respect to the digestive organs, on which account it has in certain cases been employed as an emetic and purgative. In obstinate constipation and

strangled hernia, its smoke has sometimes been injected with advantage. But its employment as a medicine is unfrequent, on account of its violent effects, and the uncertainty of its operation, which cannot be restrained within the desired limits. The use of tobacco as a narcotic luxury is now very general in most countries, it being alike relished by the most civilized as by the most savage nations, and by the higher ranks in the former as by the lower. At its first application, it invariably produces powerful narcotic effects, such as giddiness, stupor, and vomiting, and in some cases it has proved a mortal poison. But as, like other narcotics, its effects gradually disappear on its being repeatedly used, although in irritable constitutions it is apt to produce deleterious effects; and it has been remarked that persons who take much snuff, though they seem generally to escape its narcotic power, yet are often affected in the same manner as from the continued use of opium or spirits, and exhibit a loss of memory, and other symptoms of a debilitated state of the nervous system. Dyspepsia and pains in the stomach are also caused by excess in snuffing, as well as in smoking or chewing tobacco. On account of its stimulating property, snuff, by exciting a flow of mucus from the nose, has sometimes been useful in relieving headaches, ophthalmias, and toothaches; but, on the other hand, a ceasing from snuff is apt to give rise to those very disorders, and an inordinate use of it also sometimes produces them. Snuffing at first causes violent sneezing, then an increased flow of mucus, then an agreeable sensation approaching to giddiness, and lastly headache. Smoking and chewing give rise to a copious flow of saliva, then a sensation of giddiness, followed by sickness, vomiting, and headache. These effects, however, are by long use much diminished, although always liable to be induced by excess. Many people seem to be unaware of the real effects of tobacco, and to suppose that it is used merely as a custem, but it is simply on account of its narcotic effect that it is employed. These effects are most powerfully produced by chewing, next by smoking, and in a less degree by snuffing, which, however, is probably the most injurious way of taking tobacco, as it keeps up the excitement continuously, and occasionally produces violent effects. Few people addicted to the use of tobacco are willing to acknowledge its effects. The fact is, they are ashamed to own that they are little better than habitual drunkards. In all ordinary cases tobacco is much more injurious than useful: it causes a great waste of saliva, passes occasionally into the stomach, producing sickness and dyspepsia, stimulates the brain, and causes giddiness, confusion of thought, and impaired memory. In a certain dose it deadens sensibility, and by producing a kind of vertigo or drunkenness, alleviates for a time distressing care. Like wine, ale, porter, and spirits of all kinds, tobacco is productive of much more evil than good; and although its action is apparently less violent than that of spirits, yet it is always deleterious. It is in fact a poison operating slowly but surely on most constitutions, and tending to accelerate the fatuity to which many individuals are otherwise liable in advanced age. Most persons addicted to the use of tobacco are equally fond of the bottle, and the combined use of both produces that most disgusting character, a set. It is a curious fact, however, that many addicted to both are just the persons who are londest in denouncing them.

## GEOLOGY.

ORGANIC REMAINS IN THE COAL FORMATION AT WARDIE, NEAR NEWHAVEN.—Dr Paterson, in a paper read to the Wernerian Society, and published in the Edinburgh New Philosophical Journal, gives an interesting account of the fossil plants and animals discovered in the strata of slate-clay, bituminous shale, sandstone, and clay-ironstone, exposed on the shore near Newhaven. The plants generally occur in the form of impressions, and are referred to the following species:—*Sphenopteris affinis*, *S. crithmifolia*, *S. artemisiifolia*, *S. furcata*, *S. elegans*, *S. Hoeninghausi*; *Cyclopteris obliqua*, *C. flabellata*, *C. trichomanoides*, *C. reniformis*; undetermined remains of *Calamites*; *Lepidodendron elegans*, *L. Sternbergii*, *L. ramosum*, *L. aculeatum*, *L. abovatum*, *L. appendiculatum*, *L. selaginoides*, *L. lycopodioides*; *Lepidostrobus variabilis*, *L. ornatus*. "It is now generally admitted," says the author, "that these impressions (*the Lepidostrobi*) must have been made by the reproductive organs of plants, similar in form to the same parts in recent Coniferæ and Lycopodiaceæ. M. Brongniart, from their frequent connection with *Lepidodendra*, maintains that they belong to that class of plants. *Lepidophylla*, of various sizes, are very common throughout the shale in this place; and frequently attached to them is a small seed-like body, which, when compared with the division of *Lepidostrobus ornatus*, is at once seen to be the same. From this fact, we imagine that Messrs Lindley and Hutton's conjecture of *Lepidophylla* being referred to some species of *Lepidostrobus* is correct, and that they are merely the scales or bractæe of this class of plants. How beautiful, then, must these ancestral members of our vegetation have been, when *Lepidodendra* waved their luxuriant branches, crowned with *Lepidostrobi*; and these last being imbricated with *Lepidophylla*, the whole bearing not a distant resemblance to some of the Coniferæ of the present day!" *Polyporites Bowmanii*, *Kuorria taxina*, *Sphæria paradoxa*, *Poacites cocoïna*, *Antholites Pitcairniæ*, undetermined species of *Bechera*, and *Fucoides Targionii*, "sum up the list of vegetables" hitherto identified by the author.

The fishes discovered are—*Amblypterus striatus*, *A. nemopterus*, *A. punctatus*; *Palaoniscus striolatus*; *Eurynotus fimbriatus*; *Acanthodes sulcatus*, and a species of *Pygopterus*. "Coprolites or fecal balls abound in the slate and clay-ironstone; and here, as in the different coalfields in the middle district of Scotland, contain scales and teeth of fishes."

ELEVATION OF BEACHES BY TIDES.—If the earth were a spheroid of revolution, covered by one uniform ocean, two great tidal waves would follow each other round the globe at a distance of twelve hours. Suppose several high narrow stripes of land were now to encircle the globe, passing through the opposite poles, and dividing the earth's surface into several great unequal oceans, a separate tide would be raised in each. When the tidal wave had reached the farthest shore in one of them, conceive the causes that produce it to cease. Then the wave thus raised would recede to the opposite shore, and continue to oscillate until destroyed by the friction of its bed. But if, instead of ceasing to act, the causes which produce the tide were to reappear at the opposite shore of the ocean, at the very moment when the reflected tide had

returned to the place of its origin; then the second tide would act in augmentation of the first, and, if this continued, tides of great height might be produced for ages. The result might be, that the narrow ridge dividing the adjacent oceans would be broken through, and the tidal wave traverse a broader tract than in the former ocean. Let us imagine the new ocean to be just so much broader than the old, that the reflected tide would return to the origin of the tidal movement half a tide later than before; then, instead of two superimposed tides, we should have a tide arising from the subtraction of one from the other. The alterations of the height of the tides on shores so circumstanced might be very small, and this might again continue for ages; thus causing beaches to be raised at very different elevations, without any real alteration in the level either of the sea or land.

If we consider the superposition of derivative tides, similar effects might be found to result; and it deserves inquiry, whether it may not be possible to account for some remarkable and well attested phenomena by such means.

The gradual elevation, during the past century, of one portion of the Swedish coast above the Baltic, is a recognised fact, and has lately been verified by Mr Lyell. It is not probable, from the form and position of that sea, that two tides should reach it distant by exactly half the interval of a tide, and thus produce a very small tide; nor is it likely that, by the gradual but slow erosion of the longer channel, one tide should almost imperceptibly advance upon the other; but it becomes an interesting question to examine whether, in other places, under such peculiar circumstances, it might not be possible that a series of observations of the heights of tides at two distinct periods might give a different position for the mean level of the sea at places so situated.

If we conceive two tides to meet at any point, one of which is twelve hours later than the other, the elevation of the waters will arise from the joint influence of both. Let us suppose, that, from the abrasion of the channel, the later tide arrives each time one hundredth of a second earlier than before. After about 3150 years, the high water of the earlier tide will coincide in point of time with the low water of the later tide; and the difference of height between high and low water will be equal to the difference of the height of the two tides, instead of to their sum, as it was at the first epoch.

If, in such circumstances, the two tides were nearly equal in magnitude, it might happen that, on a coast so circumstanced, there would, at one time, be scarcely any perceptible tide, and yet 3000 years after, the tide might rise thirty to forty feet, or even higher; and this would happen without any change of relative height in the land and water during the intervening time. Possibly this view of the effects which may arise, either from the wearing down of channels, or the filling up of seas through which tides pass, may be applied to explain some of the phenomena of raised beaches, which are of frequent occurrence.—*Babbage's Bridgewater Treatise*.

## MISCELLANEOUS.

ST ELMO'S FIRE SEEN IN ORKNEY.—The following account of this phenomenon, extracted from a letter by William Traill, Esq., Kirkwall, is contained in the last number of the Edinburgh New Philosophical Magazine. On Sunday the 19th February last, in a tremendous gale, my large boat sunk, and it was late on Tuesday night before we could get her up and drawn to the shore, after which we had to wait till three o'clock next morning till the tide ebbed from her. She was during this time attached to the shore by an iron chain, about 30 fathoms long, which did not touch the water, when, to my astonishment, I beheld a sheet of blood-red flame, extending along the shore for about 30 fathoms broad and 100 fathoms long, commencing at the chain and stretching along the shore and sea in the direction of the shore, which was E.S.E., the wind being N.N.W. at the time. The flame remained about ten seconds, and occurred four times in about two minutes. Whilst I was wondering not a little, the boatmen, who, to the number of twenty-five or thirty, were sheltering themselves from the weather, came running down apparently alarmed, and asked me if I had ever seen anything like this before. I was about to reply, when I observed their eyes directed upwards, and found they were attracted by a most splendid appearance at the boat. The whole mast was illuminated, and from the iron spike at the summit, a flame of one foot long was pointed to the N.N.W., from which a thunder-cloud was rapidly coming. The cloud approached, which was accompanied by thunder and hail; the flame increased, and followed the course of the cloud till it was immediately above, when it arrived at the length of nearly three feet, after which it rapidly diminished, still pointing to the cloud, as it was borne rapidly on to S.S.E. The whole lasted about four minutes, and had a most splendid appearance.

GEDRITE, A NEW MINERAL.—This mineral was discovered by Count D'Archica, in the valley of Heas, near Gedre. It scratches glass readily; is scratched by quartz; sp. gr. 3.260. It is very tenacious, and receives the mark of a hammer; colour clove-brown, lustre semi-metallic. Before the blowpipe it fuses into a black enamel, slightly scoriaceous. With borax it fuses into a nearly black glass. It approaches in appearance to anthophyllite. According to DuRoi, it consists of silica 38.811, alumina 9.309, protoxide of iron 45.834, magnesia 4.130, lime 0.666, water 2.301, answering to the formula,  $5f. S^2 + M A^2 + A^3$ . This approaches to the formula of bronzite.

NEW SPECIES OF RHEA.—It is stated in the Magazine of Zoology and Botany, that Mr Darwin has brought home, among other zoological treasures, specimens of a new species of Rhea, which appears to occupy in Patagonia the place of the formerly known species, from which it is distinguished by being about a fifth less, and by having the tarsi reticulated and feathered below the ankle, or what is commonly called the knee-joint.

ZOOLOGY.

BRITISH BIRDS.—NO. V.

DESCRIPTION OF THE PLATE.—THE GALEOPTITHECI OR FLYING-CATS.

THE Galeoptithecii form a small genus of the family of Cheiroptera, which is the first of the order Carnivora, and are especially remarkable for having the skin of the sides extended into a kind of hairy membrane, which stretches from the head to the tail, including the extremities or limbs. Their body is rather elongated and slender, the head small and pointed, the legs strong, the fingers furnished with large hooked claws, the ears short and rather rounded, the tail of moderate length. They are nocturnal animals, live chiefly on fruits, suspend themselves to trees by the hind feet in the same manner as Bats, climb with great agility, and descend from branch to branch with the aid of their expanded membranes. Their native country is the Indian Archipelago, but their manners are very imperfectly known.

Fig. 1. THE COMMON FLYING-CAT (*G. volens*) is the only species of which we have a distinct knowledge. It is about the size of a domestic Cat, light red above and below, inhabits the Moluccas and other Islands of the Indian seas, climbs on trees, and emits a disagreeable odour, like that of the Fox.

Fig. 2. Female. The female is similar to the male, but variegated with grey on the upper parts.

Fig. 3. Young. The young is brownish, variegated with grey and pale reddish, the extremities spotted with whitish.

DESCRIPTION OF THE PLATE.—THE BEE-EATERS. MEROPS.

THE genus Merops is composed of a considerable number of species, remarkable for their vivid colours, slender body, long pointed wings, elongated, tapering, and arched bill, and small feet, of which the anterior toes are united for a great part of their length. They are generally distributed in the warm and temperate regions of the old continent, live on insects, which they pursue in open flight, in the manner of Swallows, and form their nests in holes in the ground, like the Kingfishers, to which they are otherwise allied.

Fig. 1. THE JAVANESE BEE-EATER (*M. Javanicus*) inhabits Java and other Islands of the Indian Archipelago. It is light green above, with a lilac patch on the throat, the ear-coverts black, the secondary quills, tail, and rump, light blue.

Fig. 2. THE SUPERB BEE-EATER (*M. superbus*) is of a beautiful deep red, with the head and rump light blue.

Fig. 3. THE RED-HEADED BEE-EATER (*M. erythrocephalus*). Green above, reddish white beneath, the throat yellow, the upper part of the head bright red. A native of India.

Fig. 4. THE INDIAN BEE-EATER (*M. viridis*). Light green, with the throat blue. It occurs in various parts of India.

Fig. 5. THE RED-WINGED BEE-EATER (*M. erythropterus*). Green above, the throat yellow, a crimson patch on the breast.

Fig. 6. THE BLUE-HEADED BEE-EATER (*M. caeruleocephalus*). Of a beautiful rose colour, the head blue, tinged with green.

NEST OF THE KINGFISHER.—A friend of mine, says R. P. Alligton, Swinohope House, Lincolnshire, while fishing in a small trout stream, near Louth, called the Crake, in the early part of June, observed a Kingfisher, with a fish in its mouth, flying several times near his hat with a whirring noise. He watched it until it entered a hole in the bank, the entrance to which was strewed with fish bones. On digging into the hole (which commenced low down in the bank, and ran upwards in a slanting direction for about two feet), he found the nest, containing seven young birds just hatched. The bottom of the nest was excessively thick, and mixed up with small bones of the Stickleback. Its structure, excepting the mixture of fish bones, was not very unlike that of a Thrush. It crumbled to pieces on being touched, and I could procure no portion worth preserving. Near the nest was another hole, which had all the appearance of having been the Kingfisher's last year's residence, the bones at the entrance being dry and crumbly; but in this the parent bird again commenced laying, and on opening the nest six eggs were found on the fragments of the structure. They were white and beautifully transparent, showing the yolk through, which gave them an inkish hue at the larger end. I have now in my collection one of the eggs, which, though so transparent, I was surprised to find thicker and stronger than the generality of eggs, and rounder in its form, the circumference being two inches and a half, the length eight tenths of an inch.—*Naturalist*, No. 11.

THE PEREGRINE FALCON, *Falco peregrinus*, is the largest British species of its genus, except the Iceland or Jer Falcon, which, however, is of extremely rare occurrence with us, its favorite abode being the arctic regions of both continents. In the olden times it was held in the highest estimation for falconry, for although the species just mentioned was considered superior, the Peregrine was much more easily obtained, and being possessed of great docility, courage, and energy, afforded prime sport to the nobles, who alone were permitted to foster these "generous" birds, which were preserved by legislative enactments. As in other species of this family, the female is much superior in size to the male, and was used for the larger sorts of game, as Herons, Geese and Ducks, while the latter, usually named a Tiercelet, on account of its being often a third less, was flown at Grouse and Partridges. The male generally measures 16 inches in length, while the space between the tips of its extended wings is 36. The corresponding dimensions of the female are 22 and 45 inches.

To form this species is full and robust, its neck rather short, its head large and round. The bill is shortish, thick, and strong, the upper mandible with a trigonal, acute, hooked point, and a strong process or tooth on either side. The legs are robust and short, the tarsi feathered more than half-way down; the toes strong, the second and fourth nearly equal, the first shortest, the third very long; the claws long, tapering, rather compressed, and very acute. The plumage is compact on the upper parts, softer on the lower; the wings very long, pointed, and when closed, reaching to within an inch of the end of the tail, which is slightly rounded. The bill is pale blue, with a bluish-black tip, the cere oil-green, the feet yellow, the claws black. The general colour of the upper parts is dark bluish-grey, the head blackish, the lower parts white, the breast transversely spotted with dusky. In the female the upper parts are tinged with brown, the lower are yellowish-white, with larger spots. In young birds the back is blackish-brown, the breast pale yellowish-red, with broad longitudinal spots. In all stages there is a large dark-brown or blackish patch on the side of the head or cheek.

The direct flight of the Peregrine Falcon, which is extremely rapid, is performed by quick beats of the half-extended wings, and is very similar to that of the domestic pigeon. When proceeding in haste from its breeding place or roosting station towards a distant part of the country, it very seldom sails, or moves forward at intervals with extended wings; but when sauntering as it were about its retreat, it employs both modes of flight, as it also does in common with many other hawks, when searching for its prey; yet it is hardly ever seen to float along in circles, as Eagles, Buzzards, and Harriers are wont to do, but performs its short gyrations as if in haste, and the moment an opportunity occurs, comes down upon its prey, either in a curved sweep, or like a stone falling from the air.

Its food consists of birds of moderate size, such as Red Grouse, Partridges, Plovers, Ducks, Auks, Guillemots, and small Gulls, which it pursues in open flight, or pounces upon by perpendicular descent. It also sometimes attacks small quadrupeds, such as Rabbits and Hares. Poultry are very rarely molested by this Falcon, which is by no means so ready to visit the farm-yard or its vicinity as several other species of the family. In raising birds from the water, should they prove too heavy, it sometimes drops them, and sets out in quest of others; yet it is capable of carrying a weight nearly equal to its own, and in the nest of one on the Bass Rock was found a Black Grouse, which had been borne from a distance of several miles.

Although a very shy and vigilant bird, it sometimes ventures to come into more immediate proximity to Man than is prudent. Mr Audubon states, that in America he has seen it fly up, at the report of a gun, and carry off a Teal not thirty steps distant from the sportsman who had killed it; and other authors have made mention of similar displays of audacity.

The cry of the Peregrine is loud and shrill, but is seldom heard, excepting during the earlier part of the breeding season. It nestles on high cliffs, especially those along the coast. The eggs, three or four in number, are of a broadly elliptical form, dull light red, spotted and clouded with deep red, their average length being two inches and a twelfth; their greatest breadth an inch and seven-eighths. The young, which are at first covered with close white down, are able to fly by the middle of July.

In Britain it is generally distributed, but prefers mountainous or rocky situations. It has been seen in the Shetland and Orkney Islands, and is occasionally met with in the Hebrides. The rock of Dumbarton Castle formerly afforded a breeding place to it, as did the Isle of May. It still breeds on the Bass Rock, and there are few rocks of

great height or extent on the eastern coast of Scotland on which it is not seen. Many pairs breed in the upper part of Moffatdale in Dumfriesshire. Holyhead, the Great Orme's Head, the Rock of Llandudno in Caernarvonshire, various parts of Devonshire and Cornwall, the Isle of Wight, and many other places, are mentioned as favorite resorts. According to authors, it is found over the whole of North America, in the southern division of that continent, in Australia, at the Cape of Good Hope, and in most countries of Europe.

Although a very beautiful bird, the Peregrine, when perched on a rock, or flying across its face, does not present so imposing an object as one might imagine from viewing a stuffed skin in a museum, for the grey colour of its upper parts blends with the tints of the stone, and its sharp wings and rapid flight have the effect of rendering its apparent size much less than that of the Buzzard. Its mode of flying differs greatly from that of the Buzzards and Eagles, and affords a good example of one of the most remarkable varieties. Birds which have the body bulky, and the wings short and rounded, as the Grouse and Partridge, have a direct flight, not generally rapid; those which have the body full, the wings long and sharp, have also a direct steady flight, but generally rapid, as is the case with the Peregrine and the Rock Pigeon. Birds having the body light and the wings short, as the Gallinules, also fly steadily, but with comparatively little speed. When the wings are large and broad, as in the Heron, the flight is sedate, and capable of being long protracted. When they are very long and rather narrow, it is unsteady and undulating, as in some Owls and Gulls; and when the body is very slender, and the wings extremely long, there is produced that unsteady, bounding, gliding, and buoyant flight, so remarkable in the Terns or Sea-swallows.

Besides the Jer Falcon and Peregrine, there occur in Britain four smaller species of this genus, namely, the Hobby, the Merlin, the Kestrel, and the Red-legged Falcon. Of the latter only five or six individuals have hitherto been met with. The Hobby is also very rare; but the Kestrel is, next to the Sparrow Hawk, the most common of our birds of prey; and the Merlin, the smallest of them, is by no means rare in Scotland, where it breeds on the moors and rocky headlands.

**THE MERLIN.**—In a paper entitled "Contributions to the Natural History of Ireland," by W. Thomson, Esq., in the June number of the Magazine of Zoology and Botany, is the following notice respecting the Merlin:—"On March the 9th, 1832, when walking on the shore of Belfast Bay, as the tide was flowing, a Merlin, which flew past me, was observed for some time coursing above the uncovered banks, the edge of the waves being the limit to its flight. This at once led me to believe that he was in search of prey, which was confirmed by his giving chase to a large flock of Dunlins (*Tringa variabilis*), in pursuit of which he disappeared. From the oldest of the "shore-shooters" in Belfast Bay, I have heard, that frequently, but chiefly in the autumn, he has seen hawks, which, from his description, were considered to be the Merlin, follow and kill Dunlins on the banks at low water. This the above circumstance, witnessed by myself, tends to corroborate. I am not aware that the Merlins thus resorting to the sea-shore have been before noticed. The weather was mild in such instances." In a work entitled "Descriptions of the Rapacious Birds of Great Britain," by W. MacGillivray, published in 1836, Mr Thomson will find the following paragraph:—"In September 1832, I had an opportunity of observing a Merlin in pursuit of a Sanderling. It came up as I was shooting along the shore at Musselburgh, searched about for some time, flying in various directions at a height of an hundred yards or so, until at length spying the bird of which it had probably been in chase before I observed it, it rushed after it. The Sanderling doubled, and endeavoured to escape by skulking among the stones, but the Merlin kept constantly over it, without, however, attempting to seize it when on the ground. The chase continued for some time, when I observed that the Merlin had perched upon a stone; when, thinking that it had secured its prey, I endeavoured to get within shot of it. On my going up to it, however, it rose, and soon after the Sanderling made its appearance, apparently undecided as to the course it ought to take, on which the Merlin swept towards it in a deep curve and seized it. But now the Hawk became in its turn the pursued party, and on its alighting to feast near one of the bathing-machines, I ran up and shot it from behind the cover."

**LARVÆ IN THE HUMAN STOMACH AND INTESTINES.**—The following report by Messrs Dumeril and Blainville is the substance of an Essay presented by M. Robineau Desvoidy to the French Academy of Sciences. A woman, aged 57, was affected with dropsy of the abdomen after a mucous fever. On the 3d March 1836, there were administered to her six drops of the oil of *Croton Tiglium*, in three equal doses, each at the interval of an hour. Among the matters ejected by vomiting, four living caterpillars were first observed, and afterwards ten more of the same kind. Two of them were enveloped in paper by the medical attendant, who carried them with him, but afterwards lost them. The rest were sent to one of his friends, who transmitted them to M. Robineau. They were preserved in alcohol, and four of them were submitted to the examination of the reporters.

M. Robineau has accurately determined the similarity of these caterpillars to those of a species of moth designated by Linnæus as the *Pyralis pinguinalis*, but of which the generic name was changed by Fabricius to *Crambus*, and again by Latreille to *Aglossa*, on account of the shortness of the tongue. The history of the development of these insects being well known, M. Robineau supposes that the origin of the larvæ in question ought to be attributed to the deposition of eggs by the parent moth in some fat alimentary substances, and their subsequent introduction into the stomach, where they were hatched and developed.

Being of opinion that *Aglossa pinguinalis* does not live in society, he considers these worms as of a new species, to which he gives the name of *intestinalis*. The reporters, however, are satisfied that they are of the first species, and that the author has probably been deceived by supposing that these caterpillars must have been developed in the duodenum, an opinion which he rests only on the report of the physician, who stated that there was a fixed and excruciating pain in the region corresponding to that part of the intestine. M. Robineau does not believe that the presence of these insects had determined the nature of the disease, but thinks that the mucous fever was a circumstance which favored their development. Supposing that these larvæ were those of a distinct species, living only in society and in the intestinal

canal, the author asks by what signs their presence may be discovered and their evacuation procured; but expresses his opinion that in the case in question their expulsion was effected solely by chance.

The reporters then state that the memoir is interesting in a pathological point of view, as it affords an authentic instance of living caterpillars existing in the alimentary canal, and give an account of the notices respecting the species in question, which they have found in various works.

In the Stockholm Transactions for 1837 is a memoir by Rolander on the species of *Pyralis*, of which he has given a full account, accompanied with a plate illustrative of its successive changes. He describes the organization of the caterpillar, and in particular that of its stigmata, which permit it to live a long time and respire in the midst of fat substances, such as butter, suet, lard, and soap; and declares that he has very frequently found them in food, such as broth, cabbage, and peas.

Linnæus, in the second edition of the Fauna Suecica, published in 1761, after repeating Rolander's observation, adds: This caterpillar is very injurious in the human stomach, and may be expelled by an infusion of *Lichen camatilis*. In Gmelin's edition it is said to be common in houses and kitchens, less frequent in the human stomach, and of all animals that live in others the most pernicious.

De Geer, in his Memoirs, has described and figured the same insect. Lastly, the synonyms have been accurately given by M. Duponchel, who has himself exhibited a perfect figure of it, in his great work on the Lepidoptera of France.

In conclusion, the reporters think that the caterpillars of *Aglossa pinguinalis*, may be introduced from without, along with fat or oily food into the cavity of the human stomach; that they have the faculty of remaining alive there for a certain time; but that this is merely a chance occurrence, and that there is no reason for believing these larvæ to be parasitic.

**THE TREE PIPIT.**—"We have lately discovered," says the Editor of the Naturalist, "that the Tree Pipit (*Anthus arboreus*) is in the constant habit of wagging its tail slowly up and down when perched. This circumstance, which appears to have escaped the notice of all previous writers, and is not recorded in our own *Song Birds*, is not only interesting in itself, but valuable in a systematic point of view. It proves the close relationship of the more arboreal Pipits to the Wagtails, which they also resemble in having short crooked hind-claws. We believe the Meadow Pipit does not wag its tail, or if it does, we have not noticed it." All our Pipits wag their tails, but not slowly up and down, and none more conspicuously so than the Meadow and Dusky Pipits, which are not arboreal.

The Meadow Pipit is a very common bird in most parts of Scotland and England, being met with on moors, in pastures, meadow-land, and cultivated fields. In the haunts of the Grey Ptarmigan, on the stony summits of the central Grampians, in the grassy valleys of the Highland streams, in the fertile plains of the south, and on the downs that border the sea, it is equally at home; but it is more abundant in the green pastures that flank the upland glens, and on the sedgy moors of the interior. There it is seen at all seasons, in small companies, flying about in its peculiar wavering manner, and chirping its weak shrill notes. In winter, however, most of the individuals betake themselves to the lower grounds, many to the seashore, where they mingle with the Dusky Pipits. During snow, they search the margins of streams and lakes, frequent unfrozen marshes, and even appear in the stack-yards. Their food consists of insects, pupæ, larvæ, and occasionally small seeds, along with which they pick up particles of gravel, and frequently in the lower districts small bits of coal and other dark-coloured substances. When searching for it, they walk by slow alternate steps, keeping the body close to the ground, in the manner of the Sky Lark, and when alarmed either crouch or spring up, uttering a repetition of their ordinary cheeping note, and fly off to a distance. Like the White and Grey Wagtails, with which they occasionally associate, they vibrate their body, although in general in a much less remarkable degree, but conspicuously when perched on an eminence, or when uttering their notes of alarm. You may sometimes see them perch on a bush or tree, frequently on a wall, a stone, or a rock; but they are essentially ground birds, and while they are employed all day in traversing the meadows and pastures, they repose at night among the dry grass of the moors and the hills, or under the shelter of tufts of heath, furze, or other shrubs. Their ordinary flight is wavering and desultory, but when travelling they fly with speed, in an undulating line. They are not generally very shy, so that they are easily shot, but at the same time they are evidently watchful and suspicious, and fly off when one approaches nearer than thirty yards.

**NOTICE OF A KIND OF CORAL BELONGING TO THE GENUS CARYOPHYLLEA FOUND OFF PLYMOUTH.**—Several months ago, I found on a dead valve of *Pecten opercularis* a specimen of coral differing from any that I had seen; but from its small size and imperfect state I could not then satisfy myself as to its place in any system. Two weeks since I found five other specimens attached to stones taken up by trawlers from deep water, and by these I was enabled to ascertain the genus. A further examination led me to suspect that it ought to be separated from *Caryophyllea cyathus* of Fleming's British Animals (*Madrepora cyathus* of Ellis's Zoophytes). My largest specimens are half an inch high, of a compressed figure, and measuring at the star four-tenths in the largest diameter, and three-tenths in the shortest. They are generally inversely conical, though the smallest are of nearly the same size at their bases as at the stars. One specimen has the star oval, and presents a curved figure from its base to the smaller end of the star. The two small specimens have the star nearly round. They are generally rough on their exterior, from the attachment of *Serpula*, *Flustra*, and in two instances of *Lepas conoides*. All of them present longitudinal striæ on the outside, derived undoubtedly from the three different kinds of lamellæ of the interior. The margin of the star is observed to project in every instance, and the lamellæ are devoid, for a short extent of their depth, of the external crust. The depth of the disk varies greatly, the centre of this part consisting of small convolutions, or twisted plaits, situate on, or rising from, the basis of the fabric. The smallest kind of lamellæ are sometimes deficient, but the second sized invariably occur between the primary ones. The only circumstance in the history of this species, calculated to afford a specific name of any value, seems to be its great deficiency of stem, and I therefore propose to name it accordingly.

*CARYOPHYLLEA SESSILIS*.—Primary lamellæ of the star thirteen; three lamellæ of less size occupying the intervals, and the middle one predominating slightly in height and breadth, and sending off from its base a thin, flexuous, and erect plate or process; all the lamellæ rough with small tubercles, and more or less plaited on their edges.—J. S. BELLAMY. *Yealmpton, 1st July, 1837.*

**NEW SILKWORM.**—It is stated that at Rio Janeiro there are several species of Bombyx, the Caterpillars of which inclose themselves in a cocoon, after having spun a thicker and stronger silk than that of the ordinary Silkworm. It has been tried, and found to form a very solid material. A species of mulberry, of which the fruit is small and inedible, grows near the city, and is to be cultivated for feeding the Caterpillars.

## BOTANY.

### THE ORANGE TREE, CITRUS AURANTIUM.

THIS tree, of which the fruit is so well known in all parts of Europe, belongs to the class *Polyadelphica*, and the order *Icosandria* of the Linnæan system, and to the natural family of *Aurantiaceæ*. It is a native of India, whence it has spread into various parts of the world, and is cultivated in the warmer countries of Europe. It attains a height of from five to fifteen feet, is copiously branched, and has a smooth greyish bark. The leaves are elliptical but rather pointed, smooth, entire, glossy, deep green, with winged or dilated petioles. The flowers are large, white, axillar, and terminal, on short, simple, or branched stalks, with a cup-shaped, five-toothed calyx; five oblong, concave petals; about twenty stamens, of which the filaments are united into three or more sets; a roundish germen, surmounted by a short cylindrical style, and a globular stigma. The fruit, being so well known, requires little description. It is a mass of cellular, pulpy matter, divided by partitions, and containing several seeds towards the centre, the whole inclosed by a thick rind, externally of an orange yellow, and having numerous glands or crypts containing an essential oil.

Oranges are brought to us chiefly from Spain and Portugal. In England, although orange trees have been long cultivated as ornamental greenhouse plants, they never produce fruit equal to that imported from the countries just mentioned. There are two principal varieties, the China or sweet orange, and the Seville, both of which are in common use. The latter, however, is the kind chiefly employed medicinally, its juice being an agreeable acid liquor, which is of considerable use in febrile and inflammatory disorders, as it quenches the thirst, promotes the secretions, and diminishes the action of the arterial system. The yellow rind, which is an agreeable aromatic bitter, has been employed with success as a stomachic, as well as in intermittent fevers. It abounds with a volatile aromatic oil, which, with the bitter contained in it, gives it a pungent and harsh taste. This part is extensively prepared in Scotland as a conserve under the name of marmalade. The flowers and leaves, which are also beset with minute glands secreting an essential oil, have been employed as a remedy against epilepsy and other convulsive disorders, but have fallen into disuse.

The lemon, the lime, and the citron, are species of the same family, and also natives of India. The production of the common orange, Dr Lindley remarks, is enormous. A single tree at St Michael's has been known to produce 20,000 oranges fit for packing, exclusively of the damaged fruit and the waste, which may be calculated at one third more. Mr Audubon found it apparently wild in Florida. "Whatever its original country may be supposed to be, the plant," he says, "is to all appearance indigenous in many parts of that country, not merely in the neighbourhood of plantations, but in the wildest districts. Nothing can be more gladdening to the traveller, when passing through the uninhabited woods of East Florida, than the wild orange groves which he sometimes meets with. As I approached them, the rich perfume of the blossoms, the golden hue of the fruits that hung on every twig, and lay scattered on the ground, and the deep green of the glossy leaves, never failed to produce the most pleasing effect on my mind. Not a branch has suffered from the pruning knife, and the graceful form of the trees retains the elegance it received from nature. Raising their tops into the open air, they allow the uppermost blossoms and fruits to receive the unbroken rays of the sun, which one might be tempted to think

are conveyed from flower to flower, and from fruit to fruit, so rich and balmy are all. The pulp of these fruits quenches your thirst at once, and the very air you breathe in such a place refreshes and reinvigorates you. I have passed through groves of these orange trees fully a mile in extent. Their occurrence is a sure indication of good land, which, in the south-eastern portions of that country, is rather scarce. The Seminole Indians and poorer squatters feed their horses on oranges, which these animals seem to eat with much relish. The immediate vicinity of a wild orange grove is of some importance to the planters, who have the fruit collected and squeezed in a bone mill. The juice is barrelled and sent to different markets, being in request as an ingredient in cooling drinks. The straight young shoots are cut and shipped in bundles, to be used as walking sticks."

**THE MELON IN BOKHARA.**—There are two distinct species of Melons, which the people class into hot and dry. The first ripens in June, and is the common musk or scented Melon of India, and not superior in flavor; the other ripens in July, and is the true Melon of Toorkistan. In appearance it is not unlike a water-melon, and comes to maturity after being seven months in the ground. It is much larger than the common sort, and generally of an oval shape, exceeding two and three feet in circumference. Some are much larger, and those which ripen in the Autumn have exceeded four feet. One has a notion that what is large cannot be delicate or high-flavored; but no fruit can be more luscious than the Melon of Bokhara. I always looked upon the Melon as an inferior fruit till I went to that country; nor do I believe their flavor will be credited by any one who has not tasted them. The Melons of India, Cambool, and even Persia, bear no comparison with them; nor even the celebrated fruit of Ispahan itself. The pulp is rather hard, about two inches thick, and is sweet to the very skin; which, with the inhabitants, is the great proof of superiority. A kind of molasses is extracted from these Melons, which might be easily converted into sugar. There are various kinds of Melons; the best is named *Kochelue*, and has a green and yellow-coloured skin; another is called *ak nubat*, which means white sugar-candy; it is yellow, and exceedingly rich. The winter Melon is of a dark green colour, called *Kara-Koobuk*, and said to surpass all the others. Bokhara appears to be the native country of the Melon, having a dry climate, sandy soil, and great facilities for irrigation. Melons may be purchased in Bokhara throughout the year, and are preserved by merely hanging them up apart from one another; for which those of the winter crop are best suited. The water-melons of Bokhara are good, and attain also an enormous size; twenty people may partake of one; and two of them, it is said, form sometimes a load for a donkey.—*Burnes' Travels into Bokhara.*

## GEOLOGY.

**FOSSIL REMAINS OF MONKEYS.**—M. de Blainville has reported to the Academy of Sciences, in his own name and that of Messrs Dumeril and Flourens, some observations upon the fossil bones discovered in the Commune of Sausan near Auch, by M. Lartet. After discussing all the facts relative to the discovery of the fossil bones of Monkeys, he goes on to say:—

"Thus, till quite lately, it was certain that no trace had been discovered left by any animal of the Monkey tribe, in even those beds which lay nearest the surface of the earth, nor even in the alluvial strata, when M. Lartet announced to the Academy, in a letter read at the scientific meeting of the 17th of last January, that he had just found in the numerous and curious assemblage of fossil bones, discovered by him in the environs of Auch, the lower jaw of an Ape, properly so called, one of the grinders of a Marmoset (*sapajou*), and the anterior extremity of the lower jaw of an animal of the family of *Makis*."

The singular interest of so unexpected a discovery, the co-existence in the same deposit, on the one hand, of the bones of the Rhinoceros, the Dinotherium, the Mastodon, the Stag, and the Antelope; and on the other, bones of *Quadrumanus* of Asia, America, and Madagascar, caused the correctness of his determination to be questioned. A second letter, containing a detailed description of the lower jaw of the Ape, accompanied by a figure, might have established beyond doubt the truth of a part of M. Lartet's announcement. Nevertheless, to prove not only that it was certainly an Ape which was under consideration, but moreover a Gibbon (a group of *Quadrumanus* which are scarcely known, except in the large islands of the Indian Archipelago), more than a representation was necessary. M. Lartet, in consequence, has sent the bone itself, as well as all those which he has thought referable to the *Quadrumanus*.

The jaw attributed to the Gibbon is an almost complete lower one, in which only the terminal parts of the rami are wanting, and it is provided with all its teeth. The total number of teeth is 16; that is to say, 4 incisive, 2 canine, 4 false grinders, and 6 true ones. It is the dentary formula of Man, and of all the Apes of the old continent.

The incisive teeth are equal in size, almost vertical, and ranged in a transverse line; the canine teeth are short, vertical, and would meet without going beyond each other; the first false grinder is not at all inclined backward from the pressure of the upper canine, and is, on the contrary, quite vertical, as in Man; the grinders have their crown armed with blunt tubercles disposed in oblique pairs. By all these characters it is easy to recognise the jaw in question as belonging to one of the *Quadrumanus*, to an Ape properly so called, and to one high in the series.

"Now," says M. de Blainville, "as the Gibbons are certainly the group of Apes which ought to follow immediately after that of the Orangs, if, indeed, they be distinct from each other, we see that M. Lartet is very near the truth, so much the more as the true grinders have tolerably distinct the fifth tubercle characteristic of these teeth among the Gibbons. Yet as this disposition is not certainly so well indicated in the fossil Ape as in the living Gibbons that we are acquainted with, and as besides this it offers a much more evident peculiarity in the proportion of the last grinder, which comes very near to that existing in the *Semnopitheci*, and even in the *Baboons*, it seems decisive that the fossil Ape should form a small separate section, unless we can refer it to the *Colubi*, which in South Africa seem to represent the *Semnopitheci* of India. The other fragments, which M. Lartet supposes, it is true,

to have belonged to *Quadrumana*, have appeared to us to be referable to other groups."

"Though we are at present unable by any possibility to admit the extraordinary fact of the assemblage in one locality of fossil remains belonging to animals so rigorously limited in their geological boundaries as the true Apes, the Marmosets, and the Makis; yet the discovery of fossil bones belonging indubitably, as M. Lartet has clearly seen and pointed out, to an Ape more nearly related to the Gibbons, which are limited to the farthest parts of Asia, than to any other living species, does not the less remain to be considered as one of the most fortunate and unlooked for discoveries which has been made in Palæontology of late years; and we propose, in consequence, that the Academy should continue to M. Lartet the encouragement which it has begun to afford him, in order to facilitate his researches."—*L'Hermès, as quoted in Loudon's Magazine.*

**EFFECT OF FORESTS ON THE SIZE OF RIVER CURRENTS.**—The following observations, translated from *L'Echo du Monde Savant*, we extract from Loudon's *Gardener's Magazine*. M. Bousingault, in a memoir recently presented to the Academy of Sciences at Paris, has endeavoured to show the effects which the clearing away of forests has upon the force and abundance of the river streams in a country. He thinks that the current of water diminishes in proportion as the clearings extend; and was led to take this view from observations made in America, especially in the lake of Valencia in Venezuela, which has no outlet. This lake, in fact, diminished in depth as fast as the forests were grubbed up; but as soon as, on account of political troubles, the grubbing up ceased, the waters began to assume their primitive level. Similar results have been furnished by the lake of Ubate, in New Grenada, and even by those of Switzerland.

M. Bousingault also thinks that clearing away the forests has a direct tendency to diminish the quantity of rain. In the provinces of San Buenaventura, of Choco, and of Esmeralda, which are situate to the south of Panama, and where rains are almost continual, the soil is covered with thick forests, whilst towards Paita, beyond Tumbez, the forests have disappeared, and rains may be said to be unknown. This want of rain is in like manner observed in all the country near the desert of Sechara, and even to Lima; yet these two countries enjoy the same temperature, they present nearly the same surface, and have a like position relatively to the mountains.

M. Arago remarks that a contrary result has been observed at Viviers, in the department of Ardèche, where the quantity of rain fallen has augmented since the clearing of forests from the country.

On the other hand, M. Devèze of Chabriol has come to the conclusion, from the examination of several historical documents, that in the department of Cantal, in the environs of Saint Fleur, there has been an abatement of temperature since the disappearance of the forests. For example, from the records of the 13th and 14th centuries, it is proved that at this period the vine was cultivated on the slope of the hill of Saint Fleur, and this culture will not succeed at present. The chestnut has also disappeared from many of the cantons where it formerly flourished; and many villages situated near the summits of mountains have been abandoned. It is also remarked that, in this country, many streams have been dried up in consequence of the clearing of the forests.

### DOLOMITES.

**ON THE PHENOMENA OF DOLOMISATION, AND THE TRANSFORMATION OF ROCKS IN GENERAL,** BY M. THEODORE VIRLET.—The general question of the Transformation of Rocks is one of the newest and most important inquiries of Geology, the solution of which ought to furnish us with the means of making rapid progress, in the study of the composition of rocks, and lead to the elucidation of a multitude of isolated facts, hitherto considered as inexplicable.

While describing to the Geological Society of France, some years ago, the modifications which presented themselves in a bed of hematitic iron, which I had an opportunity of inspecting, near Sargans, in the Canton of St Gall, Switzerland, I was led by the recollection of numerous analogical facts falling under my notice, and mentioned in my account of the Geology of Greece, to regard the phenomena of the transformation of rocks under two different points of view, and to separate the modified rocks into two very distinct classes.

1. Such as have been modified, whether by the prolonged action of heat, or by that of electro-chemical agents, or by both of these causes united, which have altered combinations or primitive arrangement of the molecules in relation to each other.

2. Rocks which have been modified by chemical actions and reactions, with the assistance of foreign agents (such as the gases), which acted directly upon them, and changed their primitive nature. It is in this class the Dolomite, or Magnesian Limestone, should be arranged.

The first manner of regarding the modification of rocks, which was originally suggested by me, serves to explain how certain beds, placed in the midst of other beds, may be more modified than the latter, or may even undergo a complete modification, without the others, whether they were in contact, or even formed the lower part of the same deposit, experiencing any sensible change in their original state, and that without any of the beds being confounded with each other. The opinion which I advance on this subject results as much from my own observations as from the manner in which I regard the first sandy deposits, as being formed at a period when the waters began to condense on the surface of the earth, and although many may consider it as somewhat heretical, I have no doubt that it will soon be admitted by all accurate observers; namely, that all stratified rocks, without excepting gneiss, the mica slates, or clay-slates, &c. have been originally rocks of sediment, formed by mechanical aggregation, and that they have acquired the crystalline characters which now distinguish them by a series of modifications, which they have undergone posteriorly to their being deposited.

It is conceived, on the contrary, according to the second kind of modification of rocks, that in the greater number of cases, all the beds are confounded in such a manner as to present a single mass without distinct stratification; such, for example, as Dolomite, certain deposits of sandstone and clay transformed into jaspers, or trachytes, or porphyries, and other rocks which I have had occasion to enumerate, for the chemical agents, by penetrating across a certain number of beds, or even the entire mass, have

separated a part of the elements of the original rocks and substituted others, or else have formed new combinations, and finally united the whole mass of the deposit. It is to these considerations that I wish chiefly to direct attention, as they have reference to the phenomena of Dolomisation.

I do not dispute, that there are Dolomites which should be called *primitive*, whatever may be their geological age; that is to say, which were the result of simultaneous deposits of carbonate of lime and of magnesia, for magnesia was at least as abundant in nature as lime, particularly at the time when the old deposits were formed. These *primitive* Dolomites, however, always present a distinctive character in being regularly stratified, like the other rocks to which they may be found subordinate; while the Dolomites of which I now speak, and which I shall designate *Dolomites of Transmutation* (such as are described by M. de Buch as occurring among the Alps, and many others which I could mention), are without stratification, presenting irregular masses, combined with other characters, which individuals accustomed to observe modified rocks can seldom mistake. No one who has visited the Dolomites of the Alps can entertain any doubt of the reality of the phenomenon of Dolomisation, however difficult the explanation of it may at first appear, since chemistry teaches us that carbonate of magnesia is not volatile, or that it is decomposed at a red heat, an objection that has not been urged by M. Thenard. It was in fact these considerations that caused me to be among the first to publish my doubts on the subject, at a time when no one undertook to ascertain, by chemical analysis, that the parts of the deposit which had not been modified were not equally magnesian, that is, did not form beds of *primitive Dolomite*, a circumstance which would have reduced the phenomenon of the change of Limestones into Dolomite to a simple phenomenon of modified crystallization, analogous to that, for example, which has determined the change of the compact Jura Limestone of Carrara, and that of the compact chalks of some parts of the Pyrenees, into granular Limestones or Statuary Marble. One of my friends, M. Des Genevez, who possessed a very extensive knowledge of chemistry, and whose early scientific works afford so much reason to lament his premature death, has unhappily been lost to the sciences before publishing the results of his chemical researches on Dolomisation. These, he has many times assured me, had demonstrated to him that there existed an insensible passage from beds of unaltered carbonate of lime to dolomite or double carbonate of lime and magnesia. Thus, the transformation of certain calcareous rocks into dolomite, posteriorly to their formation, appears to me to be a well established phenomenon, and requires, in my opinion, only to be properly explained, in order to be admitted by all.

Who does not know how many facts, perhaps among the most difficult to comprehend previously, have already been explained by the excellent researches of M. Becquerel, in electrical chemistry, and the important labours of M. Fournet, regarding the formation of veins? Numerous other facts, although not yet fully explained, have been brought forward and admitted without dispute. For example, I have proved that the Emery of Naxos comes from veins, and consequently had been formed, like the greater number of specular iron ores, by means of volatilization and sublimation; yet the corundum and oxide of iron, the mixture of which constitutes Emery, are not more volatile than the carbonate of magnesia, which forms the subject of dispute.

Since our chemical knowledge, then, does not always enable us to explain the phenomena whose existence we can prove, does it follow that we ought to call them in question? Has Nature no mode of acting which surpasses our knowledge? And could she not proceed, for instance, by means of double chemical decomposition? On this supposition the phenomena will admit of easy explanation. It is well known that all the muriates are volatile, or at least susceptible of sublimation. Magnesia might then easily reach the state of a muriate, and occasion the formation of a soluble hydrochlorate of lime, which would be carried off by the infiltration of water; while the magnesia, on the contrary, would be combined with that portion of the carbonic acid set at liberty, and would thus serve to form the double carbonate of magnesia and of lime, which constitutes dolomite, properly so called. In this there is certainly nothing inadmissible or contrary to reason, inasmuch as the hydrochloric acid gas is one of the gases most frequently disengaged from volcanoes; and the muriates ought to have been disengaged more abundantly in former times, if we admit, with geologists of the modern school, that the immense deposits of rock-salt which exist in saliferous formations, are deposited by volatilization in the midst of the strata which they penetrate.

I am therefore of opinion, that the modifications of rocks of the second class may henceforth be explained by means of double decomposition—a process which has enabled one of my friends, M. Aimé, to produce in the laboratory crystallized specular iron ore, analogous to that of the island of Elba, as well as pure iron equally well crystallized—a substance hitherto unknown to mineralogists; whence I conclude that the time is not perhaps far distant when we shall be able to produce with ease all the species of precious stones, without even excepting the diamond.

**FOSSIL FOOTSTEPS IN SANDSTONE AND GREYWACKE.**—Professor Hitchcock has discovered in the valley of the Connecticut River, the imprints of what he considers fourteen new species. Some bear so near a resemblance to the feet of living Saurians, that they have been denominated *Sauriodichnites*. The Professor says, "I have no certain evidence as yet that any of these impressions were made by four-footed animals, although, in respect to two or three species, I have strong suspicions that such was the fact. I have sometimes thought they might have been made by Pterodactyles, yet they have in general fewer toes than those described by Cuvier and Buckland. Within a few weeks past, I have found on the flag-stones, in the city of New York, some marks, which I suspect were made by the feet of a didactylous quadruped, which, like the Marsupialia, moved by leaps. The rock is slaty greywacke, from the banks of the Hudson, between Albany and the Highlands."—*Silliman's Journal.*

ZOOLOGY.

DESCRIPTION OF THE PLATE.—BATS OF THE GENERA PLECOTUS AND NYCTICEIUS.

THE Bats constitute the first family of the order Carnivora, and are peculiarly distinguished by the elongation of their anterior extremities, which are expanded, and, by the intervention of a delicate membrane between the fingers, converted into wings. This membrane also includes the hind legs, of which, however, the toes are not similarly developed, and extends to the tail. In consequence of this organization, they are technically named Chiroptera. These animals live chiefly on insects, are of nocturnal or crepuscular habits, fly with a fluttering kind of motion, betake themselves by day to caves, crevices, and retreats of a similar nature, and in cold climates become torpid during a great part of the winter. Some of the larger tropical species are frugivorous. They have been arranged under a great number of genera, of which two are represented in the plate.

The Long-eared Bats, forming the genus *Plecotus*, are characterized chiefly by the great size of their ears, which are united by a membranous flap extending across the head.

Fig. 1, 2, 3. THE COMMON LONG-EARED BAT (*P. auritus*) is of frequent occurrence in this country, as well as in various parts of the continent. It is easily distinguished by the great size of its ears, which are nearly as long as the body.

Fig. 4. THE BARBASTELLE (*P. Barbastellus*) is very similar, but has the ears much smaller.

Fig. 5. THE TIMOR LONG-EARED BAT (*P. Timoriensis*) is about the same size and colour, with the ears intermediate between those of the two former species. The peculiar characters of these animals requiring minute description, will be subsequently given at length.

A group of Bats, belonging chiefly to North America, and having only two incisors in the upper jaw, with short ears, has been separated under the name of *Nycticeius*. To this genus belong the following species.

Fig. 6. THE NEW YORK DWARF-EARED BAT (*N. Novaboracensis*).

Fig. 7. THE BOURBON BAT (*N. Bourbonicus*.) From the Island of Bourbon.

Fig. 8. THE CAYENNE or ROUGH-TAILED BAT (*N. lasiurus*). From Cayenne.

DESCRIPTION OF THE PLATE.—THE DOGS, LYCAONS, AND FENNECS.

SEVERAL species of the genus *Canis* have already been figured and described, so that it is unnecessary here to present any general character.

Fig. 1. THE GREY WOLF (*Canis Occidentalis*) is peculiar to the arctic regions of North America, but differs little from the European Wolf.

Fig. 2. THE ARCTIC FOX (*C. Lagopus*), which, as its name implies, is a native of the circumpolar region of Europe and America, is of small size, with a very soft and close fur, which in winter becomes white, its summer tint being greyish-brown.

Fig. 3. THE CORSAC (*C. Corsac*) is very similar to the Common Fox in form, but of a duller tint.

Fig. 4. THE JACKAL (*C. aureus*) is distinguished by its short bushy tail. It varies in colour, but is generally of a greyish-brown tint, the limbs reddish externally. Animals apparently of this species are distributed over a great portion of Asia and Africa; they hunt in packs; and from the ease with which they are domesticated, and their form, are supposed by some to be the original of the domestic dog.

Fig. 5. THE CAPE JACKAL (*C. Mesomelas*) is similar to the Jackal, but has the tail long, and as the pupil is elliptical, it is referred to the section of Foxes.

Fig. 6. BURCHEL'S LYCAON (*L. Tricolor*) occurs in Southern Africa, and is in a manner intermediate between the Dogs and Hyenas, having more of the general appearance of the latter. It varies in colour, being yellowish-red, or ochraceous, and marked with white spots circled with dusky.

Fig. 7. BRUCE'S FENNEC (*Megalotis Brucei*). A small group of little animals similar in most respects to the Dogs and Foxes, but especially distinguished by their very large ears, constitute the genus *Megalotis*. That first described by Bruce is of a light grey colour tinged with brown, and inhabits Nubia, burrowing in the sand.

Fig. 8. SMITH'S FENNEC (*M. Smithii*) is very similar, with the tail more bushy.

Fig. 9. LALAND'S FENNEC (*M. Lalandii*) has the ears much shorter. It is somewhat smaller than the Common Fox, and occurs in Southern Africa.

DESCRIPTION OF THE PLATE.—THE HUMMING BIRDS.

Fig. 1. THE TOPAZ-THROATED HUMMING BIRD (*Trochilus Pella*). Adult male. This, although the most common species, is one of the most splendidly coloured, being of a brilliant ruby tint, varying to dusky red, the head velvet black, the throat emerald green, changing to gold yellow. The male is distinguished, moreover, by two very long dusky feathers in the tail. This species is plentiful in Guiana and the neighbourhood of Cayenne.

Fig. 2. Represents a variety, in which the body is mottled with white, and which is remarkable in manifesting a tendency to albinism, in a family of birds almost exempted from that change.

Fig. 3. F. male. The female wants the long tail-feathers, and is of a deep green colour, with the throat yellowish-red.

Fig. 4. THE VIOLET-EARED HUMMING BIRD (*T. auritus*) is so named on account of two tufts of feathers on the sides of the head, of which one is of a violet purple colour, while the other is emerald green. The upper parts are of a gilded green tint, the lower pure white. The middle tail feathers are bluish-black, the rest white. It is one of the most common species of Guiana and Brazil.

Fig. 5. The female resembles the male, but differs in wanting the green and purple tufts on the auricular region, and in having the white of the breast and abdomen mixed with numerous brown or dusky spots.

Fig. 6. THE SAPPHIRINE HUMMING BIRD (*T. sapphirinus*). Female. Green above and on the sides, violet purple on the fore part of the neck. Inhabits Brazil.

DESCRIPTION OF THE PLATE.—THE MACACOS AND MAGOTS.

THE MACACOS (*Macacus*), as characterized by Cuvier, have molar teeth furnished with a fifth tubercle, like the *Semnopithecii*, and callosities and cheek-pouches, like the *Guenons*; but their limbs are thicker and shorter than those of the former, and their muzzle more prominent, and their superciliary ridge more bulging than those of the latter. Although rather docile in early life, they ultimately become intractable; their tail, which varies in length in the different species, is not prehensile. Most of them are natives of India.

Fig. 1. THE OUANDEROU (*M. Silenus*). Male. This species, which is distinguished by having the head encircled with a kind of beard of a whitish colour, the forehead black, and the body and limbs of a dusky tint, inhabits the forests of Ceylon, feeding on fruits, leaves, and buds, and refusing to associate with other species.

Fig. 2. THE CHINESE-CAPPED MACACO (*M. Sinicus*) is so named on account of the manner in which the hairs on the upper part of the head spread out in all directions. It is yellowish-red on the upper parts, white beneath, and is found in Ceylon and Bengal.

Fig. 3. THE HARE-LIPPED MACACO (*M. Cynomolgus*), distinguishable by an erect tuft of hair on the top of the head, has the upper parts of a greyish hue, the lower whitish, but varies in colour. It inhabits Africa, and is said to commit great havoc on the cultivated fields, which it attacks in large flocks.

Fig. 4. THE RHESUS (*M. Rhesus*) has a very short tail, and is generally of a reddish tint, the fore-parts grey. It is said by Cuvier to inhabit Ceylon.

Fig. 5. THE PIC-TAILED MACACO (*M. nemestrinus*) is of a reddish colour, with the lower parts whitish, a dark line from the head along the back, and a short slender tail somewhat curved like that of a pig.

THE MAGOTS (*Inuus*) are very similar to the Macacos, differing chiefly in having the tail reduced to a mere knob.

Fig. 6. THE BARBARY MAGOT (*I. Magotus*) is a native of Barbary, and remarkable for being the only species of quadrumanous animal that occurs in any part of Europe, it having been naturalized on the Rock of Gibraltar. It bears our northern climates better than any other species. The colour is generally light-greyish-brown.

DESCRIPTION OF THE PLATE.—THE HOOPOES AND PROMEROPS.

THE genus *Upupa* is characterized by a very long, slender, slightly arched bill, triangular at its base, convex above, compressed, without notch, and somewhat blunt; open, elliptical nostrils; an even tail, composed of ten feathers; and wings of moderate length, with the fourth and fifth quills longest. The species are remarkable for the longitudinal crest of elongated feathers with which the head is ornamented. They live on insects, are migratory, nestle in hollow trees and fissures of rocks, and moult only once in the year.

Fig. 1. THE COMMON HOOPOE (*Upupa Epops*). This species, which inhabits all parts of Africa, and migrates into most of the countries of Europe, occasionally appearing in Britain, is of a reddish colour, with a broad band of black on the back. The wings and tail are also of that colour, the former with five white bands, the latter with one. The crest, which is erectile, is red, the feathers tipped with black, and some of them having a white band. It lives in woods and thickets in the vicinity of low and moist ground; feeds on beetles and other insects, larvæ, ants, and young frogs; and nestles in the holes of trees.

Fig. 2. THE LESSER HOOPOE (*U. minor*) resembles the Common, but is considerably smaller, and wants the white band on the crest. It occurs in India and Africa.

Fig. 3 THE MADAGASCAR OR CAPE HOOPOE (*U. Capensis*) differs so much in the form of its bill, that M. Temminck has referred it to the genus *Pastor*, and M. Lesson thinks it might be with propriety placed in the genus *Fregilus*. Its crest is composed of very slender feathers, some of which are curved forwards over the nostrils.

Fig. 4. THE STRIPED PROMEROPS (*Epimachus fuscus*). The genus *Epimachus* is composed of species which agree in having a long slender bill, more curved and compressed than that of the Hoopoes, from which they differ also in wanting the crest of elongated feathers on the head, while, on the other hand, some of them have the feathers of the sides greatly developed. The species here represented is one of the smallest, and inhabits Africa.

#### BRITISH BIRDS, NO. VI.—THE BLACK GROUSE.

THE genus *Tetrao* of authors, comprehending birds of the Gallinaceous order, characterized by a full habit of body, short, concave, rounded wings, legs of moderate size, and having the tarsus completely or partially covered with feathers, a small head, and bare superciliary crests, has by some been divided into two genera, one including the Grouse properly so called, which have the toes pectinated with elongated lateral scales, the other including the Ptarmigans, of which the toes are destitute of these lateral scales and covered with feathers. There are three species of this genus resident in Britain, of which one belongs to the first or Grouse section, the rest to the second, or that including the Ptarmigans. They are popularly named the Black Grouse, the Red Grouse, and the Ptarmigan.

The Black Grouse, *Tetrao Tetrix*, is nearly of the size of the domestic fowl. The male differs greatly from the female in colour, and in the form of its tail, which is lyrate, or has the outer feathers longer and curved outwards. The general colour of the plumage is black, that of the neck and back glossed with deep blue; the lower wing-coverts, lower tail-coverts, and bases of the secondary quills, white. The female has the tail slightly forked, its lateral feathers straight; the general colour is yellowish-red, spotted and undulated with brownish-black.

In its internal organization this species exhibits the peculiar characters distinctive of the gallinaceous birds in a remarkable degree of development. The œsophagus is dilated into a very large membranous crop, which covers the fore part of the neck; it then contracts, and enlarges into a proventriculus of moderate size. The stomach is a very muscular gizzard, lined with a thick and dense rugous membrane. The intestine is of considerable length, and has two extremely elongated cœcal appendages, furnished internally with longitudinal ridges, and in which the residuum of the food receives a second elaboration.

It feeds on fresh twigs of *Erica cinerea*, *Calluna vulgaris*, *Vaccinium Myrtillus*, willows, and other shrubs, as well as on berries and leaves of various plants, gradually filling its crop, which is capable of containing a globular mass from three and a half to four inches in diameter. The food varies according to the season, although heath twigs always form the principal part. In spring the tops of eriophora, carices, blades of grass, willow-catkins, and buds of trees; in summer, leaves of various shrubs; and in winter, juicy twigs of all kinds, are found in the crop.

The Black Grouse, then, is a phytophagous bird, which, feeding on substances containing comparatively little nourishment, introduces a large quantity at a time, like a ruminating quadruped, and gradually triturates it in the gizzard, with the aid of particles of white quartz, which it picks up as required. In the gizzard the mass, acted upon by the fluid abundantly secreted by the proventricular glands, is reduced to a pulpy mass, which in the duodenum is further diluted by the pancreatic juice, and mixed with the bile. The nutritious parts are absorbed as it passes along, and the cœcal appendages subject it to a further elaboration.

In searching for food it frequents the lower grounds of the less cultivated districts, keeping for the most part in the vicinity of woods or thickets, to which it retreats for shelter or protection. Sometimes it makes an excursion into the stubble fields, or even attacks the standing corn. It walks and runs among the herbage with considerable agility, perches adroitly on trees, and may often, especially in spring, be seen on the turf tops of the low walls inclosing plantations. Its flight is heavy, direct, and of moderate velocity, but is capable of being protracted to a great distance. This species, however, does not generally wander far from its ordinary haunts, which are the lower slopes of hills covered with coppice, interspersed with heath, rank grass, and ferns, or valleys flanked by rocky and wooded ranges. In such situations, it is plentiful in many parts of the northern and middle divisions of Scotland, in several districts in the southern division, and in the north of England; but is rare in other portions of that country.

In autumn it falls an easy prey to the sportsman, but in winter and the early part of spring it is shy and difficult to be procured. As an article of food it ranks high, the flesh being whiter than that of the Red Grouse, and the males weighing from three to four pounds. Its natural enemies are Foxes, Polecats, Eagles, and Falcons. Vipers are said to destroy its eggs and young, as do Ravens, Hooded Crows, and Carrion Crows.

The males keep by themselves in autumn and winter, and towards the middle of spring join the females, fighting with each other when they meet. At this season, the red space over the eye assumes a deeper tint, and the bird manifests increased

activity and vigour; but when the excitement is over, the males appear fatigued and emaciated, meet together without manifesting animosity, and seem intent on recruiting their diminished energies.

The female forms a rather artificial nest of dry grass, in which she deposits from five to ten eggs, of a regular oval shape, generally two inches long, with a yellowish ground colour, irregularly spotted and dotted with brownish-red. As the nests are usually placed in low situations, they are frequently partially or entirely inundated in very wet seasons.

The young, which are at first covered with close, fine down, are able to run about the moment after they leave the egg.

Hybrids are sometimes, though very rarely, produced between this species and the Red Grouse, as well as the Pheasant.

Formerly another species of this genus, the Wood Grouse, or Capercailly, *Tetrao Urogallus*, occurred in the northern parts of Scotland, but has been extirpated. The last individual recorded to have been seen was killed in 1769, in Strathgass, to the north of Inverness. This species, which is about equal in size to a Turkey, is still abundant in Sweden and Norway, whence it is imported in winter, when it may frequently be obtained in the London markets.

#### BOTANY.

*Directions for the Preservation of Sea Plants.* By J. S. Drummond, M.D. Abridged from the Magazine of Zoology and Botany, No. VIII.—The first object to be attended to in preserving marine plants, is to have them washed perfectly clean before spreading. It is a good practice to cleanse them before leaving the shore either in the sea, or in a rocky pool. All foreign bodies, as fragments of decayed sea-weeds, sand, gravel, or portions of the softened surface of the rock on which the specimens may have grown, together with the smaller testacea, and corallines, must be carefully removed. On getting home, it is further necessary to prepare each specimen by examining it in fresh or sea water in a white dish or plate, so that every foreign substance may be detected and removed. The next thing to be attended to is the quality of the paper on which the specimens are to be spread. A great error is generally committed in using it thin and of inferior quality. Indeed, much of the beauty of many species depends on the goodness of the paper, just as a print or drawing appears better or worse, as it is executed on paper of a good or an inferior kind. Some species contract so much in drying as to pucker the edges of the paper, if it be not sufficiently thick. That which has been found best is a thick music paper, closely resembling that used for drawing, and of which the sheet divides into four leaves about the size of royal octavo.

Whatever pains may have been taken in cleaning the recent specimens, it is often found, when spreading them, that some foreign particles continue attached, and for the removal of these, a pair of dissecting forceps, and a camel-hair pencil of middle size, will be found very convenient. A silver probe, with a blunt and a sharp end, is the most convenient instrument for spreading out and separating branches from each other, but any thing with a rigid point, such as a large needle, or the handle of the camel-hair pencil, will answer. A large white dish serves for spreading the specimens in, and all that is further necessary is a quantity of drying papers, and some sheets of blotting paper, with three or four flat pieces of deal-board. Nothing answers better for drying than old newspapers, each divided into eight parts, but it is necessary to have a large supply of these.

The beautiful and common *Ploconium coccineum* is one of the most easily preserved species, and may be taken as an example of the mode of proceeding with most of the others. The steps to be pursued are as follows:—

1. The specimen is to be perfectly well cleaned.
2. A dinner dish to be filled about two thirds with clean fresh water.
3. The paper on which the specimen is to be spread to be immersed in the water in the dish.
4. The specimen to be then placed on the paper, and spread out by means of the probe and camel-hair pencil.
5. The paper with the specimen on it to be then slowly withdrawn from the dish, sliding it over its edge.
6. The paper with the specimen adhering to it to be held up by one corner for a minute or two, to drain off the water.
7. To be then laid on a paper or cloth upon a table, and the superfluous water still remaining to be removed by repeated pressure of blotting paper upon the specimen, beginning this operation at the edges, and gradually encroaching towards the centre, till the whole can be pressed upon without danger of any part adhering to the blotting paper, which probably would be the case were the latter applied at once to the whole specimen.
8. The specimen then to be laid on a couple of drying papers placed on a carpet or a table; two more papers to be laid over it, and then the piece of board, on which latter a few books are to be put, to give the necessary pressure.
9. These papers to be changed every half hour or oftener, till the specimen is sufficiently dry. A number of specimens with drying papers interposed, may be pressed at once under the same board.

**DESTRUCTION OF THE VINE BY INSECTS.**—The Académie des Sciences having lately appointed a commission to repair to Argenteuil, and examine into the disasters caused there by a species of insect, which destroys the vines, M. Dumeril and St Hilaire visited the place, and went over an extent of ground of a league in length, and half a league in breadth. All the vines which covered this place were entirely destitute of leaves and grapes, and nothing was to be seen but vine-props supporting blackened stalks almost in a state of atrophy, owing to several sorts of insects, among which the first place must be assigned to the *Pyralis*, of which M. Dumeril presented the Academy with specimens of the Eggs, Caterpillar, Chrysalis, and Butterfly. The presence of all these metamorphoses, and above all the deposit of eggs on the leaves of the vine, indicate that the *Pyralis* is continually reproduced, and that in consequence it would be difficult to destroy it by fire, as is generally done

with other insects. M. Duvernil gave notice of his intention of concerting with his colleagues, MM. St Hilaire and Dumas, on the means of preventing the return of this scourge.

THE MULBERRY TREE.—*MORUS NIGRA*.

This tree, which is a native of Italy, but is cultivated in many parts of Europe, belongs to the class *Monœcia* and the order *Tetrandria* of the Linnæan system, and to the natural family of *Artocarpææ*, the Bread-fruit tribe. It does not attain a considerable height, but sends off numerous crooked branches, and is covered with rough brown bark. The leaves are numerous, cordate, acute, serrate, veined, rough, bright green, and placed on short stalks. The male flowers are disposed in close roundish catkins, each floret with four oval, concave leaflets, and four stamens. The calyx of the female flower is divided into four obtuse persistent segments; the germen is roundish; and there are two rough styles, with simple stigmas. The fruit is a large succulent berry, composed of a number of roundish bodies, each containing an oval seed, and affixed to a common receptacle.

The fruit, having an agreeable subacid taste, is esteemed as an article of food, and is used medicinally for allaying thirst. The bark has an acrid bitter taste, and has been successfully used as an anthelmintic, particularly in cases of tapeworm. But the principal use to which this tree is applied is the very important one of rearing Silk-worms, which feed on its leaves. In Europe, however, the leaves of the white mulberry, *Morus alba*, and in China, those of *Morus tartarica*, are preferred. The fruit of the black mulberry is often made into a syrup or rob, in the same manner as currants; a kind of wine is also made from it, and its juice is sometimes employed to give a deeper colour to red wine. The wood is yellow, pretty hard, and well adapted for turning.

The white mulberry is a native of Asia, and is cultivated extensively in various parts of Europe, for the purpose of rearing Silk-worms. It answers in almost every variety of soil, but thrives best in light mould. It is raised from root-shoots, cuttings, or seed, or by grafts, and may be stripped of its leaves two or even three times every summer. Sheep are fond of the leaves, and fatten on them, and in Spain especially are thus fed during part of the winter. Birds also prefer the fruit of the white mulberry to most others, and it is said that Thrushes and Blackbirds fed on it are considered a great delicacy; but it is much inferior to that of the black mulberry, being nearly insipid, and therefore is not, like it, used as food by Man.

MISCELLANEOUS.

*Catalogue of Land and Fresh-water Shells found in the vicinity of Plymouth, with Remarks on their Habitats, &c.* By J. C. Bellamy, Esq., Yealinton. The arrangement and nomenclature of Turton's Manual are adopted.

BIVALVE SHELLS.

1. *CYCLAS PUSILLA*.—In stagnant pools, running water, and spots flooded by rivers. We have a shell here, found in the same situations, of a rust colour, but differing so little in shape as to be entitled to consideration only as a variety of *C. Pusilla*.
2. *UNIO MARGARITIFERUS*.—In rapid rivers. Dead and occasionally living specimens are found in the sand-pits dug in the banks. These specimens are always numerous according to the quantity of rain which falls in the autumn and winter; the violence of the stream, being thereby increased, drives the shells into these catch-pits. A person assured me that Crows watch on the banks of rivers for these shell-fish, and fly with them into the air, then drop them on some rock, in order to break the shell, and descend to devour the contents. Crows are reported to destroy, and feed on the Swan-mussel in the same manner.
3. *LIMACELLUS PARVUS*.—Found in *Limax maximus*.
4. *L. OBLIQUUS*.—In the common Field-slug. Possibly *L. unguiculus* and *L. variegatus* are to be found here, but they have not come under my notice.
5. *TESTACELLUS HALIOTIDEUS*.—I have one specimen of this shell, and it seems as yet to have been found only here and at Bideford.
6. *VITRINA PELLUCIDA*.—Among damp moss. Dead shells are very frequent under stones. I think I have found *V. elongata*, or at least elongated specimens of *V. pellucida*.
7. *HELIx ASPERSA*.—Common in hedges and fields.
8. *H. HORTENSIS*.—In hedges and gardens. Not common.
9. *H. NEMORALIS*.—Common in hedges and gardens. In winter I find this and the two foregoing species either lying loose in warm hedges, with their apertures

sealed up, or cemented firmly to stones or old trees. A few remain quiescent, without any epiphragm, and stir out for food when the weather is tolerably mild. These species also will, on receiving an injury to the mouth, secrete a thin lid of the same description, and continue quiescent in this state until the fracture has been repaired.

10. *H. RUFESCENS*.—Common in heaps of stones and among rubbish, and generally where there is much moisture and shade. Its colour varies.

11. *H. SERICEA*.—Common in damp and shaded situations, especially where dead leaves abound.

12. *H. VIRGATA*.—Very common in dry situations. In some places, particularly elevated fields, they are so numerous as to be a pest to the agriculturist. This shell and *Bulimus fasciatus* are liable from exposure to become denuded of the outer layer, and bleached.

13. *H. CAPERATA*.—Common in dry situations. In old limestone quarries, large and beautiful specimens are found crawling on the rock facing southwardly.

14. *H. SPINULOSA*.—In woods among leaves, and in heaps of stones. They seem to retire in winter into mould formed by decayed moss on rocks, or into other sheltered situations. Not common.

15. *H. FUSCA*.—In woods among moss. Rare.

16. *H. NITENS*.—Very common among wet moss and under stones. Large specimens are usually found dead. The finest I ever collected, and which were fully three-fourths of an inch in breadth, were lying on rock sloping down to the sea.

17. *H. ALIARIA*.—In the same situations as the last. I have as yet found it only in my own garden. Full-grown shells would certainly be with difficulty distinguished from *H. nitens*, were it not for their odour; but the fry have a remarkably glossy aspect, and a considerable depth at the aperture, while the young of *H. nitens* retain the characteristic bend and narrowness of mouth observable in older shells. Some of this species seem not to emit the scent until immersed in hot water.

18. *H. HISPIDA*.—Not common. In old walls and under stones. Some occur without hairs.

19. *H. CRYSTALLINA*.—Common in wet hedges among moss.

20. *H. RADIIATA*.—Common under stones, wood, &c., generally selecting damp places. I have found the white variety.

21. *H. RUPESTRIS*.—Common in dry walls and old buildings. I have noticed them on the walls of churches. In summer, when a shower falls, they will come out in numbers from their recesses, and appear greatly refreshed and enlivened.

22. *H. FULVA*.—This rare species is found with us among leaves, and under stones, especially where there is a little moisture. Specimens vary in shape.

23. *H. FULCHELLA*.—Rare. The smooth variety only has come under my notice. I have found it under stones. Mr T. Colley found a colony of the rough sort in a very dry wall at Trematon Castle in Cornwall. According to Dr Turton's experience, this last variety is found only in damp places.

24. *CLAUSILIA RIGOSA*.—Abundant in old walls.

25. *BULIMUS OBSCURUS*.—Rather rare. Chiefly found in old dry hedges. I lately ascertained that many of this kind retire in winter to the crevices of rocks, and in spring come forth besmeared with dirt derived from their habitations.

26. *B. LUBRICUS*.—Found pretty commonly under stones, and in wet hedges among moss.

27. *B. FASCIATUS*.—In fields bordering on the sea.

28. *BALÆA FRAGILIS*.—Not common. In moss attached to the trunks of trees, in old walls, and on rocks. I have occasionally found it in the cylindrical holes bored by insects in rotten stumps of trees.

29. *SUCCINEA OBLONGA*.—In pools and streams attached to stones and aquatic plants. In corroboration of Dr Turton's view of the difference of the species from *S. amphibia*, I may mention that it is found here without any admixture of the last named species.

30. *CARYCHIUM MINIMUM*.—Common among wet mosses, leaves, and stones. I have found great numbers of dead shells in summer among the moss, attached to rocks on hills. The heat of summer destroying the moss, the shells are in their turn sacrificed.

31. *PUPA UMBILICATA*.—Found with *Clausilia rugosa*, and equally common. It gets also amongst rubbish in wet situations.

32. *P. MARGINATA*.—Chiefly in spots near the sea, under stones. Not common.

33. *P. EDENTULA*.—Two specimens of this shell have occurred to me in a heap of stones. These belong to the "more elongated and cylindrical" variety.

34. *VERTIGO PYGMÆA*.—Found by Mr T. Colley under stones in a damp situation, at Broisand.

35. *V. SEXDENTATA*.—Found by Mr Colley with the last, and also by him in a similar situation, a very short distance from Plymouth.

UNIVALVE SHELLS.

36. *PLANORBIS VORTEX*.—Common in pools and streams.

37. *P. ALBUS*.—Common in pools, attached to plants and stones.

38. *P. IMBRICATUS*.—Rather local. In a standing pool near my residence I find them in plenty attached to plants.

39. *P. SPIROBIS*.—Found by Mr Colley in pools. Rare.

40. *LIMNÆUS PEREGER*.—Very common in pools, streams, and rivers.

41. *L. FOSSARIUS*.—Rather common in streams and pools.

42. *PHYSA FONTINALIS*.—Not common in ponds, streams, and rivers, attached to stones, sticks, and other objects.

43. *PALUDINA STAGNORUM*.—Very rare in pools and streams. I have never procured more than two specimens.

44. *ANCYLUS FLUVIATILIS*.—Common on stones and plants, in pools, streams, and rivers.

A dealer in shells living here sold me specimens of *Physa rivulis*, and some of *Clausilia bidens*, saying he had collected them in this neighbourhood. They have never been found by me or any other collector with whom I am acquainted, and I therefore feel great doubts on the subject. Mr Colley has a series of shells, seemingly *Helix lucida*, collected in this neighbourhood, but I am not as yet sure of their proper appellation.

I shall proceed shortly, with the assistance of Mr Colley, to make out a list of the salt-water shells of this neighbourhood.

**FALLING STARS IN THE MAURITIUS.**—M. Louis Robert, who has long resided in the Mauritius, and devoted his attention to meteorology and astronomy, has addressed to the Institute of France an extract from his Journal relative to shooting stars. The coincidence between the appearance of these luminous bodies in an island of the torrid zone, and those which have been observed at the same time over a great part of Europe, is not without interest. Towards three o'clock in the morning of the 13th November 1832, during calm and somewhat cloudy weather, there were seen from all parts of the heavens, where there were no clouds, and especially towards the zenith, at some degrees to the south, a great variety of shooting stars, which traversed the heavens in all directions. The number was so great that it was impossible to count them. Their courses were not in straight lines, as those of shooting stars generally are, but they described all sorts of curves in the sky. The phenomenon was at its height about four in the morning. A little before the rising of the sun, but few of these meteors were to be seen. The mercury of the barometer was at its usual height, and the thermometer of Reaumur was two degrees lower than for some days preceding.

**ARTIFICIAL FORMATION OF CRYSTALS.**—M. Gaudin has lately obtained microscopic crystals of some of the insoluble salts in great perfection, by means of a process which he believes to be applicable to those salts furnishing crystals of all sizes. The method consists in placing certain solutions in an artificial atmosphere; for example, placing under the same bell-glass a capsule containing carbonate of ammonia moistened, and another open glass vessel containing a weak solution of any soluble salt of lime, or baryta, strontia, lead, &c.; in a few hours we find on the sides of this vessel crystals of the carbonate of these bases. Sulphate of baryta has been obtained in crystals by placing under the same bell-glass a vessel containing strong hydrochloric acid, and in another open glass vessel, water, sulphate of lime, and carbonate of baryta. The solution of a pure salt of lime gives crystals under the rhomboidal form with its principal modification, whilst the solution of baryta gives simultaneously crystals of sulphate and carbonate of that base. The author has obtained sulphate of tin from an atmosphere of sulphur vapour. Its appearance resembles that of snow.

#### REMARKS ON VARIETIES.

No two individuals of any species of animal or vegetable are exactly similar. Examine two Elephants, two Chaffinches, two Oysters, two Oaks, two specimens of any one kind of Moss or Lichen; examine the individuals composing each pair at one time, and placed under apparently similar conditions of existence, and it will be found that differences exist between them. These differences, however, are of a very unimportant character; they affect the organization and economy of the being in the most trifling manner. Nature, for some reason, has thought fit that no two of her productions should correspond, not only through the aggregate of species, but also through the aggregate of individuals constituting a species.

Besides these minor differences between individuals generally, there are others of a higher degree occurring to a great proportion of species in all the tribes and orders of living beings. To these extended degrees of aberration from regular specific character and appearance, the term "varieties" has been arbitrarily attached by systematists; and in consequence of there being no line of demarcation, natural or artificial, between these and the minor differences first named, contraries of opinion and waverings of individual judgment commonly attend inquiries relative to specimens being deserving of the epithet "variety," just as disputes arise whether highly extended varieties may induce suspicions of their title to rank as species.

This term "variety" has also been in use in Mineralogy and Geology; but surely its application here must rest on different principles from those which gave it introduction into Zoology and Botany; for, as in the case of animals and plants, the laws of organization and vitality are undoubtedly concerned in the production of varieties, and as the boundaries of species are absolutely fixed by nature, one kind having no alliance with another, so, in the case of inorganic bodies, we witness precisely opposite facts, and a "variety" seems to be an addition to, or reduction from, the characters of the true species, or an assumption of a form of crystallization of the substance, not usual to the species. The number and degrees of these varieties are infinite, and the commixture of species seems to be in a great measure casual, and under no restrictions.

Some persons have imagined that in the original state of the globe no varieties existed; but, by arguing the importance of these in the economy of nature, I presume a refutation of this notion is effected. Yet I think it quite certain that varieties have increased numerically, the additional instances chiefly occurring among those tribes which, by their organization, allow of variation upon the interposition or presence of some circumstance not usually in operation on the species, but having the power of modifying its structure or aspect, either for a time or during the life of the individuals so affected. It is also highly probable that these new forms of difference may sometimes be permanent, and transmit their peculiarities of structure or appearance to their progeny, with or without the aid of those circumstances which originally induced these varieties.

These are the two forms of variety mentioned by authors, "accidental" and "permanent;" and besides their ordinary occurrence, they may, as I have just said, be produced afresh, or additional instances may be originated.

In prosecuting our inquiry into the present subject, there is one fact which especially excites attention, namely, the rarity of "varieties" in the upper classes of animals, and their great frequency in the lower departments, and still farther increase in numbers in the vegetable world. Indeed, with certain interruptions to the observance of this rule, it seems that varieties gradually augment in frequency as we descend in the scale of organization. Farther than this it may be remarked, that amongst the lowest of vegetable productions, no determinate configuration or general aspect of a species is observed, so that there is no standard whereby to judge of the extent of deviation, as can be done in higher classes, but with the exception of certain marks ascertained to be the specific characters, the deviations between specimens are

interminable, all is variety. We must also here notice, by the way, that this unrestrained disposition for variety in the lowest tribes of plants furnishes a proof amongst others that there is a gradual transit from the vegetable to the mineral world, for it happens, as before stated, that the varieties in the species of minerals, or the grades of difference between kinds, are infinite, so that we here find evidence respecting the chain of creation being continued by resemblances between the lowest forms of vegetation and mineral substances. Some of the zoophytes also which curiously simulate the lowest grades of vegetation in their mode of growth and other circumstances, are likewise perfectly unrestricted in the forms and aspects they assume.

In taking a view of the whole chain of being, from the most highly to the most simply organized, the interruptions to the rule of increase of varieties are frequent, and in some cases remarkable. Instances occur in most of the families of animals and plants, in which no tendency to variation can be traced; whilst, in direct contradiction to our rule, there are animals high in the scale of being suffering numerous variations in the species, and again among plants instances can be adduced, where little or no variety is detected. In the Mammalia varieties are seldom met with. Those generally observed are such as affect only the colour and size of the individual, and these varieties are seldom found to be permanent or capable of being transmitted to future races. There are instances, however, and some of them among British quadrupeds, of varieties in colour, size, and figure, being permanent. Such are the white variety of the Mole, and the three varieties of the Fox. Accidental varieties of colour occur also in the Common Rat, the Domestic Mouse, the Hare, and others. Domestication, however, occasions very considerable variations of structure in quadrupeds, and these capable of being perpetuated. Besides, accidental variations are of very frequent occurrence. But *domesticated* and *cultivated* varieties form a subject quite apart in argument from that under consideration.

Among birds varieties are rather more frequent than among Mammalia, and the slight differences between all individual specimens of each species is a circumstance much more observable here than in the preceding class. I apprehend that permanent varieties seldom occur, but that those usually observed are of the accidental kind, consisting simply in an alteration of the colouring matter of the feathers.—such are the White Starling, the White Rook, the Cream-coloured Blackbird, the Black Bullfinch, and so forth,—or in deviations from the ordinary number of tail-feathers, or in the addition of a tuft or crest. Domestication causes surprising differences in plumage and structure.

In the class of reptiles the slight variations observed between individuals are still more considerable than in birds. Varieties occur in respect of size and colour; and of these an instance is found in our common Lizard, of which three or even more varieties are enumerated. In fishes the differences between individual specimens are very general and considerable; and varieties in regard to colour and size, as well of the entire body as of parts, are frequently remarked. There is also one form of variety in this class deserving of separate notice. Some kinds of fish are not symmetrical in their parts, such, for instance, as the Flounder, which has its eyes placed on the right side of the head. Now, in such cases, varieties occur wherein the lateral arrangement of organs is reversed, the eyes and their contingent structures appearing on the left side. It seems also probable that this sinistral variety is sometimes, or perhaps always, permanent; but it cannot be a matter of much moment to determine whether a variety is constantly being reproduced locally from the original stock, or first parents or originators of that variety, or whether it is continually being produced as an accidental form of variation from parents of the ordinary configuration and appearance.

In examining the class of Molluscous animals, we find the differences between specimens of still greater degree. Varieties are likewise numerous, and are carried to a greater extent than in the classes we have yet viewed. Colour and size in particular are subjects of variation; so are relative proportion and arrangement of parts. These all form accidental or permanent varieties, and I believe that sometimes the same form of variation occurs both accidentally and permanently. In the case of Univalve shells, reversed specimens are sometimes noticed, such as the sinistral variety of *Helix Pomatia*. But, besides these, there are instances of varieties in shells, where the individual must suffer much more considerable alteration or deviation from the ordinary growth of the species. Such are the varieties in the genus *Chiton* having seven or even six valves, eight being the regular number. So also we frequently see varieties in spiral shells, where one or more whorls are superadded to the usual number. Lister records a variety of *Lymnaea stagnalis* having the tentacula or feelers branched; and I have seen a specimen of *Helix umbilicata*, collected by Mr T. Colley of Plymouth, in which the last whorl, instead of completing its gyration, protruded diagonally from the shell, forming a projection nearly a quarter of an inch long. By such circumstances it appears that great latitude of variation obtains among the animals of this class, and that these varieties are by no means confined to colour and size, instances of which abound in all collections of shells, but extend likewise to differences affecting more decidedly the structure and anatomical arrangement of the animal.

In the remaining tribes of animals the differences between specimens belonging to the same kind are very considerable, inasmuch that in the majority of species it is necessary to disregard external aspect and general appearance in distinguishing species, and to concentrate the attention on those parts likely to afford a clue to correct and final opinion. Moreover, we may observe that these differences are so great as to be equivalent to varieties in higher classes, and they seem to merge by insensible degrees into positive varieties amongst themselves. In the Asteriadae we notice an interesting form of variety, consisting of the reduction from the ordinary number of arms, or of additional developments of the same. This is seen in two or more of our native Asteriæ.—(To be continued.)

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE.—THE CIVETS AND GENETS.

THE CIVETS and GENETS form together a family of the Carnivora, characterised by their elongated form, conical and pointed head, short limbs, and long tapering tail. Their tongue is covered with pointed stiff papillæ, their claws are retracted when they walk, and in the vicinity of their anus is a deep bag into which is secreted an unctuous matter which is highly odorous. There is very little essential difference between the two genera, the Civets merely having the anal bag deeper, and the pupil round, whereas in the Genets the bag is reduced to a slight depression, and the pupil is a vertical slit.

Fig. 1. THE COMMON CIVET (*Fiverra Civetta*) is of a greyish or brownish-grey colour, irregularly banded and spotted with black; the tail is shorter than the body, and ringed with dusky; there are two black bands on each side of the neck; and along the middle of the neck and back is a kind of mane. This species, from which was obtained the civet of commerce, formerly much employed in perfumery, is a native of various parts of Africa.

Fig. 2. THE GREY-HEADED CIVET (*V. Piliocephala*), characterised by the dark brown colour of the body and limbs, the yellowish-white of the throat, and the bluish-grey tint of the head, is also a native of Africa.

Fig. 3. THE ZIBET (*V. Zibetta*), which inhabits India, is very similar to the Common Civet, being of a light-grey colour, spotted with black, the tail ringed, and the neck patched with the same; it is destitute of mane, and has a white stripe down the back.

Fig. 4. THE LUWAK (*V. Musango*), greyish-brown all over.

Fig. 5. THE JAVANESE CIVET (*V. Rasse*), brownish-yellow, longitudinally banded and spotted with black, inhabits Java.

Fig. 6. THE COMMON GENET (*Genetta vulgaris*) is grey, or brownish-grey, spotted with black, the tail banded, and as long as the body. This species is found in the southern parts of Europe, in Africa and Asia, and exhibits numerous varieties.

Fig. 7. VARIETY of the COMMON GENET from Malacca.

Fig. 8. THE FOSSANE GENET (*G. Fossa*), reddish-grey with reddish-brown spots, and four longitudinal lines of black on the back, inhabits Madagascar.

Fig. 9. THE BANDED GENET (*G. fuscata*), brownish-yellow, with longitudinal brown bands.

Fig. 10. SLENDER GENET (*G. gracilis*), clear reddish-yellow, with transverse brown bands and spots, the tail annulated with brown; inhabits Java.

#### DESCRIPTION OF THE PLATE.—THE EAGLES.

THE order of Rapacious Birds is divided into two sections, one containing the diurnal, the other the nocturnal species. The former are further subdivided into two families, the Vulturine and Falconine. Of the latter family the Eagles constitute a genus, characterised by their great size, their strong, straightish, compressed bill, of which the tip of the upper mandible is decurved and trigonal, its edges festooned. The wings are very large and rounded, and the feet extremely muscular, with strong toes, and long, curved, very acute claws.

Fig. 1. THE GOLDEN EAGLE (*Aquila Chrysaetos*) inhabits various parts of Europe, Asia, Africa, and America. The female, as in most species of this order, is much larger than the male. When full-grown, it is of a dark-brown colour, the tail uniform with the back, the hind head and neck yellowish-brown, the cere and toes bright yellow, the bill and claws bluish-black. This species has already been pretty fully described in our 20th Number.

Fig. 2. THE GOLDEN EAGLE, when young, has the greater part of the tail white, and in this state was formerly considered as a distinct species, and named the Ring-tailed Eagle.

Fig. 3. THE PLAINTIVE EAGLE (*A. Navia*) is much smaller than the Golden Eagle, and inhabits various parts of Europe, especially the southern and eastern, and is also common in Egypt. It is of a nearly uniform glossy reddish-brown colour; the tail dusky, with a terminal light red band; the bill and claws are bluish-black; the cere and toes yellow. This species feeds on hares, rabbits, other small quadrupeds, birds of various kinds, and in summer large insects.

Fig. 4. THE YOUNG of the PLAINTIVE EAGLE differs from the adult bird in having numerous large oval white spots on the wing-coverts.

#### BRITISH BIRDS.—NO. VII.—THE RED GROUSE AND PTARMIGAN.

THE PTARMIGANS are distinguished from the GROUSE by having the tarsi and toes feathered, and by the want of the lateral pectiniform scales appended to the toes of the latter. In most other respects, however, the genera *Tetrao* and *Lagopus* are so similar, that it may well be doubted whether they really ought to be considered as distinct. It has been stated, that only one species of Grouse, which was described in our last Number, occurs in Britain, while in that country there are two species of Ptarmigan, the Red Grouse of authors, or, more properly, the Brown Ptarmigan, and the Common or Grey Ptarmigan.

THE RED GROUSE (*Logopus Scoticus*) is peculiar to Great Britain and Ireland, not having hitherto been observed in any other part of the world. It is a strong full-bodied bird, the male about sixteen inches in length, its extended wings measuring twenty-seven on an average. The colour varies a little with the seasons. In winter the adult male is chestnut brown, inclining to red on the neck; on the body variegated with black; on the breast blackish, with many of the feathers tipped with white. The general colour of the female is yellowish-red, spotted and varied with black. In summer the male is chestnut brown, minutely varied and spotted with black; the head and neck also varied; the breast darker and more obscurely varied. The female is yellowish-red, spotted and varied with black; most of the feathers on the upper parts tipped with yellowish-white. The superciliary membranes or crests, which are larger in the male, are vermilion, the bill brownish-black, the iris hazel, the claws blackish-brown, greyish-yellow at the end.

Although this bird occurs in Ireland and England, it is more abundant in Scotland, where it is met with on the heaths, from the level of the sea to the height of about two thousand feet. The low sandy heaths of the eastern parts of the middle division appear to be less favorable to it than the more moist peaty tracts of the western and northern districts, where the shrubs on which it feeds attain a greater size. In the central regions of the Grampians it is equally abundant as on the moors of the Hebrides; and on the hilly ranges of the south, the Pentlands, the Lammermuir, and the mountains of Peebles, Dumfries, and Selkirk, it is still plentiful.

It is pleasant to hear the bold challenge of the cock at early dawn on the wild moor, remote from human habitation. You may fancy it to resemble the syllables *go, go, go, go back, go back*, although the Highlanders, naturally imagining the bird to speak Gaelic, interpret it as signifying *co, co, co, mo-chlaidh, mo-chlaidh*, that is, *who, who, (goes there,) my sword, my sword*.

The food of this species consists chiefly of the tops of heath, *Calluna vulgaris*, *Erica cinerea*, and the leaves and twigs of other shrubs and herbaceous plants, as has already been stated in No. xx, where a sketch of the digestive organs has been presented. On ordinary occasions, the species does not fly much, but keeps concealed among the heath, seldom choosing to rise unless its enemy comes very near. On the approach of danger, it lies close to the ground, when, being of a colour not contrasting strongly with that of the plants around, it is with difficulty perceived by rapacious birds, among which its principal enemies are the Golden Eagle, the Peregrine Falcon, the Common Buzzard, and the Henharrier. The quadrupeds which occasionally prey upon it are the Polecat, the Pine Martin, the Fox, and perhaps the Ermine. When traced by a dog, it either runs to some distance, or squats at once. On such occasions the male is generally the first to rise. He erects himself among the heath, stretches out his neck, utters a loud cackle, and flies off, followed by the female and young, affording by their straight-forward, heavy, though strong, flight, an easy mark to a good shot. Young birds often allow a person to come within a few yards or even feet before they fly off, and even the old males, unless previously harassed, rise within shooting distance.

In a district where there is choice of situation, the Red Grouse prefer the slopes of hills not exceeding two thousand feet high; but they are to be found on the lowest and most level peat-bogs, especially if there are large tufts of heath surrounded by banks. Those which in summer and autumn reside on the heights usually descend in winter; but even during that season, individuals may be found in their highest range, which is bounded less by actual elevation than by the disappearance or scantiness of heath.

This species generally flies low and heavily, moving its wings rapidly, with a whirring noise, and proceeding in a direct course without undulations. Occasionally, when at full speed, and especially when descending parallel to a declivity, it sails at intervals, that is, proceeds for a short time with expanded and apparently motionless wings. Its flight is strong, often protracted to a considerable distance, and capable

of being urged to a surprising degree of velocity, when the birds have been pursued by a hawk.

Although the haunts of the Red Grouse are the heathery moors, it has sometimes been found in stubble-fields, or among corn, bordering on uncultivated tracts; and when it finds an opportunity of feeding on oats, it does not scruple to avail itself of it. Unlike the Black Grouse, it is seldom or never met with in woods.

The male is not polygamous, nor does he at any time desert his mate. When incubation is over, and the young run about, they are tended by both parents, the female manifesting great anxiety for their safety, and feigning lameness to induce a person who has approached them to follow her. When surprised on the nest, she flies with a low undecided flight to a short distance, and runs off among the heath. The young are soon able to fly, and the flock keeps together until the end of autumn, unless scattered and thinned by sportsmen and vagabonds. Towards the beginning of winter, several flocks often unite and keep together, forming what are called packs. They are then generally more shy, and continue so until the beginning of spring, when they separate and pair, without manifesting any remarkable animosity; for although the cocks may occasionally fight, they have not those regular periodical battles described by authors as enacted by many species of the Grouse genus.

The nest is found in the midst of the heath, in a shallow cavity, and formed of bits of twigs, grass, and sometimes a few feathers. The eggs are from eight to twelve, or even more, generally an inch and seven-twelfths in length, an inch and three-twelfths across, of a regular oval form, yellowish-white, pale yellowish-grey, or brownish-yellow, thickly clouded, blotched, and dotted with blackish and amber brown.

The young leave the nest soon after they are freed from the shell. They are at first covered with a fine close down of a pale yellowish-grey tint, mottled beneath with pale brown, patched above with deep brown, the top of the head chestnut, margined with darker.

As an article of food, the Red Grouse is highly esteemed. The flesh is very dark coloured, and has a peculiar somewhat bitter taste, which by some is considered as extremely pleasant. The species is capable of living in a state of domestication, and then feeds on grain, bread, potatoes, and other substances, although it always prefers its natural food. A few instances have been known of its breeding in captivity; but, from its habits, it does not seem probable that it could be trained in subjection, like the domestic fowl.

THE GREY PTARMIGAN (*Lagopus cinereus*) is the only other species of this genus that occurs in Britain, where it is now confined to the summits of the higher mountains of the middle and northern divisions of Scotland. It resembles the Red Grouse in form and proportions, the male measuring about fifteen inches in length, and about twenty-five inches between the points of its extended wings. In winter the male is white, with a black band from the bill to the eye, the tail-feathers greyish-black, barred and tipped with white, the shafts of the primaries brown. The female in winter is also white, the feathers between the bill and the eye black at the base only, the tail-feathers brownish-black, based and tipped with white. In spring both sexes are white, mottled with dark grey, and yellow feathers, which are barred with black; the wings, lower parts, and tail, as in winter. In summer the head, neck, upper parts and sides, are spotted and barred with yellow and brownish-black; the wings, lower parts, and tail, as in winter. In autumn the plumage of the upper parts and sides is finely barred with greyish-white and greyish-black; the head, neck, and sides, retaining the yellow summer feathers longest; the wings, lower parts, and tail, as in winter. The young are spotted and barred with yellow and dark brown; the wings white, the shafts of the primaries dusky; the tail brownish-black, the middle feathers barred with yellow and dark grey.

This beautiful bird is met with in flocks on the bare and weather-beaten summits of the Grampians, and other high mountains of the North, where they reside from the beginning of spring to the close of autumn, seldom descending into the heathy tracts, unless in winter when the ground is covered with snow. Its food consists of various plants, chiefly of a shrubby nature; twigs and leaves of *Calluna vulgaris*, *Erica cinerea*, *Empetrum nigrum*, *Vaccinium myrtillus*, *V. vitis-idaea*, *Salix herbacea*, and others, being in fact similar to that of the Red Grouse. Its habits are also similar, but it generally allows a much nearer approach, and seems in no degree aware of danger from the proximity of man, remaining squatted on the ground, or on a stone until you almost trample upon it. When in packs, however, it is more shy, although even then it seldom flies off until one comes within shooting distance.

While feeding, the Ptarmigans run and walk among the lichen-erusted and crumbling fragments of rock, from which it is very difficult to distinguish them when they remain motionless, as they invariably do should a person be in sight. Indeed, unless you are directed to a particular spot by their strange low croaking cry, which is not very unlike that of a frog, you may pass through a flock without observing a single individual. When squatted, however, they utter no sound, their object being to conceal themselves; and if you discover the one from which the cry has proceeded, you generally find him on the top of a stone, ready to spring off the moment you show an indication of hostility. If you throw a stone at him, he rises, utters his call, and is immediately joined by all the individuals around, which, to your surprise, you see spring up one by one from the bare ground. They generally fly off in a loose body, with a direct and moderately rapid flight, resembling, but lighter than, that of the Red Grouse, and settle on a distant part of the mountain, or betake themselves to one of the neighbouring summits, perhaps more than a mile distant.

Early in spring they separate and pair. The nest is a slight hollow, scantily strewn with a few twigs and stalks, or blades of grass. The eggs are of a regular oval form, about an inch and seven-twelfths in length, an inch and from one to two-twelfths across, of a white, yellowish-white, or reddish colour, blotched and spotted with dark brown, the markings larger than those of the Red Grouse. The young run about immediately after leaving the shell, and from the commencement are so nimble and expert at concealing themselves, that a person who has accidentally fallen in with a flock very seldom succeeds in capturing one. They are at first covered with a light yellowish-grey down, patched on the back with brown, and having on the top of the

head a light chestnut mark, edged with darker. When fledged, they are very similar to the young of the Red Grouse, but banded and spotted with brighter reddish-yellow.

The flesh of the Grey Ptarmigan is not so dark as that of the Red Grouse, nor quite so bitter, although it has the same flavor. A very considerable quantity is annually killed, the bird being held in estimation not only as an article of food, but, when stuffed, as a domestic ornament.

HOODED CROW.—The Hooded Crow, or *Hoody*, is the Carrion Crow of Scotland; but whether identical with the English bird of that name, is doubtful. It is not migratory, like the Carrion Crow of England, but is found at all seasons on most of the headlands and rocky shores of the Highland lochs and Western and Northern Islands. In these places it does not breed in trees, as in England; for there are no trees; but it makes its nest in precipitous crags. It is the habit of this bird, as of the Eagle, that one pair appropriate to themselves a breeding-place, and drive away all intruders. If one of the mates be killed, another very speedily appears and takes its place. In like manner, two or three pairs of *Hoodies* appropriate a district of coast or an island, the numbers being always limited to the means of subsistence. These do not fight among themselves, but prevent strangers from encroaching on their feeding-grounds. The boldness, rapacity, and cunning of the Hooded Crow are very remarkable. Two gentlemen, who were lately on a visit to Barra Head Lighthouse, observed to the very intelligent chief light-keeper there, that a fine-looking Domestic Cock had lost the feathers of his neck. "That," said he, "is the consequence of fighting with the Hoody Crows in defence of his hens, which the Hoodies would kill and devour." He added, that even the lighthouse Dog was not a match for the Hoodies, but on him they practised cunning bearing the stamp of reasoning. When the Dog had got a bone, and was couching with it between his paws, one Hoody was observed to come in front, and another to approach behind: the one in front of the Dog manoeuvred impudently, till the indignant cur, losing temper, left his bone and made a spring forward at the presumptuous bird; at this moment, the accomplice Crow from behind instantly struck in and flew off in triumph with the prize!—[For the above notice, from the pen of Dr Neill, we are indebted to Mr Fraser.]

CARNIVOROUS GEESE.—The carcase of a horse lying near the Gas Works, by the side of the river at Musselburgh, at present affords an object of great attraction to the domestic Geese. These animals, which we saw crowded about it to the number of nearly twenty, have nibbled off nearly all the flesh from the back and ribs. It is remarkable, however, that they have not succeeded in making any thing of the intestines, their soft and blunt bill not enabling them to tear asunder so tough a substance. Indeed, so ill adapted is that instrument for picking the bones, that they have only been able to tear off the muscular fibres, leaving all the tendons and ligamentous parts adherent. We are aware that domestic Ducks and even Geese will eat almost any thing that comes in their way, and have seen them devour fish, snet, potatoes, blood, mice, &c.; but do not recollect to have seen the Goose recorded as a carrion bird.

Remarks on Varieties of the Fox observed in Scotland. By W. MACGILLIVRAY.  
(Read to the Wernerian Natural History Society.)

THE object of the following remarks is not to furnish anything new respecting the organization and habits of an animal so well known as the Fox, but to point out differences observed in individuals living in a limited range of country, with the view of drawing attention to peculiarities generally neglected by those who study nature from books.

It appears to me, that there are four races or varieties of the Fox in Scotland.

The first of these, the *Hound Fox*, is tall, slender in the limbs, with a very attenuated muzzle; a bright reddish-yellow fur; the lower parts of the body greyish-white; the tail greyish-yellow, with long black hairs scattered towards its extremity; and about three inches of its extremity white.

The second, the *Cur Fox*, is similar to the first variety in colouring, but is smaller, with the body deeper, and the legs shorter. These two races seem to pass into each other, and can scarcely be distinguished except in the extremes.

The third, the *Dog Fox*, is compact in form, with comparatively short limbs; the head rather broad, the muzzle pointed; the fur deep red; the lower parts brownish-red; the tail yellowish-grey, darkened with black hairs, and having the tip of the same colour.

The fourth, the *Mastiff Fox*, is larger and stronger; its limbs more robust; the head much broader; a dull, greyish-yellow fur, profusely interspersed with white hairs; the tail dusky, with long black hairs scattered over it, and a small white tip.

The first and second varieties are of common occurrence in the lower districts of the country. The third is very rare, and individuals of it being considered inferior specimens of the species, it is not to be seen in collections. The fourth kind seems peculiar to the Highland districts.

The first variety approaches in its general form to the most characteristic variety of the Shepherd's Dog. The head is of ordinary size, with a long, attenuated muzzle; the ears roundish, erect, with a slit at the lower part of the outer margin; the eyes of moderate size; the mouth opening to beneath the middle of the eye; the snout small, the nostrils terminal, with a lateral slit; the upper lip grooved; the neck of moderate length, but strong; the body rather long and compact; the limbs longish and rather slender; the tail reaching to the feet.

On the fore feet are five toes, the inner small and raised from the ground; on the hind feet four toes; the claws slightly arched, compressed, bluntish, grooved beneath, near the end; those of the hind feet broadest.

Incisores	$\frac{6}{6}$	Canini	$\frac{2}{2}$	Molares	$\frac{12}{14}$
-----------	---------------	--------	---------------	---------	-----------------

Incisors of the upper jaw incurvate, rounded, with two small lateral processes, excepting the two larger side ones, which are caniniform. Canini tapering, incurvate, long, distant from the incisors. Laniarii 4; 1st small, compressed, obtuse, with a posterior shoulder; 2d and 3d nearly equal, compressed, tapering, with two shoulders; 4th much larger, oblique, with an anterior tubercle, a central point, and a posterior

BOTANY.

THE WATER TREFOIL, OR BOG-BEAN.—*MENYANTHES TRIFOLIATA*.

THIS plant, which is generally distributed in Britain, growing abundantly in marshy places, peat-bogs, and by the sides of lakes and pools, is one of the most beautiful of our native species. It belongs to *Pentandria monogynia* of the Linnæan system, and to the natural family of *Gentianææ*. The root is perennial, long, creeping, jointed, and sends out numerous verticillate white fibres. The leaves are alternate, petiolate, ternate, the leaflets obovate, thick, smooth, and deep green. The flower stalk rises to the height of from six to ten inches, and supports an oblong or conical raceme of numerous very beautiful flowers, which are pentapetalous; the corolla previous to expansion rose-coloured externally, afterwards reddish-white, the petals on the inner surface covered with numerous fringe-like white filaments.

All parts of this plant are extremely bitter, and in some countries it is used as a substitute for hops in the preparation of ale. The root, although almost equally bitter, Linnaeus informs us, is dried and powdered by the poorer people in Lapland, to be made, with a little meal, into a coarse unpalatable bread. In this country the plant is not applied to any use, if we may except its occasional employment in some parts of the north of Scotland, as a purgative for calves. Formerly it was much employed in various chronic diseases, as scurvy, dropsy, jaundice, asthma, and gout, the paroxysms of the latter of which complaints it was supposed to keep off, but at present it is neglected on account of the preference given to gentian and other bitters. There can be no doubt, however, that, as an astringent and stomachic, it is equally powerful with many exotic plants.

MISCELLANEOUS.

ON VARIETIES.—NO. II.

(Continued from Page 116.)

AMONGST articulated animals (and I believe in most cases where any organ or part is greatly multiplied), we observe instances of the number of legs being indeterminate, such as *Julus indicus*. Another instance is found in *Aphrodita aculeata*. We also observe that extraordinary form of variety noticed above in certain fishes and in shells, consisting of a transfer of certain structures ordinarily peculiar to one side of the animal to the opposite side. This is seen in our common Lobster, in which the knobbed claw and the serrated claw exchange sides as it were capriciously. I say capriciously, because, in this instance, unlike those remarked in fishes and shells, there is no predominating arrangement of these organs.

But besides these more remarkable forms of variety in the lower grades of animals, there are others less notable, generally dispersed. The Hercules Beetle is said to vary so extensively in size, as to have raised doubts occasionally whether these variations were not entitled to specific consideration. The Tarantula has several varieties differing in regard to the quality of the hair. Varieties in regard to colour are of frequent occurrence. All the Echiidæ are disposed to vary extensively in this respect; more than thirty varieties as to colour have been observed in *Echinus angulosus*. Many species vary also largely in structure and shape, particularly in their spines. Thus there are four varieties of *Echinus cidaris*, all determined by the form of the spines.

In the extreme grades of animal organization, in which the aspect at least of vegetables is assumed, we find the differences between individuals in the same species carried to their highest pitch. Between these and absolute varieties no line can any way be drawn, although something must be allowed for our very imperfect knowledge of these plant-like animals. Yet authors have been pleased to enumerate varieties occasionally, and in these very considerable amounts of difference are set forth. Thus in *Corallina rubens* three varieties occur, distinguished by structural peculiarities:— See Fleming's British Animals, p. 514. *Halichondria ramosa* (Flem. p. 523) has several varieties, in all of which the structure differs greatly; but I apprehend that in viewing the subject of varieties in these tribes, we should keep in view their near relationship to vegetables, and that in consequence the varieties observed in them will partake of the same affinity. It might, therefore, be reasonably supposed that in

edge. Of the two molares, the anterior is much larger; both are similar in form, transverse, with two external tubercles, one interal, and a projecting margin.

In the lower jaw the incisors are smaller, rounded, with an external lateral process, the two outer considerably larger. Canini close to the incisors, smaller than those above, and more curved. Of the lanarii the first is very small, rounded, with a posterior shoulder; the rest nearly equal, with anterior and posterior shoulders, the last one with two posterior. The next tooth, which is the largest, combines the two forms, its anterior part being sharp-edged with two points, the posterior, lower, with four unequal tubercles. The first grinder has four tubercles, and the last, which is very small, has three.

The fur is rather soft, pretty close, longish, and consists of a fine woolly covering, and long hairs of a stiffish texture; the tail bushy; the hair of the limbs and face short; the soles covered with hair, excepting the tuberculous eminences on which they have been worn.

The general colour is yellowish-red, pure on the sides of the neck and chest, and lower sides of the abdomen, mixed with white hairs on the shoulders, thighs, upper flank, sacral region, and tail. The snout and lips are blackish; the inner surface and edges of the ears whitish, outer part of the ear pore black. Tail pale greyish-yellow, the tips of the hairs brownish-black, its extremity white to the length of about three inches. Lower part of the cheeks, fore part of the neck, lower surface of the body, inner thighs, pudic region, a narrow line down the fore part of the leg, and the hind and inner part of the fore legs, greyish-white. Fore part of all the feet, brownish-black, that colour extending from the toes to near the cubital and knee-joints; hair of soles deep red; claws light brown; mystacial bristles black.

The male and the female are precisely similar in external appearance; nor does there seem to be much difference in size.

Dimensions of two individuals:

	Male.	Female.
	FT. IN.	FT. IN.
From the tip of the nose to the root of the tail.....	2 6	2 4½
Length of the tail (not including the hair).....	1 4	1 3½
Total length (including the hair).....	4 0	3 10
Height at the shoulder } (following the flexure of the limbs) {	1 6	1 6
Height at the rump } {	1 7½	1 7
From the nose to the occiput.....	0 7	0 7

The second variety is similar to the first, but smaller, with the limbs shorter, the colour of a deeper red, and having a larger mixture of white hairs on the parts mentioned.

Of the Dog Fox the following is a description taken from a male shot in Peeblesshire, in December 1835. The general colour is yellowish-red, the forehead, shoulders, and haunches with greyish-white hairs interspersed. There is a dark patch between the mystacial bristles and the eye, and the lower jaw is dusky. Edge of upper lip, base of lower, throat, and fore neck, with a short band down each humerus anteriorly and internally, and another on the middle of the breast, greyish-white. The lower parts of the body are brownish-red; the axillæ and groins light red; the scrotal hairs yellowish-white; outer surface of ear black, inner pale greyish-yellow. Legs dark brownish-red, fore part black from the toes up to the cubital and knee-joints; hind part of the hips deep red; tail yellowish-grey, the tips of the long hairs brownish-black, the extremity of the same colour; claws yellowish-grey.

	FT. IN.
From the tip of the nose to the root of the tail.....	2 3
Length of tail .....	1 3
Total length (hairs of tail included) .....	3 8
From the nose to the occiput.....	0 6½

A skin and skull of a Fox procured in Sutherland by Sir William Jardine, who favored me with the inspection of them, belonged decidedly to the fourth variety, the Mastiff Fox. The skull greatly exceeds that of the other kinds in the width of its zygomatic arches, and the size of the cerebral cavity. The fur is longer and coarser, of a duller red, and much intermixed with white hairs; the lower parts light grey, and the extremity of the tail white for about three inches. Respecting this variety I am unable to furnish any further particulars, not having had an opportunity of late of examining a recent individual.

I have reason to believe that similar varieties exist in other Mammalia inhabiting this country. For example, the Red Deer of Lewis and Harris are much smaller and of a duller colour, than those of the mainland. Of the Weasel, there is a variety much inferior in size to the common; and of the Water-Rat I am aware of three, the common brown, the black, and an intermediate kind. The latter, as well as the black, may be a distinct species, it being considered as such in the neighbourhood of Keith, where it is said to lay up a store of potatoes for winter provender.

Whether the different kinds of Fox above described breed together, or remain distinct, is as yet unknown, nor are we in possession of any positive knowledge as to their peculiar habits.

THE SISKIN BREEDS IN SCOTLAND.—The following notice, interesting as affording evidence of a fact hitherto doubted, was handed to us by Mr Carfrae, preserver of animals, Edinburgh. The Siskin is a common bird in all the high parts of Aberdeenshire, which abound in fir woods. They build generally near the extremities of the branches of tall fir trees, or near the summit of the tree. Sometimes the nest is found in plantations of young fir wood. In one instance I met with a nest not three feet from the ground. I visited it every day until four or five eggs were deposited. During incubation the female showed no fear at my approach. On bringing my hand close to the nest, she showed some inclination to pugnacity, tried to frighten me away with her open bill, following my hand round and round when I attempted to touch her. At last she seized a firm hold of my finger, and held fast. I visited her almost every day, and could with perfect confidence stroke down her back. As last she would only look anxiously round to my finger, without making any attack on me. The nest was formed of small twigs of birch or heath outside, and neatly lined with hair.— J. M. Brown, Abergeldy.

simulating the aspect of plants, they would put on those forms of variation which peculiarly distinguish the vegetable world, consistently, however, with their actual animal nature. This is actually the fact. They observe no fixed or precise dimensions, although there is a limit to their growth. In numerous instances the figure of the species varies largely. Frequently the shape of some of their parts suffers great variation; very often specimens of one kind present a variety in regard to colour; and, lastly, in some, as before noticed, no adherence to any dimension or figure (as a whole or as regards parts), within limits which are allotted to other zoophytes, can be detected, so as to furnish a clue to what might be the prevailing appearance. We shall afterwards see that these forms of variety in the zoophytes are represented in various departments of the vegetable kingdom.

It must be borne in mind, that although there is a most evident gradual transition from animals to vegetables, the traces of analogy are soon lost in the predominating characteristics of the latter class, and that there are as many differences between extreme classes, or departments of vegetables, as are found between extreme classes of animals; so that it might reasonably be inferred, that a review of the classes of vegetables of the same nature, such as that we have given to the tribes of animals, would be attended with advantage. Yet, it must also be recollected, that throughout the vegetable kingdom, our knowledge of organization, and consequently our knowledge of the limitations of species, is extremely circumscribed, inasmuch, that the science of Botany, as far as regards the determination of species and varieties, is involved in opinion and conjecture. In a review, therefore, of the above named kind, we should be constantly impeded by a want of fixed rules and examples, and we shall content ourselves with an enumeration of such ascertained and determined forms of variety as are met with in this class.

In the first place, one rule must be stated relative to plants in general, that consistently with an increased proneness to vary in proportion as the subject is low in the scale of organization, they display the most extended series of variations, a great portion of which assuming too large an amount of difference from the standard structure and appearance, to be regarded as ordinary specimens, have been formally arranged by authors as varieties; yet, as would naturally be expected, disputes have occurred, first regarding the number of those specimens entitled to be ranked as varieties, and, secondly, regarding what should be deemed varieties and what species. The vegetable world, then, is a continued scene of variation, and the rule of fixing varieties, technically so termed, is in the highest degree arbitrary and artificial. The most extensive mode of variation among plants is that of size and dimensions. The same plant is liable from circumstances, such as soil or station, to suffer alterations, in this respect, of considerable amount, so that it has frequently been matter of dispute among botanists, whether the most remarkable of these should be esteemed species or varieties. An alteration in size is most commonly accompanied by alterations of other kinds, especially variations in the shape of the whole or of parts, but these also occur independently of a variety in size. The mode of growth and the habits of plants are subject to variety. A plant commonly erect may be found prostrate, and *vice versa*. Colour is a mode of variation particularly observable in plants. We here refer more especially to the flower. Frequently there are several varieties in regard of colour in one species. Varieties which affect the structure or organization of the species are extremely common. This is illustrated in a most ample manner by the hair or pubescence, a species very frequently having varieties with this kind of clothing variously disposed, and in various quantities. The number of styles is not constant in some species of plants; in *Arenaria rubella*, for instance, they vary from three to five. In *Acer Pseudoplatanus* the cotyledons are said to vary from one to four. In those species where the number of any given organ is small, and so far uniform as to furnish a specific character, varieties in respect of such number are sometimes met with. Thus *Erigeron alpinus*, which usually has but one flower or anthodium on each stem, has two varieties, in one of which the number of flowers ranges from one to three. *Orchis bifolia* is occasionally furnished with a third leaf. With the exception of such instances as these, flowers, leaves, &c., are numerically unrestricted and undefined.

As I have before stated, the lowest of vegetable forms enjoy a perfect freedom in regard of size and shape, excepting that a maximum is appointed for the first, and that the shape is at all times in some degree characteristic of the species respectively. I once more repeat, that in this second kingdom of organized beings, varieties obtain to their utmost extent, and that it is an arbitrary proceeding to appoint certain of these variations to be entitled "varieties" in books. In my remarks, therefore, I have not confined myself to these last, but have thought fit to view the subject of varieties in this class as a whole. It remains to be said, that accidental and permanent varieties are both met with amongst plants, the former by far the most numerous, and oftentimes found to be constantly liable to reproduction. Permanent varieties are very frequent, as might easily be supposed from the lasting influence exercised over vegetable productions by the soil and medium in which they are placed, and these circumstances so prone to alteration within even confined limits. Besides this, vegetables are in very numerous cases endowed with the power of originating forms dissimilar to the stock producing them. *Draba verna*, which ordinarily displays a flat pouch, has a variety with a swollen pouch; *Poa alpina* has a variety in which the spikelets are densely crowded together; *Lolium perenne* exhibits great modification in its spike; *Artemisia maritima* has two permanent varieties both found growing in the same localities, one distinguished by a drooping, the other by an erect raceme. These differences seem so far permanent and inherent in the plant, that they are occasionally seen growing from the same root. We shall return at intervals to the subject of the two kinds of varieties mentioned in this paper.

Having, in the course of the preceding remarks, enumerated and instanced the several kinds of variation occurring in animals and vegetables, we shall in the next place inquire into the causes and uses of varieties. The uses are proximate and ultimate; that is to say, either dependent in an evident way on surrounding influences or circumstances, or produced by some agency, and for some reasons, respecting which we cannot be exactly certain. It is of course easy to refer all occurrences and all productions to the great source of beauty and variety in nature; but it is the business of the naturalist to search for intermediate causes, even though the search be likely to prove fruitless, and though we should be in danger of setting that down as a cause

which is perfectly inadequate to the office, whilst the true cause remains hidden, and undetected to human comprehension. If, however, no cause can be discerned or surmised, it is equally the business of the philosopher to ascribe the circumstance to the superintending agency of God; at least until further discoveries have been made, very many circumstances in connexion with our subject must be disposed of in this way.

Varieties in respect of size are caused by soil, station, climate, and food. This might easily be conceived, for it is not reasonable to suppose that species disposed to vary should, when their individuals are exposed to adequate causes, continue unaltered in their dimensions. Some species, however, are acted on only by one or more causes, and refuse to be influenced by others though exposed to them. The tendency to variation is not displayed alike by all kinds, not even by species nearly allied. These facts seem of themselves to show that some intention or design, in regard to varieties, pervades nature. Size is perhaps of all kinds of variety the most prevalent or general, and climate, in co-operation (for the most part) with food, the most usual cause of such diversities. One of the most interesting phenomena in connexion with our subject is that of some natural productions attaining their greatest magnitude, luxuriance, and vigour, as they approach the tropics. This, of course, can only be observed in cases where the geographic range is very extensive. On a small scale, it cannot be expected to be perceptible, unless the stations occupied should present great dissimilarities in climate within confined limits. It might not be easy to cite cases of variety (technically so named) in support of these assertions, but the circumstance of great variety in size occurring to species is quite sufficient for our purpose, and of this diversity numerous instances can be furnished. The Lion and the Tiger, whose geographic ranges are considerable, attain dimensions near the equator far greater than those which they reach at their furthest limits. The Slow-worm, *Anguis fragilis*, attains the length of three feet in countries farther south, and where the heat is more considerable, while with us its usual length is one foot. But besides this rule, as regards increase of size, as the species approaches the equator or an increased temperature, there is another law, which clearly shows that each species has its peculiar station at which it enjoys the full vigour of its growth and endowments without regard to heat. The Sea Ear, *Haliotis gigantea*, in the Polar Seas attains the length of six or seven inches; but this size, as well as the number of individuals, diminishes as we recede southwards, so that here is a reverse position to that before stated. So also is it with certain kinds of plants. Some are found to degenerate in size as they get into a colder latitude, or are found elevated into the cold atmosphere of a mountain, whilst with others, whose growth is in perfection on the summits of mountains, or in a latitude equally cold, a degeneracy in size can be observed as the species recede from such spots. But, on the other hand, there are instances, as before said, of species resisting almost entirely influences affecting others so freely as occasionally to raise doubts whether they might not be entitled to specific rank when observed under the extreme of variation to which they have been submitted. The White or Barn Owl inhabits the whole of Europe and America, and yet through this vast extent it exhibits remarkably slight differences. The Wolf also, found from the torrid zone to high northern latitudes, differs chiefly in the colour of its fur only.

We occasionally see varieties induced in plants by their being inundated through some accidental cause, in which case the medium (which is equivalent to soil) effects an alteration in their stature or size, besides sometimes producing structural differences; but I have before stated that plants, beyond all other organised beings, are liable to vary.

Upon the same principle, that species suffer diminution in size and deterioration generally in their structure and functions, as they recede from the spot at which their maximum of size and utmost luxuriance are attained; they are found in very many cases to be affected almost in a similar way by the same description of causes acting in the immediate vicinity perhaps of specimens which have attained to their extreme size and full development of parts and qualities. This remark applies to the lower classes, especially such as are denied the power of locomotion, but coming into existence in an unfavorable soil or station, or where the natural pabulum is furnished sparingly, constitute, in the language of naturalists, "dwarf," "impoverished," "starved," or "depauperated" specimens. Such also not unfrequently appear in books ranked as varieties technically. On the same principle, moreover, in these tribes suffering variation so freely, "gigantic" specimens (elevated occasionally to the rank of varieties) are met with, dependent for their extravagant luxuriance on some peculiarly appropriate site, or peculiarly adapted soil or medium.

ARTESIAN WELLS.—At present more than thirty Artesian wells are in progress in the departments of France. That at the Abattoir, near the Barrière de Grenelle, becomes every day more interesting. The boring has already reached the depth of 1360 feet. This well was commenced on the 30th December 1833, and during the 1200 days which have elapsed since then, the works have been directed by M. Mulot, jun., and have not been discontinued for a single day. From this it appears that the average progress has been upwards of thirteen inches per diem. It appears that the administration are about to make an engagement with M. Mulot to bore to the depth of 1800 feet, if water be not previously met with. A well begun at Dresden had obtained in October last an abundant supply of water at the depth of 840 feet. This source, having a temperature of 68° Fahr., furnishes a supply of 14 gallons of good water per second. They penetrated through 62 feet of sand and gravel; 810 feet of marl and chalk; 43 feet of pure marl; and 22 feet of greyish freestone. Admitting the above temperature to be that of the strata at this depth, and comparing it with the mean temperature at the surface of the earth at Dresden [48° Fahr.], we find a uniform increase of temperature of 1.20° Cels. for every 100 feet, or 1° for every 78 feet of depth; but this increase being greater than that actually observed in boring, we must conclude that the water of this well comes from a greater depth.—*L'Echo du Monde Savant*.

ZOOLOGY.

BRITISH BIRDS.—NO. VIII — PARTRIDGES.

DESCRIPTION OF THE PLATE.—THE ORANG OUTANGS, PYGMIES, AND GIBBONS.

THE genera of the extensive order of Quadrumana represented in this plate, are those which exhibit in their conformation the nearest approach to the human species. They have four incisors in each jaw, a more or less prominent nose and elongated arms.

PITHECI.—MEN-OF-THE-WOODS, OR ORANG OUTANGS.

ONLY one species of this genus is known. It is that which presents the greatest resemblance to Man; and is characterized by a large and rounded head, a narrow flattened nose, with expanded nostrils, a large projecting mouth, reddish shaggy hair, and other features, which it is unnecessary to particularize here, as a full description will be subsequently presented.

Fig. 1. THE RED ORANG OUTANG (*P. Satyrus*). It inhabits Cochinchina, Malacca, and the islands of the Indian Archipelago, and is said to attain a height of six or more feet. The individuals brought to Europe have been young, and have never attained maturity. An individual described by Dr Abel did not practise the grimaces of other Apes or Monkeys, but exhibited a gravity approaching to melancholy, and a mildness superior to that of almost any other animal.

Fig. 2. THE FEMALE differs from the male chiefly in being less hairy.

TROGLODYTES.—THE PYGMIES.

OF this genus also, only a single species is known. It bears a close resemblance to the Orang Outang, from which it differs in having a prominent superciliary ridge.

Fig. 3. THE CHIMPANSEE (*T. niger*), or Black Orang Outang, inhabits some parts of Africa, and especially the coasts of Angola and Congo. It lives in troops, and is said to be very intelligent; but little is known respecting its habits; and all the individuals brought to Europe alive have been young.

HYLOBATES.—THE GIBBONS.

THESE animals are remarkable for the extreme elongation of their arms, and are further distinguished from the preceding genera by having callosities on their buttocks.

Fig. 4. THE BLACK GIBBON (*H. Lar*), is characterized by its black fur, and the circle of grey hairs which surrounds its face. It inhabits Coromandel.

Fig. 5. THE FEMALE differs in wanting the grey hairs on the face.

DESCRIPTION OF THE PLATE.—THE HARRIERS, AND SNAKE-EATERS.  
THE HARRIERS.—CIRCUS.

THE HARRIERS constitute a genus of the order *Accipitres* or *Raptores*, intermediate in some measure between the Hawks, properly so called, and the Owls. They are generally of a slender form, with elongated wings, tail, and tarsi, their toes rather short, their claws slender and moderately curved. The aperture of their ear is very large, and their head is surrounded with a kind of ruff resembling that of the Owls, but less distinct. They prey on small quadrupeds, birds, reptiles, and insects, and generally attack birds while on the ground, although their flight is rapid and buoyant.

Fig. 1. THE LONG-LEGGED HARRIER (*Circus Acoli*) is of a light greyish-blue colour above, and on the fore neck, the lower parts white, transversely barred with black, the cere rich orange, and the feet yellow. It inhabits Africa.

Fig. 2. THE BUSON HARRIER (*C. Buson*) is of a brownish red, barred with blackish-brown beneath, the quills and tail dusky, the latter barred with white spots.

Fig. 3. THE INDIAN HARRIER (*C. melanoleucus*) has the upper parts and fore neck of dusky brown, the lower parts, smaller wing coverts, and terminal portion of the secondaries and their coverts, with the tail, white.

Fig. 4. THE HEN HARRIER (*C. cyaneus*) is light blue in the adult state, with the rump white; but the female and the young, of which the latter is here represented, are brownish-red with dusky markings. In this state it was formerly considered as a distinct species, under the name of the Ringtail.

THE SNAKE-EATERS.—SERPENTARIUS.

Fig. 5. THE SECRETARY OR AFRICAN SNAKE-EATER (*Serpentarius Secretarius*). This is the only species of the genus, which, on account of its long legs and other circumstances, has by many systematists been referred to the order *Grallæ* or waders. Its true place, however, is among the *Accipitres*, as is shown by the form of its bill, its claws, and its habits, which are essentially those of a rapacious bird. It preys especially on snakes, which it attacks with its wings and feet, trampling them down, and raising them in the air to allow them to drop on the ground. It inhabits various parts of Africa, and is particularly abundant at the Cape of Good Hope. The name secretary has been given to it on account of the occipital crest suggesting the idea of a clerk with his pen stuck behind the ear.

THE generic name of Partridges was formerly applied to a vast number of birds, which, in the present improved state of ornithology, have been arranged into several distinct genera. In many respects they are very similar to the Grouse and Ptarmigans, from which they differ, however, in having the tarsi always bare, and sometimes furnished with a tubercle behind, and in generally having a bare space behind or about the eye, while they want the coloured superciliary membranes. Properly speaking, only two species are indigenous in Britain, the Common or Grey Partridge, and the Common Quail; but the Red Partridge, which is common in France, and the Virginian Quail, which is peculiar to America, have been introduced, and are spreading in some counties of England. To the genus *Perdix*, characterized by a short, strong, convex bill, a bare space behind the eye, short strong tarsi anteriorly covered with two rows of scutella, and in the male bearing a blunt tubercle behind, marginate toes, strong compressed and arched claws, wings having the first quill longer than the seventh, and a short rounded tail, belong the Red and Grey Partridges. The Virginian Colin is referred to the genus *Ortyx*, having a short and stronger bill, rounded wings, and tail of moderate length. The Quail belongs to the genus *Coturnix*, of which the species are small, have the head entirely feathered, and the tail extremely short.

THE RED PARTRIDGE, *Perdix rubra*, frequently called the Guernsey or French Partridge, is somewhat larger and more robust than the common species, which it resembles in form and proportions, but from which it differs greatly in colour. The bill, the naked space about the eye, and the feet, are bright red, as are the irides. The upper parts are reddish-brown tinged with grey; the forehead ash-grey; the throat and cheeks white; a black band extends from the bill to the eye, and thence down the neck, becoming broader on its fore part, which is spotted with the same colour; the lower parts are ash-grey and light red, the sides transversely banded with ash-grey, white, black, and red. The male has large flat tubercles on the tarsus. This species is said to occur in various parts of Asia and Africa, and to be plentiful in Spain, Portugal, Italy, and the South of France, where it inhabits the low grounds, feeding on seeds, grain, and insects. In England, where it is now not uncommon in some places, it is said to prefer waste heathy ground to corn fields, and to afford less sport than the common species, as it runs before the Dogs, the individuals composing a covey dispersing, and rising one after another. It is accused, moreover, of driving off the Common Partridge, which, it is feared, may in time be extirpated by it, as the Black Rat has been by the larger and more mischievous brown species.

THE GREY PARTRIDGE, *Perdix cinerea*, has the bill and feet bluish-grey; the upper parts minutely mottled with ash-grey, yellowish-brown, brownish-black, and brownish-red; the scapulars and wing-coverts darker, with longitudinal whitish streaks; the forehead, cheeks, and throat, light red; the neck ash-grey, minutely undulated with black; the sides broadly banded with brownish-red, of which there is a large patch on the breast. This well-known bird is generally distributed in Britain, being found in all the lower parts of England and Scotland, with the exception of some of the wilder districts of the latter country. Although not peculiar to cultivated land, it thrives best in those parts that are most extensively covered with crops, among which it finds comparative security during a considerable part of the year. It is of rare occurrence in the narrow valleys of the moorlands, and in the heaths is seldom seen unless in the immediate vicinity of corn fields. It is fond of rambling, however, into waste or pasture grounds, which are covered with long grass, furze, or broom; but it does not often enter woods, and never perches on trees. It runs with surprising speed when alarmed or in pursuit of its companions, squats when apprehensive of danger, and in flying rises obliquely to some height, and then moves off in a direct course, rapidly flapping its wings, which produce a whirring sound. Its food consists of tender blades of grass or corn, grain of all kinds, seeds of various plants, insects and larvæ. These substances, first lodged in the crop, are subsequently ground in the powerful gizzard, with the aid of numerous particles of quartz. Partridges feed principally in the morning and towards night, betake themselves during the middle of the day to places covered with shrubs or ferns, or bask under the hedges. In the evening, before betaking themselves to rest, they are often heard in the fields uttering their harsh sharp cry, apparently for the purpose of apprising each other of their position, so that the stragglers may come up, or the female join her mate. They repose at night on the ground, generally in an open and comparatively bare place. During winter they keep together in coveys, seeking their food among the stubble; but early in spring they separate, and by the beginning of March are generally paired, although the eggs are not laid until June. The place selected for their nest is various, it being found in corn and grass fields, in pastures, among shrubs, by hedges, sometimes even

by road-sides. It is merely a slight hollow scraped in the soil, with a few straws, and contains from ten to fifteen eggs, of a pale greenish-brown colour, averaging an inch and a half in length. Although the male takes no part in incubation, he remains in the neighbourhood of the nest, and on apprehension of danger to it comes up and endeavours to entice from it the person who may have approached too near for its safety. The young are led about by both parents, who manifest the greatest anxiety for their welfare. The female cowers over them in wet or cold weather, protects them in the same manner at night, and evinces the most striking marks of maternal tenderness in all her actions. The principal food of the young is insects and larvæ, and especially those of ants. During autumn and winter the brood remain with their parents, and towards the commencement of the latter season, several families unite into a pack. Partridge-shooting is a favorite diversion; but, notwithstanding the vast numbers annually killed, these birds seem to be rather increasing than diminishing; so that, as an article of food, they are not beyond the reach of the middle classes of society. The Partridge thrives in a state of captivity when properly fed, but refuses to breed in that condition. As may be expected in a bird apparently so dependent upon the labours of man for shelter and subsistence, it varies considerably in size, it being found that in the valleys of the hilly and little cultivated districts it usually attains a smaller size than in the rich plains, where it finds an abundant supply of nutritious food.

THE VIRGINIAN COLIN, *Ortyx Virginiana*, is much smaller than the Common Partridge, and has the upper parts brownish-red, variegated with black; the throat and a broad band over the eye, white; the loreal space, and a broad band passing down the neck and crossing it in front, black; the lower parts greyish-white, undulated with black. The habits of this species have been admirably described by Wilson and Audubon, the latter of whom states, that it "has been introduced into various parts of Europe, but is not much liked there, being of such pugnacious habits as to drive off the Grey Partridge, which is considered a better bird for the table."

THE COMMON QUAIL, *Coturnix dactylisonans*, is a very beautiful little bird, not exceeding eight inches in length, and having the upper parts variegated with reddish-grey and brownish-black, and marked with whitish longitudinal pointed streaks, of which are three hands on the head. It is generally distributed over Europe, and a great part of Asia and Africa. In the former region it is migratory, arriving in the beginning of summer, and departing in September, generally in vast straggling flocks. Their arrival in England takes place in the middle of May. They never appear with us in great numbers, but coming quietly, like the Corn Crane, spread over the country unobserved, and are pretty generally distributed, although nowhere plentiful, and in the northern counties very rare. It is seldom that they are now met with in Scotland. The food of the Quail consists of seeds, herbage, and occasionally insects; and its haunts are chiefly the cultivated fields and pastures, where it continues during the season, never entering the woods or perching. The nest is a slight hollow, with some dry blades, on which it deposits its numerous eggs, sometimes amounting to twenty, and of a regular oval form, reddish-yellow, marked all over with brown spots and blotches. The males are extremely pugnacious, and when they meet each other in their haunts engage in desperate combats. They utter a loud shrill cry, composed of several notes, which have been considered as constituting a kind of song, in consequence of which these birds are often kept in cages on the Continent.

#### CURIOUS HABITS OF A DOMESTIC PIGEON.

THE following account of a Pigeon, exhibiting in a very remarkable degree the social instinct misapplied, has been transmitted to us by the Rev. Mr Adam of Peebles. "About fourteen years ago," says the owner of the bird, in a letter to the gentleman just mentioned, "the right wing of the Pigeon which you saw in our house was broken by a shot, which was the means of his coming into our possession. After recovering of his wound, he showed his courage by defeating a hawk, who had the audacity to attack him, as he sat in the sole of a window. On one occasion he was sent with his mate—for we took care to furnish him with one—to the house of a gentleman in our neighbourhood; and while there, he gave many proofs of his superiority as a bird of courage, at least when opposed to others of his own species; and this superiority he maintained until his companion fell a prey to the Rats. Poor Poodle, (as we call him,) disconsolate at the loss of his spouse, now left this place for his former habitation, no doubt thinking that a change of scene might do him good; but, unable to fly, he was obliged to walk a distance of somewhat more than a quarter of a mile. Wayworn and bedaubed with mud, he trudged into the room, and emitted his wonted coo-roo as he took possession of his old castle, to wit, that part of the floor in a corner, on which stands an old table, and into which he will not allow Dog or Cat to enter, or even to approach, without a blow of his wing or bill.

"Next spring, finding no mate, he attached himself to a stocking-foot stuffed with straw, round which he built a nest. The year following he took up with a Rabbit that used to run about the house. This animal in its pranks, with a kind of half-wicked and half-sportive design, would sometimes destroy Poodle's nest. This was no doubt a great annoyance to the Pigeon, for it generally cost him the labour of a whole week to repair the injury done. It was curious to see how he proceeded in this operation: having lifted a piece of twig, and placed in the position in which he wished it to rest upon those intended to be placed under it, he perhaps found it too large, on which he would not attempt to shorten it, for some kind of intuitive knowledge seemed to assure him, that the attempt on his part would be vain; but laid aside the long twig for future use, and had recourse to one of smaller dimensions. While this Rabbit was his associate, he used to remind it at night that it was time to retire to rest; if disobeyed, he gave the intimation in another form, went out from his retirement, and compelled compliance. During the day, if the Rabbit was on the floor, he used to come out and attempt to decorate it, in which occupation he took great pleasure, especially in trimming its long ears. The Rabbit would sit still all the while, unless the Pigeon became rude, when a battle would take place. At length the Rabbit was killed, and Poodle for some time had no mate; but thinking it better to have a partner of any sort than none at all, he attached himself to the dog, who allowed him to perch on his back, and use any liberty short of inflicting pain. He always, however, keeps possession of his castle, which the hens, the cat, and the dog, sometimes seem

inclined to enter, but from which, though age has damped his fire, he succeeds in repelling them.

"Another curious circumstance is, that he seems fond of knowing all that is going on. If a person with whom he is acquainted calls, he is sure to regard him with very particular attention; and as a proof of his inquisitive disposition, it may be stated, that for some time there was a hole in the floor, at which he would place himself, frequently remaining half an hour, and giving good heed to what was going on in the apartment beneath. Again, let it be supposed that he is sitting on the outside of the window, and that he perceives preparations going on for breakfast or dinner, he manifests great joy by half flying and half tumbling down to the ground, and makes his appearance by coming up stairs. If he be asleep in his castle at supper time, and any of the family say "Poodle, why don't you come for your share?" he replies in his own way, and presently comes forth."

These remarks, says our correspondent, are from the pen of an eye-witness; and the family in which so many creatures so different in nature dwell in amity, may well be regarded as an amiable one. The dove is an emblem of peace, and if ever peace dwelt on earth since the fall of man, it is among the members of that family, in the midst of which Poodle has had the good fortune to find an asylum.

#### OBSERVATIONS ON THE JERBOAS.—BY M. F. CUVIER.

PARTICULAR circumstances having for some time directed the attention of the Author to the Glires, he has anxiously availed himself of every opportunity of extending his knowledge of them, in order to be able to apply to the numerous species of which that great family is composed, those precise rules of the natural method, without which confusion and obscurity must prevail in the study of animals. The results of his new observations on the Jerboas have recently been communicated to the Academy of Sciences.

After much consideration, naturalists had agreed in forming the genus Jerboa of Glires remarkable, more especially for the great size of their hind feet; for having three toes on these feet, which alone in walking or leaping are placed on the ground, and are articulated to a single metatarsal bone; for their broad head, short muzzle, large eyes, and short tail. These Glires, however, are subdivided into several sections, characterized by the absence or the number of the rudimentary toes on the hind feet. M. Lichtenstein, to whom we are indebted for an excellent memoir on the Jerboas, published at Berlin in 1828, has formed three divisions of these animals: 1st, those which have only three toes in the normal state on the hind feet; 2d, those which have an additional rudimentary toe on these feet; 3d, those which have two rudimentary toes on them. Further, the form of the teeth of the species of this last division was known, and was attributed to the teeth of all the species of the genus.

The possession of skulls of several species of the first division, that which is characterized by three toes only on the hind feet, has shown M. Cuvier, that these species are not distinguished solely by the number of the toes, from those which have five on the hind feet, but that they are moreover characterized by the form of the molar teeth, and by the structure of several of the parts of the head. Thus, while in these latter, the true molars present numerous irregular folds of enamel, these folds are in the others reduced to a single one on each of the lateral faces of these teeth. On the other hand, if the general structure of the head is the same in all the animals, and is characterized by the size of the skull, the shortness of the muzzle, and especially the great size of the infraorbital foramen, yet there are differences in these circumstances sufficient to mark the different divisions. Thus, the species which have three hind toes are remarkable for the great breadth of the head, and the capacity of the skull, and this breadth is in part occasioned by the enormous development of the petrous portion of the temporal bone, and the breadth of the zygomatic arch. On the contrary, the species which are furnished with five toes have the capacity of the skull much reduced, all the parts of the ear are of moderate dimensions, and those which compose the zygomatic arch are narrow, so as to present surfaces of small extent to the muscles which arise from them.

From these observations M. Cuvier concludes, that the species of Jerboa which have three toes ought to be generically distinguished from those which have five; and as among these latter are the species which Pallas names *Allactagas*, he proposes giving them that name, and allowing the others to retain that of Jerboas.

The observations are followed by the description of a new species of *Allactaga*, a native of Barbary, to which M. Cuvier gives the name of *Allactaga arundinis*, from the account of its manners given by Shaw, who appears to have known it, although he has very imperfectly described it.

Beside the Jerboas, are pretty generally placed in systems some Glires of small size, with long hind legs, terminated, like the anterior, by five more or less developed toes. These animals are collectively designated by the names of *Gerboides*, *Gerbillus*, and *Meriones*, and several of them have been considered as true Jerboas.

M. Cuvier enters into a historical and critical examination of this genus, and of all the species which have been referred to it, under one or other of the common names mentioned. This leads him, after having shown all that is known of the organization of these animals, and consequently of their generic characters, to distinguish the species which have been referred to this genus, without belonging to it; those which have been referred to it, on more or less doubtful grounds; and lastly, those which really belong to it, and which, from twenty-one are reduced to six species:—1. Olivier's *Gerbillus*, which does not differ from the *Meriones quadrimaculatus* of M. Ehrenberg; 2. M. Geoffroy's Jerboa of the pyramids, to which perhaps may be referred M. Ruppell's *Meriones robustus*; 3. The Gerbillé Pygargue of M. Cuvier, or *Meriones Gerbillus* of M. Ruppell; 4. Mr Gray's *Gerbillus Africanus*, which is not distinguished from that named *Gerbillus Schlegelii* by M. Smutz; 5. The Indian Gerbillus, for the knowledge of which we are indebted to General Hardwick; 6. The Jird, or *Mus Meridianus* of Pallas. M. Cuvier concludes his long investigation by extending and rectifying the characters of the first five species just mentioned, and describing three new species:—The short-tailed Gerbillus, which is found at the Cape of Good Hope, and appears to occur also in the Indian Peninsula; the short-eared Gerbillus, which also comes from India, and Burton's Gerbillus, from Senaar.

The result of M. Cuvier's observations as to the relations of the Gerbilli to the other Glires is, that these animals have no connection with the Jerboas, but are intimately allied to the Rats and Mice. The memoir is accompanied with numerous figures which represent Burton's Gerbillus, and the heads and teeth of eight of the nine species, which are ascertained to belong to the genus.—*Annales des Sciences Naturelles*.

## BOTANY.

THE OLIVE TREE. *OLEA EUROPEA*.

THIS celebrated plant belongs to *Diandria Monogynia* of the Linnæan system, and to the natural order of *Oleinea*. It usually attains a height of about twenty feet, and sends off numerous long branches, with opposite, lanceolate, narrow, entire bright-green leaves, of which the lower surface is whitish. The flowers are numerous, small, white, and disposed in clusters in the axils of the leaves. The calyx is tubular, with four small, erect, deciduous segments; the corolla funnel-shaped, having a short tube, and form semiovate segments. The filaments are tapering, and crowned with erect anthers, the germen round, the style short, the stigma cleft. The fruit is an elliptical drupa, containing a nut of the same form.

The Olive tree is a native of the south of Europe, and flowers in July and August. Its varieties are numerous, and distinguished by the form of the leaves, and the shape, size, and colour of the fruit. "It has been celebrated from the earliest ages, and is the second tree, with which we are acquainted, which is mentioned in the sacred writings. It must have been known before the Flood, as the Dove returned to Noah in the Ark with a leaf of it in her mouth. There can be little doubt of this incident having been the origin of the olive's being considered the emblem of peace. This tree must have been very extensively cultivated in Judea, to have furnished the vast quantities of oil which were used in the sacrifices and service of the temple; besides its general consumption as an article of food.

"Olive trees sometimes attain a great age. There is an Olive tree in the environs of Villa Franca, near Nice, the lowest extremity of the trunk of which, next the surface, measures about thirty-eight feet, and three feet and a half above the surface, nineteen feet above the circumference. One of its main branches is six feet and a half in circumference, and the trunk itself eight feet and a half in height. This is both the oldest and largest olive tree in that part of the country, and though fast decaying, still retains much of its stately appearance. The celebrated Olive tree of Pescio, which has hitherto been considered the most ancient in Italy, and is tree by Marchestioi to be seven hundred years old, is much younger than this wonder of Nice. There are records now extant, which show that as far back as the year 1516 the latter was accounted the oldest in those parts. In 1818, it bore upwards of two hundred weight of oil, and in earlier days, in good years, more than three hundred and fifty."

The Spanish and Provence olives are pickled, and in this state are to many extremely grateful. They are prepared from the green unripe fruit, which is repeatedly steeped in water, with the addition of quicklime or some alkaline salt, which quickly extracts their bitterness. They are then washed, and preserved in a pickle of common salt and water, to which an aromatic is sometimes added.

The principal consumption of Olives is in the preparation of the common sallad oil, or olive oil, which is obtained by grinding and pressing them when thoroughly ripe. The finer oil issues first by gentle pressure, and the inferior kinds are obtained by heating the residuum, and pressing it more strongly. The best olive oil is of a pale clear amber colour, of a mild taste, and without smell. It becomes rancid when long kept, and congeals at 38° Fabr. In some shape oil forms a considerable part of our food, and is very nutritious, but, as it does not readily unite with the contents of the

stomach, it does not agree with some persons, and is often brought up by eructation. As a medicine it is supposed to correct acrimony, and to relax the fibres, or lubricate the parts; hence it has been recommended in coughs, catarrhs, erosions, nephritic cases, spasms, colics, constipations, and worm cases. Externally it is a useful application to bites and stings of various poisonous animals, burns, tumours, and other affections. The application of a drop of it to the bite of a bug removes the smarting sensation in less than a minute.

## M. DUTROCHET'S OBSERVATIONS ON THE SLEEP OF PLANTS.

(Continued from Page 100.)

WHILE reflecting on this singular phenomenon, I was led to think that it is not without reason that Nature has lavished respiratory organs on the fibrous tissue, which is situated between two layers of hollow organs filled with air. As it was not by being filled with liquid that the fibrous tissue took its active state of curvation, it might be by impletion with oxygen. If this supposition were correct, the nerve, which, on being placed in aerated water, there assumed, first the outward, and subsequently the inward curvature, would, on being immersed in un-aerated water, unvaryingly preserve its first outward curvature, or that of sleep, which is due to the endosmosis of the cellules of the cellular tissue; it would thus never present the inward curvature, or that of sleep, which I considered to be owing to the oxygenation of the fibrous tissue.

I ought first to observe, that when any thin part of a vegetable is immersed in un-aerated water, the latter quickly dissolves the air contained in the pneumatic organs of this vegetable part, and takes its place, so that no respiratory oxygen remains in it. My supposition was justified by experiment. A nerve of a flower of *Mirabilis*, on being immersed in un-aerated water, assumed and retained, without change, its inward curvation. An expanded flower which, on being entirely immersed in aerated water, there assumes at the end of some hours the state of closing or sleep, does not assume this state in un-aerated water, but there unvaryingly retains its expanded state.

It might perhaps be thought, that the air contained in the pneumatic organs of the nerves of the corolla, would act in virtue of its elasticity to produce the incurvation of sleep, and not in virtue of the chemical action of the oxygen which it contains; whence it would happen, that the incurvation of sleep would not take place on immersing the corolla in un-aerated water, which dissolves the air contained in the pneumatic organs, and takes its place. But this is not the case, for experiment has proved to me, that the air never returns into the pneumatic organs that have been filled with water, in parts of vegetables which continue to remain submersed. Now, this does not prevent a corolla of *Mirabilis* from assuming the state of sleep after two or three days, when the un-aerated water in which it is plunged in an expanded state, is left to be aerated by contact with the atmospheric air. It is, therefore, without doubt, by the chemical action of the oxygen dissolved in the water, that the fibrous tissue acquires the force of incurvation which produces the state of sleep. Thus, in flowers of the genus *Mirabilis*, waking and sleep—in other words, the expansion and closing of the corolla, result from the alternately predominating action of two organic tissues situated in the nerves of the corolla, and which tend to curve in opposite directions, viz.:—1st, A cellular tissue which tends to curve towards the exterior of the flower, from being filled with liquid to excess, or by endosmosis; 2dly, A fibrous tissue, which tends to curve towards the interior of the flower, by oxygenation.

The corolla of *Convolvulus purpureus* exhibits precisely the same phenomena as that of the different species of *Mirabilis*, with reference to the mechanism which effects its opening and shutting, the internal structure of its nerves being exactly similar. The flower of *Mirabilis* opens in the evening, and closes in the morning; that of *Convolvulus purpureus* opens toward midnight, and does not close until the next evening. Thus, these two flowers are equally nocturnal as to the hour of their expansion. If the flower of the *Convolvulus* remain open during the day, while that of the *Mirabilis* shuts in the morning, this depends in a great measure upon the circumstance that the former is much slower than the latter in injecting the fibrous tissue of its nerves under the influence of light and heat.

The flowers above mentioned have only a single wake and a single sleep, followed by the death of the corolla. I now proceed to examine such as for several days present an alternation of waking and sleep, and take the Dandelion as an example. The flower of this plant generally lives two days and a half, showing during this time a state of waking in the fore part of the day, and of sleep in the evening. On the third day, the last sleep takes place in the middle of the day, and is followed by the death of the corollas. In the state of waking, the semiflorets of which this flower is composed curve outwards, producing its expansion; in sleep, they curve inwards, effecting its closing. Although these semiflorets are very thin, I have been able with the microscope to observe the internal organization of their nerves, which are very small, and four in number in each semifloret. At the internal or upper surface of each of its nerves, there is a linear cellular tissue, the cellules of which are covered with globules, and which is perfectly similar to what I have observed in the nerves of the corollas of the genus *Mirabilis*. At the outer or lower surface of the nerves of the semifloret is a very thin layer of fibrous tissue situated between a plate of tracheæ and a plate of cellules filled with air and placed superficially. This fibrous tissue, which is perfectly similar to that which exists in the nerves of the corolla of *Mirabilis*, is in like manner inclosed between two layers of pneumatic organs, and it thence becomes probable that it is more incurvable by oxygenation, and that the cellular tissue is incurvable by endosmose, as is the case with the nerves of the corolla of *Mirabilis*. In fact, experiment proves that the incurvation which produces the state of waking in the semiflorets of the Dandelion is owing to an excessive impletion with fluid, that is, to endosmose, and that the incurvation which produces sleep is owing to oxygenation. The semiflorets of the flower of the Dandelion being gathered early in the morning, when they still retain the incurvation of sleep, and being immersed in aerated water, assume in it the contrary incurvation, which is that of sleep. This takes place in darkness as well as in light. If they are immersed in un-aerated water, they assume an exaggerated curvature of sleep, and unvaryingly re-

tain this curvature. If these semiflorets thus curved outwards are transferred to syrup, they curve in the opposite direction; and if replaced in pure water, resume the outward curvature. Thus, there is no doubt that all this is owing to endosmose. If we allow the semiflorets which are in the state of waking to remain some hours in aerated water, they assume the incurvation which is that of sleep, and this incurvation is not destroyed by transporting the semiflorets thus curved into syrup, which proves that this incurvation of sleep is not owing to endosmose. As this incurvation of sleep does not take place in un-aerated water, this proves that it is owing to oxygenation. Thus the wake and sleep of the semiflorets of the flower of the Dandelion result from the alternately predominant incurvation of an organic tissue incurvable by endosmose, and of an organic tissue incurvable by oxygenation. The first is undoubtedly the cellular tissue, and the second the fibrous tissue, both contained in the nerves of the semifloret. These two incurvable tissues, alternately prevailing the one over the other, open or close the flower.

The causes which effect the prevalence of the morning incurvation of the cellular tissue, the agent of the state of waking, are, on the one hand, a more powerful ascent of the sap under the influence of light, which increases the turgescence of that tissue, and, on the other hand, the diminution of the antagonist force of incurvation of the fibrous tissue, the agent of sleep, and which takes place during the night. In fact, if the semiflorets be gathered in the evening, when they have assumed the curvature of sleep, and immersed in aerated water, they there retain without change their curve; but if there be taken next morning from the same flower, other semiflorets still retaining the curvature of sleep, and they be immersed in aerated water, they instantly resume the opposite incurvation, even in the dark. Now, by the immersion of the semiflorets in water, endosmose of their cellular tissue is excited, and in consequence the curvature of sleep is produced. If this result has not taken place in the evening, it is because the incurvation by oxygenation of the antagonist fibrous tissue is too strong, and cannot be overcome by the incurvation of the cellular tissue. If next morning, by immersing in water the semiflorets which have passed the night on the plant, their curvature of sleep be produced, this proves that the force of incurvation of the fibrous tissue has diminished, and that in consequence this fibrous tissue has lost a part of its oxygenation during the night; so that the cellular tissue incurvable by endosmosis, which is its antagonist, and which is the agent of the state of waking, then prevails.

Thus the flower, which for several days presents the alternations of waking and sleep, is that in which the fibrous tissue, the agent of sleep, loses during the night a part of the oxygen which has been fixed in its interior during the day, and which is the cause of its incurvation; so that the latter having in the morning lost some of its power, the cellular tissue by endosmose, the agent of the state of waking, becomes again predominant. The sleep of this flower takes place again in the evening, because the oxygenation of the fibrous tissue, the agent of sleep, gradually increases during the day, which renders its incurvation predominant; at the same time the diminution of light occasions the diminution of the sap, which weakens the turgescence, and consequently the incurvation of the cellular tissue, the agent of waking. These alternations cease only on the death of the corolla. The flowers which present only a single wake and a single sleep, are those of which the single sleep is immediately followed by the death of the corolla.

The entire flower of the Dandelion immersed in its expanded state in un-aerated water, deprived of communication with the atmosphere, unchangingly retains this state of waking. If the water is in contact with the atmosphere, it dissolves a portion of the latter, and the flower which is immersed assumes the state of sleep at the end of two or three hours.

It may be remarked, that these experiments confirm what I have said in my paper on the Respiration of Plants, namely, that vegetables respire like animals, by assimilating oxygen, the presence of which in the organism is as necessary in the one as in the other set of beings.

## MISCELLANEOUS.

ON VARIETIES.—NO. III.  
(Continued from Page 120.)

VARIETIES in colour are attributable to much the same causes as those producing variations in size. This, however, is a subject more difficult of investigation, so little being known of the *modus operandi* of these causes, and of the laws which regulate their influence. Observations also are not likely to disclose much to us. Some persons may be content with an explanation of this kind of varieties, derived from the idea of nature ordaining them as so many additions to the beautiful variations every where present in the universe; but if we have recourse to such an explanation in the majority of cases, in the absence of immediate causes, there are instances which, plainly contributing to the welfare of the object, or being, evince a benevolent design in the Creator. Such an instance is seen in the common Trout, which, according to the observation of anglers, conforms in colour to that of the river in which it is found, that is, to the tint of the water or of its bed. It is also seen that plants, and other stationary productions, are influenced in their colour by local circumstances. The brilliancy of their colours is deteriorated or destroyed, according to the degree of obstruction offered by surrounding bodies to the rays of the sun. Soil likewise affects the colour of plants, though in a mode entirely unknown to us. Some localities produce certain coloured varieties of a given species of plant, and it is very probable that many "accidental" varieties are attributable to the same cause.

Food is thought in some cases to produce varieties in certain animals, and this is not improbable in the case of such as are found scattered and exposed to differences in the kinds of nourishment appointed for them. Among the facts available in support of the idea of variety in colour being an ordination of nature to increase the beauty and interest of a species, it may be urged that a given colour is always liable to give rise to modifications of the same in all its gradations, and these both as permanent and accidental varieties; but then there is one rule among plants which seems to place the question on a different footing, namely, that all blue flowers are prone to produce white varieties, that is, varieties destitute of colouring matter. In cases

where two, three, or more colours appear together, and are diffused in patches over the individual, we sometimes find no regularity adopted as to the size of such patches or spots, or their figure, or relative position. Now, these are irregularities with the causes of which we are not likely to become acquainted. The great tendency to variation in colour of animals and plants is abundantly exemplified in domesticated and cultivated species.

As the causes that operate in producing varieties in size and colour are so obscure, it cannot be surprising that an investigation of the same kind relative to varieties affecting still more decidedly the species, and inducing differences in structure appreciable for the most part by the naked eye, should be equally unsatisfactory in results. Indeed, if the peculiarities distinguishing species cannot be satisfactorily explained in the majority of cases, by reference to causes presumed to be in operation, those which distinguish varieties must be also in the same predicament. The hairs and prickles of plants are a kind of structure very prone to variation, and it seems that they increase in number in dry situations, and diminish in such as are wet. But instances in which causes can be traced are extremely rare, and little else can be done than to enumerate varieties of this description. In many such we can discover without difficulty that although varieties are in themselves departures from natural structure, they are nevertheless produced under the influence or guidance of a law of formation. Thus, in the case of *Julus indicus*, the additional members are produced by pairs, it being in contradiction to suppose that a single leg could be formed by vessels, or the secreting organs, which had previously formed two members at a time, the disposition or arrangement of these secreting vessels being such that two structures instead of one must as it were necessarily ensue. So, in the production of the parts of plants, if the usual mode is by pairs, triplets, &c., the varieties will display the same arrangement. Yet this rule is by no means invariably abided by.

In addition to the forms of variety yet noticed, there are others which it is necessary to enumerate, though their causes are quite unappreciable. Plants usually odoriferous are liable to become scentless under certain circumstances, and it is thought that the rays of the sun are in some cases essential to the production of this quality. Scent is of course dependant on the presence or condition of some structure, and it would therefore be requisite to inquire what this structure is in each case, and what circumstances are liable to vary its formation and its qualities. The taste or flavor also, both of animals and plants, is liable to slight differences, dependant most probably on soil, situation, and food. The Oyster, for instance, varies, in taste according to the river from which it has been procured. The Salmon, the Trout, and the Perch, also differ in this respect. Peppermint varies in flavor according as the soil suits its constitution, and the same is well known to be the case with regard to Grapes, Melons, and many other kinds of fruit.

The song and notes of birds, especially of those which are not confined to a monotonous song, or to one particular key, is in some instances not a little different from that proper to the species. Besides, minor differences are frequently observed in individuals. On this subject see some remarks in the "Journal of a Naturalist." The habits or actions of animals, too, exhibit some individual peculiarities of the same amount, there remaining, however, those distinguishing features which serve to characterize the animal, and separate it from every other. In short, all that I contend for is this:—That, as there exist between species certain differences of a greater or less extent, by which they are respectively known and characterized; so there exist between the individuals of a species differences of a greater or less degree forming a line of demarcation, or peculiarities characterizing and separating one from another. To my apprehension, nature has been desirous of fixing these bounds, and impressing on individual productions marks which cannot be effaced, thereby preserving the same rule as regards the component parts of species, as is noticed between the specific components of the organic world. These last-named varieties are well seen in domestic animals, and in cultivated specimens of plants, though I by no means appeal to these in support of my opinion.

Much of the difficulty attached to an inquiry as to the uses of varieties would be banished by admitting that, besides nature appointing a certain series of differences between individuals of a species, she has also in very many cases appointed uses, separate or additional, for varieties occurring to species. Unless we admit that some particular office, or function, is set apart for very many varieties we meet with, I do not see how we are to account for their differences being so great. I conceive that in many instances, not only are the amounts of difference assumed as varieties, as great as those between species, but that their uses are as peculiarly important in the great scheme of the universe, as those of a vast number of species belonging to the same class or tribe as the varieties. It is not pretended, however, that these uses can be defined, and it is but an inference to say varieties execute functions different from ordinary specimens. In the case of animals and plants which we employ as food, or for economical purposes, we are led to the conviction that here varieties are indispensable, because, although some maintain existence under unaltered forms when dispersed over a large extent of country, and exposed to great diversity of circumstances, surrounding media, and conditions are ever differing, and the surface of the earth is composed of heterogeneous materials, different kinds of soil being frequently found in adjacency within very confined limits, and consequently the occurrence of such species would be very circumscribed, unless by the means of variation they could adapt themselves to such diversifications. In the vegetable world we may instance wheat, barley, maize, other kinds of grain, and various species of grass. Now, if these did not conform to the different soils, man would be debarred from participating in the benefits they confer, excepting in those particular localities which happened to agree with them. And so, if certain heights were ordained for trees, they could only be found in those soils and situations which allowed them to attain those heights.—*To be continued.*

ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE PROBOSCIS AND SOLEMN APES.

Fig. 1. THE PROBOSCIS MONKEY of Pennant (*Nasalis larvatus*), distinguished from all others by the elongation of its nose, is the only species of the genus to which it belongs. It is of a reddish fawn colour, lives in troops in the forest, and inhabits the Island of Borneo.

Fig. 2. THE DOUC (*Semnopithecus Nemaus*) belongs to a section of Monkeys which have thirty-two teeth, a facial angle of about 45°, a round head, flat nose, ears of moderate size, very long limbs, short thumbs, and a very long and slender tail. This species, which inhabits Cochin China and Madagascar, has its fur diversified with brilliant colours.

Fig. 3. THE ENTELLUS (*S. Entellus*), of a yellowish white colour, with the face and hands black, inhabits various parts of India.

Fig. 4. THE CIMEPAYE (*S. melalophus*) has its upper parts yellowish red, the lower whitish, and the face blue. It inhabits the island of Sumatra.

Fig. 5. THE CRESTED APE (*S. comatus*), gray above, dingy white beneath, with a tuft of black hair on the head, inhabits Sumatra.

Fig. 6. The TCHINCOB (*S. Maurus*), or Negro Monkey, so named on account of its black colour, is found in the island of Java.

DESCRIPTION OF THE PLATE.—THE FISHER-EAGLES.

THOSE Eagles which are characterized by having the bill nearly as long as the head, very high, and compressed, with naked tarsi, and very large toes, of which the claws are remarkably strong, have been separated from the rest, to constitute a genus, to which the name of *Haliaeetus* is given. They are mostly maritime or lacustrine, and feed in a great measure on fish, which they frequently clutch as they swim at the surface, but which they also obtain by depriving other birds of the produce of their industry.

Fig. 1. THE WHITE-HEADED FISHER-EAGLE (*H. leucoccephalus*) may be briefly described as having the head, the neck, the hind part of the back, and the tail white, the rest of the plumage being brown; the bill, cere, iris, and feet yellow, the claws black. It is about the size of our White-tailed Fisher-Eagle, *H. Albicilla*, measuring nearly three feet in length, and seven feet between the tips of the wings. It is not uncommon along the coasts, and on the lakes and great rivers of the United States of America. "During spring and summer," says an enthusiastic ornithologist of that country, "no sooner does the Fish-Hawk make its appearance along our Atlantic shores, or ascend our numerous and large rivers, than the Eagle follows it, and, like a selfish oppressor, robs it of the hard earned fruits of its labour. Perched on some tall summit, in view of the ocean, or of some water-course, he watches every motion of the osprey, while on the wing. When the latter rises from the water, with a fish in its grasp, forth rushes the Eagle in pursuit. He mounts above the Fish-Hawk, and threatens it by actions well understood, when the latter, fearing perhaps that its life is in danger, drops its prey. In an instant, the Eagle, accurately estimating the rapid descent of the fish, closes its wings, follows it with the swiftness of thought, and the next moment grasps it. The prize is carried off in silence to the woods, and assists in feeding the ever-hungry brood of the Eagle. It now and then, however, procures fish for itself, by pursuing them into the shallows of small creeks. It does not confine itself to this kind of food, but greedily devours young pigs, lambs, fawns, poultry, and the putrid flesh of carcases of every description, driving off the vultures and carrion-crows, or the dogs, and keeping a whole party at defiance until it is satiated."

Fig. 2. THE WHITE-HEADED FISHER-EAGLE. Young. In its first plumage this species is of a uniform chocolate brown on the head, neck, and upper parts, the tail dusky, with brownish-white patches.

Fig. 3. THE VOCIFEROUS FISHER-EAGLE (*H. Vocifer*), which is of smaller size than the preceding, with the head, neck, and tail white, the back and wings dark-brown, the breast white, spotted with dusky, and the abdomen and tibial feathers brownish-red, inhabits various parts of Africa.

BRITISH BIRDS.—THE RINGED DOVE OR CUSHAT.

THE Pigeons or Doves form a very natural family, perfectly distinct from the Gallinaceous birds, to which they exhibit little more affinity than is indicated by their very large crop, which, however, is of a different form, and their granivorous habits. They

vary much in form, some having the body full, others slender, while the tail is very short, moderate, or greatly elongated. In all, however, the head is small, oblong, compressed, with the fore part rounded. The bill is especially characterized by having the nasal membrane bare, generally scurfy, fleshy, and tumid, with the narrow longitudinal nostrils placed under its anterior margin. It varies in size, but the upper mandible has its ridge always obliterated at the base, by the encroachment of the nasal membranes, and its extremity horny, arched or convex, more or less compressed, with a blunt thin-edged point. The oesophagus expands into a large crop, consisting as it were of two united membranous sacs; the stomach is a powerful gizzard, of a somewhat rhomboidal form; the intestine is long and slender; and the cæca are very small and cylindrical. The tarsi are generally short and stout, either scutellate or feathered; the foot is of that kind equally adapted for walking or perching, having three toes before, and one behind, the latter on the same level, and shorter than the lateral, the claws short, and moderately arched. The plumage is various, but the feathers have always the tube very short, and the shaft thick at the base. The wings are large, more or less pointed, and the tail is even, rounded, or graduated. Several genera, some of them founded on slight differences, have been instituted in this family. The four species which occur in Britain belong to the genus *Columba*, which may be characterized as follows: The bill rather short and slender, the upper mandible tumid and scurfy at the base, horny, arcuato-declinate, convex above, compressed, thin-edged towards the end; the wings long, broad, rather pointed, the second and third quills longest; the tail of moderate length, or rather long, straight, even, or slightly rounded, of twelve broad feathers.

THE RINGED DOVE OR CUSHAT (*Columba Palumbus*) is distinguished by having the plumage of the upper parts greyish blue; the wings and scapulars tinged with brown; the hind part and sides of the neck bright-green and purplish red, with two cream-coloured patches; the fore part of the neck and breast light reddish purple; a white patch on the wing, including the four outer secondary coverts. It is the largest of our native species, measuring about seventeen inches in length, and about thirty between the tips of the wings. It is a strong bird of its size, elegantly formed, and agreeably, although not gaudily, coloured. Its food consists of seeds of the cultivated cereal grasses, wheat, barley, and oats, as well as of leguminous plants, beans and pease, the field mustard and charlock, leaves of the turnip clover, and other plants, hench-nuts, acorns, and other vegetable substances. It is generally distributed, being found in all the more or less wooded districts of England and Scotland; but it prefers cultivated tracts, and is not found in the bare and treeless parts of the country. In winter it appears in large flocks, sometimes amounting to many hundreds, when the individuals of a district congregate in some favorable locality, although in ordinary circumstances it is not so decidedly gregarious as the Rock-Dove. Its flight is strong and rapid, being performed by quick beats of the half-extended wings, with occasional intermissions, its pinions sounding as it glides along. When it has espied a place likely to afford a supply of food, it alights abruptly, and usually stands for a short time to look about, after which it commences its search. It walks in the manner of the Domestic Pigeon, that is, with short and quick steps, moving its head gently backwards and forwards. The flock disperses and spreads over the field, it being seldom that two or three individuals keep close together, and they generally take care not to approach the enclosing walls or hedges, so that it is difficult to shoot them on the ground. In the time of snow or hard frost, they frequent turnip fields, and are more easily approached; but in general they are very suspicious and vigilant, ever ready to fly off, on the slightest appearance of danger. Frequently, however, in the woods, one may surprise them within shooting distance; and by waiting for their arrival at their roosting places in winter, considerable execution may occasionally be done among them. As the flesh of the pigeon affords a sufficiently palatable article of food, it is abundant in our markets in winter and spring, but generally brings a low price, from sixpence to a shilling.

Soon after sunset, the Cushats betake themselves to their roosting places in the woods, and before settling, usually wheel round the spot selected. Should they be disturbed, they fly off to a short distance and return; but if repeatedly molested, they betake themselves to a distant station. In severe weather they sometimes perform partial migrations, but in general are stationary, not finding it necessary to extend their range in the cultivated and sheltered districts, where turnips may always be had during the winter.

In fine weather they bask in the sun on dry banks, or in the open fields, rubbing themselves, and as it were hurrowing, in the sand or soil, and throwing it about with their wings, as if washing in water, which they do like most birds. In drinking, they

immerse the bill to the base, and take a long draught; a circumstance in which Pigeons differ from Gallinaceous birds. Nor does the Cushat, like them, scrape up the earth with its feet, while searching for food.

Early in spring the Cushats make preparations for rearing their young. Their courtship is conducted much in the same manner as that of the Domestic Pigeon, the male strutting with elevated head, protruded breast, and quick step, round the female, or, if on a branch, performing various movements and often turning round, as he utters his murmuring love-notes. At times he rises in the air, produces a smart noise by striking the points of his wings against each other, descends, rises again, and thus continues to gambol in the presence of his mate. The cooing of this species may be imitated by pronouncing the syllables coo-ron-coo-coo, the two last protracted. It is softer, deeper, and more plaintive than that of the Rock-Dove.

The nests are placed on a branch, or in the fork of an oak, beech, fir, or other suitable tree, more especially a fir or pine; and in the latter case, often only a few feet from the ground. Sometimes a nest may be seen in a holly or hawthorn bush, or in a hedge, but in general a thick wood is preferred. It is composed of twigs loosely put together, in a circular form, flat above, and varying in thickness from two to four inches. The eggs are always two, of a regular oval or sometimes elliptical form, pure white, an inch and seven-twelfths in length. It appears that two or even three broods are reared in the year.

The young are at first rather scantily covered with a yellowish down, and when fledged are of the same colour as the adult, but duller and tinged with brown, the white spots on the neck and the changing tints of that part being wanting. The colours are perfected at the first moult, the only change that they afterwards undergo being to a somewhat deeper and purer tint.

The domestication of this species has often been attempted, but almost always without success; for although individuals become perfectly tame in confinement, they embrace the first opportunity of regaining their freedom. An instance, however, has recently occurred of its breeding in captivity, as appears from the following statement made by Mr Allis of York, in the *Naturalist* of last month. "I have this year succeeded in breeding the Ring Pigeon in confinement. I took the old birds from the nest in the autumn of last year. This year they bred a pair of young, which have now passed through the first moult, and are not distinguished from the old birds."

The Ringed Dove is generally distributed over Europe, but is more abundant in the southern parts.

*On the Geographical Distribution of Animals, with an Account of the Species that inhabit the South of Devon.* By J. C. BELLAMY. Yealmspton.

GREAT exertions have been made, in every department of science, to determine principles and ascertain laws. The successful prosecution of this subject must depend, in a great measure, upon acquaintance with detail; and since this species of knowledge has recently received great accessions, philosophers have been guided by a reasonable hope, that a renewed inquiry after principles would be attended with proportionately important results. It is to be feared, however, that the difficulties of the investigation have been very often insuperable, and have hitherto prevented us from acquiring any satisfactory knowledge, particularly as concerns the geographical distribution of animals. Indeed, as to primary or first causes, the reasons of the institution of laws, or the occurrence of facts in connexion with this interesting subject, we know absolutely nothing. It has been customary, until very lately, to confound together primary or general laws, and secondary or partial laws. By primary laws, I understand those ordinances constituting the plan, system, or method, according to which the whole animal kingdom is arranged or distributed over the surface of the globe; it being opposed to reason, and at variance with all scientific considerations, to suppose that living beings have been placed on the earth promiscuously, indiscriminately, and without regard of order and adaptation.

Since the greatest benefits and most important uses of natural science depend upon the determination of principles and of general conclusions, the labour bestowed on the study should centre on this great object; and in the enumeration of facts, we should be careful to inquire, as we proceed, what effect that detail has on admitted doctrines, or what influence it might have in establishing or disclosing new views and theories. In accordance with this idea, I shall combine a recognition of laws with a statement of facts in the present paper; first mentioning the primary and secondary laws by which the distribution of animals is governed; and then entering upon the detail of zoological geography, as observed in the south of Devon; availing myself, in this second part of the subject, of every occasion to advance the knowledge of the higher department of principles and general results. It will be needful to remember, that this subject of the Geography of Animals is intimately associated with several others of great interest, and more particularly with migration and the "polity of nature;" and that these have, equally with the present question, laws, and general considerations connected with them, which are by no means to be confounded with those we are now about to state.

On inquiring how far the dispersion of animals is affected by, or connected with, the relative temperature of the earth, according to distance from the extreme points of heat and cold, we find that the animal creation is greatly accumulated within the tropics, and that it gradually diminishes in extent as we recede toward the poles. Throughout these vast spaces, however, numberless exceptions and deviations from this general ordination occur, in consequence of the influence of secondary or partial laws, as will be shown in the sequel; but the fact of the tropical countries being the great seat of animal creation, the temperate regions possessing fewer, and the polar districts the least number, is incontrovertible.

But not only do the intertropical regions contain the largest proportion of animals, both as regards species, and as regards the number of individuals, but they are characterized also by giving place to the most highly organized creatures of the whole series; while the temperate climates, and polar regions, are respectively characterized by animals having less and less of this endowment. Corresponding latitudes will therefore be found to agree in their animal productions, in so far as they will present to view creatures possessing similar degrees of organic endowment. These state-

ments, however, although defensible in a general way, are greatly qualified by secondary influences, as will subsequently appear.

The laws which we have here stated will receive elucidation by reference to the Fauna of continental mountains, where, on a small but similar scale, as regards temperature, we see the progressive advancement of numbers, and of organization, from the summit to the base, though the occurrence of highly and of lowly organized beings in both extremes forms a partial impediment to the principle. It would almost appear that we had arrived at the knowledge of one of the primary causes of natural phenomena, in finding such definite results in connexion with heat and cold; but there are too many and too palpable exceptions to this rule to allow of such a conclusion. If animals were governed, in their dispersion, by heat and cold, except in a secondary and partial way, quadrupeds and birds, belonging to the same tribes as are found within the tropics, would not be present in polar or alpine situations.

There is no portion of our globe, even the most desolate, which is not at times visited by certain of the higher animals, and also permanently inhabited by certain kinds of insects and inferior creatures. It thus appears, that, besides the lower orders of animals being more numerous than the higher classes, they are likewise more generally dispersed. The resources of the lowest tribes are, in all probability, so obscure and occult as to be not only unknown, but even inconceivable to our minds; on the other hand, wherever vegetation attains to any tolerable degree of perfection in its various forms, there a whole series of animal productions presents itself. If the extent of the Flora and Fauna of any given country be examined into, the above result will infallibly be arrived at.

One primary law on which the distribution of animals depends, having a pretty general influence, and which seems indeed altogether in unison with the aggregate of our zoological knowledge, is the gradual failure in number of individuals of a given species as we recede from the point which, from their comparative plenty there, we presume to be their principal seat. Together with this numerical failure, we see likewise, as might easily be conceived, a failure, or deterioration in size, in qualities, in colour, and in all other endowments. To so great an extent is this occasionally carried, that naturalists are frequently at variance in their decisions on the species, some considering such specimens as deteriorations, others viewing them as separate species, or at least as formal varieties. It is seen that, independently of distance from the seat of luxuriant growth, and great numerical increase, specimens having all the appearance of such as are found at the very verge of the geographical range of a species, are constantly detected within short distances of, or absolutely in the metropolis itself. There are unquestionably two sets of causes in operative influence on animals in regard to distribution, and it is of great moment to refer the phenomena connected therewith to the right sources. The primary causes are quite unknown to us, and are likely to continue so, though it would appear that the various parts of the organized creation being ordained to counterbalance each other; that, as the laws of dependence pervade the world of living beings in all its parts, any determination or regulation, such as the one mentioned, namely, the diminution of numbers and deterioration in size and qualities of individuals, provided it were general, and observed in all classes and species, need not excite surprise.

The secondary causes appear to be temperature, food, situation, and the hostility of other species. The influence of these appears to be very considerable, and though we cannot be altogether warranted in attributing the above-named circumstance of diminution of number and deterioration in size, &c. to these causes, however plausible it might seem to do so, they are undoubtedly the agents that cause deteriorations generally. These secondary causes become indeed of the greatest moment in investigating the zoology of a given district. Primary laws can be seen and estimated only by reference to zoology as a whole, by taking into our view the phenomena exhibited by the entire series of animals; secondary causes must be appreciated by examining the phenomena of animal geography on smaller scales. It is then we see temperature, food, situation, and other circumstances, operating to the production of certain modifications in the distribution of animals, within a comparatively small compass, while the primary laws influencing their situation on the earth are uninterrupted, and, as it were, overrule the others. In confirmation of the supposition that the gradual lessening of numbers, and gradual deterioration in size and other qualities of individuals of a species, as we recede from their metropolis, depend on a primary law, we see the same rule applied to entire tribes and classes of animals in numerous instances. If secondary causes, such as food or climate, determined the limits of species, it would not be found that the verge of the range of one species was the principal seat of another possessing similar endowments and organization, and feeding for the most part similarly. The reasons or causes then of this peculiar law, or ordinance of Nature, are hidden from us. The great seat of the feline tribe is in the tropical regions, and we see the species there found gradually diminishing in number of individuals as we advance northward. We see also that the individuals situated at the outskirts of this great metropolis of rapacious creatures, are diminished in their size and bodily vigour, and that their ferocity has suffered decrease. The place of this tropical series is now supplied by a new set, and a third still more northwardly may without exaggeration or difficulty be detected, each undergoing within its own limits the same gradual diminution and deterioration. Eventually, if we compare the contents of the two opposite points with regard to this genus, the difference becomes remarkable: we find the species few, the individuals also few, their size small, and their vigour and ferocity greatly reduced at their northern limit, while at the point where we commenced these features are totally reversed. The principal seat of the cetaceous animals is in the arctic and antarctic seas, different species occurring at these two extremes; they gradually diminish in number as we enter the temperate regions; and are at their minimum in the equatorial seas. The Turtle and Tortoises are chiefly inhabitants of the warm latitudes; yet they extend sparingly northwards, and even in England a few stray individuals have been captured, the Hawk's-bill Turtle in the Severn, in Orkney, and in Zetland, and the Leather Tortoise in Cornwall. Peron says, "the seat of the Phasianellæ is at Maria Island; all traces of them are lost at King George's Sound, after passing through insensible gradations." The Corals and other zoophytes, so plentiful and luxuriant in tropical seas, are replaced in temperate climes by (for the most part) a new series of less size and less luxuriant aspect; yet the tropical genera and species

still linger with us in spare quantities. In England the Madreporæ are reduced to two or three species, of rare occurrence and diminutive size; the Gorgonias are also comparatively small; and the *Gorgonia flabellum* of the tropics has been two or three times found on the Cornish and Leith shores. Instances of this kind might readily be multiplied.

It appears, from the foregoing remarks, that however desirable it might be, in all inquiries like the present, to determine general or primary laws, and that however obvious it may be that such determinations should be the principal aim of naturalists, yet the subject we are inquiring into will scarcely allow us to proceed farther than the discovery of secondary influences. But since these are liable to have an undue importance ascribed to them, and to be viewed as primary laws, it would be right, as far as possible, to ascertain their absolute weight, and to see how far they modify those more general influences.

It remains to be observed, that there are a certain number of facts in the Geography of Animals which do not appear to come under any law; nor are they explainable by, or referable to, any cause of which we have knowledge. No species of animal is cosmopolitan, but the extent of geographic range of species varies very largely. The greatness of this extent, however, is, except in a comparatively few cases, so ordered that there are certain divisions of the globe inhabited by races of animals peculiar to them, these races defining, as it were, by their limits, the zoological divisions of the earth. Thus, with a few exceptions (not considering those cases in the northern parts, where the two continents join or approximate), the Fauna of America is peculiar to it; and the same may be said of Australia, with the difference only of still fewer exceptions being present. Now, besides the exceptions to this rule of exclusive Faunas, the ranges of animals within their zoological divisions is frequently very extensive; whilst, on the other hand, the limits of very many are extremely circumscribed, sometimes a small spot of land, or a single river, being the extent of the habitat; in all of which cases, no clue to the cause of such peculiarities can be discovered. Indeed, unless we at once confess that animals occupy stations on the earth assigned to them by the will of the Creator, and determined only by a Providence and an Omnipotence perfectly inscrutable by us, we must be content to believe that animal distribution depends on circumstances connected with the constitution of the species, of the nature of which we are ignorant, and likely to continue so. It is not enough to point out instances of evident adaptation of animals to the circumstances which surround them, or to show that their peculiar food is found around them; for it might easily be demonstrated, that, in numerous cases, the same circumstances and the same food abound where the animals never come, and where, if brought by man, they readily become naturalized. It is not enough to say, that, in the instances where no adaptation is manifest, it nevertheless must exist, because we see that these animals are invariably found in one particular kind of situation; for, although some do certainly confine themselves as thus stated, yet they are frequently peculiar to one region or spot, and denied to others equally suited to their existence; besides which, there are kinds that, in seeming opposition to the whole analogy of zoological science, occupy a range of country or of abode, including opposite kinds of circumstances and situations, and these instances occurring too in the same tribe or family, where, as above stated, adaptation was in some species proved by the uniform character of the abode.

With respect to migration also, the causes are not always obvious, for birds of precisely similar endowments and character observe different habits, some migrating, and some being fixed; whilst at times the migrating species will for the winter remain with us, and seem to live as well as our common residents, so that the reason of migration is not always clear. The Llama and Vicugna, and the Sapajous, are peculiar to America; the Ornithorhynchus, Kangaroo, and Wombat, to New Holland. The Jay inhabits equally almost every country of Europe, and the immediately adjoining Asiatic countries, but extends no farther. The Barn Owl inhabits Europe, America, and part of Asia, and to my own knowledge some of the South Sea Islands. The Peregrine Falcon inhabits Europe, America, and Australia. The Blue Jay is confined to North America, the *Leptocephalus morisii* to the southern shores of England; and the *Physsa alba* to the River Towyn of North Wales. The Sapajous, or prehensile-tailed Monkeys, are certainly well adapted to the forests of America; but are they less suited to the forests of other countries? The Nightingale certainly finds its peculiar insect food in those countries, and counties in England, to which it now resorts, the climate also being congenial to its feelings and habits; yet though it is found in Sweden and Germany, it is absent from Scotland and Northumberland, and though it is found in the middle and some southern counties of England, it is not seen in Devon or Cornwall. The Great Bustard is found enjoying a distribution latitudinally, whereas the same climate, situation, and food, could be obtained to the north and south of this zone. The *Achatina acicula*, though found in some limestone districts of England, has never been seen in the south of Devon, where lime abounds. The Swallow never migrates to America or China, though the food and climate there would suit its constitution. The Hedge Warbler is stationary, while the Blackcap migrates. Lastly, the Willow Wren, which ordinarily migrates, will yet at times remain with us through the winter.

The first of those secondary causes or influences, ranking as laws of geographic distribution of animals, which we shall mention, is *Climate*, a term which includes a consideration of temperature, of seasons, of winds usually prevalent, of the dryness or humidity of the air, of rains, drought, continued cold or heat, &c. It deserves notice that the presence of mountains, rivers, seas, barren spots, the quality of soil, the degree of cultivation, and the clearness or cloudiness of the sky, have all some influence in forming the climate, and in consequence the Fauna of a country. Secondary laws seem to act and re-act largely on each other, so that no one of them appears to have a separate or unmixed influence on animal distribution. The influence of climate on the distribution of animals may at once be seen by considering the vast increase of living beings as we approach the equatorial regions from the poles; but then it must be clearly understood, that this effect of climate, or rather of heat, is observed only in a very general way, and that, owing to a great variety of causes, some quite incomprehensible, others connected with food, situation, &c. The interruptions of this rule of increase are both numerous and important; still, on the whole, heat may be considered

one of the secondary causes that influence the geography of animals. The alternations of the seasons, which, besides bringing an alteration of temperature, induce considerable difference on the food of animals, have a decided influence on their situations, causing a variety of movements termed Migrations. These changes of place are more immediately dependent on temperature and the state of the atmosphere, than on food, or other causes. Winds frequently affect the Fauna of a country, by driving aquatic animals to land, or by putting migrating animals from their destined courses. The state of the atmosphere as regards dryness or humidity, together with a continuance of rains or drought, will affect the general nature of the climate, and thereby the vegetable produce and animals of the country in which such conditions occur. Unusually hot or fine summers are most likely the causes of our receiving certain birds from the southern parts of Europe at that season. Long continuance of wet and cold at the time of the autumnal migration, will influence the period of departure of perhaps all our summer visitants.

Geographical situation, relations, and arrangement of a country, have considerable power over the extent and nature of a Fauna. The adjacency of an ocean, or large river in connexion with the sea, implies of course the presence of marine productions; the intersection of a country by smaller rivers and inland waters, will afford fluviatile and lacustrine animals; mountains and hills are the resorts of a variety of creatures; heaths and uncultivated spots have their peculiar animals; cultivated land, by originating a large proportion and variety of plants and trees, invite thither a great variety of passerine and other birds, either in search of insects in connexion with the vegetation, or for the purpose of feeding on the various seeds; together with the passerine birds are found the Climbers, they being insectivorous; and, lastly, certain of the Hawks, or other predatory birds allured thither by the presence of smaller species.

Such is the usual ornithology of many of our wooded districts in Devon, and notwithstanding that we owe much to our hills and heaths, perhaps our geographical position and our relations to other countries, and, above all, the extent of our woods and cultivated ground, may be considered as more generally influential in determining our species of birds than any other secondary cause. Certainly Devon and Cornwall are two of the mildest counties in England, and in conformity with that character, the Stone Curlew has been known, according to Montagu, to remain all winter with us at the Start, the most southern point of land in England, except the Lizard in Cornwall. So also the Chiff-chaff was observed by the same eminent naturalist to stay the winter with us near his house at Kingsbridge.

Storms and other phenomena of weather referable to the head Climate are, as above said, and as will in the sequel be illustrated, of considerable consequence in forming and influencing a Fauna; but Climate is very much dependent on situation, arrangement, and other local circumstances of a country, especially adjacency of sea, which renders the temperature of all countries bordering on it mild and agreeable, provided the prevalent winds are in a direction from it. If Devon were not situated in connexion with the sea, of course no mildness of climate, or storms, or phenomena of that kind, could confer on us those marine products so conspicuous in our Fauna; and if our situation were not at the southern limits of the island, and opposite to the southern states of Europe, we should necessarily have none of those animals which by accident, or the invitations of unusually fine weather, cross over to experience the gentle warmth of our summer, or else are driven by the violence of equinoctial storms on our coasts; or, lastly, in the case of autumnal migrants, are enticed to stay the winter with us by reason of our southernmost locality, together with agreeably genial warmth.

The Flying-fish has occurred to the north of us, in the Bristol Channel, possibly under the influence of equinoctial gales; yet our situation must be taken into account rather than this phenomenon of our climate. The *Hippocampus vulgaris* and *Echineis Remora* have both been captured on our shores, yet situation, equally with, or probably more than climate, should be regarded as the cause. Many of our birds are influenced in their visits hither, and in their stay with us in winter, as well as in many peculiarities of movements exhibited by them, by our climate; but the abundance of wood and shelter, and the diversification of the surface of our country, will alone supply some explanation of the vast number of terrestrial birds found with us. Consequently, not only must we be compelled on most occasions to consider these two causes of distribution, climate and geographic position, with the other physical conditions of a country, in connexion, but to reflect that the latter influence is of the two the more powerful and extensive in operation.

If it were demanded of us to state the general nature and qualities of the climate of South Devon, we should say it was characterized by equality of temperature and humidity of atmosphere. Our summers are short, generally fervent, and attended by long droughts; our autumns are particularly rainy; our winters stormy, and sometimes very cold and lengthened; our springs chilly, unsettled, deceptive, and on the whole characterized by frequent intervals of gentle warmth of short continuance, between the long-continued rains, the protracted blasts, and blighting winds, ordinarily prevalent. Vegetation having made several unavailing efforts in these intervals, and having received frequent checks and blights, is at length permitted to put forth its energies in May. Occasionally this month is with us unusually dry and fine, so as to be productive of calamitous consequences both as regards the feeding of cattle, and the crops of grass and corn; for at this period vegetation makes its greatest efforts, and requires a supply of moisture to proceed with, in defect of which the harvests are rendered late and scanty, and cabbages and other garden produce are greatly injured. All this happened to us last year. Occasionally also, and such was our lot in the present year, May is uncommonly unpropitious, and vegetation makes no decided advances till June. On 24th March, snow fell and lay three or four inches deep, and ice formed in the estuary of the Yealm half an inch in thickness. On the 2d April, snow again fell; on the 11th, a fresh deposit took place, and in some spots remained two weeks. There were no leaves on the trees till after the first week in May! In the end of March, frosts even entered our hot-houses, and destroyed the young grapes.

According to my remarks, the arrival of spring birds of passage is deferred in accordance with the weather experienced in that season. They arrived late in the present year, or, at all events, were not seen or heard till after their usual periods. It is much easier to state facts than to assign reasons for facts; and so in the present

case it will be found rather speculative to trace out the sources of these characters of our climate, and which it is requisite to do, because these sources will be found in the other physical conditions of the country, and themselves influential on the geography of animals, proving, as before said, that these secondary causes do not act independently of each other.—(To be continued.)

**THE SPARROWHAWK.**—Every person who attends to the habits of birds, must have seen this Hawk pursued by a troop of Swallows or other small birds, which hover over and behind it, for what purpose is not well known. One fine evening last month, just after sunset, we observed one flying at a moderate rate over the fields, with a Pied Wagtail close upon it, and loudly uttering cries of alarm. It is probable that the Hawk had carried off its companion, although we did not perceive any thing in its talons. It is commonly said, that small birds venture to pursue these marauders only in bands, which, by flitting about, distract their attention, and thus prevent them from siogling out an individual; and we do not remember to have ever before seen a single bird have the audacity to follow its dreaded enemy.

## BOTANY.

### THE CINNAMON TREE—*LAURUS CINNAMOMUM*.

The natural family *Laurineæ* contains many highly interesting plants, which are strikingly similar in their properties, and perhaps none is more important than the present species, which grows in great abundance in the island of Ceylon. It has also been introduced into several parts of South America, and many of the West India islands. The tree grows to the height of 20 or 30 feet, and the diameter varies from 12 to 18 inches. The bark of the trunk is ash-coloured and scabrous, while the inner bark, which is of a reddish colour, is the cinnamon of commerce. The bark of the young shoots is smooth, and often beautifully variegated. The leaves are opposite, elliptical, pointed at both ends, entire, three-nerved, and of a bright green colour. The flowers are arranged in the form of a paniculated umbel, and are of a greenish white colour; corolla of six acute, oval, and spreading petals, of which the three outer are broader than the others; stamens nine in number, thus referring it to the Linnean class *Enneandria*, while the single pistil indicates the order *Monogynia*; filaments flattened, and arranged in three sets, shorter than the corolla, and at the base of each inner petal two small round glands are situated; the germen is oblong; stigma angular and depressed. The fruit is of a deep blue colour, being a pulpy pericarp containing an oblong nut, and the whole somewhat resembles a small olive. The cinnamon of commerce is the inner bark; camphor may be obtained from the root; a highly flavored oil is distilled from the leaves; the cassia buds of the shops are supposed to be the receptacle of the seed; and in Ceylon, candles are made from the kernel. The cinnamon generally arrives at perfection when the tree has attained the age of about six years, and only the small shoots are stripped of their bark, which, being made into bundles, is sent to Europe. Independently of its well known use as a condiment, it is also employed in medicine. The fragrant smell, the pungent and glowing taste, as well as all its properties, depend on an essential oil, of a whitish yellow colour, which is obtained by distillation from the bark. Cinnamon, being a most grateful aromatic, is stimulating, stomachic, and tonic, but is seldom used alone, being commonly exhibited along with other remedies which are more powerful. The oil has a very pungent taste, and is a powerful stimulant, being sometimes employed in cramp of the stomach, paralysis of the tongue, and in toothache. But its principal use is to cover the taste of other disagreeable drugs. A watery infusion of the bark is often advantageously given to check vomiting, and relieve nausea. Cinnamon, however, is more prized by the cook than by the physician.

**VICTORIA REGINA.**—Mr R. H. Schomburgk has recently communicated to the Botanical and Geographical Societies of London, an account of a remarkable species of plant belonging to the natural family of *Nymphaeaceæ*, which he discovered on the 1st January 1837, on the river Berbice, in British Guiana. The leaves are from five to six feet in diameter, orbicular, flat, with a raised margin from three to five inches high; their upper surface bright green, the lower crimson, with eight principal nerves, nearly an inch high, and numerous subordinate branches, and beset with prickles. The

young leaf is convolute, and expands but slowly, rising at first above the surface, but when expanded falling upon it. The stem of the flower is an inch thick near the calyx, and, like the leaf-stalk, is covered with prickles. The calyx has four sepals, each upwards of seven inches in length, and three in breadth, reddish-brown, and prickly externally, white on the inner side. The petals are very numerous, those next to the sepals larger, fleshy, and of a white colour, their general form oblong; the inner petals gradually smaller, bright red, and passing into the stamens. The flowers measure from twelve inches to nearly two feet in diameter, and finally assume a pink colour all over. The fruit is globular, prickly, many-celled, with numerous seeds. It appears, however, from a note by Dr Weissenborn, in London's Magazine, that it is the *Euryale Amazonica* of Dr Pöppig; and even if it were new, its name, if it is necessarily to confer honour on our Queen, or to be honoured by her, ought to be Victoriana at least, agreeably to all precedent. A coloured figure will be seen in the Number for December 1837 of the Magazine of Zoology and Botany.

## MISCELLANEOUS.

**REMARKABLE CAVERNS IN BRAZIL.**—Dr Lund, a Danish traveller, now in Brazil, has discovered in the mountain chains between the Rio Francisco and the Rio das Valhas, a great number of caverns, among which, Sappa nova de Marquidé, in the Sierra de Marquiné, is one of the most remarkable. The mountain consists of clay-slate, flinty-slate, and transition-limestone, in which last is the cavern described. Its total length, from north to south, is 1440 feet, the height being from 30 to 40 feet, and the breadth from 50 to 60. It is separated by masses of stalactite into twelve divisions, of which only three were known before Dr Lund explored them. The others, especially the innermost, were of such extraordinary beauty, that his attendants fell on their knees, and expressed the greatest astonishment. On the river Valhas, the banks of which the traveller afterwards traversed, the vegetation assumes a peculiar character. The inhabitants call the forests *catuigas*, or white forests. They form a thicket of thorny trees and bushes, interwoven with parasitical plants of the same nature. The leaves fall in August, and, from the beginning of September till the rainy season, the *catuigas* are as bare as European forests in winter. On this excursion Dr Lund had an opportunity of examining nineteen caverns, all of which confirmed his opinion of their geological formation. He has collected many remarkable particulars respecting the circumstances which must have taken place in a great inundation, as well as respecting its effects, and convinced himself, by several indications, that its course in South America was from north to south. In three of the nineteen caverns which he explored, he found petrifications of quadrupeds, which he had not discovered in the Marquiné cavern, viz. *Cervus rufus*, *Coelogenys paca*, *Cavia aperia*, six Bats, four Mice, *Lepus Braziliensis*, and an Owl. In the first mentioned cavern he found two species of ruminating animals, far larger than those now living in Brazil, and a Megatherium, of the size of an Elephant.—*Literary Gazette*.

**EARTHQUAKE IN CROATIA.**—The following is an extract from a letter, dated Agram, October 15.—“We have lately witnessed an extraordinary phenomenon. Since the 1st of October, loud rumblings have been heard, proceeding as if from under our feet; the affrighted cattle were hurrying in all directions, the wild animals entered even into the very streets of the city, and the birds of prey settled on our roofs, and allowed themselves to be taken without resistance. The would-be-wise and fortune-tellers, of whom we have an overabundance, predicted the end of the world, or, at the very least, some great revolution of nature. On the 6th of October, about three o'clock, a loud noise similar to a discharge of artillery was heard, and the earth trembled. The alarm was now general, and people quitted their houses, and fled to the open country. The bells rung of their own accord, and many houses were overturned. These reports continued at intervals of half an hour, or an hour, till the evening; during the night they occurred at longer intervals, and the trembling of the earth was less powerful. On the morning of the 7th, two reports were heard, and the motion of the earth then ceased altogether. The air became cooler, and a north wind began to blow. The barometer was at 28° 4' 10'', and the thermometer at 7° above zero. Fortunately no lives were lost by the falling of the houses, but three women and two children have died from fright, and more than sixty persons are suffering seriously from fear and exposure to the weather. Letters from different parts of the country announce that the noise was heard and the shocks felt throughout the extent of Croatia, and that much damage has been done and many lives lost.”—*Athenæum*.

**CORROSIVE QUALITY OF EARTHY SUBSTANCES.**—M. C. Moritz, a German, who is now travelling in the north of South America, and whose letters are successively publishing in the *Berlinische Nachrichten*, passed near Guigue, over tracts from which the lake has retired,—the former extent of it being indicated by strata of little petrified fresh-water shells of the same species, which are still living in the lake. The dust which arises from the pulverization of these shell-beds has a corrosive quality, and, when brought into contact with the human skin, causes a very disagreeable burning sensation, from which M. Moritz had much to suffer, and which he ascribes to the remains of the helicitæ. The inhabitants of the district use to say, *El arena de la laguna pica*. It appears, however, that this quality of the dust is to be accounted for by the admixture of saline particles, as M. Michel Chevalier was annoyed in the same manner in 1835, when travelling in Mexico over those beds of ancient lakes, which, by the laceration of their high banks through earthquakes, have been changed into dry savannahs. These lakes appear to have been salt, as there are many extensive deposits of rock-salt, and as the ground is in many places so impregnated with muriate of soda, that it is altogether unfit for cultivation.—*W. Weissenborn, in London's Magazine*.

FEBRUARY, 1838.

## ZOOLOGY.

## DESCRIPTION OF THE PLATE.—THE BEARS.

THE genus *Ursus* is composed of animals, generally of large size, which are for the most part frugivorous, although some of them feed also on flesh, and all of them readily become carnivorous when their ordinary food cannot be obtained. They belong to the Plantigrade Tribe of the Carnivora, characterized by walking on the entire soles of their feet, and by having five toes on the posterior as well as the anterior extremities. The Bears are of an apparently unwieldy form, with thick and muscular limbs, a very short tail, rounded ears, and a rather sharp muzzle. They pass the winter in a semitorpid state, without food, in cavities dug by themselves, and lined with leaves.

Fig. 1. 2. THE POLAR BEAR (*Ursus maritimus*). The size and ferocity of this species was greatly exaggerated by the older navigators, one of whom alleges that the skin of a White Bear killed by him and his companions measured twenty-three feet in length, while another states that the Bears frequently seized on the seamea, carried them off with the greatest ease, and leisurely devoured them within sight of the survivors. It appears, however, that the ordinary length does not exceed from seven to eight feet, and that, although carnivorous, it is not essentially a predatory animal, but prefers the carcasses of whales and fishes. It also lies in wait for seals at the openings of the ice, and seizes them with great dexterity. Dr Richardson states that, in autumn, it searches the shores for berries and other vegetable substances. The Polar Bear is of a more elongated form than the species which live in the forests, and the outline of its forehead and muzzle is straight, without the indentation between the eyes observed in them. Its neck is nearly twice as long as the head, its ears are very short, and its feet are larger than those of the Brown Bear. The fur is yellowish white, short on the head, of moderate length on the back, long and woolly on the sides, belly, hinder parts, and legs. It inhabits the shores and icebergs of the polar seas, rarely extending its range beyond the arctic circle. The females retire to their winter quarters in December, and come abroad with their young in March or April.

Fig. 3. 4. THE BROWN BEAR OF EUROPE (*U. Arctos*). This species formerly inhabited the whole of Europe, as far south as the Alps and Pyrenees; but it has long been extirpated in the interior of France, in Holland, Germany, and the British Islands. It is plentiful in Siberia, extends as far eastward as Kamtschatka and Japan, and occurs more sparingly in North America. Its usual length is about four feet, its height two and a half, and it is covered with a long, soft, woolly fur, which, in young individuals, is of a deep brown, while, in the older, it has a mixture of yellowish-grey and reddish-brown. During the summer and autumn it lives chiefly on roots, leaves, and fruits, occasionally also on small quadrupeds; and at the approach of winter betakes itself to the hollow of a tree, or a crevice in a rock, or a retreat constructed by itself of branches of trees, and lined with moss, subsisting during the winter by the absorption of the fat which it has accumulated. Towards the middle of spring it again comes abroad, and at this period, being urged by hunger, is more dangerous than at any other, although it never attacks man unless provoked.

Fig. 5. THE BLACK BEAR OF AMERICA (*U. Americanus*). The American Black Bear differs from the Brown Bear of Europe, in having the forehead less elevated, and the fur, which is of a glossy black, composed of soft smooth straight hairs. It is abundant in Canada, the Rocky mountains, and most of the thinly peopled districts of the United States. Its food consists chiefly of vegetable substances, but it also preys on animals of various species, sometimes makes great havoc among pigs, and now and then seizes a calf or a sheep. The females always retire to their winter quarters when the frost sets in, but, in the southern districts, the males often remain abroad all winter. The flesh of this species, as well as that of the European, is considered good food, and the bear hams are said to be excellent.

## DESCRIPTION OF THE PLATE.—THE MUFFLED COCKATOOS AND PARROTS.

THE Parrots, which Linnæus considered as constituting a single genus, have latterly been constituted into a family, under the name of Psittacidæ, the various subdivisions of which it is unnecessary here to describe, as the subject will be resumed in another part of our work. These birds may be briefly characterized by their short feet, of which the toes are flattened beneath, two of them only directed forward, their compact body, large rounded head, and short strong bill, of which the upper mandible is hooked, while the lower is truncate at the extremity. Their wings are generally short, and their tail exhibits a great variety of forms, being sometimes short and even, sometimes graduated and of extreme length. They are all frugivorous, and reside in the

warmer regions of the globe, climbing among the branches by means of their feet and bill. Their plumage is ornamented with the most gaudy colours, and as they are easily kept in captivity, and may generally be taught to articulate words, they are favourite domestic pets.

Fig. 1. THE ROSE MUFFLED COCKATOO (*Calyptorhynchus Eos*) has the head, neck, and all the lower parts, rose coloured, the rest of the plumage grey. It inhabits Malacca.

Fig. 2. THE RACKET-TAILED PARROT (*Psittacus setarius*) is so named on account of the elongated shafts of the two middle feathers. It is of a bright green colour, with a red spot on the head, and a band of red and yellow across the hind neck.

Fig. 3. HUET'S PARROT (*P. Heutii*). Light green, the head yellow, the edge of the wing and the tail feathers bright red, the latter tipped with green.

Fig. 4. PRETRES' PARROT (*P. Pretrei*). Light green, the forehead and sides of the head, with the edge of the wing, the alæ and primary coverts carmine red.

Fig. 5. THE MITRED PARROT (*P. mitratus*). Bright green, with the upper part of the head rose coloured.

## BIRDS OBSERVED ON THE FRITH OF FORTH IN DECEMBER 1837.

On the 27th December, accompanied by a young friend, I crossed by the ferry-boat from Trinity to Kirkcaldy. The water was exceedingly smooth, for although fleecy clouds drifted rapidly eastward, it was calm below, and the sun emerging from the clouds gave promise of a fine day. At first, no birds were to be seen, excepting one or two wandering Gulls, which hovered and wheeled in silence over the water; but when we had proceeded about a mile, small parties of Tarrocks, *Larus ridibundus*, advanced, screaming, and now and then dipping in pursuit of their prey. Farther on, numerous little bands of Guillemots and Auks, *Uria Troile* and *Alca Torda*, were seen flying up the Frith, or floating on the water. These birds, which are precisely similar in their manners, and differ very little in appearance, float lightly, with erect necks, dive with rapidity, partially opening their wings as they plunge headlong into the water, and fly in strings, at the height of two or three feet from the surface, with a direct and rapid motion, simultaneously inclining themselves alternately to either side. Six large Cormorants, *Phalacrocorax Carbo*, with sedately flapping wings and long outstretched necks, presented an interesting sight, as they flew past in a line, almost touching the smooth water. Small groups of Red-throated Divers, *Colymbus Septentrionalis*, composed of from two to four or five individuals, now and then shot past in rapid flight, and scarcely at a greater height than the Guillemots, although on many occasions I have seen them fly at a great elevation, especially in rough weather. A few Great Northern Divers, *Colymbus glacialis*, also made their appearance, flying precisely in the same manner as the red-throated species, but with somewhat less rapid motions of the wings. A single Great Black-backed Gull, *Larus marinus*, sailed quietly along at a considerable height, and now numerous groups of the Black-headed Gulls, at this season of the year however unhooded, danced buoyantly and gaily at the distance of a few yards from the water, often wheeling, and occasionally stooping to pick up some small fish.

The tide was rising, and almost all the birds were advancing in the same direction toward the entrance of the inner Frith or estuary. Passing Kinghorn, and entering the Bay of Kirkcaldy, we found the number of Guillemots and Auks diminished, while the Gulls had disappeared; but here vast numbers of Velvet Ducks, *Oidemia fusca*, were dispersed over the waters in groups of from two to fifteen or twenty. In a flock that rose before us, however, I counted thirty-eight individuals. These birds, on account of their black colour, and large size, have a remarkable appearance, which is rendered still more so when they are on wing, as then the white patch across that organ becomes exceedingly conspicuous. They swim lightly, and fly with moderate speed, at the height of three or four feet. In rising from the water, they ascend very gradually, striking it with their wings along a distance of two or three yards, and in alighting they settle as it were upon their hinder part, and then fall forward. Interspersed among them in smaller numbers were groups of the Black Duck, *Oidemia nigra*, a species very similar, but inferior in size, and destitute of white on the wing. It exhibited precisely the same modes of flying and swimming. A shot fired by a person on board at the ducks, started from a rock off Seafield Tower, a large flock of Turnstones, *Streptilas Interpres*, and from another in its vicinity, a smaller flock of what seemed to be Dunlins, *Tringa alpina*. Finally, on approaching the harbour of Kirkcaldy, we saw a single beautiful Long-tailed Duck, *Anas glacialis*.

Having walked to Queensferry, we there went on board the steamer from Newhaven to Stirling, at eleven o'clock next day. The surface of the Frith was exceedingly smooth, and from Queensferry to Charleston was sprinkled with Guillemots, Auks, Divers, and Gulls. The latter, however, were chiefly congregated, to an extent that one could hardly have conceived, along the northern shores, over the eddies of which they hovered in pursuit of the young herrings that had been stationary there for several weeks. The number seen at one glance along the coast could not be less than a hundred thousand. The different species were easily distinguishable. Possibly nine-tenths of the individuals belonged to the Black-headed kind, *Larus ridibundus*, a most inappropriate name by the by, as its cries bear no resemblance to laughter. The young birds of this species were comparatively few, and did not generally keep apart, though sometimes small groups of them might be seen; of the remaining tenth, one half belonged to the Common Gull, *Larus canus*, of which there seemed to be more young than old birds. The other half was composed of Herring Gulls, *Larus argentatus*, young and old, Smaller Black-backed Gulls, *Larus fuscus*, and Greater Black-backed Gulls, *Larus marinus*, the latter in very small numbers. Two Feasers were seen, both young birds, of a dusky colour, with the wings mottled with whitish, the tail even, and therefore probably *Lestris pomarinus*. They did not attack the Gulls, but fished for themselves, picking up the small herrings from on wing.

The Guillemots, which were very numerous, but kept chiefly in the open part of the Frith, sometimes rose as the vessel approached them, and ran, as it were, along the surface in a straight line, flapping their wings all the while, to the distance of a hundred yards or more, although most of them dived when we came near them. The Red-throated Divers, which, although similar in colour to the Guillemots, were easily distinguished by their superior size, and the comparatively greater length of their necks, also frequently rose and splashed along to the distance of from two to four hundred paces. Although they fly with great speed when fairly on wing, they are heavy birds, and, in removing to a short distance, apparently do not think it necessary to rise into the air as a Gull or Tern would do, but shoot out in a straight line, striking the water with their wings and feet, the latter, in particular, throwing it to a distance behind.

Above Charleston, the Gulls and Divers disappeared from the open water, and the flocks of the former seen along the bays were not more numerous than they would be in ordinary cases. At Bo'ness, on the southern side of the Frith, not a single bird of any description was to be seen. Near Alloa, however, we observed a flock of smaller Black-backed Gulls, *Larus fuscus*, composed of thirty-eight individuals; and farther up many birds of the same species, with a few of *Larus canus*, *Larus argentatus*, and *Larus ridibundus*, were seen floating here and there in the bays. In the narrow part of the estuary, of which the flat margins are secured by low embankments, and sometimes fringed with very tall reeds, *Arundo Phragmites*, a Heron, a flock of Knots, *Tringa cinerea*, several Mallards, *Anas Boschas*, and three Red-breasted Mergansers, *Mergus serrator*, were observed.

On the whole, few sights could be more interesting to the ornithologist than that of the vast number of sea-birds which are at present collected in the Frith, and especially in that part of it above Queensferry, to which doubtless they have been attracted by the great shoal of small Herrings which have sought refuge there, and which are caught in great quantities by the fishermen, and sold in the neighbouring towns as an article of food.—W.M.G.

#### ON THE GEOGRAPHICAL DISTRIBUTION OF ANIMALS.—NO. II.

THE great source of the general equability and mildness of our climate is certainly our connexion with the sea. The humidity of the air is referable also to the adjacency of the ocean, the sea winds conveying with them the continued exhalations from its surface; but it depends likewise on the presence of our hills, which are great accumulators of vapour, and attractors of the lower clouds. A great influence is also exerted by our inland waters, which exhale considerable quantities of moisture. Lastly, the great abundance of trees, and of vegetation generally, must have the effect of condensing a large quantity of vapour, and of collecting a great quantity of rain, and subsequently yielding it to the atmosphere. But the great alterations effected in the appearance of our country by such extensive plantation and culture of various kinds of vegetable produce, influence not only indirectly our Fauna through the medium of climate, but also act directly on animals by accommodating a larger number than could otherwise find subsistence with us. This adoption of new residences by animals is a fact so generally allowed that I need not here insist on it.

I have stated that equability and mildness of climate influence our Fauna; but does humidity also? I am not aware that it does. The two principal seasons in which our Fauna is rendered extensive are, on the one hand, winter, when cold and storms cause a great variety of waders and water-fowl to seek our shores, and, on the other, summer, when the sun approaches us for a short space of time, and when humidity is in a great measure obviated by the absence of sea winds. At all other seasons but summer, our climate is rendered colder than it would otherwise be, by the great abundance of our wood, which forming considerable shelter, keeps off the benign influence of the sun's rays. Perhaps also, when our summers are not very hot, the earth does not imbibe so much caloric as to allow of its giving off any subsequently, to temper the severity of the winter's cold. This is in some measure borne out by our experience of the last year. On the other hand, a compact soil, such as is ours, generally has the quality of imbibing the fervour of the summer's sun, without restoring it to the air so readily as do loose sandy soils, so that a scorching atmosphere is to a great extent prevented. On the whole, our summers may be stated as being generally moderately hot, thereby preserving the character of uniformity to our climate, other circumstances above named having only minor degrees of power. Other alterations in the surface of a country besides planting and culture affect the number, condition, and situation of animals; many are exterminated by man's interference, some are thereby excited to unusual multiplication, many are restricted in their numbers, or in their range, or in both; and some are encouraged to disperse locally or generally. The alterations here referred to comprise tillage, draining, irrigation, fencing, building, &c. As regards Devonshire, we find the number of quadrupeds

diminished by the advances of agriculture and civilization. Many kinds of birds also have been thereby lost to us, though possibly some species have been gained, and certainly the number of individuals has in many cases been increased, and a great variety of alterations effected in geographic position. The number of our Insects and Molluscous tribes has certainly been increased, and their geographic limits and positions considerably interfered with, contracted, or enlarged. Many instances in point will be afforded in the sequel.

Very little needs be said on the subject of food as affecting the geography of animals. By the polity of nature, the vegetable world and the series of animals are intimately blended and connected: an extensive Flora will for the most part imply a large proportion of animals, and so likewise the weaker creatures draw to them the carnivorous tribes. In our county we find an extensive Flora, and our woods are numerous and deep; the series of animals also is found very perfect, and the parts of it would, if not subjected to our interferences and persecutions, be relatively proportionate. Food influences the migration of animals to and from this country, subject, however, to the higher influence of weather. In order to comprehend the relative proportions of influence exerted by these two causes, we must suppose adverse and propitious cases in point. If food is plentiful, and the weather intemperate, a summer bird of passage will forthwith undertake its journey, if near the usual period for migrating; if food is scarce, and the weather fine, it will also depart; if both circumstances are adverse, it will hasten its departure still more decidedly; and if provision be in plenty, and the weather fine, its stay will be prolonged. Similar remarks might be made relative to winter migrants. Food has considerable influence in determining the other kinds of migrations besides the vernal and autumnal. It also causes a variety of unusual movements in animals, as will appear in detail. Food is known to determine with precision the habitats of many kinds, though, as shown under the head of Primary Laws, it has not that amount of power supposed by some, and many situations producing the required pabulum, yet do not produce the animals so dependent, and where, if removed, they thrive well. Our *Bulimus fuscatus* and *Helix virgata*, which seemingly need maritime localities from some preference of food, do not occur universally all along the coast, though the vegetation is seemingly uniform in character, but they are collected together in parties at certain spots.

Man conducts a warfare against certain animals, which he finds or supposes to be prejudicial to his interests. In some cases, as where by our agricultural operations, &c. animals have been permitted to multiply more than their natural enemies would have allowed, our destruction of their superfluous number is justifiable; and likewise, in the case of such creatures, whose lives and actions are incompatible with our security and actions, extirpation is demanded. Many of those animals, however, consigned to unlimited destruction, form important links in the chain of creation, and, in consequence, their deficiency will cause alterations of various kinds in the proceedings of those other creatures with whom they were associated in the general scheme and polity of nature. The general destruction of our rapacious birds by gamekeepers and others, must permit a vast accumulation of those species of smaller animals on which they feed, and, in consequence, a more general and unnatural dispersion. A consideration, therefore, of the operations of man, whether as respects his agricultural or his other improvements and refinements, or whether as regards his hostilities to the animal creation, is worthy of some regard in framing an estimate of the causes in active influence on the positions, ranges, and migrations of our native animals of Devon.

It is fairly to be presumed, that our acquaintance with secondary causes is as yet very imperfect; at least we are still unaware of the reasons of a very great number of phenomena which, from being peculiar to certain tribes, or to certain species, cannot possibly be referable to general laws; and until some light has been thrown on these circumstances, our knowledge on this head must be deemed incomplete.

Upon the whole, it will be found difficult to render an inquiry into circumstances and detail interesting, though the chief objects and questions we shall have in view will be—firstly, to determine or illustrate general laws, if the limits of such an investigation should by possibility admit of it; secondly, to determine and illustrate secondary laws, or causes of geographic distribution, by attention to the following circumstances:—Comparisons of the phenomena of this district with others of similar extent, and similar or dissimilar aspect, and contingencies; irregular distributions; the occurrence of varieties, and other modifications, as provisions to suit local circumstances; the times selected for migration (of the various kinds), with an attention to the causes possibly influencing these movements; modifications of habits; peculiarities in the Zoology of the whole of the spot selected, or in any of its parts; remarkable deficiencies in its Zoology; general, numerical, and other results. Lastly, it will be right to make mention of a variety of other circumstances, though no explanation of their occurrence can be given, since records of unexplained facts may serve to invite notice and inquiry into causes.

There are two methods of considering the Natural History of a given spot, each having its peculiar advantages. We may investigate it with regard only to those phenomena and circumstances properly and peculiarly its own, irrespectively of all interferences and additions by the inroads of agriculture, planting, &c.; or we may consider it in its present state under all its alterations. The first mode has the advantage of being the more natural, and it is also calculated to display a great number of remarkable features of the spot. The second plan has the advantage of setting things in their present light, and serves also to show to what extent animals are influenced by our proceedings, how far their distributions are modified by our advances and operations; the instincts guiding them in their defences against our intrusions; and, lastly, it serves to demonstrate an important principle in the economy of a great proportion of creatures, namely, that of adaptation to variety in surrounding conditions, a quality almost unrestricted in the human species, but enjoyed in a more limited degree by animals, but without which their lives would be dependent upon the slightest alterations in surrounding circumstances, and without which we should not have been enabled to subject any of them to our uses and pleasures. I believe it will be expedient to examine the Zoology of this district with reference both to original and to existing features, giving to each its respective value, and peculiar considerations.

A CUCKOO SEEN IN MORAYSHIRE IN DECEMBER.—Mr John Barclay of Calcots, near Elgin, has transmitted to us the following very interesting account of the appearance of a Cuckoo in his neighbourhood:—"The winter, so far as it is gone, has been remarkably mild in Morayshire, and I suppose all over the kingdom. The last ten days have been like April or May. On Friday last (29th December) my neighbour, Mr James Geddes, at Meft, told me he had seen a Cuckoo on the paling about his garden, and not only seen it, but heard it utter its well-known cry. I see Bewick mentions that they have been found in this country in a torpid state in winter; and I remember an old man in the parish of Auchterless, Aberdeenshire, who said he had found one among whins which he was cutting, and that on being brought into his house, after some time it uttered the peculiar note, cuckoo, and escaped. But the fact I have mentioned is something new, so far as I know. I enclose a note from Mr Geddes, whose word may be relied on. He also mentions the Black Snail being out as another proof of the mildness of the season. I have not seen any; but a shoot of a rose on the outside of my window, looking to the Lossie, has grown upwards of five inches since the beginning of November." Mr Geddes's note to Mr Barclay is as follows:—"Meft, January 2, 1838.—My dear Sir,—I was not at home when your note came yesterday. The Cuckoo perched upon the railing of my garden on Wednesday last. One of my boys, taking it for the common hawk that flies about at this season, fired at it, when it flew down to the nearest wood, about a hundred yards, and perched on a tree, and immediately began its call "cuckoo," which it continued for five minutes, leaving it no longer doubtful what kind of bird it was. I find the large Black Snail has been seen out lately by others as well as myself. I only saw one about the beginning of last week. I have never before observed them out till May, and even then at the beginning of a course of fine weather only.—I remain, yours truly, J. GEDDES."

THE PIED WAGTAIL.—Mr Gould has recently offered some observations, in Loudon's Magazine, respecting our Pied Wagtail, which he considers to differ from the *Motacilla alba* of Linnæus. "While engaged upon this tribe of birds during the course of my work on the Birds of Europe, I was surprised to find that the sprightly and Pied Wagtail, so abundant in our islands at all seasons, could not be referred to any described species, and that it was equally as limited in its habitat (as *M. flava*); for, besides the British Islands, Norway and Sweden are the only parts of Europe whence I have been able to procure examples identical with our bird, whose place in the temperate portions of Europe is supplied by a nearly allied, but distinct, species, the true *M. alba* of Linnæus; which, although abundant in France, particularly in the neighbourhood of Calais, has never yet been discovered on the opposite shore of Kent, or in any part of England. As, therefore, our bird, which has always been considered as identical with the *M. alba*, proves to be a distinct species, I have named it after my friend W. Yarrell, Esq., as a just tribute to his varied talents as a naturalist.

"The characters by which these two species may be readily distinguished are as follows:—The Pied Wagtail of England (*M. Yarrellii*) is somewhat more robust in form, and, in its full summer dress, has the whole of the head, chest, and back, of a full deep jet black; while in the *M. alba*, at the same period, the throat and head alone are of this colour, the back and the rest of the upper surface being of a light ash-grey. In winter, the two species more nearly assimilate in their colouring; and this circumstance has, doubtless, been the cause of their hitherto being considered as identical: the black back of *M. Yarrellii* being grey at this season, although never so light as in *M. alba*. An additional evidence of their being distinct (but which has, doubtless, contributed to the confusion) is, that the female of *M. Yarrellii* never has the back black, as in the male; this part, even in summer, being dark-grey, in which respect it closely resembles the other species."

COSSUS LIGNIFERA.—The larva of this insect is capable of living to a surprising length of time without sustenance or food, and also without preventing its coming to maturity or the perfect imago, as the following circumstances will corroborate.—On the 13th of June 1836, I took an excursion for the purpose of procuring a few specimens of the Cossus, in company with an intelligent naturalist, in the neighbourhood of Nottingham, where they so greatly abound among the willow trees. I was fortunate in procuring a dozen chrysalids. I also found abundance of the larva, in all its stages, one of which was in its second year, and this I put into a tin box, the lid being perforated by small holes to admit air. On my return home, I placed the box in a situation which for six months afterwards escaped my recollection, when I again laid my hand upon it, and, on opening it, to my surprise the Caterpillar was not only alive and healthy, but to all appearance larger than when I first saw it. I afterwards removed it into a large box, which could not be perforated, and watched its progress very closely for a considerable length of time, when I put in a small quantity of sawdust, for the purpose of allowing it to spin itself a cocoon or nest, respecting which, at the time, it appeared careless. But about the beginning of May 1837, it commenced operations, which it completed in a few days, since which time it remained until the 17th of July, when it emerged into the perfect moth (which I placed in my cabinet), thus remaining without food or support in the larva state ten months, and two in the chrysalis. The box was placed in a very warm situation, in a cupboard near the fire.—R. H. COWLISHAW.—*The Naturalist*.

SPECIES OF THE GENUS MUSTELA.—The Prince of Musignano, Charles L. Bonaparte, has recently communicated to the Magazine of Natural History, a notice respecting the genus *Mustela* of authors, which he has divided into four genera: *Zorilla*, *Martes*, *Putorius*, and *Mustela*, the latter including the small slender-tailed species, such as the Ermine and Weasel. The following are the species of this genus, as he has restricted it.

1. *Mustela Erminea*. Linn. Europe.
2. *M. Cicognanii*. Bonap. North America.
3. *M. Boccamela*. Bonap. Sardinia.
4. *M. vulgaris*. Linn. Europe.
5. *M. Richardsonii*. Bonap. (*M. Erminea*, Richardson, Fauna, Bor. Amer.) North America.
6. *M. longicauda*. Bonap. (*M. Erminea*, Richardson, Fauna, Bor. Amer.) North America.
7. *M. frenata*. Licht. Mexico.

SKULL OF THE GUADALOUPE HUMAN SKELETON.—In the number for July 1837 of Silliman's Journal, is a description of the skull of the fossil skeleton found in Guadeloupe, and deposited in the British Museum. It was procured on the spot by M. L'Herminière, and has been placed in the collection of the Literary and Philosophical Society of South Carolina. Dr Moultrie, Professor of Physiology in the Medical College of that State, having examined the fragments with the view of ascertaining whether it belonged, as was supposed, to an individual of the Carib race, is decidedly of opinion that they do not, but finds in them all the marks of the American variety, in so much that were it possible to detach them from their incrustation, the vacancies might be filled with the corresponding parts taken from the head of the Peruvian.

## BOTANY.

## THE MISSELTOE.—VISCUM ALBUM.

THIS singular and celebrated plant, which belongs to *Tetrandria monogynia* of the Linnæan system, and to the natural family of *Loranthæ*, is parasitical, growing mostly on Apple trees, but also on the Pear, Hawthorn, Service, Oak, Hazel, Maple, Ash, Elm, and many others. In Worcestershire and Herefordshire it is very common in orchards, but in the northern counties it is seldom met with. It is an evergreen shrub, insinuating its radical fibres into the wood of the trees on which it grows. Its branches are numerous, regularly dichotomous, smooth and yellowish green; its leaves oblong, entire, striated, opposite, on short stalks; the flowers small, axillar, in close spikes; the calyx of the male flower divided into four ovate equal segments; the anthers four, attached to the calyx, which in the female flower is divided into four small ovate leaves, and placed upon the oblong, three-edged germen, which is surmounted by a blunt and somewhat notched stigma; the fruit, a globular, white, smooth one-celled berry, containing a fleshy, heart-shaped seed. It is supposed to be propagated by the Missel Thrush and Fieldfare, which are said to eat the berries, of which the seed passes through

them unchanged, and adheres to the branches of trees where it germinates. There is no proof of this, however, and it has been observed that the roots are always inserted on the under side of the branches, but this again is accounted for by the action of rain. Withering states that sheep eat it very greedily, and that it is frequently cut off the trees for them in hard weather. Birdlime is sometimes made from the berries, whence the saying, *Turdus suum malum caecat*. Their pulp is so slimy and tenacious, that if they are rubbed on the smooth bark of almost any tree, they will adhere and produce plants the following winter. It was formerly in great repute as a remedy in epilepsy, but is now entirely disregarded. Boyle mentions a case of this disease in which it was employed with remarkable success. Colbach strongly recommends it in various convulsive disorders, and other authors consider it as tonic and astringent. If we add to this that the Druids attributed to it the most astonishing virtues, we have all that can be said in its favour. At the present day, it is not employed in medicine, and attracts attention merely on account of its peculiar habit and aspect; for even its use as birdlime has been superseded by that of the bark of the bolly.

HYBRID FERNS.—A triumph has been obtained by M. Martens, the professor of chemistry at the university of Louvain, and Dr L'Herminier, over those who assert that no hybrid plant can be produced where no stamina exist. The former shook the fronds of *Gymnogramma colomelanos* and *G. chrysophylla*, reciprocally over each other, at the time when the fructification was fully developed, and thus produced a new plant which is to be called *G. Martensii*. It is worthy of remark, that the hybrid plant bids fair to be easily propagated in our greenhouses, while the parents constantly languish and die. While M. Martens was making his experiment at Louvain in Belgium, Dr L'Herminier watched the same process taking place naturally in the woods and savannahs of Guadeloupe, and sent some dried fronds, in excellent preservation, of the hybrid to M. Bory St Vincent.—*Athenæum*

## REVIEWS.

*A History of British Birds.* By William Yarrell, F. L. S. Secretary to the Zoological Society. Illustrated by a Woodcut of each species, and numerous Vignettes. London: John Van Voorst.

THE author of this work, already so well known to the public as a naturalist, cannot fail to increase his reputation, and add to the advancement of ornithological science, by the publication of a series of descriptions of the Birds of Britain, so judiciously drawn up, and so beautifully illustrated. In the prospectus, we are informed that it will be completed in two volumes, 8vo, and will contain a greater number of British Birds than has yet been included in any work on the same subject. Four parts have made their appearance, so that we are enabled to form an estimate of its value, and compare it with other works on the same subject at present in the course of being published. The figures are generally good, and in all cases beautifully engraved. Of those most to our mind, as exhibiting the natural aspect and attitude of the birds, we may mention the Gyr-falcon, the Kestrel, the Hen Harrier, the Snowy Owl, the Great Grey Shrike, the Red-backed Shrike, the Wood-chat Shrike, the Flycatchers, the Dipper, and the Fieldfare. They are all, in our opinion, much superior to the figures of Selby's Illustrations, which, indeed, we have always considered as neither accurate in a scientific point of view, nor creditable as works of art. But, if we were disposed to criticise them, we should find some faults here and there, although possibly those very faults might by others be considered as beauties. Thus, the Golden Eagle has the bill too large; the white-tailed Eagle is not well-shaped, the body being too full and rounded, the bill not deep enough, and the tail so represented that one cannot decide as to which of its surfaces is exhibited; the Merlin, the Hobby, and the red-footed Falcon, are clearly skins stuffed with tow, and not living birds; the brooding Buzzard, at p. 80, has the bill at least three times as large as it ought to be; the Marsh Harrier is flat and stiff; and the Goshawk is more like a Buzzard than it ought to be. Nevertheless, the cuts seem to us to be very beautiful, and we know none else in which fewer faults exist. But neither the merits nor the defects of this department belong to Mr Yarrell, whose descriptions we conceive to be uniformly good, and to contain much interesting information, obtained, however, less from personal observation than we had anticipated or could wish. The distribution of the species, not only in the different parts of Britain, but also in foreign countries, is carefully traced; their habits are given in detail, although sometimes rather briefly; their nests and eggs, as well as their external appearance, are described in a succinct manner; and occasionally some particulars relative to their organization are given and illustrated by vignettes. However, that the reader may be enabled to judge for himself as to the execution of this part of the work, we lay before him Mr Yarrell's description of one of our winter visitors.

"The Fieldfare is a well-known migratory Thrush that comes to us from the north, and is one of the latest, if not the last, species that makes its annual and regular winter visit to Great Britain and the North of Ireland. It seldom appears before the beginning of November, depending on the temperature of the season, and frequently later than that, arriving here in large flocks in search of food; and if the weather continues open and mild, spreading themselves over pasture-lands to look for worms, slugs, the larvæ of insects, and any other soft-bodied animals of that sort; but, on the occurrence of snow or frost, they betake themselves to the hedges, and feed greedily on haws, and various other berries. At this time they are much sought after by youthful gunners, who find them shy and difficult to approach; the whole flock taking wing and keeping together, settle by scores on some distant tree, from whence, if again disturbed, they wheel off in a body as before. Should the weather become very severe, the Fieldfares leave us to go farther south, and are again seen on their return. They are known to go as far to the south and to the east as Minorca, Smyrna, and Syria. The Fieldfare does not return to its breeding-ground till late in the season. I have known them shot on the 12th of May, and others have been seen much later. White of Selborne says, that one particular season they remained till the beginning of June; and he asks, why do they not breed in the Highlands? Some instances have occurred of the Fieldfare breeding in this country; and Pennant, or the editor rather of the last edition of the British Zoology, mentions two instances that came to his knowledge. More recently, a nest has been found in Kent, and others in Yorkshire and Scotland; but in Orkney and Shetland, according to the observations of Mr Dunn, it is only seen on its passage to and from other countries. Mr W. C. Hewitson, whose zeal in the cause of Natural History induced him to visit Norway a few summers since, in the hope of obtaining many rare specimens for illustration in his excellent work on the Eggs of British Birds, thus describes the nesting habits of the Fieldfare:—After a long ramble through some very thick woods, our attention was attracted by the harsh cries of several birds, which we at first supposed must be shrikes, but which afterwards proved to be Fieldfares, anxiously watching over their newly-established dwellings. We were soon delighted by the discovery of several of their nests, and were surprised to find them (so contrary to the habits of other species of the genus *Turdus* with which we are acquainted) breeding in society. Their nests were at various heights from the ground, from four feet to thirty or forty feet, or upwards, mixed with old ones of the preceding year: They were, for the most part, placed against the trunk of the spruce fir; some were, however, at a considerable distance from it, upon the upper surface, and towards the smaller end of the thicker branches. They resembled most nearly those of the Ring Ouzel. The outside is composed of sticks, and coarse grass and weeds gathered wet, matted together with a small quantity of clay, and lined with a thick bed of fine grass: None of them yet contained more than three eggs, although we afterwards found that five was more commonly the number than four, and that even six was very frequent. They are very similar to those of the Blackbird, and even more so to the Ring Ouzel. The Fieldfare is the most abundant bird in Norway, and is generally diffused over that part which we visited, building, as already noticed, in society, two hundred nests or more being frequently seen within a very small space. The eggs are light blue, mottled all over with spots of dark red-brown; the length one inch three lines, the breadth ten lines. William Christy, Esq., junior, who, with a party of naturalists, visited Norway in the summer of 1836, says, on the mountains called the Dovrefield, Fieldfares were rearing their young; they were just

able to fly about on the 6th of August. The call-note of the Fieldfare is harsh, but its song is soft and melodious. In confinement it soon becomes reconciled, and sings agreeably. At night, when at large, it frequents evergreens and thick plantations; but, unlike its congeners, it has frequently been known to roost on the ground among fern, heath, or furze, on bushy commons. This bird is well known in Sweden, Russia, and Siberia, where it is found only in summer; in Poland, Prussia, and Austria, it remains the whole year; but in France, and the still more southern countries of Europe, it is only a winter visitor, extending its migration in that season, as before stated, to Minorca, Smyrna, and Syria."

It will be seen from the above, that there is in Mr Yarrell's History more careful and judicious gleaming from other works than original matter. To the student, however, this is rather a recommendation than otherwise; and, in acknowledging his sources of information, the author evinces a degree of honesty which we in vain look for in the writings of many other candidates for ornithological renown.

*The Natural History of the Birds of Great Britain and Ireland. Part I. Birds of Prey.* Illustrated by thirty-six Plates. By Sir William Jardine, Bart. F.R.S.E., F.L.S. &c. Edinburgh: W. H. Lizars.

THIS work, which professes to be, not a history, but *The History of British and Irish Birds*, differs in some essential respects from Mr Yarrell's. In the first place, the Figures of the birds described are engraved on copper, and coloured, so as to resemble nature in more respects than one. Secondly, the peculiarities of the bills, feet, and wings, are illustrated by woodcuts. In the third place, the descriptions are more original, and their style bolder, although not so uniformly correct. Of the plates, several are excellent, some good, and others very poor. In the first class may be ranked those of the Orange-legged Falcon, the Golden Eagle, the Honey Buzzard, the Marsh Harrier, and the White Owl; in the second, the Jer Falcon, the Hobby, the Kestrel, and the Swallow-tailed Nauclerus; in the third about half of the whole number. Thus, for example, the Eagle Owl has the head much too small, the markings on the breast not sufficiently minute, and the feathers on the sides and tibiae stiff, in place of being peculiarly soft and almost downy. Thus, also, the Long-eared Owl is washed with blue, of which it in reality has no traces; the Tawny Owl has light blue eyes, whereas they are in nature so dark as at a little distance to seem black; the Kite has the bill too elongated; the Goshawk is too clumsy and awkward; the female Sparrowhawk is much more like the species last mentioned; the grey tints generally are converted into blues; and the eggs seem to us remarkably ugly. As to the woodcuts, we can only say that their execution is in all respects exceedingly poor. In this volume are described as British, one vulture, *Neophron Percnopterus*, of which a single specimen was killed in Somersetshire in 1825; twenty Falconidæ, among which are included the Swallow-tailed Nauclerus, of which two specimens have been killed, the one in Argyleshire, the other in Yorkshire, and the Crested Spizactus, which is added to the British Fauna, on the authority of Mr Wingate, animal preserver at Newcastle-upon-Tyne, who received a skin, in a fresh state, from Aberdeen; and eight owls, among which is the Hawk Owl, of which an individual is recorded to have been captured "a few miles off the coast of Cornwall, on board a collier, in a very exhausted state."

In an Introduction is given a sketch of the progress of ornithological science in Britain, together with some remarks on the changes that have taken place in the number and distribution of our native species. The characters of the order *Raptores*, or Birds of Prey, and of the genera and species of which it is composed, are briefly sketched, and illustrated by woodcuts. In the descriptions of the species, the author evidently strives hard to imitate Wilson, Buffon, Audubon, and others, who have succeeded in combining popular narrative with scientific information; but his attempts are generally unsuccessful, and often ludicrous, although, on the whole, the histories of the species may be recommended as generally correct, however ungracefully managed. If they be compared with the notes to Wilson's Ornithology and White's Selborne, it will be found that he has improved considerably, although he is still far from being an adept in composition. As an example of his manner, we here give a portion of his history of one of the most celebrated of our native birds.

"The Golden Eagle has ever been associated with majesty or nobility; in ancient mythology, an Eagle was alone thought worthy to bear the thunder of Jove. By rude and savage nations he is combined with courage and independence. The young Indian warrior glories in his Eagle's plume as the most distinguished ornament with which he can adorn himself. The dress of the Highland chieftain is incomplete without this badge of high degree. And if, by the trammels of system (which, nevertheless, is indispensable, when the number of objects to be arranged exceeds eight thousand), we are forced to place him in an aberrant or less honourable situation, yet, when met with on his native mountains, free and uncontrolled, we cannot refuse the tribute which has been rendered to him by our predecessors.

"In England and the south of Scotland the Golden Eagle may be accounted rare, very few districts of the former being adapted to its disposition, or suitable for breeding places. Some parts of Derbyshire are recorded as having possessed eyries, in the mountainous parts of Wales there are others, and the precipices of Cumberland and Westmoreland also hoisted of them. Upon the wild ranges of the Scottish border, one or two pairs used to breed, but their nest has not been known for twenty years, though a straggler in winter sometimes is yet seen amidst their defiles. It is not until we really enter the Highlands of Scotland by one of the grand and romantic passes, that the noble bird can be said occasionally to occur, and it is not until we reach the very centre of their "wildness," that he can be frequently seen. But the species must be gradually, though surely decreasing, for such is the depredation committed among the flocks during the season of lambing, and which is the time when a large supply of food is required by the parent birds for their young, that every device is employed, and expense incurred by rewards, for their destruction."

MARCH, 1838.

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE.—THE PANDAS AND COATIS.

THE genus *Ailurus* is composed of a single species of carnivorous quadruped, allied to the Civets and Martins on the one hand, and to the Benturongs and Coatits on the other, being in some measure plantigrade like the latter, but in form more resembling the former.

Fig. 1. THE SHINING PANDA (*A. fulgens*), of a light red colour above, paler on the sides, the face white, and the lower parts and legs dusky. It inhabits South America.

The Benturongs have been separated from the genus *Viverra*, to constitute a small group characterized by their semipalmated feet, plantigrade mode of walking, and long spirally twisted tail, which, however, is not prehensile. They inhabit the Indian Peninsula, and in habits resemble the Civets, feeding on small quadrupeds, birds, and other animals.

Fig. 2. THE WHITE-FRONTED BENTURONG (*Ictides albifrons*) is characterized by having the fur long, and formed of a mixture of black and white hairs, the forehead whitish, the tail black, and a patch of the same colour including the eye.

Fig. 3. THE BLACK BENTURONG (*I. niger*), the Musanga of Raffles, is of a black colour all over, excepting the face, which is whitish.

The Coatits, which by Brisson were referred to the genus *Ursus*, and by Linnæus to *Viverra*, are now separated to constitute the genus *Nasua*, so named on account of the prolongation of their nose, which is also possessed of considerable mobility. They are small, plantigrade, nocturnal animals, with an elongated tapering head, limbs of moderate size, and a long tail. They feed on animal substances, climbing on trees like the Opossums, and inhabit South America.

Fig. 4. THE BROWN COATI (*N. narica*), of a dusky-brown colour, the tail ringed with dark brown, and with three white spots near the eye.

Fig. 5. FEMALE BROWN COATI.

Fig. 6. THE RED COATI (*N. rufa*). This species differs from the Brown, in having its fur of a light brownish-red colour, the bands on the tail lighter, and the muzzle greyish-black, with white spots round the eye.

#### DESCRIPTION OF THE PLATE.—THE PROMEROPSES.

THE genus *Epimachus* is referred by Cuvier to the family of the Tenuirostres, or slender-billed birds, and is nearly allied to the Hoopoes, having the bill longer than the head, arched, and tapering; the mandibles pointed; the tarsi short, the outer toe united at the base to the middle one. The plumage is glossed or velvety, the tail elongated, and the wings long and rounded, the fourth and fifth feathers longest. These birds, which inhabit Africa and New Guinea, are supposed to live chiefly upon insects.

Fig. 1. THE RED-BILLED PROMEROPS (*Epimachus erythrorhynchus*), which has the bill and feet red, the plumage black, but lightly glossed with green and purple, the tail very long, with all the feathers, excepting the two middle, marked near the end, with an oval white spot, inhabits Southern Africa.

Fig. 2. THE SUPERB PROMEROPS (*E. superbus*) resembles the Birds of Paradise in the extraordinary development of its hypochondrial feathers, and in the texture of its plumage, of which the colour is black, with purple and green reflections: the scapulars sickle-shaped, purplish-black on the inner web, greenish-yellow on the edges and tip. The tail is extremely elongated, so that the bird, although its body is not much larger than that of a Jay, measures four feet in length. It inhabits New Guinea.

Fig. 3. THE BLUE PROMEROPS (*E. caruleus*) is of the same form as the red-billed, but of a greyish-blue colour all over.

#### BRITISH BIRDS.—NO. X.—THE ROCK DOVE.

HAVING in a former Number described the Ring Dove or Cushat, we now present an account of the Rock Dove, which is the original of our Domestic Pigeons, and is of frequent occurrence on many of our rocky coasts. The plumage of this species is light greyish-blue, the lower parts being as deeply coloured as the upper. The middle of the neck all round is splendid with green, its lower part with purplish-red. The back and the upper part of the sides, from near the shoulders to near the tail, are pure white, as are the lower wing-coverts and axillaries. The primaries and their coverts

are brownish-grey on the outer web, the former dusky towards the end, as are the outer secondaries. There are two broad bars of black on the wing, one extending over the six inner secondary quills, the other over the secondary coverts, the outer two excepted. The tail has a broad terminal band of black, and the outer web of the lateral feathers is white. The downy part of the feathers is greyish-white, excepting on the white part of the back, where it is pure white. The horny part of the bill is brownish-black, as is the anterior half of its tumid portion, of which the rest is white; the iris is bright yellowish-red; the bare space around the eye flesh-coloured; the tarsi and toes carmine-purple; the claws greyish-black. The length is fourteen inches, and the extended wings measure twenty-seven. The female is a little smaller, and has the shining colours on the neck less extended.

This beautiful bird occurs in great abundance in the outer Hebrides, in Skye, Mull, and other islands on the north-west coast of Scotland, in Shetland and Orkney, and here and there along the rocky shores of all parts of the northern division of Britain, as well as on some of the southern. At early dawn, the Pigeons may be seen issuing from their retreats in straggling parties, which soon take a determinate direction, and meeting with others by the way, proceed in a loose body along the shores until they reach the cultivated parts of the country, where they settle in large flocks, diligently seeking for grains of barley and oats, pods of the charlock, seeds of the wild mustard, polygona, and other plants, together with several species of small shell-snails, which abound in the sandy pastures. When they have young, they necessarily make several trips in the course of the day, but from the end of autumn to the beginning of summer, they continue all day in the fields. In winter they collect into flocks, sometimes composed of several hundred individuals; and, as at this season they are anxious to make the best use of the short period of day-light, they may easily be approached by a person acquainted with the useful art of creeping and skulking. In general, however, they are rather shy, and very seldom allow a person to advance openly within sixty or seventy yards. After the corn has ripened they soon become plump, and continue in good condition until the middle of winter, or even later, should the season prove mild; but in spring and summer they are lean and tough. Their flesh is superior to that of the Wood Pigeon, but not equal to that of the Golden Plover, a bird which is equally abundant in the northern and western islands.

The manners of the Rock Doves are similar to those of our Domestic Pigeons. When searching for food, they walk about with great celerity, moving the head backwards and forwards very prettily at each step. In windy weather, they usually move in a direction more or less opposite to the blast, and keep their body nearer to the ground than when it is calm, the whole flock going together. When startled, they rise suddenly, and by striking the ground with their wings produce a crackling noise. Their flight is very similar to that of the Ringed and Golden Plovers, birds which in form approach very nearly to the Pigeons; when at full speed, they fly with great celerity, the air whistling against their pinions. They usually alight abruptly when the place is open and clear, and if very hungry immediately commence their search; but on other occasions they fly over the field in circles, gradually descend, and on alighting stand and look round them for a few moments. The notes of this species resemble the syllables coo-roo-coo, quickly repeated, the last prolonged. Its nuptials are celebrated with much cooing and circumambulation on the part of the male, and the first eggs are laid as early as the beginning of April, several broods being reared in the season. The nest is rudely constructed of straws, grass, various other plants, and frequently a few feathers; the eggs, like those of all other Pigeons, are two in number, smooth, and pure white. The young, which are at first covered with loose yellow down, are fed by their parents, who, applying their bill to that of the nestlings, force up the food from their crops, so as to be within reach of the bill of the young, which all the while flaps its wings, and utters a low cheeping note, indicative of its eagerness to have its wants supplied. When fledged, they are of the same colour as the old birds, the head and neck, however, being of a dull purplish-blue, without the bright green and purple tints of the old, and the wings tinged with brown. At the first moult they acquire their full colour.

In Shetland, according to the Rev. Mr James Barclay, they are met with in considerable numbers, and are especially abundant in the parishes of Sandwick and Dunrossness, as well as in Fetlar, these places being the most extensively cultivated. They flock twice in the year, first in August or September, and again in winter. One pair when tamed generally breed four times in the season; and so great is their

fecundity, that they are frequently seen sitting on eggs long before the former brood is able to leave the nest, so that the parent bird has at the same time young birds and eggs to take care of. Mr Smith, of the same country, has also transmitted us specimens, and states that in Feltlar they are seen in large flocks in the winter and spring months, when they frequent barn-yards, especially should the ground be covered with snow. The crops of Mr Smith's specimens were completely filled up to the mouth: that of one with a mixture of barley and oats, together with a considerable number of eggs of snails, and some fragments of the pods of charlock; that of another, with oats, a few seeds of polygona, and fragments of charlock; and that of the third with oats alone. The number of oat seeds in the crop of the second amounted to 1000 and odds, and the barley seeds in that of a specimen sent by Mr Barclay were 510. From these facts it may be imagined what a quantity of seeds is annually devoured by all the Pigeons, wild and tame, in Britain.

After a long continuance of snow, these birds become extremely emaciated, for they scarcely find any thing to eat on the shores, and they do not appear to betake themselves to turnip fields, like the Wood Pigeons. Indeed, in most of the districts in which they abound, turnips are very rarely cultivated. From ten to twenty have sometimes been killed at a shot, when they have settled on corn-stacks, and it is not uncommon to obtain as many as four or five even on stubble or newly sown fields, for they often move very close together. The Peregrine Falcon and the Sparrowhawk seem to be the only feathered enemies of this species, whose power of flight, however, is such as to render it little liable to persecution even from them, while its rocky haunts exempt it from the attacks of rapacious quadrupeds. It is easily tamed when procured from the nest, and readily breeds with the Domestic Pigeon. On the other hand, individuals of the latter often fly off to the rocks, and either form colonies apart, or mingle with the Wild Pigeons. In its truly wild state, the Rock Dove presents no remarkable variations of colour, and the variously coloured individuals sometimes seen among the rocks are emancipated slaves, or their descendants.

Another British species, the Stock Dove, is very similar to the present, but differs in having no white on the rump, and in its habits and distribution, it being entirely unknown in the northern parts of the country; but of this and the Turtle Dove, we shall present the principal characters on another occasion.

**ORNITHOLOGY OF AUSTRALIA.**—Mr Gould, whose splendid illustrations of the birds of Europe, and other ornithological works, have gained him a well merited celebrity, intends to leave England, this spring, for New Holland, where he proposes to remain two years, for the purpose of studying the habits of the numerous species of birds occurring in that country. Having already commenced a work on them, he will carry out with him the materials necessary for continuing its publication. The outlines will be drawn by himself, and the lithography will be executed, as formerly, by Mrs Gould, who will accompany him for that purpose.

**LONGEVITY OF BIRDS.**—Dr Weissenborn gives an account, in the last number of the Magazine of Natural History, of a Nightingale which had been caught in its adult state, and had lived in captivity nearly thirty years. He also states that a German paper, the Nürnberger Correspondent, (October 1837,) mentions that an Amsterdam merchant has been in possession of a grey Parrot for the last thirty-two years, after a relation had had the same bird forty-one years, so that its age is now seventy-three years, besides the time it may have lived previously to its transportation to Europe. It is now in a state of marasmus, and its powers of vision and memory are gone. Till sixty, it regularly moulted once a year, and the last time, the red feathers in its tail were exchanged for yellow ones.

**DISEASES OF BIRDS.**—The pathology of birds has hitherto received little attention. Domesticated individuals, as might be supposed, seem to be subject to more diseases than those in a state of freedom. We recently examined a parrot, of which the lungs were in a state of atrophy, and had moreover undergone a change similar to that exhibited in the human species when affected with melanosis. The internal or cuticular lining of the gizzard, which, in its natural state, is hard and dense, resembling the skin of the heel, was enormously thickened, and presented the appearance of a mass of transparent jelly.

**MR. SHAW'S EXPERIMENTS ON THE DEVELOPMENT OF THE FRY OF THE SALMON.**—At a recent meeting of the Royal Society of Edinburgh, Mr John Shaw presented a very interesting account of experiments on the development of the young of the Salmon, which has been published in the Edinburgh New Philosophical Journal, and of which the following is an abstract. Mr Shaw had formerly stated his opinion that the Parr is the young of the Salmon, but it had been objected to his observations, that they were made upon ova taken from the bed of the Nith, which might have belonged to another species. The ponds in which these recent experiments have been made are three in number, two feet deep, thickly imbedded with gravel, and supplied by a small stream in which larvæ of insects abound. The waste water from them is conducted by wooden pipes secured by grating, and any accidental overflow is prevented by embankments two feet high.

With a bag-net extended on an iron hoop five feet in diameter, he caught, on the 4th January 1837, two Salmon, a male and a female, which were engaged in depositing their spawn; and having drawn them ashore, placed them successively in a trench on the beach made for the purpose, pressed out a quantity of the ova and melt, allowing the latter to pass down the stream, so as to be mingled with the former, and then transferred the spawn to a basin, and deposited it in a stream connected with a pond previously formed for its reception. The temperature of this stream was 39°, of the river Nith, from which the Salmon were taken, 33°, and of the atmosphere 36°. On the 23d February, fifty days after impregnation, the embryo fish was distinctly visible to the naked eye, and moved feebly in the egg. The temperature of the stream was 36°, and of the atmosphere 38°. On the 28th April, a hundred and fourteen days after impregnation, the young were excluded from the eggs. At this period the little fish has a very peculiar aspect; the head is large, the entire length is five-eighths of an inch, and the colour pale blue or pink; the bag attached to the abdomen conical, and of a beautiful transparent red, so as to be easily distinguishable at the bottom of the water, even when the fish itself can with difficulty be observed. A slightly indented

fringe extends from the dorsal and anal fins, to the termination of the tail. On the 24th May, twenty-seven days after being hatched, the young fish had consumed the yolk; but in a few days afterwards, the whole of this family, with the exception of one individual, was found dead at the bottom of the pond, a circumstance which, having more than once occurred before, Mr Shaw attributes to a deposition of mud.

To show the effect of increased temperature in hastening the development of the infant fish, he relates an experiment made upon a few of the same ova. On the 20th April, a hundred and six days after impregnation, finding these ova unhatched, and the temperature of the stream being 41°, he took four of them and placed them in a tumbler of water, covering the bottom with fine gravel, in which he imbedded the ova. He then suspended the tumbler from the top of his bed-room window, above which he placed a large jar, from which a stream of pure water was directed into the tumbler, the overflowings of which were carried out at the window along a wooden channel. The average temperature of the room was 47°, that of the water 45°; but during the night it was considerably increased, and the young fish in the tumbler were hatched in thirty-six hours, whereas those remaining in the stream did not hatch till the 28th of April, a difference of nearly seven days.

At this stage they are so very transparent, that their viscera are distinctly visible. Their pectoral fin is continually in rapid motion, even when they are otherwise in a state of perfect repose. On the 24th May, thirty-nine days after their birth, the fish in the tumbler were completely divested of the yolk, and the characteristic bars of the Parr had become visible. At this time they measured nearly one inch in length. They were returned to the pond, where they perished with the rest of the family.

In another experiment, the ova were procured in the same manner, and deposited in the stream entering a pond, on the 27th January 1837, the temperature of the stream being 40°, and that of the river 36°. On the 21st March, fifty-four days after impregnation, the embryo fish was visible to the naked eye. On the 7th May, a hundred and one days after impregnation, the little fish had burst the shell, and were to be found amongst the shingle of the stream. The temperature of the water was 43°, of the atmosphere 45°. When two months old, the fry presents in miniature the proportions of a mature fish; at the age of four months, the characteristic marks of the Parr are distinctly visible; when six months old, it is only three inches and a quarter in length, but its approximation to the features of the parent fish is more striking, and on comparing it with the Parr in the river, no marked difference can be observed. The whole of this family, as well as another family in a separate pond, were in December in perfect health, and fed freely on worms and larvæ, with which they had been supplied during the summer.

On comparing the Parr taken from the river at a corresponding period with those taken from the pond, they were found to be uniformly of a darker colour, which Mr Shaw attributes to the more impure or muddy quality of the river water.

In the course of Mr Shaw's visits to the experimental pond, he had often observed, that, while the little fish remained stationary in any particular part, they were always found to be of a colour corresponding to that of the bottom, and when they removed to any part of a different colour, that, after resting on it for a few minutes, they gradually assumed a corresponding hue. Wishing, therefore, to prove the fact of this assimilation by actual experiment, he procured two earthenware basins, one nearly white inside, the other nearly black, placed a living fish in each, and kept up in them a constant supply of fresh water. The fishes, which at first were of their natural colour, had not remained in the basins more than four minutes till each had gradually assumed a colour nearly approaching to that of the respective basins. He next took the fish out of the white basin and placed it in the black one, and the fish which was in the black basin he placed in the white, and the results were the same. He next placed both fishes in one basin, when the contrast for a short time was exceedingly striking. Exclusion of the light by means of a mat produced a dark colour, which gradually disappeared when the mat was removed.

Mr Shaw, in conclusion, considers that he has now succeeded in establishing the fact, that the young Salmon does not proceed to the sea the same year in which it is hatched, and hopes that his experiments will therefore be admitted as beneficial both in a scientific and economic point of view. The belief that the Salmon migrates the same year it is hatched, he observes, has created an indiscriminate slaughter of that fish, at an age when it especially requires the protection of the legislature. There being no fish in our rivers that takes the fly more readily, the destruction of the fry by juvenile anglers is incalculably great.

Although the author of these experiments may not have succeeded in convincing naturalists that the Parr and the fry of the Salmon are identical, he is persuaded that they are so. But the apparent maturity of the sexual organs of the male, and the immaturity of those of the female Parr, are perplexing circumstances, which cannot be reconciled with any of the proposed theories respecting that fish. He suggests the hypothesis of an analogy between the female Salmon and the queen Bee, and imagines that the former like the latter may have the aid of a plurality of males in propagating her species. At the same time these male Parrs attend the female partly for the purpose of devouring the ova which descend with the stream.

In conclusion, Mr Shaw, in our opinion unnecessarily, disclaims all pretension to scientific attainments, wishes to be considered only as an honest inquirer after truth, possessing facilities of observation peculiarly advantageous, and states that he intends to continue his investigations. If all the naturalists who have so confidently spoken on this interesting and important subject, had bestowed as much care upon it as Mr Shaw has done, their observations might have proved useful in place of being so contradictory and vague that no reliance whatever can be placed upon them.

**THE BERNACLE SHELL.**—The animal represented by the accompanying figure belongs to the Pedunculate Cirripedia, which, agreeably to Lamarck's definition, are characterized by having their body supported by a tubular coriaceous contractile peduncle, of which the base is fixed to marine bodies. The plurivalve shell of these animals is considered by the author just mentioned as analogous to the operculum of the sessile cirripedia, of which the external crust or calcareous envelope does not exist in the pedunculate species. The genus *Anatifa*, to which our animal belongs, is defined as having the body covered by a shell, placed upon a tubular, flexible, tendinous,

and contractile stalk; with numerous ciliated and jointed tentaculary bodies attached to the respiratory organs; the shell compressed, of five unequal contiguous valves, the lower lateral valves larger. Several species are known, of which the most common is that here figured.

*Anatifa lavis*, the Smooth Bernacle Shell.—In this species the shell is compressed and comparatively smooth, the striae on its surface not being prominent as in another species, named on that account *A. striata*. This shell is composed of five pieces, two lateral, and one dorsal; the lower lateral pieces much larger than the upper, and the dorsal very narrow and keeled. The pieces are connected by membrane, unless in front towards the top, where the tentacula project. The body of the animal is of an oblong compressed form, curved and enveloped in a soft skin or mantle. Appended to the branchiæ or respiratory organs are ten pairs of long, slender, tapering, curved, and ciliated tentacula, five pairs on each side. At their base are two shorter pairs, and several small flattened and curved organs, equally ciliated, but connected with the mouth. The shell is about an inch and a quarter in length, and is supported upon a peduncle varying in length from a few inches to a foot or even two feet, and in diameter from a quarter of an inch to half an inch. This peduncle is of a reddish colour, and has an external, transversely corrugated, elastic, cuticular envelope, which at its base is attached to a piece of wood, floating or fixed in the sea, and at its upper part to the shell. Internally it consists of a cylinder of longitudinal, whitish, muscular fibres, separated by a large quantity of aqueous fluid, and at the base adhering to the cuticle, which covers the wood, while at the top of the peduncle they are continuous with the body of the animal. The contraction of these muscular fibres of course shortens the peduncle, and throws its envelope into strong transverse wrinkles. These animals adhere often in great numbers to timber of any kind floating in the ocean, to logs, portions of wrecks, casks, and the bottoms of vessels, and are frequently thrown ashore on the western coast of Britain. Gulls of different species, but particularly the Great Black-backed and Herring Gulls, sometimes eat the animal as well as its fleshy peduncle. A foolish notion was once generally entertained respecting this animal, and is still prevalent among uneducated persons, namely, that the Bernacle or Brent Goose, *Anser Bernicla* and *A. Brenta*, originate from it. The ciliated tentaculary organs, which have some slight resemblance to feathers, were the cause of this misconception, having been taken for the sprouting quills of the young bird.

#### BOTANY.

*VICTORIA REGIA*.—On the 22d January was read to the Royal Geographical Society of London, a note upon this plant by Professor Lindley. "I have great satisfaction in stating to the Society, that some specimens of the flowers of this extraordinary plant, which have lately been received from M. Schomburgk, completely confirm the statement of that traveller in all essential particulars, and at the same time establish the new genus *Victoria* upon the most complete evidence. The most startling circumstance named by M. Schomburgk was, that the flowers measured fifteen inches in diameter; one of the specimens now received measures fourteen inches in diameter, although its petals have rotted off in consequence of the bad manner in which they have been prepared. With respect to the genus, it has been already mentioned in the *Journal of the Geographical Society*, at my request, that although *Victoria* is possibly the same as the *Euryale amazonia* of Pæppig, yet it is, in my opinion, quite

distinct from the latter genus. I am not aware that any one in this country, of any botanical reputation, has called this opinion in question; and therefore it may appear unnecessary to notice it further. But Professor Pæppig is so good a naturalist, that it is due to him to state upon what grounds I consider him to be wrong in the genus to which he referred the plant. *Euryale* is an East Indian water plant, with very large floating leaves, sometimes as much as four feet in diameter, light purple underneath, and there reticulated with numerous very large prominent veins. It is, however, covered with sharp prickles on the under side of the leaves, the leaf-stalks, flower-stalks, and calyx. In these particulars it agrees with *Victoria*, but in little else. *Victoria* has the inner petals rigid, and curved inwards over the stamina, into which they gradually pass; in *Euryale* there is no transition of this kind. In *Victoria* there is a double row of horn-like sterile stamens, curving over the stigmas, and adhering firmly to their back; *Euryale* has no such structure. In *Victoria* there are thirty-six large, uniform, compressed fleshy stigmas; in lieu of this very singular character, *Euryale* has only the margin of a cup, with six, seven, or eight curvatures. *Victoria* has twenty-six cells to the ovary; *Euryale* only from six to eight. And, finally, to say nothing of minor distinctions, the ripe fruit of *Victoria* lies at the bottom of a regularly truncated cup, which stands high above the water, while the flower of *Euryale* sinks into the water after flowering, and the fruit, when ripe, is invested with the decayed remains of the calyx and corolla. These facts will, I think, confirm my original statement, that, notwithstanding the prickles of the leaves and stalks, the genus *Victoria* is more closely allied to *Nymphaea* than to *Euryale*, and will, I hope, set at rest all future ingenious speculations upon the first of these genera being untenable."

#### GEOLOGY.

REMARKS ON THE ERRATIC BLOCKS OF THE JURA, BY M. AGASSIZ.—Having spent several months in the neighbourhood of the Alps, for the purpose of studying the glaciers, and of examining the observations of MM. Venetz and Charpentier on the great moraines found at a distance from existing glaciers, he was not less struck by the polished appearance presented by the rocks on which they had moved. The flanks of the valley of the Rhone are entirely polished, even to the borders of the Lake of Geneva, more than a day's journey from the glaciers, wherever the rock has been hard enough to withstand the action of the weather. On seeing this phenomenon, evidently produced by the glaciers, which, when they retired, left on their edges the concentric masses of rolled blocks named *moraines*, he remembered that the northern slope of Jura, which faces the Alps, presents similar polished surfaces, termed *laves*, and on his return to Neuchâtel, he hastened to examine them more attentively. He found that they have no connection with the stratification of the rocks, or with the direction of the chain of mountains, and that they extend along the whole surface, following its undulations, and presenting an uninterrupted smooth surface wherever the rock has been recently exposed. The furrows which often traverse these surfaces never occur in the direction of the slope of the mountain, but are oblique, so that they could not have been caused by currents of water; and the minute markings on the surface are generally parallel to these furrows. It appeared evident that this polishing had been produced by ice; it was found to occupy an extent of more than twenty leagues to the east and west of Neuchâtel, although no one had taken notice of it. As the erratic blocks of the Jura are found resting on these polished surfaces, the question naturally occurs, whether, as M. Charpentier once supposed, the glaciers had extended to the Jura, pushing before them blocks of Alpine rocks, and polishing the surface on which they moved. Such an idea is confuted by the fact that the erratic blocks of the Jura are angular, while those of the moraines are always rounded, as are also those of existing glaciers. If, therefore, the erratic blocks in question had been pushed by glaciers to so great a distance, they ought to be much more rounded than those of the moraines, which ought also to have been the case had they been transported by currents of water. Had the latter been the agent, it is impossible to account for the lakes between the Alps and Jura not having been filled up, especially as it can be demonstrated that they existed previously to the blocks. Nor can the phenomena be accounted for by the supposition of the angular blocks having been transported on floats of ice moved by currents of water: for the erratic blocks of Jura do not rest immediately on the polished surfaces, but on a bed of rolled pebbles several feet in thickness, the larger at the surface, and the smaller, often as fine as sand, at the bottom. Now, had the transportation been effected by currents, the reverse would have been the case. The existence of fine sand on the surface of the polished rocks, also proves that no powerful cause has acted on the surface of Jura, since the period at which these Alpine rocks were transported; and the fine lines on the polished surfaces are no doubt due to this sand, which, however, could not have been moved by a current of water, for neither torrents nor lakes, when charged with sand, produce any thing analogous on the same rocks. M. Agassiz is of opinion that most of the phenomena attributed to great diluvial currents, and especially those recently described by M. Selfstroem, have been produced by ice.

#### MISCELLANEOUS.

PEARL-FISHING IN ARABIA.—The Pearl-bank extends from Sharja to Biddulph's Group. The bottom is of shelly sand and broken coral, and the depths vary from five to fifteen fathoms. The right of fishing on the bank is common, but altercations between rival tribes are not unfrequent. Should the presence of a vessel of war prevent them from settling these disputes on the spot, they are generally decided upon the island where they land to open their oysters. In order to check such quarrels, which, if permitted, would lead to general confusion, two government vessels are usually cruising on the bank. The boats are of various sizes, and of various construction, averaging from ten to fifty tons. During one season it is computed that the island of Bahrein furnishes, of all sizes, three thousand five hundred; the Persian coast, one hundred; and the space between Bahrein and the entrance of the Gulf, including the Pirate Coast, seven hundred. The value of the pearls obtained at these several ports is estimated at forty lacs of dollars, or four hundred thousand pounds. Their boats carry a crew varying from eight to forty men, and the number of mariners thus employed

at the height of the season is rather above thirty thousand. None receive any definite wages, but each has a share of the profits upon the whole. A small tax is also levied on each boat by the Sheikh of the port to which it belongs. During this they live on dates and fish, of which the latter are numerous and good, and to such meagre diet our small presents of rice were a most welcome addition. Where polypi abound, they envelope themselves in a white garment, but in general, with the exception of a cloth around their waist, they are perfectly naked. When about to proceed to business, they divide themselves into two parties, one of which remains in the boat to hand up the others who are engaged in diving. The latter having provided themselves with a small basket, jump overboard, and place their feet on a stone, to which a line is attached. Upon a given signal, this is let go, and they sink with it to the bottom. When the oysters are thickly clustered, eight or ten may be procured at each descent, the line is then jerked, and the person stationed in the boat hauls the diver up with as much rapidity as possible. The period during which they can remain under water has been much overrated; one minute is the average, and I never knew them, but on one occasion, to exceed a minute and a half.

Accidents do not very frequently occur from Sharks, but the Saw-fish, *Pristis antiqorum* of Linnæus, is much dreaded. Instances were related to me where the divers had been completely cut in two by these monsters; which attain, in the Persian Gulf, a far larger size than in any other part of the world where I have met with them. As the character of this fish may not be familiar to the general reader, I will add a few words in the way of description. They are of an oblong rounded form, their head being somewhat flattened on the fore part, and tapering more abruptly towards the tail. They usually measure from thirteen to fifteen feet in length, being covered with a coriaceous skin, of a dark colour above, but white beneath. The terrific weapon from whence they derive their name is a flat projecting snout, six feet in length, four inches in breadth, armed on either side with spines resembling the teeth of a Shark. Diving is considered very detrimental to health, and without doubt it shortens the life of those who much practise it. In order to aid the retention of the breath, the diver places a piece of elastic horn over his nostrils, which binds them closely together. He does not enter the boat each time he rises to the surface, ropes being attached to the side, to which he clings, until he has obtained breath for another attempt. As soon as the fishermen have filled their boats, they proceed to some of the islands with which the bank is studded, and there, with masts, oars, and sails, construct tents. They estimate the unopened Oysters at two dollars a hundred.—*Wallsted's Travels in Arabia*.

**PERIODICAL THUNDER-STORMS AT CONSTANTINOPLE.**—In a letter to M. Arago Admiral Roussin states, that on the 10th August a violent thunder-storm occurred at Constantinople, and that about the same period one generally occurs yearly. It commenced in the south, and then veered to the north, approaching the Black Sea, its ordinary domain. It lasted from one o'clock in the morning to daybreak, and was accompanied by furious rain. The lightning struck three points near each other at Pera, at the Danish embassy; and at that of Spain, it broke the doors, and burnt the carpets and curtains, but did not touch the glass. The other bolt fell on a small Greek vessel, broke its mast, killed a man, and injured another. He says that at other times thunder-storms are by no means frequent.

#### LEARNED SOCIETIES.

**ZOOLOGICAL SOCIETY OF LONDON.**—At the meeting of the 9th January 1838, Thomas Bell, Esq., F.R.S., in the chair, Mr Gould exhibited a collection of Australian birds, and laid on the table descriptions and characters of the whole for publication in the Society's Transactions. He also described forty species of birds from Mr Darwin's collection, about a third of which were new. Mr Gray described a small marsupial quadruped from Van Dieman's Land, which he named *Perameles facialis*. A communication was read from Captain Harris, descriptive of a new Antelope found by him in South Africa, about the size of a Horse, black above, white beneath, with the horns beautifully curved. It inhabits the great mountain range in the country of Mataveld, and is gregarious in small families.

Jan. 23d.—Richard Owen, Esq., F.R.S., in the chair. Mr Ogilby gave an account of several new species of Mammalia contained in the collection made by Captain Alexander in South Africa; and Mr Gould described several new birds from the same collection. Among the rapacious species were an Eagle with a white breast and red tail, two small Falcons scarcely larger than a Sparrow, and a very small Owl; among the insessores a Jay which perches on the horns of the Rhinoceros, and which the hunters of that animal anxiously watch, as when they see it fly up, they know that the object of their pursuit is alarmed. Mr Ogilby described a new species of Galago from Madagascar, in which the fore-finger was of the same size as the other, and partially opposable to them. Mr Owen also read some observations on the anatomy of the Giraffe, from dissections of the animals which died at the Regent's Park and Surrey Zoological Gardens.

#### PROCEEDINGS OF THE ROYAL SOCIETY OF EDINBURGH.

The first ordinary meeting of the 55th Session of the Society took place on Monday, 4th December 1837, Sir T. M. Brisbane, Bart., President, in the chair. A communication on the Food of the Vendace, Herring, and Salmon, by John Stark, Esq., was read. The author, after some preliminary observations, stated, that fishes, like the Vendace, residing in lakes, and feeding on animal food, must necessarily subsist on the small aquatic animals found in these lakes; that there is no reasonable analogy between the Vendace and the Herring, because they live in different mediums, the one in salt, the other in fresh water; that their food cannot therefore be the same; that writers on natural history state the animalcules which are found in the stomach of the Vendace, and the other minute animals found in lakes, to form the food of fresh-water fishes generally; and that Leeuwenhoek had even figured the identical animal found in the stomach of the Vendace in 1633 more than 130 years before. As to the Herring, the author stated that its food was known and described from personal observation by Neucrantz, previous to 1654, by Leeuwenhoek in 1696, by Fabricius in 1781, by Muller in 1785, by Bloch about the same period, by Lacepede and

Latreille in 1798, by Scoresby in 1820, and by many others; and that what has been stated by all authors on the subject is corroborated by the examination of the stomach and intestinal canal of that fish, and by specimens on the table of the Society. With regard to the food and reproduction of the Salmon, he gave an account of the observations of the most esteemed authors, and exhibited preparations by Dr Parnell, confirming their statements. He noticed the valuable evidence taken before a committee of Parliament in 1824 and 1825, which corroborated the statements of systematic writers; and gave an abstract of the evidence as to the period of the ascent of the Salmon in the different rivers.

Dr Barry made some verbal remarks on the physiology of *Proteus anguinus*.

#### REVIEW.

*Illustrations of Ornithology.* By Sir William Jardine, Bart., F.R.S.E., F.L.S., M.W.S., &c.; and Prideaux John Selby, Esq., F.R.S.E., F.L.S., M.W.S., &c. 3 vols. Edinburgh, Daniel Lizars; London, Longman, Rees, Orme, Brown, and Green, and S. Highley; Dublin, Hodges and M'Arthur.

SOME writers have affected to make a distinction between naturalists, whom they arrange primarily into professional and amateur; but this arrangement is altogether artificial being dichotomous, otherwise we should have referred the authors of this work to the latter section, seeing that they assume the pen and the pencil more from a benevolent desire to benefit the human race, or a wish to distinguish themselves, or a pure love of their favorite science, than from any necessity of taking it up as a trade or profession. As it is, however, we must simply view them as working ornithologists, painters, and engravers, for not only have they elaborated the descriptions of the objects which they have selected, but they have also represented them *more pictorum et sculptorum*. Their purpose has been to advance the progress of science by describing new and rare or remarkable objects; and their performance, besides in some measure accomplishing this object, will remain a monument of praiseworthy perseverance. The figures, although not generally characterized by a perfect semblance of living birds, are yet in all cases sufficiently accurate to enable a person, by comparing his specimens with them, to satisfy himself as to their specific identity. Some of them are very well executed; for example, *Pteroglossus maculatus*, *Cursorius bicinctus*, *Aegolius inulatus*, *Sitta castaneo-ventris*, *Gallus Bankiva*, *Tropidorhynchus corniculatus*, *Emberiza erythroptera*, *Trogon Reinwardtii*, *Corythix Buffonii*, *Passer Indicus*, *Trichoglossus hematodus*, *Squatarola rubecula*, *Platyarchus Stanleyi*, *Halecyon Macleayi*, which, with several others, are all that could be desired; but generally the forms and attitudes are ungraceful; the head in many of the smaller species is not nearly large enough, and the curvature of the neck is often absurd, as in *Ptiloris paradiseus*, female, and *Tachyphonus Vigorsii*. The descriptions are generally brief and confined to the external form and plumage, the internal organization of animals not forming, in the estimation of our best naturalists, an object of sufficient importance to attract attention. As to the manners or habits of the species represented, it was not to be expected that persons residing in England could know much about them, and thus the display of erudition made by the authors consists of remarks as to affinities of species and genera, without much that could be of interest to the philosophical ornithologist, who combines in his notion of the science the internal and external structure, the habits, relations, and distribution. Yet, to those who can afford to purchase it, the work will be useful, chiefly because it will afford them the means of naming the skins represented there, should they happen to possess them or see them in a museum. In several cases, a synopsis of all the known species of a genus is given, and in general all is done that might reasonably be expected in the matter of mere dried skins, the animating principle of which has not been taken into consideration. The specific characters are given in Latin, but as we think unnecessarily, and had the learned authors employed their vernacular tongue, they might have avoided the many grammatical errors and inelegancies, which many school-boys might detect. Had a lad in the Rector's Class of our High School written such a version as the following, he ought to have been whipped:—*Accentor supra fusco-cinereo, dorso strigis fuscis vario, gula alba fusco-maculata; tetricibus alarum nigris, apicibus albis, infra cano-rufescente maculato, tetricibus lateralibus apicibus rufo albidis*. However, this is, after all, nothing very remarkable, for one of our first naturalists in many cases fails to give the correct orthography of the very names which he himself invents, and our ornithologists, from Montagu downwards, have too often manifested a contempt of the rules of composition.

Finally, the work seems to us creditable to its authors, as indicative of great perseverance and love of approbation, as well as of science, so called at least; but it exhibits no quality beyond what hundreds of individuals might manifest, had they the means of collecting skins, comparing them with published figures and descriptions, and giving them to the world, not caring much whether the expenses should be covered or not. Mere descriptions of bills, feet, and feathers, are easily manufactured, for in this branch of science a short apprenticeship is sufficient to make a tolerable journeyman; and as to the affinities and analogies, which one might suppose to require a little judgment, nothing more is needed than to obtain a knowledge of the slang employed by the founders of a system, and carry out their views, taking care to overlook every circumstance unfavorable to the adopted theory, and to abuse all who place truth and nature in opposition to it. What we especially admire the authors for is, the dexterity they have attained in transferring the delineations of their pencil to copper; although we conjecture that there are not many journeymen engravers who would feel disposed to boast of such performances as theirs. In short, we give them all the credit due to laborious and well-meaning cultivators of ornithology, and recommend to our readers to patronize them accordingly. If they do not attain the summit of Parnassus, it is not for want of scrambling.

## DESCRIPTION OF THE PLATE.—THE OSTRICHES.

In the system of Cuvier the Ostriches and Cassowaries constitute the family of *Brevipennes*, belonging to the order of the *Gralla*. They are characterized by the shortness of their wings, which prevents them from flying; by a form of bill and granivorous habits which indicate an affinity to the Gallinaceous birds; and by the great length and muscularity of their legs, which approximate them to the other *Gralla*. They are destitute of the hind toe, as well as of the crest of the sternum; their forcula is imperfect, and their pelvis complete. The Ostriches, of which two species are known, have the bill horizontally depressed, of moderate length, with the point blunt; the tongue short and rounded; their œsophagus dilated into a large crop; their stomach a powerful gizzard; their intestines large, and their cœca long. Their eyes are large, and their eyelids furnished with lashes. Their plumage is soft, the feathers are in a manner double, the plumage being equal in length to the other part, and the wings, instead of quills, are ornamented with gracefully undulating plumes, of which the filaments are disunited, while the tail is similarly decorated.

Fig. 1. THE OSTRICH properly so called (*Struthio Camelus*), male. This is the largest bird known, its height sometimes exceeding seven feet. The male is generally black, mixed with white, of which latter colour are the beautiful plumes of the wings and tail, which are in great request as ornamental articles of dress. Ostriches live in large flocks in the sandy deserts of Africa and Arabia. Although incapable of flying, they run with extreme rapidity, so as, for a time, to outstrip the swiftest steed; and their legs, which are of vast size, are furnished with only two toes, a rudimentary inner toe, however, having been recently detected beneath the skin. Their flesh is considered good when the birds are young, but otherwise it is extremely tough, although it was considered a delicacy by the Romans. The eggs, which are about twenty times the size of those of our domestic fowl, are of an elliptical form, with a very thick, yellowish shell, which is sometimes used as a cup. Their number, according to Vaillant, is about ten, but so many as forty have been found deposited together. They are laid on the sand, and are hatched by the heat of the sun, although the female sometimes sits upon them at night; but, in the more temperate regions, and particularly near the Cape of Good Hope, they are deposited in a pit about three feet in diameter, and the female sits regularly upon them. The young are tended with the greatest care. The food of this bird consists of vegetable substances. Like other granivorous and graminivorous birds, it swallows fragments of stone to aid its trituration, and, in captivity, is not nice as to the articles selected for this purpose, picking up pieces of iron, copper, lead, &c. This circumstance has been attributed to the peculiar obtuseness of its taste, but with little reason, for in granivorous birds, which swallow their food without mastication, the tongue is an organ of prehension and deglutition, but not of taste, so that in this respect the Ostrich does not differ from other birds.

Fig. 2. Female. The female is generally of a grey colour, and is somewhat inferior to the male in size.

## DESCRIPTION OF THE PLATE.—THE LORIES AND PARRAKEETS.

The numerous family of the *Psittacide* is divided into several sections or families, representatives of two of which are here figured.

Fig. 1. THE SPARKLING LORY (*Lorius scintillatus*) is so named on account of the bright yellow streaks on the plumage of its breast and sides. It is from New Guinea.

Fig. 2. THE TIRIBA PARRAKEET (*Psittacula cruentata*), having the top of the head dark brown, the plumage generally green, with patches of bright red, yellow, and purplish blue, was discovered in Brazil by Prince Maximilian of Neuwied.

Fig. 3. THE COQUETTE (*Ps. placensis*), male. This species was found in New Guinea, by the Dutch naturalists Macklot and Müller, who visited that country in the Triton corvette.

Fig. 4. THE COQUETTE, female.

Fig. 5. THE SLENDER PARRAKEET (*Ps. euteles*) was discovered by the same naturalists in the island of Timor.

Fig. 6. THE IRIS PARRAKEET (*Ps. Iris*) was also found by them in the same island, where it appeared to inhabit the woods near the shores in great numbers.

SYMPATHETIC AFFECTION AMONGST CROWS.—During a severe winter, when the snow had lain long and deep upon the ground, the feathered tribes were reduced to the point of starvation. One morning the Strathendry Crows had fixed on some barley, a little to the east of the steading, and had nearly uncovered the stack to get at the grain. To save the barley, one of the men took his gun, and contrived to get within range; but the moment he raised his head, the sentinel on duty sounded the alarm, and the man fired into the dense cloud, as they floated off the stack. Amongst the wounded, one had lost the extremity of his right wing by the joint. Thus disabled, he was soon secured, and given in charge of a servant's wife, who had shown herself an adept in training birds and cats, to try what we could elicit of the innate dispositions and mental faculties of the Crow.

Daily were this person's birds and cats to be seen feeding, in perfect harmony, from the same dish; and I have frequently seen a cat pretty sharply admonished by a blackbird, when overstepping the bounds of good manners while feeding. No cages were wanted for her birds, though both doors and windows stood open as occasion required. Her feathered and feline family went and came as pleased themselves. If any were absent at feeding time, she went to the door and called them in Gaelic, as she said she never could make bird or cat obey her in English.

The first lesson given to the poor mutilated crow was to place him on her knee, while yet starving, with a hand over his shoulders to prevent his stirring, but allowing him full freedom to look down on Larks, Linnets, Blackbirds, and Cats, forming a circle round the feeding dish. He seemed to eye the cats with suspicion, but "hunger tames the Tiger." Stretching his neck towards the provisions, and indicating a desire to raise his wings, he was allowed to go down. He shyed at first, walked round them for a time, but at length struck in, and made a hearty meal. From this time he felt quite at home, seemed to study the rules of the house, and kept his place in the crowd, or before the fire, where he often lay quite at his ease, along with the cats, enjoying himself on the warm hearth. It was quite amusing to see with what familiarity he would stalk about, with all the strut and dignity of a lord of the manor, mixing inquisitively among the servants, and eyeing all their motions, like an attentive superintendent, returning to head-quarters when called, or marching off to dine with the servants in the bothy. The servants dubbed him "Captain." The most remarkable part of his history, however, remains to be told.

Experience had taught him that his confidence was not misplaced. His gratitude for the protection and ease which he enjoyed was evinced in his filial familiarity and obedience. One day, however, he was observed evidently watching an opportunity to carry off a piece of boiled potato, which he at last accomplished, and walked with it to the door, as if to hide it, for some future occasion. This he was observed to repeat as often as he found opportunity, as he conceived, unobserved. The circumstance was mentioned to me, and I resolved to watch him out of doors. To prevent detection within, he left the house, and I soon after observed him casting his eyes about him, pause, and then march off towards the bothy,

"Looking round wi' canny care,  
Lest boggles catch'd him unaware,"

walk cautiously forward, drive his beak into a cold boiled potato, march away in double quick time, crouching as if afraid of being detected in the act of thieving, and, turning the nearest stack, disappear. Something prevented my following him at the moment, but he soon reappeared for a further supply, took the same route, and again disappeared. I immediately took a cold potato in my hand and followed. On rounding the stack, to my astonishment I found him in the act of feeding another disabled crow. I cautiously neared them. The stranger shyed, lifting his wings to fly off. Captain, however, remained undisturbed. I held out my potato. Captain came with evident satisfaction, took a portion of it from my hand, while the stranger, who halted at a safe distance, was looking on. Captain then walked with the potato towards his friend, who met him, and in the course of feeding I observed, with a painful sensation, that the poor stranger had lost his bill, and consequently was incapable of helping himself, although food had lain before him. What free-masonry passed between them I know not; but on Captain's returning for the remaining portion of my potato, the stranger followed in his rear, with all the familiarity and confident bearing of an old acquaintance. However much my admiration was excited on this first interview with the stranger, I was still more astonished to see him walk side by side with his preserver into the servants' bothy, while the servants were at dinner,

(Continued from page 130.)

without shying, or betraying the least symptom of fear. When they had been fed sumptuously, Captain marched him over to head-quarters, and introduced him to his mistress, cats, and comrades, by whom he was "most graciously received." There he remained an inmate, under the title of Nebby.

Nebby could fly as well as ever, and took frequent flights round, for intelligence or amusement. I have often seen him on returning alight, and implore his mistress for water, by gently moving his wings and holding up his head. On her sitting down, Nebby was immediately on her knee, to receive it; and it was given him by dipping the finger, and dropping it from the point into his throat.

One Sunday, some idle blackguard boys, from some of the mills down the water, carried off both Captain and Nebby. I made every inquiry, but never recovered them.—GAVIN INGLIS.

REMARKABLE ELONGATION OF THE BILL OF A ROOK.—The accompanying figure represents the head and bill of a Rook, shot near Dalkeith in the beginning of March, and submitted to our inspection by Mr Carfrae, preserver of animals in Edinburgh. The bird was in every other respect of the ordinary appearance of the species, and was in good condition, notwithstanding the extreme severity of the season, and although one might imagine it impossible for it to pick up its food with a bill so constructed. The malformation consists of an elongation of the upper mandible, of which the point extends beyond that of the lower an inch and a quarter, being curved gently downwards, grooved beneath, and having a breadth of about a quarter of an inch.

We have seen instances of a like elongation in other birds, although not to the same extent; and in the Rook itself a case occurred in which the upper mandible was not only elongated, but deflected laterally. On the other hand, we have seen the lower mandible abbreviated, and imperfect, in as much as its two sides did not meet at the commissure, which presented a vacant space. In birds kept in captivity not only the bill, but also the claws, frequently become extremely elongated; and the same circumstance is occasionally observed in the hoofs of ruminating animals. In such cases the elongation is easily accounted for by the want of the ordinary action of the animal, which would tend to wear down the extremities of the horny parts, or repress their extension by the pressure applied to them. The case is somewhat analogous to the occasional elongation of the incisors of the gires; and we would humbly suggest to the quarian systematists, that the Rook, and consequently the Crows in general, are analogous in their own circle to the Hares! Indeed, they have often seized upon less palpable analogies to support their peculiar views.

PISCATORY HABITS OF THE CARRION CROW.—"Stobo-hope, Peebles-shire, 22d January 1838.—In a former communication, which you have inserted in your History of British Birds, I told you of two Carrion Crows that for upwards of twenty years have inhabited the ground of which I have charge. In this glen is a small meadow irrigated from the stream which runs along its bottom. On the brink of its principal head I noticed my old friends busy eating, and thinking it might be some part of a sheep, I made towards them, and found them standing with their heads toward each other, pecking with all their might at something that lay between them. In their eagerness, they sometimes tossed it athwart, to obtain mouthfuls. When I went near, one of them carried off the remainder of the feast in his bill. I found neither wool nor feathers, however, bones nor entrails, nothing, in short, but a little blood on the snow; but, on a more minute inspection, I observed a small trail, as if something had been pulled out of the lead, and the marks of some drops of water that had been splashed out and sunk among the snow. I could make no more of it, and so left it, carelessly thinking it might have been a water-mouse which they had seized in a fit of desperate hunger. A day or two after, I fell in with Sir James Montgomery's man, who has charge of the watered meadows, ditches, and drains, and told him of the circumstance, when he assured me that he had oftener than once surprised the Carrion Crows devouring fish, taken in the meadows, and that one time they had eaten all but the bones of the head. The reason why this happens in a meadow is as follows. To irrigate a meadow rightly, the water must be taken off at times, and on the occurrence of certain changes in the state of the air. During the time that it is flooded, small fish or trouts sail down the principal lead, then distribute themselves along the small canals where sustenance for them abounds. When the water is instantaneously let off, the poor trouts can find protection nowhere from the Heron, who diligently searches all the sinks and shallows of the half-dried pool. But I had no conception of the Carrion Crows taking and feeding on fish; this I thought had been a prerogative of fowls and other animals whose structure adapted them for searching in and under water. I had no doubt, when I considered the omnivorous nature of this Crow, however, that if it found a dead fish, it would readily eat it up; but that it would plunge into the water, and seize a fish swimming deep, I could not have supposed; yet this had certainly been done on this occasion, for the water out of which they had dragged the fish was rather more than a foot deep, and on taking a second look of the place, I found that no protection could be afforded to the trouts, as there were neither stones nor hanging banks.—WM. HOGG."

CONTINUING our subject, we propose to include in our survey that portion of Devonshire which extends from the heart of Dartmoor to the southern coast, and which is included between the rivers Exe and Tamar respectively on the east and west. There is thus presented to the view an extent of country having in its northern part the character of sterility, and in its southern that of fertility. Now, as we have already had occasion to observe, the animal part of the creation is almost entirely dependent on the vegetable world; whilst the vegetable kingdom, in its turn, is dependent on inorganic matter. Accordingly, if it appears that the northern division of our limits is not calculated, from the nature of its superficial soil, to maintain vegetable life, except in a limited degree; so also, it is obvious that the animal productions of this spot must be likewise restricted. The central districts of Dartmoor present to the eye a series of hills of great size, covered with detached blocks of granite. On the summits of many of these hills are found swamps, and even pools of great depth, and between them streams pass on for future coalescence; and where the surface is level for a sufficient space, the drainings of the country rest, and form morasses and lakes. Altogether, Dartmoor and its vicinity present a large proportion of water, since it appears that five principal rivers, twenty-four secondary streams, fifteen brooks, two lakes, and seven heads, are found on it.

The Flora of this wild district consists, with but few exceptions, of the lower tribes, such as mosses, ferns, lichens, &c., and of such plants as are peculiar to marshes and other collections of water. The soil cannot possibly support many of the higher orders; but the beauty, variety, and luxuriance of those vegetable forms which mantle the rude blocks of granite, spring from the spongy soil of the hogs and marshes, raise themselves into notice above the stream, or maintaining their existence in the body of the current, attached to some fixed point, move in conformity to its undulations, are sufficient to attract the notice of even the incurious. In this sterile spot the most common creature excites regard, and those which are peculiarly its own cannot fail to be contemplated with much interest.

The Quadrupeds of Dartmoor, though now reduced to a small number, were formerly pretty numerous. The following are recorded as its ancient inhabitants: the Wolf, the Brown Bear, the Boar, the Wild Ox, the Red Deer, and the Wild Cat. The Wolf appears to have become extinct on Dartmoor about the close of the reign of Elizabeth. It was a pure native of our country, and required great exertions for its removal. The Bear seems to have been extirpated in the eleventh century; and unless its food consisted chiefly of vegetable productions, it is difficult to understand how its existence could have been maintained. The Boar and Wild Ox have been taken under the protection of man, and the date of extirpation of the wild stock is not recorded. That noble animal the Red Deer was, until within the last fifty years, pretty common in the remote wooded districts of the county. Its race, too, has undergone extirpation in a very gradual manner. "Sometimes, but rarely, one has been perceived near Ashburton;" and it is not more than three years since I saw an account in a paper of the chase of one near that town, which had unfortunately been spied in some coppice. It is quite reasonable to suppose that both the Wild Cat and the Goat were natives, or rather frequenters, of this district, so perfectly congenial in its aspect to their natures. All these were most likely found in a less degree throughout the woods and wilds that lie to the south of Dartmoor; but by increase of population and agriculture they were no doubt soon removed from these spots, and eventually their limits restricted to the Moor itself. But here also they suffered extermination soon after the king took part in the more noble field amusements, and when punishments were inflicted for interference with the game.

At present, the following are the Quadrupeds found in the south of Devon, inclusive of the Moor, though there are some of them which are unfitted to live in spots so barren and wild as are the more remote and central portions of this district.

1. Barbastelle Bat. *Vespertilio Barbastellus*.
2. Horse-Shoe Bat. *Rhinolophus Ferrum-equinum*.
3. Common or Pipistrelle Bat. *Vespertilio pipistrellus*.
4. Great Bat. *Vespertilio Noctula*.
5. Long-eared Bat. *Plecotus auritus*.
6. Smaller Horse-shoe Bat. *Rhinolophus Hipposidevos*.
7. Hedgehog. *Erinaceus Europæus*.
8. Common Shrew. *Sorex araneus*.
9. Water Shrew. *Sorex aquaticus*.
10. Mole. *Talpa Europæa*.
11. Badger. *Meles Taxus*.
12. Fox. *Canis vulpes*.
13. Weasel. *Mustela vulgaris*.
14. Stoat. *Mustela erminea*.
15. Polecat. *Mustela putorius*.
16. Common Martin. *Mustela foinea*.
17. Pine Martin. *Mustela Martes*.
18. Otter. *Lutra vulgaris*.
19. Common Mouse. *Mus domesticus*.
20. Field Mouse. *Mus sylvaticus*.
21. Harvest Mouse. *Mus messorius*.
22. Black Rat. *Mus Rattus*.
23. Brown Rat. *Mus decumanus*.
24. Squirrel. *Sciurus vulgaris*.
25. Hare. *Lepus timidus*.
26. Rabbit. *Lepus Cuniculus*.
27. Dormouse. *Myoxus glis*.
28. Water Vole. *Arvicola amphibia*.
29. Field Vole. *Arvicola agrestis*.
30. Fallow Deer. *Cervus Dama*.

We have here a list of thirty terrestrial mammalia. The extent of this catalogue must needs excite surprise, for the present state of Dartmoor would by no means lead to the belief of its supporting more than two or three quadrupeds of the smaller kind; and, indeed, upon inquiry into facts, we find that the barren open portions are frequented only by the Rabbit, Mole, Weasel, and perhaps the Stoat. How then can this region have maintained those large animals recorded as extirpated? There is undeniable evidence that the central department of what we ordinarily term Dartmoor was in former years a forest, and that it was set apart for the king's use as a royal chase. With this explanation difficulties vanish. At the present period the woods and plantations in the immediate vicinity of the Moor harbour the same quadrupeds as those found in the southern districts. The Martin and Polecat, however, are now more peculiarly frequenters of the deep woods, remote from cultivated parts. The former, indeed, I have not known to be captured anywhere but in the noble woods at Buckland-in-the-Moor; but it is reported to be also found in the woods at L. dford. I am told that the Yellow species (*M. Martes*) is found with the other. The Otter is said to confine itself to the river Dart, probably from its superior size and depth, and from its being better supplied with fish. The fur of specimens from hence is said to have an admixture of white hairs. The Mole is a creature by no means limited to cultivated districts, as appears by its occurrence on a barren hill, of very considerable height, in the immediate neighbourhood of the Moor. The most numerous and characteristic species, however, is the Rabbit, which, as will subsequently be seen, draws thither a variety of rapacious birds that otherwise would not find food in such a district.

The Ornithology of Dartmoor is in many respects interesting. The Rabbits which abound there draw numerous species of rapacious birds to it. The Raven, *Corvus Corax*, Carrion Crow, *C. Corone*, and Hooded Crow, *C. Corvix*, likewise traverse in their wanderings these wild spots. The Ring Ouzel, *Turdus torquatus*, frequents many of the rocky and rapid streams, in parties, nestling, to my knowledge, in hollows of the rocks. The Water Ouzel, *Cinclus aquaticus*, is a frequenter of similar situations, being a great lover of solitude; and I am not aware that either of these birds has been traced, except sparingly, beyond the barren portions of the Moor. The Tit-lark, *Anthus protensis*, Stonechat, *Saxicola Rubicola*, Whinechat, *Saxicola Rubetra*, and Grasshopper Warbler, *Sylvia Locustella*, are found occupying their respective stations on the heaths and stony fields; and the Wheatear, *Saxicola Oenanthe*, and Reed Warbler, *Sylvia Phrogmitis*, are reported to make their abode within the limits of the more barren parts of the district. It has been told me that Cuckoos, *Cuculus canorus*, are at times seen haunting rocky spots on the borders of Dartmoor; and this may be true enough, although it is possible that my informant may have mistaken the Nightjar, *Caprimulgus europæus*, for it, as they are not very dissimilar in appearance, and since I well know that Nightjars are found on the borders of the Moor in large wooded inclosures, but particularly at Buckland-in-the-Moor, where the oaks have attained a great size. From these woods they usually select positions in the adjoining commons or brakes for nesting. The Great Bustard, *Otis Tarda*, which formerly frequented the Moor, has, I fear, been extirpated. In times past also, no doubt, the Crane, *Ardea Grus*, frequented Dartmoor. One was shot, in 1826, on the borders, and there is a hill in the heart of the Moor, having on its summit a pool of great size, called Cranmere Pool, a name signifying the abode of Cranes, as though these birds had been in the habit of resorting thither, as is the practice of some other birds at present. The Thick-kneed Plover, *Edicnemus crepitans*, frequents the downs and wastes; and it would seem that they wintered with us, and were driven to inclosed lands, as in severe winters they have been brought to Plymouth market, where I have myself seen them, though rarely. In the summer months I have seen Curlews, *Numenius Arquata*, on the marshy grounds, where indeed they breed, but I presume the numbers killed on the coast in severe winters must be derived principally from the northern counties. It has been proved that many individuals of the Snipe family breed on Dartmoor, but it is only of late years that this fact has been observed. The same observation applies to the Duck, Wigeon, and Teal, according to report, though I can answer only for the Wild Duck, *Anas Boschas*, which unquestionably breeds in several spots on the Moor, besides in those situations in our cultivated grounds where care has been taken to protect it. The swamps of the Moor are also the breeding-places of many individuals of several species of wading birds found in the autumnal and winter months in our cultivated lands and shores. The Lapwing, *Vanellus cristatus*, descends in flocks in winter. I have noticed them arriving in vast quantities in December yearly, on the high grounds bordering Bigbury Bay. It has been found also that the Golden Plover, *Charadrius pluvialis*, Grey Plover, *Charadrius Helveticus*, and Dunlin, *Tringa cinclus*, breed with us, and there is great reason to suppose that very many other similar birds do so likewise. The Coot, *Fulica atra*, Water Hen, *Gallinula chloropus*, and Water Rail, *Rallus aquaticus*, are well known to breed not only in the marshes of Dartmoor, but also plentifully in very many swampy woods, and other secluded watery spots not far from Plymouth, dispersing from these retreats as soon as the cold sets in. The Black Grouse, *Tetrao Tetrix*, is sparingly dispersed over the moors, and in winter roams with its progeny over the woods and cultivated parts of the country, being occasionally shot, and brought to market in the severer months.

Besides the above named birds, there are others recorded to have been observed sparingly on or in the vicinity of the Moor. The Honey Buzzard, *Pernis apivorus*, Sea or Cinereous Eagle, *Haliæetus Albicilla*, Golden Eagle, *Aquila Chrysaetos*, Goshawk, *Astur palumbarius*, Kite, *Milvus vulgaris*, Little Owl, *Strix passerina*, Short-eared Owl, *Strix brachyotus*, Nutcracker, *Nucifraga Caryocatactes*, Greater Spotted Woodpecker, *Picus medius*, Lesser Spotted Woodpecker, *Picus minor*, Rose Ouzel, *Turdus rosæus*, Wryneck, *Jynx torquilla*, Cross-bill, *Loxia curvirostra*, Hawfioch, *Coccothraustes vulgaris*, Hoopoe, *Upupa Epops*, Snow Bunting, *Plectrophanes nivalis*, Turtle Dove, *Columba turtur*, Quail, *Coturnix dactylisonans*, Little Bustard, *Otis tetrax*, Great Snipe, *Scolopax major*, Barker, *Totanus fuscus*, Spotted Rail, *Gallinula Porzana*, and Little Rail, *Gallinula minuta*, are some deserving notice. But it is to the deep and unfrequented woods before named, as bordering the

Moor, that we are principally indebted for these rarities; and it cannot be altogether surprising that these spots, so secluded, and so generally calculated to be the abodes of the feathered tribes, should contain within them objects so precious to the naturalist. They who have read Vaillant's Travels in Africa will, I think, agree with me in the remark, that the transition from these woods to the sterile tracts of the Moor contiguous, where even in summer little else can be seen save the Carlew flying from the summit of one Torr to another, and by its harsh note adding to the dreariness of the scene, the Stonechat, the Ring Ouzel, or perchance a Buzzard hovering aloft, is not very unlike the sudden changes experienced by that adventurer, and which he so touchingly describes; at one time surrounded by hundreds of beautiful birds, enlivening by their actions and notes the thick groves; then situated in a trackless desert, and guided only on his way by the harsh note of a duck, flying at a great height in quest of some rock which might happily contain water in its basin.

The arid and remote portions of the Moor are frequented by only a few birds, not found (or but rarely and at certain times) in the southern and cultivated districts. The Eagles and birds of that kind are generally, however, partial to remote spots, or restricted to them by our interference. The Golden Eagle, if still a Devon bird, must be accounted as in some measure peculiar to Dartmoor, though most of this kind roam to immense distances at certain periods. The Sea Eagle, too, has been seen both on Dartmoor and frequenting cultivated land, and has likewise been captured at the Eddystone. The Goshawk, Kite, and Honey Buzzard, may be considered almost confined to Dartmoor; the latter, however, has been noticed at Slapton Ley. The Short-eared Owl has been killed both on Dartmoor and Exmoor, but seems to be very rare, and to confine itself to open and remote spots. The Dipper and Ring Ouzel are both lovers of the Dartmoor solitudes. The Black Grouse, Little Bustard, Thick-kneed Plover, and the various waders before named as most likely breeding on the moors, together with the Great Bustard and Crane (if still resident in the county), must be considered in some degree peculiar to Dartmoor, though they are all constrained, on the occasion of severe weather, to seek shelter and food in the cultivated parts.

The woods bordering Dartmoor are well adapted to shelter a variety of birds of the rarer kinds; but yet none that I know of are limited to them, though the Turtle Dove is more frequent in these situations than in the southern parts, and several species of the rarer Hawks are mostly obtained from thence.

I am not aware that anything need be said relative to the amphibia of Dartmoor, excepting that the Lizard, *Lacerta agilis*, and Viper, *Coleber Berus*, are both found pretty commonly on the downs and other dry situations, as indeed they are throughout the whole county. Nothing can be said relative to the Ichthyology, nor anything on the Conchology, unless it be that *Helix trochilus* has been noticed close to the Moor. Having but slight acquaintance with Entomology, I can only say that the lists of the Dartmoor insects are very extensive.

When we come to examine the Fauna of the central districts of South Devon, we find considerable alterations in its character, besides its extent being greatly increased. The diversification in the surface of the country, together with every variety of soil, and vegetable produce, is no doubt one great reason of this circumstance, while another cause is our being situated at the southern limits of the island, by which means we are more likely than other counties to partake of the ornithology of the continent, and likewise to receive a variety of birds which migrate from northern counties or kingdoms.

Reverting to the mammalia, we have still a few remarks to make. The Stoat has been known to assume in winter the white clothing ordinarily supposed to be peculiar to northern latitudes, or at most to some of our northern counties, and I have myself seen a specimen particoloured. Our woods and thickets are so numerous, and sometimes so little frequented, that the Hedgehog, Badger, Fox, Hare, Squirrel, and Dormouse, are all found pretty abundantly, and the Shrew, Weasel, and various kinds of mice, frequent in plenty our fields and hedges. The cream-coloured Mole is found with us, but I believe only in one locality. White Rats have been captured at times in rabbit-grounds, where they are known to resort for the sake of the young rabbits. I am not quite sure respecting the Water Shrew, but believe I have taken it while a boy in the stagnant waters of the entrenchment round Davenport, and it is generally believed to be a common animal, though very shy in its nature. In the space of ten years, I have not seen above three or four specimens of Polecat in this neighbourhood, though I have been much in the habit of inquiring on such subjects among gamekeepers. On the other hand, the Stoat and Weasel are plentiful throughout the county. I have good evidence that the Harvest Mouse is found in Cornwall; and, from reports, there is great reason to believe it is tolerably common in Devon. I very lately captured the Mouse figured in Shaw's Miscellany as a rough-haired variety of the Meadow Mouse, or Field Mole, but, in all probability, a distinct kind. The Black Rat is very scarce with us, if found here at all, and I have never yet noticed it. A white Hare was last year seen in a wood near my house during the winter months, and, though that season was unusually severe, it is certainly difficult to understand why certain individuals of this animal, and of the Stoat, should assume this change, while all others of the species remain unaltered.

In all cultivated districts abounding in wood, and productive of an extensive Flora, as is the south of Devon, we necessarily meet with a great variety of birds belonging to the Passerine order. In the central portions of South Devon, now under consideration, there are but few birds besides the Passeres observed, and these, excepting half a dozen species at the most, may be regarded as peculiar to their central part. The Ring Ouzel and Water Ouzel may to a certain extent be considered as Dartmoor birds, though some, no doubt, have been seen beyond those precincts, and a pair of Water Ouzels build yearly in a fish-house not far from my house, and very close to a flour-mill, a saw-mill, and several houses besides, being within fifty yards of the main road. The Rock Lark, *Anthus petrosus*, is a frequenter only of the sea-coast; as is the Red-legged Crow, *Fregilus Graculus*, though I see they are both marked as Dartmoor Birds in an ornithological list of that place by Dr Tucker, a good naturalist. The Raven, Hooded-Crow, and Nutcracker, are likewise birds

which can scarcely be claimed for the ornithology of a cultivated tract, though the two first roam at times over every variety of country. The Nutcracker has only twice been killed in Devon, according to a late authority, and then not within the limits we are now treating of, though Dr Tucker's list, prefixed to Canington's Dartmoor, has authorized our naming it among the birds of that spot.

The entire number of birds, wholly or partially inhabiting the cultivated, wooded, and well watered part of Devon we are now speaking of, may be estimated at about 134, allowing about 14 to be Accipitres, 5 Scansores, 5 Gallinæ, 8 Palmipedes, about 22 Grallæ, and 80 Passeres, the total being more than one-half of the whole South Devon list, which may be computed at 237. or 242 Devon Birds, the remainder being made up by those few birds more peculiarly belonging to the Moors, and by the great variety of those birds and web-footed birds furnished by our coasts, and hereafter to be noticed. But, giving all due weight to these last-named sources in swelling our ornithological list, that part of it which we are now more especially examining is found, by comparison with ornithological lists of well wooded and well cultivated counties, to be unusually extensive. The number of birds in Oxfordshire does not exceed 120, inclusive of several kinds of web-footed birds (besides the more common sorts of Ducks, &c., which, we may presume, would form part of most ornithological lists), which occasionally roam inland, or are driven thither by stress of weather, instanced by the Herring Gull, and Leach's Petrel, three kinds of Waders which are at times detected in inland localities, the Ibis, Phalarope, and Greenshank; so that, more properly, not above 106 land and fresh-water birds are found in Oxfordshire, making a difference of 28 species between the two counties. This difference we shall examine into, as it will serve to illustrate in some measure the peculiarities, and more remarkable features of the ornithology of the cultivated parts of Devon.

First, with regard to the Accipitres, the deficiencies consist of these birds (not taking into account certain species which I shall have to mention in considering the third portion of the south of Devon):—the Rough-legged Falcon, *Buteo Lagopus*, Ash-coloured Falcon, *Circus cinerascens*, Moor Buzzard, *Circus aruginosus*, Gyrfalcon, *Falco islandicus*, Great-eared Owl, *Bubo maximus*, and Little Owl, *Strix passerina*. In examining into such subjects, we may perceive that, with respect to some species, the reasons of absence are evident enough, while, with respect to others, the causes of restriction of limits, and occasional or vacillating appearance are quite unknown. Speaking generally, the cause of our possessing so many species of this tribe, indeed, all the British species, except the *Scops Aldrovandi*, a straggler, and the Snowy Owl, *Surnia Nyctea*, whose range does not extend so far southward, seems to be the rocky and mountainous character of our county, together with so great an abundance of uncultivated land interspersed, and a vast number of woods of great depth, and removed from the neighbourhood of man. The only species of the Accipitres, however, which may be accounted at all common in Devon, are the Kestrel, Sparrowhawk, Common Buzzard, Moor Buzzard, White Owl, and Brown Owl. In former years the Kite was a common bird in this country, but, at the present day, it is particularly scarce, furnishing an illustration of the uncertainty of the geographical position of rapacious birds, and a proof likewise that we are inadequate to fathom very many of the phenomena of animal dispersion, for we know no reasons why that species should abandon us, and according to Dr Pulteney, it is very frequent in Dorset, and by an authority of my acquaintance, it is not very uncommon in Oxfordshire. But this uncertainty of position is not confined to rapacious birds.

When we turn to the Passeres of Oxfordshire, we do not find more than 12 deficiencies, allowing 80 to be the number observed in the cultivated parts of Devon, so that it is not in this department that the chief part of the difference is found. They are the Mealy Redpole, Golden Oriole, Pied Fly-catcher, Dartford Warbler, Bearded Titmouse, Cirl Bunting, Twite, Siskin, Bee-eater, Lesser Redpole, Wood Lark, and Reed Warbler; the last three being doubtful; and allowing the whole to be deficient, there is but one which is not a rarity in the British Isles. I have considered the Ring Ouzel and Water Ouzel to be almost wholly moorland birds in Devon; but although the latter is not met with, so far as I know, in Oxfordshire, the former has been sparingly observed. But although we seem to possess almost every rarity not ranked in the ornithological lists of other countries, there is one bird found in Oxfordshire and not with us, the Mountain Sparrow, *Passer montanus*. I have likewise noticed the following birds as common in that county, which with us are scarce; the Redstart, Grasshopper Warbler, and Lesser White-throat. The Pettychaps is likewise much more frequent in Oxfordshire than in Devon. The Nightingale is common in Oxfordshire, but in Devon has not been noticed farther west than Exeter, though in Dorset it is plentiful, hereby defining very accurately its south-western limits in England. It was once only heard at Kingsbridge by Montagu. Now, in all these instances of remarkable dissimilarity between the two counties, no explanation whatever can be given of the preference for localities so observed. The distribution of some animals is latitudinal, that of others longitudinal; some species inhabit a district of a rounded or irregular form, some are found regularly dispersed through the whole of a natural geographical division of the globe, some are found inhabiting one division, and only partly one or more of the others; some inhabit one or more countries, omitting, or refusing to dwell in, certain spots in that range, whether large or small; some are uncertain in their stations, are continually changing their position, or remain an indefinite period, and then disappear *in toto*, or return after the lapse of some time; in all which phenomena little can be detected of secondary causes exercising a decided influence, and yet I cannot but think we are largely indebted to these causes for the great variety of natural productions of which we boast, allowing all necessary weight to those unknown primary laws of dispersion under which very many species appear with us, and many are denied to us. But depending upon all these causes combined, we are enabled to rank as Devon birds a very large number of rarities, perhaps more than any other county in Great Britain. Perhaps the whole number of British birds may be considered as 274, and upon inquiry where our deficiencies of 37 chiefly occur, it is found that they consist in part of stragglers and rarities, and in part of birds whose limits of distribution are confined to the Northern Isles, Scotland, or to certain counties to the north of us; or, lastly, whose geographical po-

sition may with greater propriety be referred to the north than to the south of Devon. In the Passeres, now under consideration, our list is defective in the Pine Grosbeak, Crested Tit, and Tree Sparrow, the first two being limited to the Scottish pine forests, and the last to the central counties of England.

There are certain passerine birds which are irregular visitors of Great Britain, such as the Bee-eater, Oriole, Rose Ouzel, and Hoopoe, which have several times been found with us, and which, properly speaking, have their station in Africa, but migrate into Europe yearly, and at times pass over to the British Isles, so that this offers some explanation of the fact of so many of the British specimens having been captured in the south, and especially in Devon. Another class of irregular visitants seem to arrive from opposite sources. The Nutcracker is in our list an instance of this, as the northern countries appear to be its true station, the cause of its coming hither not being evident. A third series of irregular emigrants, consisting of the Pied Flycatcher, Bohemian Chatterer, Crossbill, and Greater Grosbeak, are in all probability derived from the Continental states. The Bearded Titmouse, *Parus biarmicus*, has been noticed only near Thorverton and Dacolise. The Cirl Bunting, *Emberiza Cirlus*, is, as regards Devonshire, confined to its southern parts adjoining the sea, frequenting furze-brakes. It has been noticed also in Cornwall, and seems for the most part limited to the southern portions of the kingdom, where they enjoy a climate more in accordance with that experienced by the bulk of this species on the continent, its chief station. The Reed Warbler is found sparingly with us, though it has not been noticed in Wilts, Somerset, and Dorset. The Dartford Warbler is said to have been common near Plymouth in former years, but is now scarce and local. The Brambling and Snow Bunting are chiefly observed in winter. The Great Shrike, *Lanius excubitor*, Lesser Redpole, *Linaria minor*, Mealy Redpole, *Linaria canescens*, Twite, *Linaria montium*, and Siskin, *Carduelis spinus*, are all noticed only sparingly and casually.

WILD SWANS.—The unusual severity of the winter, although it has driven many individuals of the Duck family farther to the south than usual, has not caused the appearance in Scotland of any rare visitants belonging to other families. A great number of Swans has been obtained in different parts of the country; but among those which have come to Edinburgh, we have not observed specimens of any other than the common species. The windpipe of this bird, from its great size, and the facility with which it may be made to emit a sound resembling the ordinary cry of the bird, is one of the best that can be selected to show that the bronchi and lower larynx are the parts in which the cries of birds are produced. On blowing into those of the Swan, one may, by relaxing the membranes in a sufficient degree, produce a sound exactly similar to that emitted by the bird while alive, and almost as loud. If the trachea be cut across, the sound is still produced, but is then considerably more acute. This proves that the cry is not produced in the upper larynx, as is the case in the Mammalia, the glottis merely performing the office of dividing the current of air, so as to form it into distinct notes.

## REVIEWS.

*Annals of Natural History; or Magazine of Zoology, Botany, and Geology.* Conducted by Sir W. Jardine, Bart., P. G. Selby, Esq., Dr Johnston, Sir W. J. Hooker, and Richard Taylor, F.L.S. London. R. and J. E. Taylor.

THE Magazine of Zoology and Botany, which, notwithstanding its excellence, and its being replete with "scientific papers and facts, unadorned and truthful," as its editors state, and although, in their opinion, it was conducted "in a manner which they believe has been acknowledged to stand high in the estimation of those who were inclined to dip below the surface of the subjects which others pretend to study and admire," ceased with the twelfth number, in February 1838, and has been incorporated with Hooker's Companion to the Botanical Magazine, and metamorphosed into the "Annals of Natural History," of which "a number will be published on the first of every month, containing from five to six sheets, with plates, coloured or uncoloured, according to circumstances." "No. 1. New Series, price 2s. 6d." has accordingly appeared. As to the boast of dipping below the surface, we are not aware that either its former or its present editors have exhibited any diving propensities, with the exception of Dr Johnston, who, as a gentleman, a scholar, and a naturalist, stands high in our estimation. The "Annals" contain an account of a new Ocellatoria by Dr Drummond; Remarks on the Germination of *Limnanthemum lacunosum*, by Dr Grisebach; a continuation of Mr Thompson's excellent and highly interesting contributions to the Natural History of Ireland; an account of some new species of quadrupeds and shells, by Mr J. E. Gray; Prodrômus of a Monograph of the Badiata and Echinodermata, by Dr Agassiz; continuation of Dr Johnston's *Miscellanea Zoologica*, composed of "the Scottish Mollusca nudibranchia," which, being more than a description of the external form, and written in the author's usual elegant and perspicuous manner, cannot fail to be interesting as well as instructive; and, lastly, some straggling "Information respecting Botanical Travellers, showing how Mr Cuming collected 1150 species of plants in the island of Luyon, secured about 60 species of Orchideæ, and 125 Fungi, &c. Then come Bibliographical Notices, Proceedings of Societies, and Miscellanea. Some additional information is given "respecting the splendid Nymphæaceous plant discovered by Dr Schonburg in the River Berbice. A new genus has been formed of it, which has been dedicated to our young Queen. It is the *Nymphaea Victoria* of its discoverer; *Victoria Regina* of Mr Gray; *Victoria regia* of Dr Lindley," &c.

ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE CAT TRIBE CONTINUED.

IN the Number for January 2, 1836, is an account of several species of this genus, which is characterized by the ferocity, agility, and insidious nature of its different species. Among the larger of these is the Jaguar, which on the New Continent may be considered as analogous to the Tiger of the old.

Fig. 1. THE JAGUAR (*Felis Onca*). Although this animal is the most powerful of the American Cats, it is inferior in size and strength to the Tiger, and so closely resembles in form, as well as in the distribution of its colours, the Leopard, that the two species have been confounded by many naturalists. The Jaguar, however, is much superior in size to that animal, individuals often measuring nearly five feet from the nose to the insertion of the tail. The body is much thicker, the limbs shorter, and the tail inferior in length, so that its tip scarcely trails on the ground. Both animals are of a yellowish-red colour, marked with circular dusky rings, which in the Leopard are smaller, and composed of rather widely separated spots, whereas in the Jaguar they rather form continuous rings. This species appears to be generally distributed over South America, but does not extend northward beyond the isthmus of Panama. Although not uncommon in the parts remote from cultivation, it has disappeared in the neighbourhood of the cities, and is daily becoming more scarce, as its predacious habits, together with the value of its skin, render it an object of pursuit. The Jaguar, like other species of this genus, lies in wait for its prey, and springs upon it unawares, bearing it down by its weight and great strength, and instantly depriving it of life, when it devours a portion of it on the spot, or carries it off to the thickets. It very rarely ventures to attack a man, unless urged by extreme hunger, and, notwithstanding its great vigour, is considered as cowardly. It climbs trees with facility, swims with almost equal ease, and although generally nocturnal, sometimes hunts by day. Its strength is so great, that it can drag so large an animal as a horse or a cow to a considerable distance.

Fig. 2. THE JAGUAR. Female. The female differs from the male chiefly in being somewhat smaller, and in having the colours less bright.

Fig. 3. THE PERSIAN LYNX (*Felis Caracal*). The Lynxes are distinguished from the other Cats by having the ears pointed, with a tuft of hairs at their extremity. The present species, which is of a yellowish-red colour, and the tail reaching to the heels only, inhabits various parts of Asia and Africa. The Persian variety here represented is marked with small dusky spots.

Fig. 4. THE COLOCOLO (*F. Colocolo*), which inhabits South America, is of small size, with the head short, broad, and flattened, the body greyish-white, with longitudinal streaks of dusky and red, and the tail beautifully ringed with the same.

DESCRIPTION OF THE PLATE.—THE SHORT-TAILED CROWS OR BREVES.

The genus *Pitta* of Temminck is composed of birds generally of very splendid plumage, of a singularly abbreviated form, arising chiefly from the shortness of the tail, whence the name *Breves* applied to them by the French. They are in a manner intermediate between the Crow and Thrush families, having the bill of the former with the feet of the latter. According to Mr Swainson, they have the gradually curved bill of the true thrushes, but much stronger; the predominant colour of their plumage is green, the sides of the head and the wings being generally variegated with vivid blue; and all are confined to New Holland, and the neighbouring isles of the Indian seas.

Fig. 1. THE GIANT BREVE (*Pitta cyanoptera*) is one of the largest species, but inferior in beauty to many of the rest, although coloured with green, blue, yellow, and black. It was discovered in Sumatra by Messrs Diard and Duvaucel.

Fig. 2. MACCLOT'S BREVE (*P. Maccloiti*) has the head reddish-brown, the throat dusky, the fore-neck light blue, the lower parts dull-red, and the upper green.

Fig. 3. THE NOISY BREVE (*P. strepitans*) is a very beautiful species, having the upper part of the head brown, the throat and upper part of the neck, with a patch on the breast, black, the fore-neck, breast, and sides, yellow, the abdomen red, the back green, and the wing-coverts and secondaries blue. It inhabits New Holland.

Fig. 4. THE GRENADINE BREVE (*P. granatina*) is also splendidly coloured with red, brown, green, and blue; as is

Fig. 5. THE RED-BREADED BREVE (*P. erythrogastra*), which inhabits the Philippine Islands, has the head brown, the neck azure blue, the back green, and the wings blue, with two white spots.

ON THE GEOGRAPHICAL DISTRIBUTION OF ANIMALS.—NO. IV.

(Continued from page 140.)

THE remark which we made relative to the Accipitres as being prone to roam, of individuals of one species being stationed in localities of very different natures, of their partaking of a variety of food, and of the same species being found in various quarters of the globe, applies, though less forcibly, to the family of the Pies, and to the Shrikes. The appetite of the Raven extends to every sort of animal food: it has of necessity a roaming disposition, and it is spread over the globe from the northern countries to the Cape of Good Hope. The Crow and Magpie also enjoy a very extensive range, and the latter is found in America. Those Pies, however, which are in some degree granivorous, or less decidedly carnivorous, are not so widely dispersed, or of so roaming a disposition: the Rook, the Jackdaw, the Jay, the Hooded Crow, and the Chough. The Great Shrike, *Lanius Excubitor*, has a range almost equal to that of the Raven, while the Flo-her, *Lanius Collurio*, which is chiefly insectivorous, is confined to Europe, or extends at most to Egypt. Among land birds, therefore, the Accipitres and rapacious or carnivorous Passeres, enjoy the most extensive distribution. The Kingfisher, a piscivorous bird, is also very widely dispersed, being common to Europe, Asia, and Africa. The Waders and Web-footed birds are, however, more extensively distributed than land birds, more especially the former, as we may have occasion to observe hereafter. Fish enjoy a very wide range, but quadrupeds seem to characterize the natural divisions of the earth, at least in a great measure. The other tribes are likewise in some degree characteristic of different quarters of the world.

Proceeding in our comparison of the cultivated parts of Devon with Oxfordshire, we come next to the Scansores, in which division we do not possess more species than are met with in Oxfordshire, or most other counties. There are two stragglers, the Black Woodpecker, *Picus martius*, and the Hairy Woodpecker, *Picus villosus*, which have not been noticed with us. The Lesser Spotted Woodpecker, *Picus minor*, and Wryneck, *Funx Torquilla*, are rare with us, and seemingly prefer some stations to others.

In the Gallinæ, we have the advantage of Oxfordshire, in possessing the Stock Dove, *Columba Oenas*, a bird which appears here in large flocks in winter, but is not noticed at other times. The Rock Dove, *C. Livia*, is not known to exist on our coasts in any considerable numbers. The Quail is rather scarce with us: it is found principally in October, at the time of departure, but a few stay with us through the winter.

The order of Waders, *Grallæ*, comprehends some which reside in swampy situations, or in connexion with inland rivers and lakes, besides being principally composed of those usually termed shore birds (which likewise at times resort to rivers and lakes, and for the most part breed in fens or retired swampy spots), and a few other species which are by no means water birds, and are found in very different situations from the other *Grallæ*. Accordingly, some birds of this order find a place in the Oxfordshire list, and may with propriety be enumerated amongst our own birds of the South Hams. Of these birds some breed on Dartmoor, and appear in autumn and winter in the cultivated lands, as before noticed with respect to the Golden Plover, the Grey Plover, and the Lapwing. Some individuals of the Woodcock and Snipe also breed in retired moorland situations, and appear with the main body of those migrators in the cultivated parts, on the occurrence of the first cold. The Curlew and Dunlin (or some of them) breed on the moors, and pass over to the shores and rocks in winter; while very many species may be regarded as common to the cultivated parts and to the coasts, rendering it in some degree questionable which situation should claim them. The *Grallæ*, however, generally are shore birds. I enumerate about twenty-two Waders as frequenters of the cultivated districts of South Devon, of which thirteen are found in Oxfordshire, the remainder consisting of the Grey Plover, the Great Snipe, Olivaceous Gallinule, Spotted Gallinule, Dottrel, Little Bustard, Little Gallinule, Ruff, and Green Sandpiper, all of which are, as in the preceding instances of birds found here and not in Oxfordshire, rarities, or at least uncommon birds. Nor does that county claim any species not found with us, as may readily be imagined from the fact that there are but two British birds belonging to that division of the *Grallæ* which we may term inland and fluviatile Waders. Sabine's Snipe, *Scolopax Sabini*, and the Courser, *Cursorius isabellinus*, have been seen in England but twice or thrice. The Thick-kneed Plover, however, which in our cultivated districts is scarce, is in Oxfordshire common, though probably this depends on that county possessing such a noble and extensive forest, and other uncultivated tracts. In Oxfordshire the Golden Plover appears only in winter, whereas here it breeds on our moors, and appears in

the southern parts afterwards. Considering the very confined limits usually observed by the Ruff, it is surprising that any of them should have been noticed in Devon, however rarely. One Devon specimen was shot in December 1808, on that fertile source of aquatic birds, Slapton Ley, which may serve perhaps in some degree to illustrate the eligibility of our county for such birds, and species from every class of birds are known occasionally to remain in England through the winter, whilst the main body observe the accustomed migration; and, on the other hand, some also remain to breed if the position is found eligible, whilst the bulk of such species retire to other countries or to other countries, where the rearing of young is conducted with certain concealment. These may possibly be cases of altered character of species, but in respect of the rarity of the Ruff in this country, it should be taken into consideration that though it is now restricted to certain of the eastern counties, it may possibly in former years, when cultivation had made no great advances, have extended generally over a much greater number, our own included. Slapton Ley is a lake of rather large size, situated towards the verge of the southern coast of Devon. By a wise ordination of Nature, the birds peculiarly termed marine, or rather some of the species, upon the occasion of want in the winter months, divide their search after food between the ocean and inland waters; besides which, some individuals of these species betake themselves wholly to the waves, or wholly to inland water, roaming for the entire season from spot to spot, or keeping constant to one locality; conclusive proofs against the notion of instinct being a defined, constrained, and very limited mental operation in brutes, a doctrine adverse also, to the history of most species in which instinct is detected. Upon the occurrence then of cold, Slapton Ley adds to its visitors a great variety of shore-birds and pelagic fowls, so that this piece of water alone sufficiently shows the arbitrary nature of making the coast a geographical limit for the marine birds. In consequence of our maritime situation, and the freedom with which marine birds pass the limits of the coast, it becomes difficult to state precisely which of the Grallæ should be enumerated as belonging to the cultivated districts, and I have allowed myself to be guided in some measure by the Oxfordshire list, because that county is not maritime, but it is very likely that many birds of the Heron kind which I shall rank as shore-birds are equally entitled to be considered as inland Waders. It should be mentioned, that not only do the shore and marine birds pass the limits of the coast, and obtain food inland, but the land and fresh-water Grallæ are very often in winter, especially if it be severe, found exploring the shores for provender. The Heron, Coot, Gallinule, Lapwing, Golden Plover, Grey Plover, and I believe some other kinds, act thus. I am not aware of any species of the Waders we are now speaking of quite peculiar to South Devon, but the Little Gallinule deserves notice, as having been first discovered here; only three specimens are known, two of these being Devon birds, and the other obtained from the river Ware.

The last tribe of birds belonging to Oxfordshire, and to the cultivated districts of South Devon, consists of those few web-footed birds which roam to inland waters, meadows, stubbles, &c., or from our own coasts, or which breed and abide wholly or partially in such situations. In order to state the case as near the truth as possible, I have allowed the same number of these birds to South Devon as are found to occur in Oxfordshire; though, from our adjacency to the sea, those species which in an inland locality would be stationary, with us change their situation, and again some marine birds of our coast at times repair inland, which in counties remote from the coast are never seen. The following are the species referred to:—The Little Grebe, the Wild Duck, Teal, Wigeon, Grey Lag Goose, Common Gull, Great Black-backed Gull, and Golden-eye. The Little Grebe breeds in all the fish-ponds and small lakes in the county, and in winter very many are seen busy diving in all our inlets. The several kinds of Ducks frequent the marshes and large ponds during winter, some of the Wild Duck, as before stated, breeding with us. The Wild Goose is a frequenter of meadows, marshes, and stubbles, besides the sea coast, during the winter. And, lastly, the two Gulls, and perhaps other birds also, particularly the Red-legged Gull, make excursions in winter to inland waters and marshes after food, and some of them are known to abide during the breeding season at certain ponds, and other collections of water in the south of this county. We here bring to a close our comparison between the ornithology of Oxfordshire, and that of the South Hams of Devon. We have found a difference of twenty-eight species, or, excluding the doubtful deficiencies in the Passeres, a difference of twenty-five. It is of course always desirable to trace out the principal features in such deficiencies, and upon examination it is seen, that the proportion of deficiencies in the Accipitres and Grallæ is equal. It is here, then, that our county excels in the ornithological department, at least such is the fair conclusion by comparison with the products of another county, possessing a tolerably extensive ornithological Fauna, and considering the respective histories of the species in which Oxfordshire is deficient, our advantage cannot be set down to maritime position. On the contrary, I believe the true reasons may be stated as follows:—1st, There are certain European birds, whose chief situation is in France, Italy, Holland, and other adjoining countries, but whose range extends to the southern portions of Great Britain, just as the range of others is found to extend from Europe to the northern shores of Africa. There are other species also whose principal station is in Africa, and which migrate yearly into Europe, reaching in small numbers the British Isles; and since the number of animals generally diminishes northward, the proportion of birds resident in, or migrating to, the southern shores of Britain, will be greater than that of the northern parts. 2dly, Montagu states as his opinion, that in the autumnal migration of the long, soft-billed Waders (and I suppose other kinds also) from their northern haunts to the southern portions of Europe, they experience in their transit across the north sea, equinoctial gales which gradually drive them to the southern parts of England, so that hence we are more likely than northern counties to have rarities conferred on us. 3dly, This county contains almost every kind of retreat for the various sorts of birds: it is mountainous, well-wooded, and well-watered. 4thly, In the retreat of those birds which come to this country from southern latitudes to their winter residences, the southern coasts of England offer them a resting place previous to their departure, so that here we see a larger number both of individuals and of species, than the generality of other counties; besides which, many, upon finding suitable abodes and mild climate, are induced to abide with us through the winter. Lastly, the occurrence of some species in this county, which have never been noted,

or but sparingly, in others, must be set down either to accidental causes, or to influences of which we are ignorant. Since the reasons of our ornithology being so extensive are so various, the species of which we boast as supernumeraries, or as being found here, whilst they are but very sparingly scattered over the rest of England, cannot be exclusively Grallæ, or Accipitres, although, as before hinted, it is in these classes that the greatest preponderance is observed; neither must we be altogether guided by the ornithology of any one county, such as that selected for comparison, in arriving at conclusions respecting the peculiarities of our own, or respecting the ornithology of the southern counties of England generally. As we proceeded, we pointed out instances which illustrate the various reasons here given for the extent of our ornithological list. Other cases might be cited, but as our knowledge of their geographical ranges is imperfect, they could be mentioned only with great hesitation.

A few words on the remaining tribes of animals will close our consideration of this division of our subject. With respect to the Reptiles of South Devon but little can be said, as they do not differ materially either in number or in geographical position from those of most other counties. The Nimble Lizard, *Lacerta agilis*, is found in plenty on our heaths and commons, but is not confined to these spots, as I have taken it in gardens, and I have likewise once seen it on the stump of an old tree in a willow-ground. The Dumfries-shire Snake, Warty Eft, Edible Frog, and Natter Jack Toad, do not occur in Devon, so far as my knowledge extends.

It is not in my power to add any thing on the Fresh-water Fishes, or on the Insects of Devon. A list of Land and Fresh-water Shells of this county has already appeared in this Journal, so that it is here only necessary to remark how singularly well defined are the limits of some species of these tribes, so much so, as to induce the belief that these limits in some cases correspond with the boundaries of soils, or with the geographical distribution of certain vegetable productions on which they feed, though possibly the facts of these cases may after all be quite as inexplicable as the limits of dispersion observed by the Nightingale, and some other birds. At the least, however, it will be allowed, that comparisons between the geographical limits of the various productions, mineral, vegetable, and animal, of a given district, would in all probability lend considerable assistance in the determination of the causes of a great number of now unexplained facts; for the three kingdoms of nature are not merely associated, but intimately connected, and since secondary causes have so great influence on animal and vegetable dispersion, we may not unfrequently discover the cause of distribution of these to rest with the qualities of the soil on which they are maintained, and still more frequently the phenomena of animal distribution to depend on the nature of certain vegetable products occurring on the spot, or diffused over those tracts to which certain animal forms are peculiar. Again, the selection of particular food by certain of the carnivorous animals, will, in a great number of instances, determine with exactness the limits of such species.

THE CROSSBILL A PERMANENT RESIDENT IN SCOTLAND.—The Crossbill, *Loria curvirostra*, is not found in great numbers in any part of Scotland. It remains with us during the whole year, and may be met with in small flocks of from eight to twenty or more individuals, among the pines in the midland and higher districts of the country. They feed most eagerly on the seeds extracted from the cones of the Scotch fir, larch, and spruce, and whilst thus occupied, they keep very quiet, and can be discovered only by the chuckling noise made by their tearing open the cones with their powerful and curious beaks, and the occasional dropping of the cones they have rifled. They always move from one part of the forest to another at a signal given by one of the party that acts as leader, and is stationed on the summit of the tree. They manifest their desire to move by uttering a sharp loud note; and when the watchman observes any symptoms of impatience among those below among the branches, he takes the lead in uttering his shrill note in a louder and more rapid manner than the others for a few seconds, and on his taking wing the others instantly let go the cones on which they have been operating, and accompany him, flying in a compact body, and uttering their note as they fly along. They often take long flights, and frequently return to a neighbouring tree after making a few circuits. When feeding on the low branches of a tree, it is surprising how little fear they exhibit, even when approached so closely as to be almost within reach of the hand. Having slightly wounded one in the wing, I carried it home and placed it in a cage, with a quantity of larch cones, which it immediately attacked, without showing any symptoms of fear, and after helping itself most plentifully, died shortly after, which I attributed to my neglect of supplying it with water to drink. I have often endeavoured to find out the nests of these birds in the usual season, but never succeeded; and was surprised at last on discovering that their broods are all on the wing before their neighbours of the woods have set about preparing their nests. I was attracted one day in the end of February, or early in March, during a heavy snow-storm, by the peculiar chirping of nestlings in the act of feeding; and, on ascending the tree, found five or six young Crossbills, almost fully feathered, and quite vigorous, notwithstanding the severity of the weather, snugly huddled together in a nest composed of small sticks externally, and well lined with matted wool. In mild seasons I suppose they breed, even in this country, during the month of January. They are not entirely destitute of song. I have often been delighted with a concert of these birds perched on the sunny side of a tree. Their song is not loud, but pleasingly varied, a good deal resembling that of the Water Ouzel, when you chance to overhear his gentle warbling, as he sits on a ledge of ice, in a frosty winter day.—J. M. BROWN.

A few statements like the above, by persons who have had opportunities of seeing the Crossbills in their native forests on the Dee and Spey, would settle definitively the questions so much agitated respecting the breeding and dispersion of those birds, which, on appearing in the lower parts of the country, are supposed to come from the Continent. The Siskin in all probability breeds in the same districts, as it has been seen there in flocks very early in August. The Snow-Bunting has also been found in summer on the higher Grampians, such as Benmucdui, Bennabuir, and Lochnagar.

Many parts of the mountainous and more remote districts of Scotland have as yet merely been cursorily visited, and even some birds known to occur in them, such as the Crested Tit, have never been subjected to minute examination as to their habits and distribution.

DIGESTIVE ORGANS OF BIRDS.—NO. II.

In the Number for May 1837, p. 94, was presented an outline of the digestive organs of the Red Grouse, *Tetrao Scoticus*, accompanied with a short description. The subject being of great importance, both in an anatomical point of view, and in reference to the classification of birds, the intestinal canal of a bird of another family is here figured and described. It has been seen that the Grouse, and Gallinaeous birds in general, have an extra-thoracic dilatation of the œsophagus, or in other words a crop; a powerful muscular gizzard, lined with a dense and tough epidermis; intestines of great length; and coecal appendages usually of a capacity equal to that of the intestine. In the birds of prey there is a different arrangement, which will be shown by the digestive organs of the Golden Eagle, *Aquila Chrysaetus*, here represented in outline.

In this bird, which is carnivorous, the tongue, *a*, is short, emarginate, fleshy above, horny beneath towards the end, and papillate behind. There are numerous crypts along the sides of the tongue, beneath it and anteriorly to the glottis or aperture of the windpipe, which pour forth a viscid fluid, analogous to saliva. The hyoid bones, *b, b*, are seen in their natural situation. The œsophagus, *c, d*, is of great width, and on the fore-part of the neck, previously to its entering the thorax, is dilated into an extremely extensile sac, or crop, which has not a narrow aperture like the crop of the Gallinaeous birds, but is simply a dilatation of the œsophagus, having the same structure as it. Behind the crop, where it enters between the coracoid bones, the œsophagus is a little contracted; and at its lower part enlarges to form the proventriculus, *g, g*. At its upper part, the œsophagus has a thin layer of longitudinal muscular fibres, some of which extend over the crop. In its whole length, it is encircled by transverse fibres, forming a distinct muscular coat. Its inner or mucous coat is soft, smooth, and perforated by the apertures of numerous mucous crypts, the secretion from which is copiously spread over it. This inner or mucous coat is less elastic than the muscular, and when the œsophagus is empty, is thrown into longitudinal folds.

In the proventriculus, *g, g*, is a broad belt of cylindrical glandules, having a central cavity, with thick walls, and a spongy or villous inner surface. Their inner extremity is narrowed, and they open on the mucous membrane by an inconspicuous aperture, placed in the centre of a small rounded eminence. The fluid secreted by these glandules, and copiously poured out so as to cover the entire surface of the proventriculus, as well as part of that of the stomach, is of a greyish-white colour, clammy, and when cold having the consistence of slightly coagulated albumen.

The stomach, *h*, which commences at the lower edge of the proventriculus, is of a roundish form, a little compressed. Its outer or muscular coat is thin compared with that of birds of other families, but yet of considerable thickness, and is composed of fibres arranged in fasciculi, which are broader in their middle, or along the edges of the organ, and are inserted into two thin tendinous spaces, *i*, one on each side. At its upper part, the fibres diverge. Within the muscular coat is a thin layer composed of whitish interlaced fibrous tissue. The inner coat is of a softish homogeneous texture, elevated into strong rugæ running in various directions. It is considered as analogous to the cuticle, and somewhat resembles that on the heel in man; for which reason it is named the cuticular lining, or epithelium.

At its commencement, the œsophagus is placed directly in front when not distended, but when filled inclines immediately to the right side, on which the crop lies. At the lower part of the neck it inclines to the left side, passes into the thorax in the centre, when the trachea, which had run along the left side, comes in front, and bifurcates over it. The stomach occupies the middle and left side of the abdomen, and when distended fills a very large portion of its cavity.

The intestine is short, and of very small diameter, in proportion to that of the œsophagus. The pyloric orifice of the stomach has a kind of knobbed valve. The duodenum, or first curve of the intestine, *j, k, l*, is of much greater capacity than the succeeding portion. It is accompanied by the pancreas, which lies in its curvature, and after receiving its ducts, terminates at *l*, immediately under the right lobe of the liver, where it receives the biliary ducts. The intestine then diminishes in capacity, *m, n*, and is convoluted, lying chiefly on the right side. Over the stomach this contracted portion terminates, and the rectum commences, which is much dilated, runs along the sacrum, enlarges at the end, to form the cloaca, *o*, which receives the urine by the two ureters, *q, r*, and ends at the anus, *p*. Besides the peritoneal covering, the intestine has a muscular, and an inner or mucous coat. The former is thickest in the duodenal portion, the inner surface of which is delicately villous. On the rest of the small intestine are long slender villi, which, towards its lower part, become more sparse. The inner surface of the rectum is furnished with numerous mucous crypts.

The cœca, in the Golden Eagle, *t, t*, are very different in capacity from those of a Gallinaeous bird, being mere mucous sacs, scarcely more than a quarter of an inch in length. They are seen to occupy the same place, namely, the commencement of the rectum, *t, v*. The smaller figure shows the termination of the small intestine, *s, s*; the cœca, *t, t*; the rectum, *t, v*; the cloaca, *u*; the anus, *v*; and the ureters, *w, w*.

The Golden Eagle is a bird organized for rapine; its frame is firm and compact; its long and broad wings enable it to fly with great speed; its legs are furnished with strong muscles, and its claws are curved, tapering, and capable of being thrust into the vitals of its victims, which it can also carry off in its talons when of moderate size. But it does not feed exclusively on animals which it has itself captured, for it often devours carrion of all kinds. Keeping its prey down with its feet, it deprives it in a rude manner of part of its hair or feathers, and then tears up and swallows fragments of the flesh. Its bill, being hooked at the point, and sharp-edged, is obviously well adapted for this use. If the subject be large it fills the stomach, and then the crop and œsophagus, these parts being capable of holding more than two pounds of flesh. The crop is merely a recipient for the food, which is found in it quite unaltered. When the crop, stomach, and intermediate part are found filled, the solvent action is first perceived in the proventricular space; and it is probable that the secretion from its glandules effects the solution of the food in all species, for in those of which the inner coat of the stomach is thick and horny, there can be no effusion from it. The mass of flesh, mixed with feathers, hair, and bones, being in the stomach reduced to a soft pulp, the nutritious parts pass into the intestine by the pylorus, which rejects the indigestible substances. The hair and feathers are, by the contraction of the muscular fibres, thrust into the œsophagus, the muscular fibres of which contract in succession, so that the pellet is ejected. In the duodenum the pulpy mass of the food is further diluted by the pancreatic fluid, assumes a homogeneous appearance, and is of a light red colour. On being mixed with the bile, it assumes a yellowish or greenish tint, and deposits the chyle on the surface of the intestine, whence it is absorbed. The refuse enters the rectum, where it is diluted by the urine, and is finally ejected in a semi-fluid state, of a dull green colour, mixed with flakes of white, being projected to a considerable distance, so that the feathers be not soiled.

The digestive organs of Vultures are similar to those of Eagles and Hawks; but various modifications are observed in those of the different species. In the Falconine species generally, the intestinal canal is about three times the whole length of the bird. Owls differ from Hawks in having no crop; but their cœca are much larger, and even approach in size to those of some of the Gallinaeous Birds.

On comparing the figure and description here presented with those of the Red Grouse formerly offered, it will be seen that the digestive organs of the Rasores and Raptores differ in several essential respects. Similar differences occur in all the really natural groups of birds, such as the Geniteres or Pigeons, the Deglubitores or Conirostral tribe, the Cantatores or Songsters, the Parrots, Snipes, Divers, and Ducks.

**PROLIFICACY OF THE BLACKBIRD.**—A pair of these birds built four successive nests last season upon the island in St James's Park, and succeeded in rearing seventeen young ones; the three first broods consisting of five each, and the last of two only. There cannot be the least doubt as to the identity of the female, as she is well known to the person who attends them, and so tame as to take food from his hand while sitting on the eggs. There were, moreover, no other individuals of the same species near the place. Another isolated pair which I knew of raised, unmolested, three broods in a garden near my residence, so that the Blackbird would appear to raise as many young as the Partridge, which produces only one brood in a season.—*Edward Blyth*, in "The Naturalist."

## GEOLOGY.

**DEPTH OF THE FROZEN SOIL OF SIBERIA.**—In a paper on this subject, communicated to the Geographical Society by Professor Baer of Petersburg, the author stated that it has long been ascertained that the soil of Siberia, over a great extent of country, is never entirely free of ice, the summer heat producing only a partial thaw at the surface. Gmelin the elder mentions that the ground at Yakutzk, in Lat.  $62\frac{1}{2}^{\circ}$  N., Long.  $130^{\circ}$  E., was found to be frozen at a depth of 91 feet, and that the people were compelled to desist in sinking a well. Many similar facts had been collected by travellers, but they were not generally credited; and even in 1825, Von Buch rejected them as erroneous. Yet they have recently been corroborated by Erman and Humboldt. Within these few years, a merchant, of the name of Schargin, having attempted to sink a well at Yakutzk, was about to abandon the project, when Admiral Wrangel persuaded him to continue his operations. The whole stratum of ice was at length perforated, and, at the distance of 382 feet from the surface, the soil was very loose, and the temperature  $\frac{1}{2}^{\circ}$  Ream. ( $31^{\circ}$  Fahr.) Near the surface it was much lower, and had increased as follows:—at some feet from the surface,  $6^{\circ}$  R.; at 77 feet,  $5^{\circ}$ ; at 119 feet,  $4^{\circ}$ ; and at 217 feet,  $2^{\circ}$ ; at 305 feet,  $1\frac{1}{2}^{\circ}$ ; at 350 feet,  $\frac{1}{2}^{\circ}$ ; at 382 feet,  $\frac{1}{2}^{\circ}$ . As the soil had become loose at 350 feet, and as the aperture of the well was eight feet square, and the work carried on partly during the winter, when the column of cold air must have lowered the temperature, it is probable that the spot at which the thermometer marked the freezing point was at that depth. This vast thickness of frozen ground indicates that Siberia must have been for a long period in the same physical condition as at present. Although the extent of this layer of ground ice is not determined, yet enough is known to show that it occupies a vast space. Humboldt found the soil frozen at the depth of six feet at Bosgolowsk, near the Ural, in  $60^{\circ}$  N. Lat. Near Beresow, Erman found the temperature at a depth of 23 feet, still  $+1^{\circ}.6$ , ( $35\frac{1}{2}^{\circ}$  F.); but, in 1821, a body was disinterred which had been buried 92 years, and it showed no signs of decomposition, the earth around having been frozen. It has long been known that, at Obdonk, in N. Lat.  $68^{\circ}$ , the ground is always frozen. Near Tobolsk, no ice is found in the soil, but, as we proceed eastward, the ground ice advances farther south. From the discussion which followed the reading of this paper, it seemed to be generally considered that the experiment at Yakutzk had not been made with sufficient care to authorize the belief that the frost penetrates to so great a depth as 350 feet; but that the statements of Arago and Von Buch, and of individuals in this country, had been fully borne out by M. Schargin's observations, and almost exactly in the same ratio as hitherto found. Captain Back stated, that in the cold regions of North America, even in the height of summer, he had never found the ground thawed more than four feet below the surface; but that experiments on the subject were wanting before correct information could be obtained.

**RAISED BEACHES AT COQUIMBO.**—In a letter lately received from Mr Pentland, Her Majesty's Consul-General in Bolivia, and dated Tacna, Peru, 3d September 1837, he says:—I had occasion to observe at Coquimbo raised Beaches on a very large scale, and attaining an elevation of 400 to 500 feet above the present sea-level. They consist of beds of sea sand, alternating with others, exclusively formed of large oysters, and in general capped by a mass of boulders and gravel, some of the former weighing several tons, and covered with parasitic marine mollusca. It is this modern marine deposit which forms the parallel roads spoken of by Captain Hall, and referred to by Lyell, and has evidently been raised at a very modern period, many of the shells preserving their brilliant colours. The vicinity of Coquimbo is composed of a transition granite, with masses of porphyry in veins, and both contain the rich metallic veins of that celebrated metalliferous district. The Andes in this neighbourhood are very high, and if the position of the peak seen from the port is accurately laid down in the map (and which I had no time to verify), its elevation must exceed 20,000 feet, according to some zenith distances I took of it. The country around the town from which I now write is an arid sandy desert, without a trace of vegetation. It is covered with loose sand of the new red sandstone series, through which the quartziferous trachyte rises near Tacna, and continues to form a band at the base of the Andes.—*Edinburgh New Philosophical Journal.*

**LARGE PAIR OF FOSSIL HORNS FOUND IN ESSEX.**—Though the geological feature of the county of Essex may not be of that highly interesting character exhibited by the mining districts of England; and though the facts respecting the physical history of our planet are not developed in such quick succession here as they are found to be in some other localities, owing in a great measure to the mineral properties of our tertiary beds not being of that quality to warrant extensive excavations; still as the constant action of the sea upon the blue-clay cliffs of our coast washes those cliffs down, and brings to our notice the fossils which they have so long concealed, or if, by any of our artificial removals of soil, those relics are brought to light, the facts are as worthy of being recorded, as if the organic remains were of still higher antiquity. I am induced to make these observations by my having just received from a friend the two bony portions (commonly called the core, or slug of the horn) of the interior of a pair of very large horns of the Ox, lately discovered at Clacton, on the Essex coast, about ten miles south of Walton. They were found in a mass of drift sand, overlying the London clay, and in consequence of the cliffs slipping down, they were disintegrated. Many portions of the skull were found with them, and the *os frontis* was attached to them. By measurement, I find them to be three feet long on the outer curve, from the base to their tips; they are curved about eight inches, and are eighteen inches in circumference at the base. The diameter of each horn at the base is six inches in one direction, and five inches in the other. They have not the fluted character so conspicuous in the horn which I found three years ago at Capford, but they have the punctures so common to the bony portions of horns in general. In both instances the remains of the Elephant were found associated with those of the Ox. At Capford, a vertebra and the cuneiform bone of the right fore-foot of the former was discovered, subsequently to those of the Ox above mentioned. And with the horns recently discovered at Clacton was found a perfect Elephant's tooth, eleven inches in length, and three inches wide upon the grinding surface, and eight inches in depth.

—*John Brown, in Magazine of Natural History.*

## MISCELLANEOUS.

## DESCRIPTION OF THE FRITH OF CROMARTY, AND REMARKS ON ESTUARIES.

(Continued from page 96.)

THE term Estuary is generally, although not in popular language, applied to that part of a river which the tide ascends. It has also been defined a space traversed by a river, and into which the tide enters. By geological writers and others, it is frequently employed to designate a basin, partially or entirely filled with sea-water, more or less mixed with fresh-water, and in which are deposited quantities of sand and mud carried into it by a river or rivers during floods. Indeed, this latter seems to be the general acceptance of the term. The words frith and estuary are to a certain extent synonymous, for all the inlets in Scotland called friths, viz. the Solway Frith, the Frith of Clyde, the Frith of Forth, the Frith of Tay, the Beaully Frith, and the Cromarty and Dornoch Friths, are in some part of their extent estuaries, that is, receive large rivers, which deposit in them mud and sand. Most of them, in fact, are actually named after their principal rivers, and have thus evidently been considered as either formed or greatly influenced by them. It is therefore clear that the 'Frith' of Tay is thus but another word for the estuary of that river. Why the general principle of popular nomenclature should thus have been deviated from in a few cases is not apparent. What, agreeably to it, ought to have been named the Ness Frith or Beaully Frith, has been named the Moray Frith, probably because of its great extent, and of its being bounded on one side by that province; while the Cromarty and Dornoch Friths have taken their names from the towns so called. In the parts of Scotland where the Gaelic language has prevailed, the inlets are named lochs, a term which is also applied to bodies of fresh water. But very few of these sea-lochs receive rivers of considerable size, and almost all of them are named from circumstances having no connection with their streams.

Of the larger rivers of Scotland there are very few that have an estuary of the most simple kind, or, in other words, which open directly into the sea, without the intervention of a basin common to the river and the ocean. Such, however, are the Dee, the Don, and the Ythan, in Aberdeenshire, of which the estuary or tide-way is not two miles in length. Were rivers generally of this kind, there could be no disputes concerning their estuaries. The highest tide mark might then be considered as the upper, and the boundary of the lowest tide as the lower limit.

As an example of the second kind of estuary mentioned above, or that formed by a space traversed by a river, and into which the tide enters, may be mentioned the basin of Montrose, which is about eight miles in circumference, and is left dry at low water excepting the channel of the South Esk, by which it is traversed. There can be no dispute as to the propriety of considering this basin an estuary.

The estuaries of the Forth, the Tay, the Clyde, and the Beaully, are of the third or most common kind, being basins, from a great part of which the sea never recedes. They vary in extent, some being longer and broader, and their channels are more or less deep, according to the original nature of the ground, or the force of the currents by which it is traversed. But no rule can possibly be laid down for the determination of an estuary of this kind, which is neither a river, nor yet the sea, but a compound of both. The medium level of the sea at high and low water, which has been proposed for determining the limit by which a river is separated from the sea, is obviously a merely arbitrary character, which may answer for defining the mouth of the river properly so called, but which can separate it from the sea only when no basin intervenes, when the sea itself is in fact the basin, into which the river pours its waters. On the contrary, when there exists an intermediate basin or estuary, common to the sea and the river, the line in question may form a boundary between the river properly so called and the estuary, but it can have no reference to the lower limit of the latter, which must be determined by other means.

(To be continued.)

## LITERARY NOTICES.

*Works preparing for Publication.* (Longman and Co.)—The Rev. L. Vernon Harcourt (son of the Archbishop of York) has in the press a work on the "Doctrine of the Deluge." His object is to vindicate the Scriptural History of the Deluge from the doubts which have been recently thrown upon it by geological speculations. This the author has endeavoured to accomplish by showing, upon the testimony of a long list of ancient and modern authors, that since the era of that catastrophe a set of religionists never ceased to exist, whose opinions and usages were founded upon a veneration of the Ark as the preserver of their race. In 2 vols. 8vo.—Mr Westwood's "Popular Introduction to the Modern Classification of Insects," which has been so long announced for publication, is at length in the press, and will be published in Monthly Parts; the first will appear on the 1st of June. The author has for eight years been employed upon it, collecting materials, from the Continental as well as British Museums. It will be illustrated with many thousand figures engraved on wood. The author has paid very minute attention to the Natural History of the Transformations of Insects, and confidently hopes that there will be found much new and interesting matter in his work. It is intended to form a sequel to the popular work of Messrs Kirby and Spence. 1 vol. 8vo.

—*Essays in Natural History.* By Charles Waterton, Esq. With a view of Walton Hall, and an Autobiography of the Author. 1 vol. fcap. 8vo.

The second volume of Mr MacGillivray's History of British Birds, including the *Cantatores*, *Reptatores*, *Scansores*, *Volitatores*, and *Excursores*, being all the remaining land birds, the *Raptores* excepted, will be published in autumn.

ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE BABOONS.

THE Cynocephali constitute a well marked section of the great tribe of the Simiæ, being characterized by having a muzzle somewhat like that of the Dog, whence their name, terminal nostrils, large canine teeth, flattened and angular ears, cheek-pouches, longitudinal streaks on the face, large callosities on the buttocks, limbs of nearly equal length, and a moderately long tail. They attain a considerable size, are active and vigorous, excitable, ferocious, and indomitable.

Fig. 1. THE GUINEA BABOON (*Cynocephalus Sphinx*), which inhabits the coast of Guinea, is of a light yellowish-brown colour, with the face black, and the cartilages of the nostrils surpassing the jaws.

Fig. 2. Represents a young female of the same species.

Fig. 3. THE LITTLE BABOON (*C. Babouin*) is a native of Southern Africa. It has the fur of a greenish-yellow tint, the face of a livid flesh-colour, the cartilage of the nostrils of the same length as the upper lip.

Fig. 4. THE CHACMA (*C. porcarius*) is of a dusky green colour above, with the face dusky, and the circumference of the eyes pale. The male, which has the hairs of the neck long, forming a kind of mane, is extremely ferocious. This species inhabits the Cape of Good Hope.

Fig. 5. THE DOG-FACED BABOON (*C. Hamadryas*) is said to occur in the neighbourhood of Mecca on the Persian Gulf, and in Arabia. Its general colour is ash-grey, the face flesh-coloured, and the hands black; the hair on the neck and fore part of the body elongated. It exhibits the same ferocity as the other species, becoming unmanageable when old, although at first somewhat docile.

Fig. 6. Represents a young female of the same species.

DESCRIPTION OF THE PLATE.—THE VULTURES.

THE order of Rapacious Birds may be divided into three great sections, the Vultures, Hawks, and Owls. The former birds are always of large size, and are easily distinguished from the others by their having the head and part of the neck bare. Their bill varies, being in some very strong, in others slender, but the point of the upper mandible is always curved and acute. The feet are strong, but the claws are not so large or curved as in Eagles and Hawks. The wings are very large, being not only long, but of great breadth. The flight of these birds is accordingly powerful and sustained. They often ascend to a vast height, and float as it were in circles. Their sight is extremely penetrating, but their smell, although by some alleged to be very acute, is by others denied to be in any way remarkable. They feed on dead animals of all kinds, and are extremely useful in the warmer regions of the globe, where they chiefly abound, in often disposing of putrid carcasses which would otherwise infect the air with noxious effluvia. Their feet are not formed for pouncing upon live prey, or for carrying off objects in their talons; and, therefore, they generally remain satisfied with dead prey, which they gorge to an excessive degree whenever an opportunity occurs; they are for this purpose furnished with a large crop; their stomach is membranous, like that of the Eagles; their intestine of moderate length, and their cæca extremely small.

The Vultures, properly so called, constitute a genus of this group, peculiar to the Old Continent, and characterized by having the bill strong, straight at the base, convex above; the nostrils large and transverse, the head and neck destitute of feathers, but sparsely covered with a very short down; a collar of large feathers at the lower part of the neck; the wings very large, the first and sixth quill nearly equal, the fourth longest. Two species occur in the south of Europe, the rest in the warmer parts of Asia, and in Africa.

Fig. 1. THE AQUILINE VULTURE (*Vultus Ægyptius*) inhabits all the northern parts of Africa.

Fig. 2. THE CRESTED VULTURE (*V. galariculatus*) is a native of India.

Fig. 3. THE PONDICHERY VULTURE (*V. Pondicerianus*) also inhabits India.

Fig. 4. THE INDIAN VULTURE (*V. Indicus*) belongs, as its name implies, to the same region.

BRITISH BIRDS.—THE CUCKOO.

THE Cuckoo arrives in the south of England about the 15th of April, in that of Scotland towards the end of the same month, and in the northern parts of Britain soon after the beginning of May. The periods, however, vary considerably according to the character of the season, and as the birds do not always announce their return by emitting their well known-cry, they may sometimes be met with at a time when their presence is not suspected. There seems to be hardly any part of the country which they do not visit; for while some remain in the southern counties, others settle in the most remote islands of the north, and although they are met with in the most cultivated districts, they also frequent the valleys of the wildest of our hilly and mountainous tracts. Perhaps the most favourite resorts of the species are the parks and plantations bordered with fields and pasture-grounds, or the woods and thickets of the upland glens; but on the rocky hills of the most treeless regions, and the bleak moors or fern-clad slopes of the interior, it is found often in great numbers, although never in flocks, for if gregarious during its migrations, as some suppose, it manifests no social disposition during its residence.

In the maritime Highlands and Hebrides, after the time of the arrival of the Wheatear, every one is on the look-out for the Cuckoo. Both birds are great favourites with the Celts, the latter more especially, but both may be the barbingers of evil as well as of good; for should the Wheatear be first seen on a stone, or the Cuckoo first heard by one who has not broken his fast, some misfortune may be expected, whereas, should the reverse be the case, the individual will prosper all that year. Such at least is the popular creed in the North. The Saxons of the south have no such fancy, and the lover of nature, Saxon or Celt, gladly hails the bird of summer.

“Cuckoo! Cuckoo! O welcome, welcome notes!  
 Fields, woods, and waves rejoice  
 In that recovered voice,  
 As on the wind its fluty music floats,  
 At that elixir strain,  
 My youth resumes its reign,  
 And life's first spring comes blossoming again.”

Early in the mild mornings of May and June, and towards the close of day, he who wanders along the wooded valleys will be sure to be greeted by the ever-pleasing cry of the Cuckoo, unvaried though it be, as the bird perched on a rock, or lichen-crust ed crag, or balancing itself on the branch of some tall tree, coos aloud to its mate. You hear nothing but the same *hu hu*, or, if you please so to syllable it, *coo coo*, repeated at short intervals, but if you attend better you will find that these two loud and mellow notes are preceded by a kind of churring or chuckling sound, which, if you creep up unseen, you will find to consist of a low and guttural inflection of the voice, during which the throat seems distended. But the Cuckoo, ever vigilant and shy, has observed you, and flies off, followed by two small birds, which, by their mode of flying and incessant cheeping notes, you know to be Meadow Pipits. They keep pace with it, and when it alights on the grassy bank, they alight too, and take their stand in its vicinity. You have heard that Cuckoos lay their egg in the nest of a Pipit or other small bird, and you at first suppose these to be its foster-parents; but this is not a young Cuckoo, but an old grey male, just arrived from Africa mayhap. They attend it, fly after it, stand beside it, and seem to be concerned about it, to be distrustful of it, to watch its motions, and to indicate their dislike to it by their continued cries. But Cuckoos are not always followed by Pipits, for often you may see them gliding among the trees without any attendants.

The flight of the Cuckoo is swift, gliding, even, rapid on occasion, generally sedate, usually at no great height. In the hilly parts it may be seen skimming along the ground, alighting on a stone or crag, balancing itself, throwing up its tail, depressing its wings, and then perhaps emitting its notes. In woody districts it glides among the trees, perches on their boughs, and makes occasional excursions into the thickets around. On the ground it is not often seen, unless when cooing, and there it walks in a constrained manner; but on trees it alights with facility, clings to the twigs with firmness, glides among the foliage, and by the aid of its tenacious grasp and ample tail,

throws itself into various and always graceful postures, as it searches for its prey. Its food consists of coleopterous, lepidopterous, and dipterous insects, in procuring which it must visit a variety of places; and very much of hairy caterpillars, which it picks from among the grass and heath, where, however, it cannot search by walking, like the Plover or Curlew, as its feet are too short, and its toes misplaced for such a purpose. Yet it can hobble round a bush to pick the worms from it, as well as cling to its twigs, and is thus greatly beneficial to the gooseberry bushes in large gardens in the neighbourhood of its haunts. The inner membrane of its stomach is often found stuck full of the hairs of caterpillars, so as to present a very curious appearance, the hairs being disposed in a circular manner, showing the rotatory motion of the contents of the organ. The remains of its food are ejected in pellets, as in Hawks and Owls. It has been conjectured that it occasionally feeds on eggs, especially those of the small birds in the nests of which it deposits its own; but I am not aware of its having been caught in the act. It has also been accused of eating young birds, but no one has found bones or feathers in its stomach.

The most remarkable trait in the character of the Cuckoo is its confiding the charge of hatching its eggs, and rearing its young, to some other bird, always much smaller than itself. The species on which it thus imposes its progeny is generally the Meadow Pipit, *Anthus pratensis*. In Scotland its egg has not been found in the nest of any other bird, but in England it has been discovered in those of various species:—the Hedge Chantrel, White Wagtail, Sky Lark, Nightingale, Garden Warbler, and others. The egg is small in proportion to the size of the bird, being generally not much larger than that of its foster-parent, its average length being ten and a half-twelfths of an inch, its greatest diameter eight-twelfths, its colour white, greyish-white, or reddish-white, speckled with ash-grey or greyish-brown. Various conjectures have been hazarded as to the cause of this disproportionately small size of the eggs. If we say that as the Cuckoo is physically constrained to deposit its egg in the nest of some small bird of the insectivorous kind, its egg must be nearly of the size of those of its dupe, we may state a truth, but we afford no explanation of the phenomenon. Why should it be so constrained; why does it not form a nest, hatch its eggs, and rear its young? Because, as some say, it leaves its summer residence only in July, and as it remains but two months or a little more with us, it could not leave its young in a sufficiently advanced state to shift for themselves. By why should it thus hurry away? has it not abundance of food? does it not go at the very time when insects are most abundant? If it dreads the cold of autumn, is not that of April or even May much greater; and if its tender young find enough of heat until September, how is it so much more sensitive? It has been alleged, conjecturally, that the ovary is much less plentifully supplied with blood than that of other birds of similar size, and therefore the eggs are not developed; but, in fact, no difference exists between the Cuckoo and Jay in this respect; and if there were, although the smallness of the eggs might be accounted for in so far, how is it necessary that they should be so small?—In short, all that we know about the matter is just this: the Cuckoo arrives in the end of Spring, and departs in July; it forms no nest; but deposits its eggs singly in the nests of various small birds, which hatch them, and rear the young. The latter remain until September. The great size of the stomach, the dilatation to which it is subject from the nature of its food, which chiefly consists of hairy caterpillars; the necessity of being ever in motion to procure a sufficiency of this food, which in proportion to its bulk contains very little nutriment, and other fanciful notions, have also been adduced as reasons why the Cuckoo does not nestle and hatch its eggs. All our Owls have stomachs equally large, and swallow as much hair, yet they all rear their young. According to Wilson, the Carolina Cuckoo has the stomach capable of great distension, and covered internally with hair, so that in all probability it is precisely the same as that of our Cuckoo; yet it also hatches its own eggs.

It appears from the observations of various persons, that the Cuckoo, having found a nest, watches for the absence of its owner, then deposits its egg, and flies off; that, in general, the nest in which it places its egg contains none or few eggs; that the owners of the nest sometimes eject the intruded egg; and that in a few instances two Cuckoo's eggs have been found in the same nest. It is also stated that the Cuckoo, on depositing its egg in a nest already containing eggs, sometimes carries off one or more of them; but frequently nests have been found containing the ordinary number of eggs along with that of the Cuckoo. Pipits or other small birds, finding a Cuckoo at or near their nest, manifest alarm, anxiety, and hatred towards it, just as they would toward a Jay or other suspected bird.

It was known to the ancients that this bird leaves its egg to be hatched by another, but they mingled truth with fable, believing that the young devoured not only those of its foster-parents, but finally the latter themselves. The manner in which the young Cuckoo's fellow-lodgers disappear from the nest is perhaps as marvellous as any thing else in the history of this strange bird. A pair of Pipits, Wagtails, or Hedge Chantrels, would find it a sufficient task to provide their own young with food, and probably would be unable to satisfy, in addition, the incessant cravings of the young Cuckoo, which grows very rapidly; and as it soon completely fills the nest, would crush to death or suffocate its feeble fellow-lodgers. The young Cuckoo, as if in order to obtain sufficient nourishment, and prevent the protracted misery of its foster-brethren, ejects them from the nest, and their parents, unable to replace them, or failing to recognize them, leave them to perish. The exclusive occupation of the nest by the young Cuckoo was first satisfactorily accounted for by Dr Jenner, the discoverer of vaccination, who, in the Philosophical Transactions for 1788, states, that having found a nest of the Hedge-Sparrow, containing a Cuckoo's egg and three of the Hedge-Sparrow's, but on the day following a young Cuckoo and a young Hedge-Sparrow, two of the eggs having disappeared, he "saw the young Cuckoo, though so lately hatched, in the act of turning out the young Hedge-Sparrow. The little animal, with the assistance of its rump and wings, contrived to get the bird upon its back, and making a lodgment for its burden by elevating its elbows, clambered backwards with it up the side of the nest."—"It remained in this situation for a short time, feeling about with the extremities of its wings, as if to be convinced whether the business was properly executed, and then dropped into the nest again. With these, the extremities of its

wings," he continues, "I have often seen it examine, as it were, the egg and nestling before it began its operations; and the nice sensibilities which these parts seem to possess seemed sufficiently to compensate the want of sight, which as yet it was destitute of. I afterwards put in an egg, and this, by a similar process, was conveyed to the edge of the nest and thrown out. These experiments I have since repeated several times, in different nests, and have always found the young Cuckoo disposed to act in the same manner." He then states that its shape is well adapted for this purpose, as its back is very broad, with a depression in the middle, which is not filled up until it is about twelve days old. When two Cuckoo's eggs happen to be deposited in the same nest, a severe contest takes place between the newly-fledged young, and continues until the weaker is ejected.

These observations have been verified by Montagu, who having taken a young Cuckoo, five or six days old, to his house, "frequently saw it throw out a young Swallow for four or five days after. This singular action was performed by insinuating itself under the Swallow, and with its rump forcing it out of the nest with a sort of jerk. Sometimes, indeed, it failed after much struggle, by reason of the strength of the Swallow, which was nearly full-feathered; but after a small respite from the seeming fatigue, it renewed its efforts, and seemed continually restless till it succeeded. At the end of the fifth day this disposition ceased, and it suffered the Swallow to remain in the nest unmolested." Mr Blackwall also having taken a young Cuckoo that was hatched in a Tit-Lark's nest seven days after the old birds had quitted the neighbourhood, had an opportunity of observing the same phenomenon. "The nestling, while in my possession, turned both young birds and eggs out of its nest, in which I had placed them for the purpose, and gave me an opportunity of contemplating at leisure the whole process of this astonishing proceeding, so minutely and accurately described by Dr Jenner. I observed that this bird, though so young, threw itself backwards with considerable force when any thing touched it unexpectedly."

Beyond this, there is nothing very marvellous in the history of the young bird, which, carefully fed by its foster-parents, who no doubt believe it to be their own progeny, grows apace. It appears that very many species of birds, having hatched the eggs of others, consider the produce to be really their own; and that many also, without having incubated, will adopt a helpless youngling and feed it. It is not more wonderful that the Pipits or Wagtails should harbour no suspicion of the alien character of the large bird that fills their nest, than that a hen should continue to perform a motherly part toward the ducklings which manifest the difference of their nature by gladly betaking themselves to the water, of which she has a salutary dread. While the young Cuckoo remains in the nest, it is plentifully supplied with food by its friends, who having their parental feelings excited by its continued demands, cheerfully labour in its behalf. When it can fly, and has left the nest, they continue to provide for and protect it to the best of their power, and this conduct of theirs seems the more strange that it contrasts with that of other little birds, even of the same species, but especially Swallows, which fly after and endeavour to molest it. The young are extremely voracious, and when threatened or seized assume an air of boldness, ruffle their feathers, and show a disposition to fight. When confined they may be fed with raw meat, but seldom survive the winter.

The old birds cease to emit their notes about the end of June, and are never seen beyond the middle of July. The young disappear about the beginning of September. This species is dispersed over the whole of the Continent, extending to Norway and Lapland, from which, and all the northern and middle regions, it departs early in the season. It is also found in Africa, as far as its southern extremity. The old birds arrive in full plumage, and depart without having moulted. The young also take their departure previously to moulting, which, as in the old birds, takes place in winter.

A curious instance of a young Cuckoo's being fed by a Thrush is related by the Bishop of Norwich. "It was taken from the nest of a Hedge-Sparrow, and a few days afterwards, a young Thrush, scarcely fledged, was put into the same cage. The latter could feed itself, but the Cuckoo, its companion, was obliged to be fed with a quill; in a short time, however, the Thrush took upon itself the task of feeding its fellow-prisoner, and continued so to do with the utmost care, bestowing every possible attention, and manifesting the greatest anxiety to satisfy its continual cravings for food. The following," he continues, "is a still more extraordinary instance, corroborating the above, and for the truth of which we can vouch in every particular. A young Thrush, just able to feed itself, had been placed in a cage; a short time afterwards, a young Cuckoo, which could not feed itself, was introduced into the same cage, a large wicker one, and for some time it was with much difficulty fed; at length, however, it was observed that the young Thrush was employed in feeding it, the Cuckoo opening its mouth and sitting on the outer perch, and making the Thrush hop down to fetch food up. One day, when it was thus expecting its food in this way, the Thrush seeing a worm put into the cage, could not resist the temptation of eating it, upon which the Cuckoo immediately descended from its perch, and attacking the Thrush, literally tore one of its eyes quite out, and then hopped back: the poor Thrush felt itself obliged to take up some food in the lacerated state it was in. The eye healed in course of time, and the Thrush continued its occupation as before, till the Cuckoo was full grown."

A case of a like nature, but referring to the Cow-Bunting, a small bird, whose mode of propagation is similar to that of the Grey Cuckoo, is related by Wilson, in his American Ornithology. Having taken from the nest of a Maryland Yellow-Throat a young male Cow-Bunting, he "placed it in the same cage with a Red Bird, *Loxia cardinalis*, who, at first, and for several minutes after, examined it closely, and seemingly with great curiosity. It soon became clamorous for food, and from that moment the Red Bird seemed to adopt it as his own, feeding it with all the assiduity and tenderness of the most affectionate nurse. When he found that the grasshopper which he had brought it was too large for it to swallow, he took the insect from it, broke it in small portions, chewed them a little to soften them, and, with all the gentleness and delicacy imaginable, put them separately into its mouth. He often spent several minutes in looking at and examining it all over, and in picking off any particles of

dirt that he observed on its plumage." But this assumption of the office of a nurse has been manifested by many birds of the orders Cantatores, Deglubitores, and Vagatores, with regard to helpless individuals, not only of their own, but of other species; insomuch that it would seem to result from the excitement of the parental instinct affected by the solicitations of the destitute orphan.

In form, as well as colour, the Cuckoo is one of the most elegant of our native birds. Its entire length is fourteen inches, the extent of its wings twenty-three, the length of the bill ten-twelfths. The wings and tail are very long, the former straight and pointed, the latter broad and graduated. The plumage is soft and blended. The mouth wide, the bill shorter than the head, compressed toward the end, pointed, and somewhat arched. The feet are small, and zygodactyle, that is, having the outer, as well as the inner toe, directed backwards. The bill is greyish-black, at the base orange, the iris also orange, and the bare margins of the eyelids gamboge-yellow, the feet orange, the claws ochre-yellow. The upper parts are bluish-grey, more or less tinged with green; the quills dusky, the inner webs of the primaries marked with oblong transverse white bands; the tail greyish-black, glossed with green, the feathers tipped, and along the shafts and inner edges spotted with white. The throat and fore-part of the neck are light ash-grey; the breast and sides white, transversely barred with brownish-black. The young has the upper parts variegated with light red and dusky.

GIZZARD OF THE GALLINACEOUS BIRDS.

We have in two preceding Numbers given a short account of the digestive organs of the Gallinaceous and Rapacious Birds. The structure of the stomach in the former, however, requires more particular notice, as it has frequently been misrepresented. The accompanying figures are taken from the gizzard of the Black Grouse, *Tetrao Tetrix*.

Fig. 2.

Fig. 1.

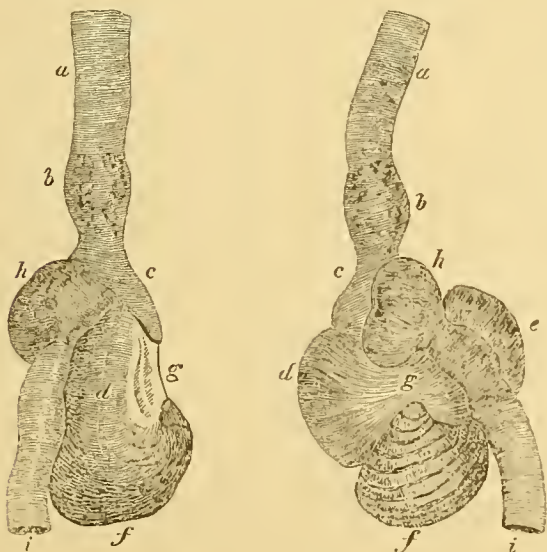

Fig. 1. represents the lower part of the œsophagus, *a*; the proventriculus, *b*, which may be considered as part of the stomach, it being composed of a great number of hollow glandular bodies or crypts, which secrete an abundant clammy fluid of a greyish colour. This fluid is carried along with the food into the cavity of the stomach, and is by many supposed to be a solvent of the alimentary mass, analogous to the gastric juice in Man and the Mammalia. There is reason, however, for doubting this, and it is probable that the real gastric juice is exhaled by the minute vessels upon the inner surface of the stomach, in the space marked *c*, of which the cuticular lining is soft. The mass of food, lubricated by the mucous fluid of the œsophagus and proventriculus, being deposited in the stomach, is there ground to a pulp by the action of the two lateral or digastric muscles, *d, e*, the fibres of which converge toward two tendons, one of which is seen at *g*. The lower part of the gizzard is furnished with a muscle, *f*, less thick, but still powerful, which, after trituration is completed, probably aids in propelling the mass towards the intestine, *i*, while it is prevented from escaping into the œsophagus, *a, b*, by the contraction of the superior muscle, *c*. The internal coat of the stomach is thick, tough, elastic, and rugous, and has two much thickened portions opposite the muscles, *c, d*, which perform as it were the office of millstones. There is a muscular dilatation or sac at *h*, from which the intestine proceeds. The view here given is that of the parts seen from above. Fig. 2. shows the same parts viewed from the right side,—*a*, the œsophagus; *b*, the proventriculus; *c*, the superior or anterior muscle; *d*, one of the lateral muscles; *f*, the inferior muscle; *g*, the tendon; *h*, the sac from which proceeds the intestine, *i*.

The birds in which this extremely muscular stomach is found are very numerous. All those belonging to the Gallinaceous order, the Pigeons, most of the Gallatores, and the Swans, Geese, Ducks, and Mergansers, exhibit it in its highest degree of development. A less muscular stomach, although formed on the same plan, is seen in the order Passeres or Insectores of authors, but there it presents various modifications. Many, but not all birds, which have a powerful gizzard, are also furnished with a crop, or dilatation of the œsophagus, as is the case more especially with the Rasores and Pigeons; the former of which have extremely large cœca, while in the latter these organs are reduced nearly to the minimum. On the modifications thus presented might be founded an arrangement of birds, which would at least have the merit of placing together those of similar habits.

(Continued from page 142.)

WE now pass on to consider the third division of the subject, the shores and marine productions of South Devon, subjects in a great measure apart from those first discussed; and, although we found it convenient to consider the Fauna of Dartmoor, and the uncultivated districts separately, the productions of those spots are not so distinct or peculiar as those of the shores and sea will be found to be. Divisions of this kind, arbitrary as they are, will nevertheless be found useful, because, as the qualities of the elements and constitution of the climate in each may be expected to differ, it might be also ascertained, that the tribes of creatures inhabiting or frequenting them were more or less classified or brought together by reason of those influences. It is farther convenient for the purpose of comparison with other spots of similar or dissimilar natures. We must, in the first place, say a few words on the Mammalia.

The chief abode of our Bats is toward the coast, because they principally reside during their daily and diurnal quiescence in the caves and fissures of our limestone rocks, and these occur for the most part toward and on the coast. All our rarer species have been chiefly noticed in caverns on the coast. Thus Montagu found the two species of Horse-shoe Bat in Kent's Hole at Torbay, and one of these has been captured near Plymouth. The Barbastelle has occurred at Kingsbridge, and the Great Bat I have seen several times affecting quarries round Plymouth. The two common sorts seem (perhaps because more plentiful) to resort as freely to old buildings, hollow trees, &c., as to cavities of rocks; but, I believe there is no decided preference shown by these animals for natural cavities of the earth; hollow trees, &c., being the appointed substitutes, where and when caves cannot be obtained. It is the same precisely with the Barn Owl, to which hollow and wild trees form a natural resort, and caves a natural succedaneum; but both with Bats and the Barn Owl, old buildings, such as barns and sheds, are to be considered in some respects as unnatural habitations, because the creation of animals was anterior not only to the erection of such buildings, but to the adoption of this island as a residence by our race. It has, however, been most wisely directed that the instinctive faculties of brutes should not be so definite and so limited in their operation, as to preclude all departure from their more peculiar habits and actions, and hence it has been found, that the construction and situation of the nests of birds have at times varied remarkably from ordinary rule; hence birds have been enabled to sustain themselves on novel food, when driven by stress of weather, or other adverse circumstances, to countries which they have never before seen; hence, when detained by weakness, or the allurements of climate, and supply of food, from making their accustomed migration, they can support themselves against unaccustomed impressions; and hence, amongst a great variety of other instances not only with birds, but with other kinds of creatures, we are enabled to domesticate them, and to cause, by our interference, extraordinary alterations in character and variations, or rather improvements in instinctive powers. With respect, however, to the adoption of our buildings as places of resort, and situations for nesting by birds and other animals, I believe too little has been said by writers, because such irregularities have been made to pass current in their mode of expression, and doubtless in the mind of many readers, as the natural habits of such species: whereas an useful lesson might be thence drawn, relative to the faculties and mental operations of the beings around us. With us the natural nesting places of the Jackdaw are on the sea-cliffs, and rocky eminences in general are its natural abodes wherever found. In defect of these, however, Nature has prompted it to make use of hollow trees and rabbit holes in some instances; but towers, and ruined buildings, are such faithful imitations of its native cliffs, that this bird is diffused very generally through our country. With the Wheatear, old walls and heaps of stones answer the purpose of rocks, both for obtaining food and for nesting. This bird chiefly resides during the breeding time on our coasts, and though it frequents quarries and old walls, these situations are never far removed from the sea-side. At other seasons, it either quits us, or frequents fallows, &c., for food. The natural breeding-places of the Martin, with us, are the cliffs, but owing to similarity of position, and that extraordinary dependence on man observed in this and other species, it usually builds against houses, and frequents our neighbourhood. It is remarkable, however, that in the Swift and Swallow so few instances should be on record of their building in other situations besides houses, out-buildings, and churches. I have known a pair of Swallows build a nest in some ury under a bridge not far from my house, and this too in a loose state, so that it was constantly swinging about with the least current of air, but I am not aware of another instance in this neighbourhood of either of these birds affecting other than the above-named situations; but, in all likelihood, their natural abodes are like the Martin's and other species known to build similarly, such as the Cliff Swallow and Esulent Swallow. It would be easy to cite other cases of adopted nesting-places of the same class, but these are here named because the birds in question seem to belong almost wholly to that portion of South Devon into the productions of which we are now inquiring. The whole character and history of species, and consequently the philosophy of Zoology in general, can only be arrived at by tracing the habits, physical endowments, &c., of animals in each different locality they inhabit; and hence this is one cogent reason for prosecuting the natural history of districts, and comparing and combining the same.

Now, the Otter is an illustration of this. It is usually thought to be a fluvatile animal only; but in Devonshire it is both fluvatile and marine, quite as many residing on the coast, and fishing to a short distance off the land, as on the banks of our rivers. In the former case, they take possession of small hollows in the rocks, and are yearly hunted in these situations near Plymouth. It might be expected that the Seal would find a place among our Devon animals, but I know of no instance of its capture here, though, from its occurrence in Cornwall, we might reasonably expect that it would be found with us also.

The Cetaceous Mammalia of our coast deserve more than usual notice in this place, because these animals have never been properly examined by British naturalists, and because those which have been seen on our coasts have as yet received very li-

mitted notice, at least in respect to the number of species. In the first place, it is highly probable that the distribution of this class has never yet been completely understood, and that, so far from their being scarce in the British seas, as usually supposed, they are tolerably common even now, and were doubtless more so formerly. I have a most respectable authority for stating that, in the middle of July 1836, several Whales were seen between the Azores and the Land's End. The crew of the ship in which he took his passage indeed captured one, and one was noticed by him immediately off the Land's End. The species, however, he could not tell. A Whale was found dead off Penzance not long since. Amongst the "rarer fish of Cornwall" is mentioned the Blower or Fin Fish, *Balæna Physalus*, Linn. I have seen a tooth of a Whale thrown ashore a few miles from Plymouth, which proves to belong to the *Physeter Microps*, L. In October 1831, a Sharp-lipped Whale, *Balæna Boops*, L., found dead off the Eddystone, was towed into Plymouth Sound. In 1814, a specimen of *Delphinus Tursio* was captured about five miles up the Dart. The Grampus is found in the Channel, and has been often seen off the coasts of Cornwall; and the Porpoise is common on all our coasts in herds, and frequently enters our estuaries in pursuit of fish. We have here, therefore, an account of six species, or probably more, found off the coasts of Devon and Cornwall.

We have now to conclude the subject of the Birds of Devon by speaking of those on the shores and sea. With regard to the Accipitres, we enumerate the following as more or less peculiar to the coasts:—The Peregrine Falcon, Red-legged Falcon, Osprey, Sea Eagle, and Kestrel. In this tribe of birds we perceive that, besides their disposition to roam and change residence, there are remarkable examples of diversity of habitat in the same species. Thus, while the Kestrel is found pretty commonly in inland counties, with us it is almost wholly confined to the coasts. The Red-legged Falcon, *Falco rufipes*, has only been once obtained here, and then in the Channel. I must here state, that I owe my acquaintance with this last fact, and also a great many others relative to the rarer birds of Devon, to the "Catalogue of the Birds of Devonshire," published by Dr Moore of Plymouth in the Magazine of Natural History. The Peregrine Falcon and Osprey are not very uncommon; but the Sea Eagle is decidedly rare. A few Passerine birds must be mentioned in connexion with the coasts. The Rock Pipit, *Anthus petrosus*, is stationary, its food seeming to consist of the smaller marine insects. The Chough is likewise a coast bird, but is not stationary on the Devon shores, visiting us only in small numbers towards Winter. Both these birds occur in the list of Dartmoor birds prefixed to Carrington's poem of that name. They seem to me to be the only true Passerine birds of our coast; at least, alterations have taken place in the geographical situation of the Wheatear, Jackdaw, and Martin, as before named; in addition to which, these do not confine themselves to one abode, and are, moreover, observed to affect inland rocks equally with shores. Their appetites are not limited to shore productions, and though the Chough is in some other countries an inland bird, it is not so in England, save through accident or necessity. The Raven at times builds on our cliffs. The Crow is noticed very frequently in Autumn and Winter, examining the rejectamenta of the tide. The King-fisher migrates partially to the sea-side in October; and those which are found there remain till Spring. This is another instance of diversity of action in individuals of one species according to situation. It is certainly an ordination of Nature to allow of more extensive dispersion of the whole of the species during the season of greatest want; for by this arrangement of their appetites the removal of some portion of the species to the estuaries and coasts permits a very general though very slight change in the position of all the members of the kind, and at the same time gives to each a more extensive range for capture of prey during the time of necessity. Mr Knapp observes that the universality of the Robin, that is to say, its general dispersion, is remarkable. This is confirmed by my notice of it, though rarely, on the furze of our cliffs, far removed from farms or villages. How remarkably does the history of one species differ from that of another, when thoroughly investigated, and how evident is it that the completion of these histories is essential to the development of those various plans instituted by the Creator for the perfection of his wondrous scheme of nature. There is one of the Gallinaceous birds recorded by Polwhele as a frequenter of the Devon coasts, the Rock Dove, *Columba Livia*, though he refers it exclusively to Combe Martin and Lundy Island on the north of Devon. It is, however, now understood to be an inhabitant of the southern shores, occurring rarely in the caves.

We calculate that there are fifty-six Waders belonging to South Devon, and since twenty-two of these may be regarded as belonging to the terrestrial and fluvial portion of this class, there is a preponderance in favour of the marine portion. With respect to very many of this class, it is quite impossible, as before remarked, to assign to them unequivocally an inland or marine station. They are either so imperfectly known that their preference is merely suspected by their accidental occurrence in one of these situations on the occasions when seen, or they have been found to resort equally to both kinds of habitats; even in the case of those species which breed on our moors, and appear in Autumn and Winter on the coasts, allowing that they do not at those seasons visit lakes and rivers also, it must cause a doubt on the mind whether it would be natural to refer them to the inland or to the marine class exclusively. In fixing the numbers, however, as above, at twenty-two for the cultivated districts, and the remainder, thirty-four, for the uncultivated parts and the shores, I have been guided thus: I first selected those respecting whose station no doubt could be felt, and then classified the rest by ascertaining, as far as possible, which parts of South Devon they evinced the most preference for, or in the case of the rarer birds by considering that to be their station where each had by good accident been observed, unless it seemed to me that this station was at variance with the general character of the bird, and assumed only by mere casualty. Of the thirty-four, then, I have reckoned two as belonging to Dartmoor, and thirty-two as shore birds. Then, besides the two which are peculiar to the moor, namely, the Great Bustard and Crane, more than two dozen other species have been noticed on that spot, very many of which breed there. Some of these I have considered as belonging to the cultivated parts, and some to the shores, according to the bias they exhibited. Again, of the twenty-two Grallæ of the cultivated parts, seventeen are also at times visitors of the coast.

And, lastly, of the thirty-two shore birds about to be named more particularly, only one-half have exclusively been seen on the coasts, and at the mouths of rivers.

## REVIEWS.

## REMARKS ON THE NATURAL HISTORY PERIODICALS.

The *Magazine of Natural History* for May contains several interesting papers. The first, on the Influence of Man in modifying the Zoological Features of the Globe, by Dr W. Weissenborn, being part of a series, is devoted to the Zubr, *Bos Urus*, which anciently inhabited the whole tract between the Baltic and Haemus, whilst the Black Sea and the Steppes of Russia confined it on the east, and the cold hindered it from penetrating farther in a north-easterly direction, but which "is now restricted to a single habitat, the wild and swampy forest of Bialowieza, in Lithuania." After reviewing and comparing the statements made by authors from Aristotle downwards, he comes to the result, "that the *Urus* and *Bison* are the same animal; and that we have for the creature now called in the systems *Bos Urus* four sets of synonyms, viz. one probably of barbarous origin, but employed by Aristotle, *Bonassus*, *Monassus*: One, it seems also of barbarous origin, *Bison*, *Visen*, *Wisont*, *Wisant*, &c.; one derived from the same root as *Taurus*, (the syllable *or*, or *ur*, of the primitive language, from which the Greek *ὄρος*, and the very word *origin*, are derived, and which conveys the idea of what is ancient and grand), *Urus*, Gall. and Lat. *Our*, *Auer*, *Ur*, *Auerochs*, Germ., *Ureox*, Engl., *Tur*, Pol., *Tor*, Russ., *Tyr*, Dao.; and one of Slavonian origin, *Zimbr*, Mold., and *Zubr*, Lith."—"We may, therefore, with much probability, consider the zubrs of the forest of Bialowieza as the only survivors of a species which was formerly found, in great numbers, in the vast swampy forests of the whole of Middle Europe, and perhaps Great Britain, whilst no other bovine animal inhabited the same tract within the historical times." The next paper is by Mr Blyth, Curator to the Ornithological Society, and is entitled "Outlines of a new Arrangement of Insectivorous Birds." This arrangement is professedly formed on the basis of anatomy and physiology, and he takes occasion to show some of the more palpable defects of the "posterous mode of classifying" usually denominated the quinary system. The class of birds appears to him "resolvable into three primary divisions, which might be respectively styled—*Insessores*, *Gressores*, and *Natatores*, that is, Perchers, Walkers, and Swimmers. The class of mammalia might be divided precisely in the same manner, namely, into Perchers, as Monkeys and Squirrels; Walkers, as Horses, Oxen, and Tigers; and Swimmers, as Seals, Shrews, and Whales. If into a single "subclass" are admitted Perchers, Parrots, and Woodpeckers, as well as Falcons, Owls, and Pigeons, we see no reason why into another should not be admitted Baboons and Opossums, Mice and Elephants. Mr Blyth's *Insessores* then include all birds that do not belong to his *Gressores* and *Natatores*, for it is impossible to define them otherwise. His *Gressores* include the Gallinaceous birds and Waders. His *Natatores* we presume are the palmipede birds. We can scarcely admit that all the *Insessores*, including Vultures, Falcons, Owls, Crows, Shrikes, Thrushes, Warblers, Cuckoos, Parrots, Swallows, Woodpeckers, Creepers, and King-fishers, are modelled on a single anatomical type; but when the different orders and families are explained, we shall be able to form some idea of the system. In the meantime, it is pleasant to us to observe that from our own small beginnings in the physiological method of arranging birds, there is thus presented a prospect of the science's being rescued from the hands of mere collectors of dry and arsenicated skins. In the third article Mr Newman combats the idea of the antennæ of insects being analogous to the ears of higher animals. "Further Observations on Rules for Nomenclature," by Mr Ogilby, are amusing and clever, but the subject, having been so much discussed of late, and the parties being as pugnacious as ever, sober folks would rather hear of something else.

The *Naturalist* for the same month commences with a pleasantly written paper by Mr R. Adie on the physical power of insects as labourers, and on their architecture. The next paper affords an explanation of a peculiar mechanism in the trachea of Birds, which appears to have been overlooked, and which consists of an arrangement of the rings, so managed that one side of a ring slips over the sides of its two neighbours, while the other side of the same ring slips under their sides. Mr H. C. Watson then corrects an error in the *Meteorological Journal* of the Royal Society, regarding the minimum of the thermometer in January last. Mr Rylands favours the young entomologists with "farther hints," and earnestly cautions "the student against suffering a passion for collecting to choke the desire of investigating nature." From this results the misfortune which Mr Swainson justly regrets, "that nearly all naturalists are more bent upon increasing the contents of their cabinets, than on studying the economy of those living objects which are perpetually crossing their path." Mr Swainson we presume classes himself among the small number of persons who study nature more than the contents of their cabinets; yet we are not assured that the gentleman may not be decrying his hesitating sin. A long list of flowering plants for May occupies four pages and a fifth; the remaining four-fifths being allotted to the "British Swans," of which absolutely nothing is said by "G. L. Lister, Game-waler," &c. Mr T. B. Hall deals more hardly with Mr Yarrel's "British Birds" than we should feel disposed to deal were we to criticise the engravings. Proceedings of societies, with reports of lectures and various notices, occupy the remainder.

The *Annals of Natural History* contain "Observations on the Coregoni of Loch Lomond," by Dr Parnell; an account of a journey to and residence of nearly six months in the organ mountains in Brazil, with remarks on their vegetation, by Mr George Gardner; continuation of Mr Thompson's Contributions to the Natural History of Ireland; on a new English species of *Urtica*, namely, *U. Dodartii*, by Mr Babington; and other articles which we have not room to notice.

ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE EURYLAIMES.

THE genus *Eurylaimus*, first instituted by Dr Horsfield, is composed of birds remarkable for the great size of their bill, of which the upper mandible has its dorsal outline convex, the sides sloping, the tip small and deflected, the notches very small; the lower mandible dilated at the base; the bristles generally of moderate size. The tarsi are short, the toes rather small; the claws compressed, moderately curved, and acute. The plumage is compact, often splendidly coloured. They inhabit the tropical regions of Asia, and are considered as belonging to the family of Flycatchers.

Fig. 1. THE CORYDON EURYLAIMES (*Eurylaimus Corydon*), of a brownish-black colour, with the bill blood-red, the middle of the back orange-red, the throat whitish, and a white band on the primaries and tail feathers.

Fig. 2. THE GREAT-BILLED EURYLAIMES (*E. nasutus*), which has the upper parts, the chin, and a band on the fore-neck, bluish-black, the rest of the lower parts and the rump deep red, and the scapulars white, inhabits the Indian Islands.

Fig. 3. HORSFIELD'S EURYLAIMES (*E. Horsfieldii*), originally made known by Dr Horsfield under the name of *E. Javanicus*, is bluish-black above, vinaceous beneath, the wings and tail patched with yellow. It occurs in Java.

Fig. 4. HORSFIELD'S EURYLAIMES. Female. Dusky, spotted with yellow above; yellowish-white beneath.

Fig. 5. THE HOODED EURYLAIMES (*E. cucullatus*), crested, the head and upper parts black, the breast rose-coloured, a white ring on the neck, the scapulars yellow. It is nearly allied to the last species, and inhabits the same country.

DESCRIPTION OF THE PLATE.—THE THRUSH-SHRIKES.

THE Thrush-shrikes, constituting the genus *Laniarius*, are distinguished by having the bill less curved at the tip than in the Shrikes, and approaching somewhat in form to that of the Thrushes. They inhabit Africa and India, and are in general remarkable for the beauty of their plumage.

Fig. 1. THE BACBAKIRI THRUSH-SHRIKE (*Laniarius Bacbakiri*), greenish-yellow above, ochraceous beneath, with the head ash-grey, and a semi-lunar black band on the fore-neck.

Fig. 2. The Female is deep green above, paler beneath.

Fig. 3. THE GREEN THRUSH-SHRIKE (*L. viridis*), green above and on the sides; the throat and breast bright red, a black semi-lunar band on the fore-neck.

Fig. 4. THE WHITE-THROATED THRUSH-SHRIKE (*L. albicollis*), green above, yellow beneath, with the head black, and the throat white.

Fig. 5. THE OLIVE THRUSH-SHRIKE (*L. olivaceus*), green above, yellow beneath, with a black band on the side of the head and neck.

Fig. 6. THE BARBARY THRUSH-SHRIKE (*L. Barbarus*), black above, deep red beneath, the head and neck yellow.

THE AUROCHS OR ZUBR, *Bos URUS*.—Dr Weissenborn states that this animal, which formerly inhabited a great part of Europe, is now confined to the marshy forest of Bialowicza, where it is protected by very strict laws. The size of the animal in its present confined abode is much less than it was in former times, when it was uncontrolled in its range. A six-year-old male measured seven French feet from the crown of the head to the *tuber ischi*, and its height at the withers was four feet nine inches; but in 1795, an individual thirteen feet long, and seven feet high, was killed near Friedrichsburg, and another killed in Bialowicza in 1752 weighed 1450 lb. The game-keepers say it lives to the age of fifty years and upwards. Its strength is enormous, and it easily defends itself against the Wolf or Bear, an old Zuhr being a match for four of the former. It runs with great speed, but has little bottom, swims with agility, is exceedingly shy, and is incapable of being tamed. Its food consists of the bark of trees, lichens, and various herbaceous plants. Its voice is a short grunt. "On the 12th of October 1836, a hunt was held with a view of furnishing some of the museums in Prussia with specimens; and Prince Dolgorukow, the governor-general of the province of Balystock, who presided at it, caused it to be conducted with more than usual solemnity. Two thousand drivers and marksmen were assembled, besides an immense number of spectators whom curiosity had drawn to the spot, where a balcony of fir trees had been erected for the prince and his suite. Thither different herds of Zubrs were driven, to be fired at, and the flesh of the largest bull was dressed, to give additional interest to the concluding act of the party, a plentiful dinner."

BRITISH BIRDS.—THE GOATSUCKER.

THE Goatsucker or Nightjar arrives in this country from the middle to the end of May, being among the latest of our summer visitants, and departs about the end of September. It is generally distributed, but is nowhere very common, and in many large tracts is not met with. Dr Edward Moore states, that it is "common about the South Hams of Devonshire, where they frequent orchards," and my friend Mr Barclay has met with it near Elgin. It is chiefly found on furzy commons, wild bushy heaths, and broken hilly ground covered with ferns, especially in the neighbourhood of thickets and woods. It is rarer in Scotland than in England, which is the reverse with the Cuckoo, a bird in some respects similar in its habits, and which appears to be much more plentiful in the wild valleys of the north, than in the cultivated plains of the south.

The bill of this bird is extremely small and feeble, the mouth excessively wide, the palate flat, covered with a smooth membrane, which is transparent, as are in some measure the bones. The tongue is very small and triangular. The gullet is rather wide, the stomach large, round, membranous, its muscular coat being composed of fasciculi, as in the Owls and Cuckoos, the intestine short, the cæcal appendages small. The eyes are very large, as are the apertures of the ears. The head is very large, depressed, and flattened above. The feet are extremely small; the tarsus very short, anteriorly feathered except at its lower part; the first toe very short, slender, and directed inwards, the second and fourth about equal, the third much longer, the anterior toes connected by membranes as far as the second joint; the claws very small, arched, and compressed; that of the middle toe is proportionably longer, and has its inner convex edge expanded and pectinated, being cut in two by parallel slits. The plumage is full and blended; the wings very long and narrow; the tail very long, often broad, rounded feathers. The bill and claws are dusky, the feet flesh-coloured; the general colour of the upper parts is ash-grey, minutely dotted and undulated with dusky, and variegated with brownish-black and pale yellowish-red, the head and back being marked with elongated spots of the latter colour. On the inner webs of three of the primaries is a large roundish white spot; the two lateral tail-feathers have also a large patch of white at the end. The lower parts are transversely barred with dull reddish-yellow and dusky; and on the throat are some white feathers. The length is eleven inches, and the extended wings measure twenty-three.

This unfortunate bird has a strong claim on our sympathy, on account of the manner in which all its actions and habits have been misrepresented. The ancients accused it of milking goats, and thus it received the names of *Caprimulgus* and *Goatsucker*, which it retains to the present day. Then it was alleged to be so awkward as to be obliged to fly with its mouth wide open, and so slovenly as to need an instrument on its foot with which to cleanse its chops. Lastly, so malignant were its traducers, as to hint that it could not see like other creatures, but was obliged to gape widely, and then turn its eyes downward to look through the roof of its mouth for which purpose that part was made thin and transparent.

The substances which I have found in the stomach of this bird were remains of coleopterous insects of many species, lepidoptera, and sometimes larvæ. I have seen the inner surface slightly bristled with the hairs of Caterpillars, as in the Cuckoo. Towards evening the Goatsucker may be seen skimming along the edges of woods with a light and buoyant flight, winding in varied curves, in the manner of a Swallow, but with less velocity, and by its noiseless motions also reminding the observer of the Owls. As it proceeds, it now and then emits a shrill squeaking cry. It is seldom that more than one or two individuals are seen at a time; but Montagu remarks that he observed "in Scotland eight or ten on wing together in the dusk of the evening, skimming over the surface of the ground in all directions, like the Swallow, in pursuit of insects."

During the day it generally rests on the ground, among furze or fern, or on the branch or bough of a tree, on which it reposes in a direction parallel to its axis. This arises from the disposition of the toes, which is such, that it cannot securely grasp a branch in the ordinary way. When disturbed while on the ground, it flies off with a wavering buoyant flight, and generally alights on a tree, if there be one in the neighbourhood.

The eggs, which are two in number, broadly elliptical, whitish and clouded with ash-grey and brown, are deposited on the bare ground, among furze, heath, or fern. The young are densely covered with long whitish down. During the breeding season, according to Montagu, "it makes a singular noise, like the sound of a large spinning wheel, and which it is observed to utter perched, with the head lowermost."

The serrature of the middle claw of this and the other species has elicited various conjectures as to the use of so curious a structure. Several persons have supposed or imagined it to be for the purpose of enabling the bird to clear away from between the bristles that fringe its mouth, the fragments of wings or other parts of lepidopterous insects, which, by adhering, have clogged them. This at first sight seems a remarkably plausible account of the matter, but a very little reflection, with a slight inspection of the parts, will suffice to show its futility. The bristles are large, strong, and placed at some distance from each other. The teeth of the claw are extremely thin, and very close, being separated only by mere chinks. The claw then cannot act as a comb, because one of the bristles is as broad at the base as two or three of the teeth, so that it cannot enter between them; and although it tapers away toward the end, yet even there it is too wide to be insinuated. But, although the claw may not act as a comb, it may be said that its serrated edge will more readily than a continuous edge catch hold of any thing stuck between the bristles. This is likely enough; but then the species of the genus *Podargus* or strong-billed Goatsuckers have similar bristles, but are destitute of clefts on the claw. Gannets, Herons, and other birds, that have no bristles, have yet a serrated claw. Therefore, the serrature is not intended for the purpose of clearing the bristles. Yet it may be quite true that the Goatsucker uses its claw to produce that effect; but it is not less true that Parrots, Finches, and other birds, having no such serrature, employ their claws for scratching the parts about the head. And so another reason must be sought for.

The young Goatsucker has at first no serrature on its claw, any more than the young Gannet. One fully fledged, and shot about the end of September, now before me, has the toe scarcely half the length of that of an old bird, and with only five teeth, the old bird having ten. The chinks in the young bird's claw are less deep than those in that of the old bird. A young fledged Gannet shews the same circumstance. All birds whose middle claw is serrated, have that claw elongated, and furnished with a very thin edge. It therefore appears that the serration is produced by the splitting of the edge of the claw, after the bird has used it, but whether in consequence of the pressure caused by standing or grasping can only be conjectured.

The Flycatchers, and other birds of the same family, which have strong bristles, intended for the same use, have not serrated claws; yet if their bristles become clogged, they no doubt will clean them in the same manner.

It appears that the use of the serratures is not that of clearing the bristles of the scales of lepidopterous insects, because fish eating birds without any bristles have similar serratures; but there is no reason for doubting that Goatsuckers brush away adherent matter with their claws, just as other birds do, the domestic fowl, for example.

Another supposition is, that the serrature enables the Goatsucker to hold more securely a large insect which it has caught with its foot. And observers have stated that they have been pretty sure of having seen that bird, when flying, raise its foot to its mouth, as if, in the manner of a Parrot, to carry to it an insect. It may be so; but as yet no one has quite satisfactorily seen a Goatsucker catch a moth or a beetle with its foot; and this cannot be the use of the serrature, for the Gannet and Heron, which do not seize their prey with their feet, have serrated claws.

The notion of a bird's flying with open mouth, for the purpose of seizing its prey, is preposterous. It has been alleged that Swifts and Swallows do so; but I have satisfactorily ascertained that they do not; and there is no reason to suppose that Goatsuckers are so awkward as to require to keep their jaws constantly wide open lest their prey should escape them.

But the most absurd notion of all is that expressed by Mr Selby as follows. "The membrane that lines the inside of the mouth is very thin and transparent, particularly opposite to the posterior part of the eye, which organ is pretty clearly discernible through the membrane. As the mouth opens to such great lateral extent, it has been suggested that the bird may possibly be capable of turning the eye in its socket, so far as to look through this almost transparent veil in a straightforward direction, when the mouth is extended in its nocturnal flights. I have consequently directed my attention to this point, but as yet without any satisfactory result." Indeed, it was unworthy of exercising the observation of so sagacious an ornithologist. How desperately imaginative must those persons be, who, not content with allowing a bird to seize its prey like other birds, by opening its bill when it comes up to it, must represent it as flying about with its mouth wide open, and instead of using its eyes as all other birds use them, turning them round, to the imminent danger of separating the optic nerve, so as to spy moths and beetles through a window in the palate!

## OBSERVATIONS ON RABIES IN DOGS, OXEN, HORSES, PIGS, AND SHEEP.

BY DR WAGNER.

THE following is a condensed account of some important observations made by Dr Wagner on the diseases commonly called Rabies or Madness in domestic animals.

1. *The Dog.*—Dread of water is not always present, nor is the habit of gnawing wood, straw, or hides, or snapping in the air, a sure symptom. An appearance of dejection and shyness, drooping of the head and tail, flashing of the eye, foaming at the mouth, refusal of food and drink, are suspicious, but not peculiar to the disease. The only decisive indication of it is a dog's running about and recklessly attacking men and animals, especially those of its own species. In a rabid state, some dogs will even leap over high fences, in order to reach dogs or cats which they discover to be on the other side, thus showing that smell, sight, and hearing, are still unimpaired. Others will sneak along a wall, or run forward in a straight line, attempting to bite whatever they meet with. Some again never move from one spot, but gnaw at every thing within reach, snap at vacuancy, and ultimately refuse food and drink, or if they attempt to partake of either, appearing incapable of deglutition. In such cases, paralysis of the loins and posterior extremities appears to have taken place at the outset. The moment a dog evinces any appearance of illness, he ought to be locked up, or fastened to a strong chain. When it begins to gnaw wood, to show a dull eye, or snap at animals, to bark hoarsely, to attempt to run away or break its chain, to eat and drink in a snapping manner, to appear alternately lively and sulky, to disregard its master's call, to growl and snarl at well known persons, it ought to be killed, for no doubt can remain of its being rabid.

2. *In Oxen.*—The disease occurs in horned cattle in two distinct forms. In the first, the animal loses its appetite, eats and drinks by fits only, appears at times as if suddenly stupified, recedes from the manger, forgets to chew, then chews on, listens keenly to any noise, notices every object, but continues to obey its keeper. Borborygmi, however, are heard, and sometimes there is slight straining or disposition to tenesmus. In the open air, the animal ceases to graze, seems as if lost, and strays from the herd, but generally allows itself to be led back. The symptoms increase: hunger and thirst are not experienced, the eyes flash at times, without seeming inflamed, the animal seldom lows, but when it does, either emits a hoarse noise or a clear and strong cry. The borborygmi increase, the animal licks some parts of its body, especially one of the feet, where probably it has been bitten, until it is excoriated and bleeds. Paralysis of the loins ensues, the animal remains lying, can only rise with great difficulty, and totters on its hind-legs; an increased straining is remarked, and is followed by hard but ultimately thin evacuations; it moves its head from side to side, licks at cloth or fur, which it by degrees gets between its teeth and tears. The secretion of milk, which has been diminishing, now ceases. On the sixth or seventh day, the animal is unable to stand, refuses food, being unable to swallow; the straining at the rectum continues; but a dread of water is never observed. Sometime between the sixth and ninth day, it sinks on one side, commonly the left, the head stretched backwards, but the eye still lively and uninfamed. The trunk continues motionless, but the legs are languidly agitated, until the animal dies. In this form of the disease there is little danger in approaching the animal. The other form commences in the same manner. In the stall, the animals recede still more from the manger, and will try to break the rope with which they are fastened. Their bellowing is not frequent, but prolonged, and its tone clear; they scratch the ground with their fore-hoofs so violently as to throw the dung to the roof, and with their hind-feet kick at any one who approaches. The paroxysms are periodical, and in their intervals little is to be observed, except a reluctance to feed or drink. About the fourth day they will snap every kind of fastening during the paroxysm, attack and gore all who approach them, rage about in the stable, and gnaw the cribs and other objects, until paralysis of the limbs supervenes, when they fall, and ultimately lie on one side. On the seventh, eighth, or at most the ninth day, they die. On dissection, nothing unusual is to be discovered, excepting extreme distension of the gall-bladder.

3. *In Horses.*—The symptoms are at first unwonted activity, kicking and biting of their fellows, refusal of food and drink, frequent nodding or jerking of the head, and a fiery eye. On the second or third day the symptoms have greatly increased in degree, the animals become furious, and strive to bite and kick, so that it becomes necessary to destroy them.

4. *In Pigs.*—Only one instance occurred to the author. A fattening boar had been bitten by a mad dog four days previously to his seeing it, but it already raged with such violence that he could only observe it through the crevices of the sty. It gnashed its teeth, leaped against the sides of the sty, and threatened by its violence to burst through them. A butcher, who killed it with a hatchet, cut it up, contrary to orders, and exposed it to sale, but no mischief resulted.

5. *In Sheep.*—Five sheep, which were bitten by a mad dog, all became affected after the lapse of a few weeks, left off grazing, and dispersed the flock by indiscriminate attempts to butt and mount upon their fellows. They were all killed save one, which, being confined in a stall, kept quietly staring at the wall, but on hearing the slightest noise turned to the direction whence it proceeded, and jumped up against the sides of the stall. It neither ate nor drank, but the proprietor declined to wait the natural termination of the disease.

Country people frequently hold fast the tongue of the rabid cattle with one hand, while they thrust the other into the throat to endeavour to force nourishment into the stomach; yet, although the hands and arms could scarcely on all such occasions be entirely free from injury, and the people neglected to wash their hands, the author never witnessed any evil effects to result. However, he knew a farmer who died of rabies merely from having washed out the wound inflicted on a pig by the bite of a mad dog. He has frequently known the milk of rabid animals to be taken without detriment; and in two instances the flesh of rabid oxen, which was clandestinely eaten, proved innocuous. But, at a period when many cattle perished of rabies, the instances of canine madness became unusually numerous. He concludes with remarking, that having witnessed many instances where the bite of decidedly rabid animals has produced little or no effect upon the human subject, although the remedies employed were merely such as were suggested by superstition, he infers that in the human species a predisposition to hydrophobia rarely exists.

## ON THE GEOGRAPHICAL DISTRIBUTION OF ANIMALS.

(Concluded from p. 149.)

DEVONSHIRE boasts of all the English marine Grallæ except seven, one of which, the Red Coot-foot, does not extend in range beyond Orkney, and the rest are either stragglers or great rarities. Among the rarer Grallæ of our shores, the following deserve enumeration: the Great White Heron, Purple Heron, Little White Heron, Freckled Heron, Night Heron, White Stork, Black Stork, Little Bittern, Spoon-bill, Ibis, Brown Snipe, Pigmy Curlew, Temminck's Sandpiper, Little Stint, Sanderling, Phalarope, Greoushank, Wood Sandpiper, Stilt, Avocet, and Spotted Redshank; and if the records of the occurrence of these birds in England be consulted, it will be seen that not only are they of extreme rarity, but that some of them have occurred more frequently in Devon than elsewhere. Some of our other Grallæ also are tolerably common, while in other parts they are scarce. What then are the reasons of our possessing so very many rarities, and of having so many individuals of the less rare birds of this division of the Grallæ? Is it because our climate is so genial and uniform, because our shores and harbours are so suitable for their sustenance and retreat; on account of our southern situation; or from all these causes combined? The Oyster-catcher seems partial to the rocks and portions of the coast far out towards the open sea, where it occurs in small parties in autumn and winter. The Ringed Plover has been supposed to repair to other countries on the occurrence of the winter's cold; but in Devon, I am quite sure, it resides on the coasts of our estuaries through the winter. The common Godwit, *Limosa rufa*, has been regarded as a species arriving in this country in autumn, and departing in spring; yet, besides having received this species during winter, I have had it on the 10th of May (1830), and, according to Dr Moore, four out of a brood were shot on the estuary of the Tamar in June 1828.

The web-footed birds of Devon are very numerous, compared with those of other maritime counties; and yet, if we regard Devon relatively to its marine ornithology alone, the greatest number of deficiencies will be found amongst the present tribe; for whilst we are deficient in seven of the marine Grallæ, or nine Waders altogether, out of 39, or 65 altogether, we are wanting in 13 of the Palmipedes out of 67, or 75 inclusive of those allowed as inland birds. This deficit of 13 makes up the number 37 formerly mentioned as the amount in which Devonshire was wanting in respect of the whole of the British Birds. These deficient species are either rarities, or such as are limited to the northern isles; so that we may fairly state that we possess all the English Birds any way common, and which are not by the laws of their physical distribution confined to more northern abodes, and farther that we have a very large proportion of those rare birds which occur, however sparingly, in nearly all parts of our island, or on the other hand, have been noticed a very few times in the whole of the country. The following are the rarer birds of this class observed with us:—Crested and Red-necked Grebes, Black-throated Diver, Black Guillemot, Little Auk, Puffin, Cinereous Shearwater, Fork-tailed Petrel, Skua (one shot in September 1831 off the Eddystone), Arctic Jager, Glaucous and Little Gulls, Sandwich, Arctic, Lesser, and Black Terns, Goosander, Merganser, Ferruginous, Eider, Scoter, Velvet, Golden-eye, Harlequin, Long-tailed, Garganey, Pintail, Gadwall, and Shoveller Ducks; Bean, White-fronted, Red-breasted, Bernacle, and Brent Geese, and Wild Swan. The occurrence of so many of the rarer pelagic birds on our coasts seems to allow of readier explanation than that of rarities from amongst other tribes, because we find that the former are bestowed on us in most profusion and very frequently only, on the occasion of storms, or of very severe cold. A long-continued or violent squall from the south-west has afforded us specimens of the Little Auk, the two Petrels, and the Phalarope. A severe winter confers on us specimens of the Wild Swan, Bean, White-fronted, and Brent Geese; Pintail, Golden-eye, Pochar, and other species of Ducks. The object of nestling has likewise influence with some; but winter is the season in which by far the greater number of the web-footed species appear here; and not only do many of those reared in more northern countries migrate thus far south, but others come from their breeding places in our own island. Thus, the Gannet repairs to us in winter from Lundy Island on the north of Devon, and the numbers are greatly increased if the season be severe. The Shieldrake breeds in Braunton Burrows in the north of the county, and many individuals appear here in winter. The Red-legged Gull is abundant at that season, having come from some of the northern English counties, where it breeds; it is scarce in summer, but one was shot near Plymouth in the first week of March 1835. The Herring Gull breeds here, and after that its numbers are lessened on our coasts until the next spring. The Shearwater and the Puffin breed on Lundy Island, and are seen off our shores, and in the channel, chiefly in winter. A great many of the water birds, however, occur on our coasts without our being able to assign any cause for their appearance, as they have arrived independent of storms or severe cold. The Little Gull has been obtained in England seven times, and five of the birds were from Devon. The rarer kinds of Tern mentioned above have occurred without assignable causes, besides many other birds; but possibly the security of our bays and harbours, together with the mildness of climate, may be the attractions to such of them as lead a wandering life.

The geographical distribution of fishes is so very imperfectly known, that but very little can be offered respecting it. About 150 species have been recorded as British, and of these about 30 have hitherto been taken only on the coasts of Devon and Cornwall. About 60 species have come under my observation, or are known to occur on the coast. Many approach our shores at fixed periods, and of these none is more interesting than the Pilchard, on account of its numbers and its importance as an article of winter food to the poorer inhabitants. It appears in August, and generally remains till the end of September. Its comparative scarcity with us for the last few years is remarkable.

Our subject gradually loses interest as we descend to the lower tribes. Of the Mollusca we possess a considerable number. They seem to predominate, however, in those portions of the class which characterize bold, rocky shores; and possibly the same remark holds good relatively to other tribes of marine animals. It is likely that this will account for the same animal being frequently found on shores of the same character, though far distant. Thus, we very often meet with shells stated to have been taken on the coasts of Devon and Shetland, so that although the geography of

shells is so very intricate, it may yet be detected that situation has much control over it. The British Marine Mollusca at present may be computed at 497, of which number nearly 60 are recorded as peculiar to Devon. But, as in the case of Ichthyology, much may be set down to the want of attention to the science in other parts, so it appears that in Conchology we have been peculiarly fortunate in the possession of such observers as Montagu and Turton.

Since the time of Montagu, but little has been done in illustration of the remaining marine tribes of Devon, the Radiata, of which, however, at the present time we can boast of more than twenty species peculiar to the Devon shores; and I have certainly no doubt that this number might be greatly increased by diligent and keen research. The sponges of our coast in particular require illustration; and I am of opinion that not more than three-fourths of them have been named. We see frequent instances, among the lower tribes, of species peculiar to the southern shores of England, representing, by their general similarity, species peculiar to more northern stations. But altogether these facts require elucidation and careful consideration; and no naturalist should deem such matters unworthy of his attention, upon finding that detail of this kind is not merely essential to the development of the laws of animal geography, but that it is requisite to complete the history of species, and to become acquainted with many of the laws regulating their existence and their actions, and in general operation upon the entire series of living beings.

We have shewn that our county yields to none in the importance of its Fauna, and this chiefly because of the peculiar eligibilities of its physical conditions. I do not know, therefore, that it would be of use to inquire into the relative proportions borne between the various tribes, or to institute a comparison between the animals of the south of Devon, and those of any given spot of the same extent. An answer to the former question will be found only by tracing the dependence observed in nature from the inorganic kingdom, to the highest conditions of organization. A competent reply, indeed, cannot be given till our knowledge of the laws of life shall be greatly increased, and till we recognize, as the denizens of our country, hundreds of creatures which have as yet escaped notice. A comparison of our animals with those of any other district would avail nothing, since any enumeration of species does not imply a knowledge of the conditions which influence their situation, or control their limits. In framing a list of animals inhabiting a given spot or country, it would be very right to apply the principles of zoological geography. To speak of the frequency or scarcity of animals independent of these, is to betray ignorance to those who can judge, and to perpetuate error to those who would learn. It is not questionable but that one half of the lists published have been formed without regard to the circumstances causing the residence or visits of animals; nor is it doubtful, but that in asserting that an animal is scarce or frequent, the authors of these lists have overlooked the fact, that it is one scarce or frequent in the country as a whole, or scarce or frequent in many countries conjointly. Supposing a bird stated in books, and known to be found generally as a common inhabitant of England, to be recognised as such in any provincial list; it is clear that no knowledge is thus communicated; and supposing that in any other district it was found not quite so common, and yet reported as common in the ornithological catalogue of that district, it is obvious that the truth is kept back. In short, the manner of these communications is altogether far too general, and deficient in the necessary precision. If such terms as "common," "scarce," and the like, be not used relatively, and if there be not precision used in referring to the occurrence of animals, but little information is imparted by these lists; and I think also that their value would be doubled, if, to the bare intimation of the frequency or scarcity of occurrence relatively to the aggregate of each animal respectively, there were added the causes in operation, and a reference to the conditions by which the number is controlled.—J. C. B., Yealton, October 5, 1837.

## BOTANY.

TEA-TREE.—In a letter from the Abbé Voisin to M. Stanislas Julien, we find a statement which proves that the Tea-tree may be cultivated in our northern climates. He has resided twelve years in China, near the frontiers of Thibet, in which country all the species of tea are successfully cultivated in the plains, as well as on the mountains; although the degree of cold there much exceeds that of our winters, and the snow never melts before the end of April. Twenty-four treatises concerning tea have been composed in Chinese, from the seventeenth century to the present time, and which contain all the requisite instructions for the culture and preparation of this plant, and will be translated by M. Voisin, if required in Europe.—*Athenæum*.

VANILLA.—M. Charles Morron has succeeded in raising the Vanilla in France, and making it produce fruit. He placed the plants in coke, strewn with the remains of rotten willow wood. In this situation the same plant bears fruit only every alternate year, and twelve months elapse between the fecundation of the flower and the maturity of the fruit.—*Ibid*.

CUSCUTA EPILINUM—A BRITISH PLANT.—Mr Bowman states in the Magazine of Natural History, that having, in 1836, gathered a species of *Cuscuta* upon flax, in a field near Ellesmere, Shropshire, and forwarded specimens to Sir W. J. Hooker, the latter found it to be the *Cuscuta Epilinum* of Weihe. It "may be distinguished from *C. Europæa*, by its simple not branched habit, and by its very pale capitula or heads, which are without any of the rosy tinge of the latter. These heads consist of fewer flowers than in the latter species (about five), and these are large, fleshy, and succulent. Both the heads and their component flowers are more decidedly sitting than in *C. Europæa*; the heads are subtended by a membranous, obovate, reflexed bractea, of a reddish-brown colour; but there is no bractea under each individual flower. The calyx is large and spreading, its segments thick and deltoid, almost as long as the corolla, which has very acute segments and a globose tube, even before the enlargement of the germen. The filaments are also very short and very acute; beneath each of which, at the base of the corolla, is inserted a broad membranous scale, whose jagged tips do not reach so high as the insertion of the stamens. The capsule is globose, two-celled, the cells two-seeded, and the seeds subtriquetrous from compression as they swell, covered with chaffy granulations and deeply pitted. It is supposed to grow exclusively on flax, and to have often been mistaken for *C. Europæa*.

## GEOLOGY.

**SUBMARINE VOLCANO.**—On the 25th of last November, the captain and passengers of the brig *Cesar*, from Havre, on passing the bank of Bahama, saw an enormous fire, which increased till it had tinged the whole of the sky and part of the horizon. It was kept in sight for four hours, and could only be accounted for as proceeding from a submarine volcano. On the 3d of January, the captain of the *Sylphide*, also from Havre, being on the same spot, found the sea disturbed, and whitish in colour, which he attributed to the same cause.

**NATURAL SODA FOUNTAIN.**—An American Missionary, Mr Spalding, gives an account of a natural soda fountain which he and his party passed, on their route across the Rocky Mountains, at the distance of three days' journey from Fort Hall. One of the three openings of this fountain "is about fifteen feet in diameter, with no discovered bottom. About twelve feet below the surface are two large globes, on either side of this opening, from which the effervescence seems to rise. However, a stone cast in, after a few minutes throws the whole fountain into violent agitation. Another of the openings, about four inches in diameter, is through an elevated rock, from which the water spouts at intervals of about forty seconds. The water, in all its properties, is equal to any artificial fountain, and is constantly foaming and sparkling. Those who visit this fountain drink large quantities of the water with good effect to health.

## CHEMISTRY.

**GOLD.**—The medical properties of gold have lately occupied the attention of M. Legrand; and he is of opinion that this metal, reduced to an impalpable powder, its metallic oxides, and the perchloruret of gold and sodium, possess in a very high degree the property of restoring vital strength, and of increasing the activity of the organs of digestion and nutrition.

**LEAD.**—Chemists have long turned their attention towards the different combinations of water and acetic acid, with oxide of lead, and which are so valuable to medicine, the arts, and analysis. M. Payer has discovered a new acetate, and an equally new combination of water and protoxide of lead. In the course of his researches, he has been able to explain several phenomena hitherto unknown, and which are highly interesting in the matter of analysis.

## REVIEWS.

*Yarrell's History of British Birds.* London: Van Voorst.

It has been alleged, that, in the recent numbers of this work, a great falling off in the execution of the engravings has been observed; but, on carefully reviewing the whole, and comparing the figures with each other, we are unable to perceive either deficiency or improvement in those that have lately appeared. As a series, we cannot but consider them as extremely beautiful, although, as in all other productions of art, deficiencies may be pointed out. In form, and especially with regard to the bill, they are, in our opinion, generally superior even to Mr Gould's much larger figures; and there is scarcely any of them that a person moderately acquainted with the species could fail to recognize. The heads of some, however, as of the Black Redstart, and especially the Grasshopper Warbler, are obviously much too small. The information afforded in the descriptive part continues to be of that condensed and carefully elaborated character which it has all along presented.

*Essays on Natural History, chiefly Ornithology.* By Charles Waterton, Esq., Author of "Wanderings in South America." With an Autobiography of the Author. London: Longman.

This is merely a reprint of various articles that have appeared in Mr Loudon's Magazine of Natural History, some of which, however, are highly interesting, as affording accurate information respecting the habits of our native birds, written in a very pleasing, although diffuse and discursive style, of which the following, painful as the subject is, may be taken as a good example:—"Sad and mournful is the fate which awaits this harmless songster (the Chaffinch) in Belgium, and in Holland, and in other kingdoms of the continent. In your visit to the towns in these countries, you see it outside the window, a lonely prisoner in a wooden cage, which is scarcely large enough to allow it to turn round upon its perch. It no longer enjoys the light of day. Its eyes have been seared with a red-hot iron, in order to increase its powers of song, which, unfortunately for the cause of humanity, are supposed to be heightened and prolonged far beyond their ordinary duration by this barbarous process. Poor Chaffinches, poor choristers, poor little sufferers! my heart aches as I pass along the streets, and listen to your plaintive notes. At all hours of the day we may hear these hapless captives singing (as far as we can judge) in apparent ecstasy. I would fain hope that these pretty prisoners, so woe-begone and so steeped in sorrow to the eye of him who knows their sad story, may have no recollection of those days when they poured forth their wild notes in the woods, free as air, 'the happiest of the happy.' Did they remember the hour when the hand of man so cruelly deprived them both of liberty and eyesight, we should say that they would pine in anguish, and sink down at last, a certain prey to grief and melancholy. At Aix-la-Chapelle may be seen a dozen or fourteen of these blind songsters, hung out in cages at a public-house, not far from the cathedral. They sing incessantly, for months after those in liberty have ceased to warble; and they seem to vie with each other which can carol in the loudest strain. There is something in song so closely connected with the overflowings of a joyous heart, that when we hear it, we immediately fancy we can see both mirth and pleasure joining in the party. Would, indeed, that both these were the constant attendants on this much to be pitied group of captive choristers! How the song of birds is involved in mystery! mystery probably never to be explained. Whilst sauntering up and down the Continent in the blooming month of May, we hear the frequent warbling of the Chaffinch; and then we fancy that he is singing solely to beguile the incubation of his female, sitting on her nest on a bush close at hand. But on returning to the town, we notice another little Chaffinch, often in some wretched alley, a prisoner with the loss of both its eyes, and singing, nevertheless, as if its little throat would burst.

Does this blind captive pour forth its melody in order to soothe its sorrows? Has Omnipotence kindly endowed the Chaffinch with vocal faculties, which at one time may be employed to support it in distress, and at another time to add to its social enjoyments? What answer shall we make? We know not what to say. But be it as it will, I would not put out the eyes of the poor Chaffinch, though by doing so I might render its melody ten times sweeter than that of the sweet Nightingale itself. O that the potentate, in whose dominions this little bird is doomed to such a cruel fate, would pass an edict to forbid the perpetration of the barbarous deed! Then would I exclaim, O king of men, thy act is worthy of a royal heart. 'That kind Being, who is a friend to the friendless, will recompense thee for this.'" Truly, Mr Waterton, thou art a kind-hearted man; but how, seeing thou abhorrest the cruelty of burning the eyes of birds, hast thou aimed so many red-hot shafts at a brother ornithologist? Let the reader compare the above with some criticisms contained in the *Essays*, and he will be led at least to suppose that "birds of a feather" are not always apt to be friendly. The autobiography is not the least interesting part of the work.

*A Geographical and Comparative List of the Birds of Europe and North America.* By Charles Lucien Buonaparte, Prince of Musignano.

This Pamphlet of 67 pages, containing merely a list of the names of the birds of two portions of the two great continents, the booksellers value at five shillings. The species found in Europe are 503, those in North America 471. As to the genera, it is useless to speak of them, as these imaginary groups, formed on no principle whatever, have existence merely in the realm of fancy. Wilson and Audubon, the principal discoverers of American species, have scarcely a single name of all that they imposed left to them. A great man in science erects an edifice, beautifully proportioned, as he thinks, and the next giant in science who comes to the building ground, just quietly sweeps it away to make room for a new pagoda; picking up, however, most of the stones, on which, when aptly disposed, he inscribes such magic characters as Linn. Ill. Vieill. Briss. Dum. Brehm. Sav. Cuv. Vig. Bechst. Boie. Tem. Lath., with a profusion of Nob, Nobs. In this catalogue the genera are reduced to the minimum size; and the ornithology of Europe and America is thus "brought up to the present level of the science." The species which were generally understood to be common to both continents, such as *Falco Peregrinus*, *Corvus Corax*, *Corvus Pica*, are greatly reduced in number, the American Peregrine being named *Falco Anatum*, the Raven *Corvus Catotl*, the Magpie *Pica Hudsonica*; but as distinctive characters are not given, we are unable to imagine the grounds on which some of these distinctions are made. The author professes to adopt always the specific name used by Linnæus, and then presently converts *Falco Buteo* into *Buteo vulgaris*, *Falco Milvus* into *Milvus regalis*, *Strix Otus* into *Otus vulgaris*, &c. However, he certainly does retain a large proportion of the Linnæan specific names, for which he merits the thanks of the ornithologists. The figures of the works of Audubon and Gould are "quoted as types of the species under consideration;" but while the latter is characterized as "the most beautiful work on ornithology that has ever appeared in this or any other country, of the former it is stated merely that the merit of M. Audubon's work yields only to the size of his book." What this phrase is intended to signify, we cannot comprehend; but we will maintain against prince or peasant, that Mr Audubon's drawings of birds, being taken generally from entire individuals, and executed in a peculiar manner, cannot be with truth placed on a level with those of Mr Gould, of which the forms are very frequently defective, and the parts disproportioned. At the same time, Mr Gould's work is truly beautiful; but Mr Audubon's is magnificent, not merely in size, but in character. Both works, however, are less useful to the world than a good octavo volume of plain letterpress would be, for they are beyond the reach of ordinary students. To those who already know the birds of Europe and America, the prince's List will be useful, but to the student it is a sealed book. A comparative Catalogue, having ordinal, generic, and specific characters, is a desideratum.

*The Naturalist's Library.* Vol. X. Flycatchers. By William Swainson, Esq., with a Memoir of Baron Haller.

THE Memoir is certainly the best written and not the least interesting part of the book. The Muscipidae, sectioned as usual into five, and analogised into Raptorial, Rasorial, Grallatorial, Natatorial, and Insectorial, will be found by those who have adopted this fanciful system to be treated in a very interesting manner. Even they who have other views will find it advantageous to give this essay a careful perusal, as the elucidation of affinities of any kind must be useful. But the work is obviously intended, not for the student, so much as for the adept. The thirty-two plates illustrative of the text are remarkably well executed, the drawing, engraving, and colouring, being all of a superior character, and the resemblance of the figures to their originals being found by us perfectly satisfactory, although, it is true, we have only prepared skins of some of the species to compare with them, and we suppose the author can have had nothing better. The decorations are also much to our taste, the scenery introduced being beautiful and appropriate. The illustrations of this volume, in short, are among the best of the series; and as pleasing pictures, are worth the price even to those who can understand little of the descriptions. The conductor and publisher certainly deserve praise for their exertions in rendering the series of essays not merely amusing, but more or less instructive, by employing individuals of acknowledged talent, such as the author of the present volume, of whose extensive knowledge and ingenuity, however much we may differ from him as to the most useful method of examining birds, we have, without presuming to pass judgment upon a master in science, a very high opinion.

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE.—THE BABOONS AND MANDRILLS.

THE BABOONS, or *Cynocephali*, are generally large and ferocious species of Monkeys, having cheek-pouches, callosities on the hips, an elongated and truncate muzzle, and a tail varying in length, but usually rather long. The only species here represented is,

Fig. 1. THE LITTLE BABOON (*Cynocephalus Babouin*). A variety of a more uniform green colour, with the face dusky. It inhabits Western Africa.

THE MANDRILLS have the muzzle more elongated than any other species of this family. Its extremity is truncate, as in the Baboons, the nostrils being terminal; their tail is extremely short and erect; and they have callosities behind. In character they are similar to the Baboons, being ferocious, irritable, and malicious. They are all natives of Africa.

Fig. 2. THE GREAT MANDRILL (*Papio Maimon*). Male. The adult males of this species are of a greyish-brown colour above; white beneath; their callosities blue, as is the face, the latter being obliquely banded with white, and the extremity of the muzzle more or less tinged with red. The hair on the head is elongated, that of the cheeks being yellowish-brown, and there is a short yellowish beard on the chin. It is said to attain nearly the size of a Man, and to be an object of dread to the Negroes on account of its ferocity.

Fig. 3. THE GREAT MANDRILL. Young.

Fig. 4. THE DRILL (*P. leucophaeus*). Male. This species is very similar to the former, being about the same size, greyish-brown, tinged with green above, white beneath, but the face black. It inhabits Guinea and the Gold Coast.

Fig. 5. THE DRILL. Female.

Fig. 6. THE DRILL. Young.

#### DESCRIPTION OF THE PLATE.—THE PIGEONS.

THE PIGEONS, which were included by Linnaeus in the single genus *Columba*, have recently been arranged under several genera, and by some ornithologists have even been formed into a separate order. The position of this group has been a subject of much dispute, some referring it to the Gallinaceous order, others to the Passerine, to both of which it in fact presents affinities. Cuvier places the Pigeons at the end of the Gallinaceous Birds, and considers them as forming only a single genus, which may be divided into three subgenera: the *Columbi-Gallina*; *Columba*, or common Pigeons, including Turtles; and the *Vinagines*, or thick-billed Pigeons. The species represented in this plate belong to the second of these subgenera.

Fig. 1. THE SPECKLED PIGEON (*Columba scripta*), having the sides of the head marked with dusky bands on a whitish-ground, the upper parts brown, the inner secondaries and their coverts bronzed, is a native of New Holland.

Fig. 2. THE MANTLED PIGEON (*C. lacernulata*), with the head and lower parts bluish-grey, the throat yellow, the abdominal feathers and lower tail-coverts bright-red, occurs in Java.

Fig. 3. THE GREY-HEADED PIGEON (*C. capistrata*). The upper part of the head ash-grey, the throat cream-coloured, the hind neck and back light-red. Java.

Fig. 4. THE DOUBLE-CRESTED PIGEON (*C. dilopha*), so named on account of the disposition of the elongated feathers on its head, of which the posterior are crimson, is from New Holland.

Fig. 5. THE RED-COLLARED PIGEON (*C. humeralis*), with a half-collar of red on the hind neck, the upper parts light-brown, the tail graduated. New Holland.

DENTITION OF THE WALRUS.—Individuals of this remarkable animal present so great differences in the number of their teeth, some of which are always wanting in adults, that authors have given different statements on the subject, some representing it as having four, others as five grinders, on each side in either jaw, and all being in error as to the incisors. "The Mosses," says Cuvier, "resemble the Seals in their limbs and the general form of the body, but differ much in the head and teeth. Their

lower jaw has no incisors or canine teeth. The grinders have all the form of short and obliquely truncated cylinders. There are four on each side above and below; but at a certain age, two of the upper fall out. Between the two canine teeth are moreover two incisors resembling the grinders, and which most authors have not recognised as incisors, although they are inserted in the intermaxillary bone; and between them are, in young individuals, two others which are small and pointed."

Having recently examined a number of skulls, I have come to a different conclusion. The normal dentition of this animal is shown by the skull of a young individual in the Museum of the Edinburgh College of Surgeons. In the upper jaw there are on each side three incisors, the first or inner extremely small, the second a little larger, the third or outer disproportionately large, being equal to the largest grinders. The socket of this tooth is placed in the intermaxillary bone, but, towards its mouth, is partly formed by the maxillary. The small incisors have deep conical sockets. The

canine tooth is displaced, being thrust outwards, and of enormous size, the lateral incisor is on the level of its anterior margin, and the first grinder is opposite its middle. There are five grinders, having conical blunt sockets, and consequently single roots, the first smaller than the lateral incisor, the second and third largest, the fourth much smaller, the fifth very small; all shortly conical and blunt, with enamel only at the tip. The canine tooth is also at first enamelled at the end. In the lower jaw are two very small incisors on each side; the canine tooth is wanting; five grinders, with single conical compressed roots, and short compressed conical crowns, enamelled at the point; the first, second, and third nearly equal, but the latter a little larger, the fourth much smaller, the fifth very small. The tusks are compressed, conical, directed downwards, a little curved backwards, from one to two feet long, somewhat diverging, but when very long converging again towards the point. In old individuals the incisors are obliterated, excepting the lateral pair in the upper jaw. The fifth grinders in both jaws are also obliterated, although not always, and sometimes the fourth in one or both. One of the most remarkable circumstances with regard to

the teeth of this animal is, that although the grinders are so placed as to meet at the points only, the outer surface of the lower not falling within the line of the outer so as to meet the inner surface, nor the reverse, in any possible case, yet the upper and lower grinders are always worn so as to present an oblique flattened surface on their inner side, which of course cannot be produced by the rubbing of the teeth against each other. Indeed, the jaw is incapable of lateral motion on account of the form of its articulation, and the manner in which it is jammed in between the tusks. The food of the Walrus is said by some to consist of fuci, by others of fish, or of both; but the mastication of neither seems capable of producing the peculiar kind of flattening described.

A HONEY BUZZARD KILLED IN SCOTLAND.—Having been permitted, through the kindness of Mr Carfrae, to examine a recently killed individual of the Honey Buzzard or Pero, *Pernis apivorus*, a species of which I have seen only one other specimen obtained in Scotland, which was shot at Drumlanrig, and is now in the Museum of the University of Edinburgh, I embrace this opportunity of presenting a full description of it. This bird, a male, and apparently full, the neck of ordinary length or rather short, the head ovato-oblong. The bill, although slender compared with that of other birds of this order, is rather stout; the aperture of the mouth is wide, and extends to beneath the anterior angle of the eye; the cere large; the upper mandible with its outline as far as the edge of the cere convexo-declinate, then curved in the third of a circle, the sides convex, the edges soft to beneath the anterior angle of the nostrils, then hard, direct, and sharp, the tip slender, descending, acute; the lower mandible comparatively small, with the back broad, the sides rounded, the edges as in the upper, the tip rounded. The gape-line is arched from the base. Nostrils oblongo-linear, large, and oblique. Upper mandible a little concave, lower broadly channelled,

with a median prominent line. Tongue deeply concave above, with the sides nearly parallel, the tip rounded but emarginate. The legs are short; the tarsus anteriorly covered with feathers half way down, on the rest of its extent with angular scales. The toes are of moderate size; the first stouter, the second next, the fourth least so; the first with four large scales above, the second with three, the third with four, the fourth with three. The claws are long, rather slender, tapering, arcuate; the first and second strongest, the third longest, with a thin inner edge, the second next in length, the fourth smallest.

The plumage is compact. The feathers on the fore part of the head and cheeks are ovate, compact, and small, especially on the loreal space and around the eye. The feathers in general are ovate, curved, with a large downy plumule. On the lower parts they are nearly as compact as on the upper. The wings are long, very broad, and extend to two inches and a half from the end of the tail. There are twenty-three quills; the outer six are separated at the end when the wing is extended, and have the inner web cut out towards the end; all the rest are broad and rounded, with a minute tip. The tail is long, a little emarginate and rounded at the end, the feathers broad. The first quill is short, being two and seven-twelfths inches shorter than the second, which is eleven lines shorter than the third, this latter being the longest; the fourth is only a line shorter, and the other primaries gradually diminish. The middle tail feathers are three lines shorter than the third, which exceeds the lateral by ten-twelfths.

The cere is palé yellow at the base, but dusky in the greater part of its extent. The bill is black; the base of the lower mandible flesh-coloured; as is the mouth internally, excepting the mandibles and the horny part on the back of the tongue, which are black. The margins of the eyelids are also black, the iris yellow, the tarsi and toes orange, the claws black. The loreal space and anterior part of the forehead are brownish-grey; the head reddish-brown; the rest of the upper parts umber-brown. The feathers generally are darker on the shaft and towards the end. The primary coverts and primary quills are blackish-brown at the end, and in the rest of their extent have generally on both webs three bands of dark-brown on a lighter ground; the inner webs white, except at the end, where they are light-brown mottled with darker. The outer quill has, however, only a single dark band, reduced to two spots, the second and third two bands, also reduced to spots; on the secondaries the dark bands are reduced to two, and gradually approximate inwards. The tips of the tail-feathers are brownish-white; there is then a broad band of brownish-black, and a dusky space with seven indistinct darker bands, between which and the base are three large blackish bands; the upper tail-coverts are light umber. The throat is light reddish-brown; the rest of the lower parts umber, each feather with the shaft and a portion near it dusky. The feathers of the legs are lighter, as are the lower tail-coverts, which have two bands of white towards the base. The concealed and downy part of the whole plumage is white, that colour appearing externally on the hind neck and head when the feathers are raised, as it there extends over more than half their length. The lower wing-coverts are umber brown.

Length to end of tail twenty-four and one-fourth inches; extent of wings fifty-two; wing from flexure sixteen and three-fourths; tail eleven and one-half; bill along the ridge one and four-twelfths; tarsus one and eleven-twelfths; first toe eleven-twelfths, its claw one; third toe one and nine-twelfths, its claw one and three-twelfths.

This species was formerly referred to the genus *Buteo*, but has recently been considered as, with some others, constituting a distinct genus, to which the name of *Pernis* was given by Cuvier. In some respects, *Pernis* is more nearly allied to *Milvus* than to *Buteo*, especially in the shortness and thickness of the tarsi, the slender moderately curved claws, the very long wings and tail. *Pernis apivorus* is in fact intermediate between *Buteo vulgaris* and *Milvus regalis*, and its habits are in correspondence with this circumstance, for both the birds mentioned are insectivorous, and I have found even earth-worms in the stomach of our Common Buzzard. The Honey Fern, although fond of the larvæ of Bees and Wasps, cannot live exclusively on them; but as yet, from its very rare occurrence in this country, little is known of its habits. The individual above described was shot in the county of Stirling, and affords the third authentic instance of the occurrence of the species in Scotland.

The digestive organs were in all respects similar to those of the Common Buzzard and Kite. The œsophagus, *a, b*, which is very wide, has a large dilatation or crop in front; the proventriculus, *c*, is furnished with a belt of cylindrical glandules; the stomach, *d, e*, is large, roundish; its muscular coat very thin, and composed of fasciculi of fibres, without distinction of lateral muscles; the tendons rather large and roundish. The intestine, *f, g*, 22 inches long, the duodenal portion only 3½, and the biliary ducts entering at the distance of 3 inches from the pylorus; the diameter varies from five-twelfths to two-twelfths; there are no cœcal appendages; and

the cloaca is 2 inches long, and of an elliptical form. The stomach was filled with fragments of bees and numerous larvæ, among which no honey or wax was found.

“ Besides various specimens obtained in Suffolk, Norfolk, and along the eastern coast as far north as Northumberland, the Honey Buzzard,” says Mr Yarroll, “ has been killed in several western counties, including Dorsetshire, Devonshire, and Worcestershire. Dr Heysham considered it very rare in Cumberland, and had only met with one specimen. Mr Thomson of Belfast has recorded one example killed in the north of Ireland. According to Linnæus, Brunnich, Muller, and Pennant, the Honey Buzzard inhabits Denmark, Norway, Sweden, and Russia. From thence southward, it is found in Germany, France, Italy, and the south of Europe generally. M. Temminck considers it very rare in Holland. It is said to be a native of Eastern climes; and Mr Gould states that he has seen it in collections of skins from India.

## BOTANY.

SCOTTISH OAKS.—Although the Oak does not attain in Scotland dimensions equal to those of English trees of the species, and in the native forests of that country is generally of diminutive size, yet many individuals have been marked as entitled to some consideration. Of these the following list is presented in Mr Loudon’s splendid *Arboretum Britannicum*, recently published. In the neighbourhood of Edinburgh, there is an oak in Dalmeny Park 70 feet high, with a trunk 15 feet 9 inches in circumference, diameter of the head 96 feet; another oak, 70 feet high, has a trunk only 6 feet 5 inches in circumference, but carries nearly that thickness to the height of 30 feet before it throws out branches. At Barnton Hall is an oak 80 feet high, with a trunk 11 feet in circumference, and a head 82 feet in diameter; the trunk is sound, and without branches to the height of 20 feet, but the head is stag-horned and much decayed. At Hopetoun House is a growing tree 75 feet high, with a trunk 11 feet in circumference. At Melville Castle is an oak 70 feet high, with a trunk 18 feet in girth, at 4 feet from the ground, and a head 90 feet in diameter. South of Edinburgh. In Ayrshire, at Kilkerran, is an oak 50 feet high; the girth of the trunk is 12 feet 6 inches, and the diameter of the head is 90 feet. In Haddingtonshire, at Yester, is an oak 89 feet high, with a trunk 12 feet in girth, and a head 70 feet in diameter. In Lanarkshire, at Bothwell Castle, is an oak 59 feet high, with a trunk 14 feet in circumference, and a head 98 feet in diameter. In Roxburghshire, at Minto, are several oaks about 200 years old, which are 70 feet high, the girth of the trunk about 12 feet, and the diameter of the head 63 feet. North of Edinburgh. In Aberdeenshire, at Fintray House, are four oaks with trunks varying from 5 feet 6 inches to 5 feet 10 inches in circumference. The oak does not ripen its acorns, and rarely its young wood, in this county. In Banffshire, at Gordon Castle, is an oak 66 feet high, with a trunk about 10 feet in girth, and a head 66 feet in diameter. In Cromarty, at Coul, there is an oak 162 years old, which is 80 feet high, the circumference of the trunk 12 feet, and diameter of the head 60 feet. In Fifeshire, at Donibristle Park, is one 70 feet high, with a trunk about 11 feet in girth, and 40 feet clear of branches, diameter of the head 45 feet. At Largo is an oak 100 feet high, with a trunk 9 feet 6 inches in circumference, and 35 feet clear of branches, and a head 53 feet in diameter. In Forfarshire there is an oak on the estate of Lord Gray, at Gray House, which was 68 feet high, the circumference of the trunk 17 feet 6 inches, and the diameter of the head 90 feet, when it was measured in June 1836, by Mr Robertson, his lordship’s gardener. The same oak, when measured in 1821, was, we are informed by Mr Robertson, then only 16 feet in circumference, and consequently it has gained 18 inches since that period. It is *Quercus pedunculata*, and is in great health and vigour. In Perthshire, at Taymouth, is a growing oak 45 feet high, with a trunk 14 feet in girth, and a head 72 feet in diameter. The tree stands in the park in a loamy soil, on a dry subsoil, and is about 100 years old. In Ross-shire, at Brahan Castle, is an old oak 80 feet high, with a long straight trunk 12 feet in circumference, and a head 90 feet in diameter. In Stirlingshire, at Blair-Drummond, is a growing oak 120 years old, 86 feet high, with a trunk 20 feet in the bole, and 14 feet in circumference, diameter of the head 60 feet. There are many fine oaks at Blair-Drummond from 15 feet to 50 feet in the bole, but no other is quite so much in circumference. In Callender Park, *Q. sessiliflora* is 50 feet high, the circumference of the trunk 15 feet 6 inches, and diameter of the head 58 feet. In Sutherland, at Dunrobin Castle, is an oak 10 feet high, the diameter of the head 47 feet, and the girth of the trunk about 11 feet.

DESTRUCTION OF MOSSES IN PASTURES.—Mr Thomas Bishop, Methven Castle, has recently made experiments with the view of ascertaining the best method of destroying mosses growing in pasture land. The results of these experiments are communicated in the last number of the *Transactions of the Highland and Agricultural Society of Scotland*. “ The growth of musci will always be found rapidly to take place when rye-grasses are the only grass seeds sown, excepting on the very best land, as it is not the nature of that kind of grass to form a close sward. The production of them is also much encouraged in older pastures, by eating the grass too bare in August, and the early part of September, as also by taking a crop of meadow-hay where the ground is not much trodden upon, or has been under water in irrigation or otherwise. With the view to destroy musci and invigorate the better grasses, top-dressings have been used and found very expensive, and their effects as evanescent. Experiments have been made here for that purpose with bone-dust, put on in spring, at twenty bushels per acre, price 2s. 6d. per bushel. Lime and soot to the same amount of cost. Common salt was also tried to a fifth part of less expense, and found very efficient, although fears were entertained, for a time, that the grass would suffer. The soot in the following season gave evident indications of its tendency to extirpate the musci, but not so powerfully as the salt; the lime and bone-dust used had little or no effect. Liquid manure collected in a tank, under cover, from the feeding and cow byres, and washings of the dung-yard, have also been used, but not for the length of time to warrant a decisive opinion of its tendency to destroy musci, although their beneficial effects on grass land is unquestionable. The last and most efficient remedy for the prevention and destruction of musci, and easiest to have recourse to, when the ground has not become altogether exhausted, or in an over damp state, is to allow a

great portion of the summer's grass to remain unconsumed on the ground, until the following winter, when the barer it is eaten before the new growth of spring, the finer will be the following summer's grass. But should the repetition of this treatment fail to extirpate the mousi, it will be more profitable to put the grass lands under a rotation of crops, and sow them out anew with a mixture of grass seeds suited to the soil and climate. A little more manure than would have sufficed for a top-dressing will thus be repaid with a richer and much more enduring herbage."

**BOTANY OF THE NEIGHBOURHOOD OF THE LAKE OF THUN.**—In a communication from Col. P. J. Brown of Eichenbühl, Switzerland, read to the Botanical Society of Edinburgh, it was stated that the Lake of Thun, having an elevation of about 1900 feet above the sea, and the surrounding country being much intersected by hills or long ridges, the vegetation assumes a subalpine character on the pastures about 1500 feet above the lake, comprising *Trollius europæus*, *Hieracium aureum*, *Tussilago alpina*, &c. The following was given as an approximation to the species usually met with at different altitudes on the surrounding mountains. Between 2000 and 3000 feet, *Arenaria verna* and *ciliata*, *Dryas octopetala*, *Cotoneaster vulgaris*, *Hieracium villosum*, &c. Between 3000 and 4000 feet, *Silene acaulis*, *Cerastium alpinum*, *Phaca astragalina*, *Oxytropis uralensis*, *Saxifraga oppositifolia*, *Hieracium aurantiacum*, *Arbutus alpina*, *Ajuga alpina*, *Orchis pallens*, *Carex atrata*, &c. Above 4000 feet, *Gnaphalium alpinum* and *Leontopodium*, *Petrocallis pyrenaica*, *Draba tomentosa* and *stellata*, *Androsace bryoides*, &c.

### GEOLOGY.

**FOSSIL BONES OF YEALM BRIDGE CAVE.**—Mr Bellamy, to whom we are indebted for an account of his discovery of this cavern, has recently favoured us with the following additional remarks on the subject.

Notwithstanding that the bones from the cave I was so fortunate to discover betray no symptoms of altered character, so far as external aspect and superficial examination go, being to appearance in no way different from bones which have been exhumed after a few years' interment, it is natural to inquire whether, in their intimate composition, alterations cannot be detected whereby some information may be added to the chemistry of bone, and to the inquiry concerning the operation of those circumstances under which these bodies were placed, as well as the period during which they have lain entombed. So far as respects the hard earthy portion of bones, it seems that when excluded from the action of air, they will remain for ages unaltered; though when I exposed some of my specimens for two or three days and nights to the action of the weather, in a rainy season, they soon split and cracked, showing proofs of incipient disintegration. Even without this exposure to the weather, the whole of my specimens suffered so much from contact of the air, as to oblige me to use a kind of varnish for their protection. But this decomposition must be regarded as the effect of unusually lengthened age; for in general we see that bones of ancient date do not suffer in this way on being brought to light. Besides the durability of their external figure, these bones had lost much of their moisture, and had imbibed in lieu the droppings from the cavern, which convey much of the calcareous matter of the rock; this latter circumstance in particular determining their absorbent quality noticed before. With respect to the animal part of their composition, I shall have to offer a modified opinion. That it is somewhat lessened in quantity in all bones of this class and date, I have no doubt; but I also think that there are differences dependent on the bone selected for examination, on its being entire or fractured, on its situation in the cave, and so forth. If you experiment on a small fragment, the result will seem to be very different from what it is when experimenting on an entire bone, at least so far as regards the ordinary method of employing muriatic acid to dissolve the earths, and exhibit the remaining animal portion. Thus, when by experiment I endeavoured to determine the comparative difference between these and bones of ordinary occurrence, I found that after selecting a fragment of fossil bone and a piece that had lain exposed on the high-road for some months, each weighing half a drachm, and putting them in maceration in glass vessels, violent and rapid escape of carbonic acid gas, due no doubt to the imbibed calcareous matter, proceeded directly on the fossil piece being immersed; gradual corrosion, or rather gradual removal of the earthy portions, was soon evident, and in the space of seven hours nothing remained of the original fragment but a small spongy, flocculent mass, or pellicle, weighing eleven grains. On the contrary, the other fragment gave off slowly and deliberately gaseous matter; the process of removal of the earths was not finished for a very long time, and at the end, the original form of the immersed piece was retained; it was soft, fibrous, flexible, and elastic, and weighed eighteen grains. But again my brother finds that in exhibiting the animal form of bones, no external difference is observable between specimens of this kind derived on the one hand from a phalangeal bone of the fossil Hyæna, and on the other from any common bone. The first seems to exhibit the fact as well as the other; but I decidedly think there is a diminished quantity of the albuminous substance, though it may not appear so. Mr Martyn, in his Treatise on Fossils, speaks cautiously on the subject of the chemistry of fossil bones by saying, through Professor Playfair, that they often contain a portion of gelatin (or rather, by recent examination, albumen) in their composition, particularly in their interior, the surface only having undergone a change. In other instances, he adds, the gelatin (albumen) is wholly displaced, while a greater proportion of carbonic acid than that which existed in it originally is found united with the calcareous matter. Those in the Rock of Gibraltar seem to have been so circumstanced. The question, therefore, respecting the composition of fossil bones must be answered in a cautious and qualified manner, and with reference to the conditions of each particular case.

The occurrence of the bones of Mice in the substance of some of the stalagmite, is a circumstance to which too much attention cannot be directed in framing a theoretic statement of the age of the contents of this cavern, because, as before mentioned, they are not identically the same species with those now in existence, and from their peculiar position seem not to have been contemporary with the other animals. Yet in consideration that other specimens of these remains were discovered in the diluvial clay, it may not be unfair to suppose that those found in stalagmite were so impacted previously to the catastrophe which effaced the whole series of Antediluvian crea-

tures, during indeed that period in which the Hyænas and other predatory beasts employed this cavern, or its compartments, as their dens. There is the same analogy or resemblance of these Mice to the present kind, as subsists between the other Antediluvian creatures, and their representatives of this day,—the same remarkable affinity. Looking also to the wise provisions of Nature in regard of food, we see that these small creatures would hold a decided relation to the predaceous habits of the animal I have ventured to designate Glutton, from its evident similarity to our *Mustela Gulo*.

I perceive that two animals named in my manuscript as having been identified among the rest, have been omitted in the printed account. The reason of this I am well aware of: it was thought that some mistake had arisen in naming the specimens, particularly perhaps the *Sheep*, this animal seeming to be inconsistent with an undomesticated or unreclaimed state. Of this I have been warned in a private letter from Dr Buckland; but what precludes our supposing the existence of a wild animal allied to our *Oves Aries*? and what shall forbid the conclusion, when by comparison it is seen that the analogy is most perfect? Messrs Clift and Owen, of the College of Surgeons, have through Colonel Mudge, in his paper before alluded to, confirmed my original statement made in 1835 by the test of comparison with recent teeth. With regard to the *Duck*, I can only say I have diligently compared the specimens with recent skeletons in my museum, and feel fully justified in renewing the assertion. Dr Buckland mentions "a bird" in his list of the animals of the Kirkdale Cave, and Colonel Mudge mentions in his account of the Yealm Bridge Cave (1836) "a bird of considerable size."

I cannot avoid mentioning, in conclusion, that Colonel Mudge's account of the strata found in the cave is incorrect. The red clay was unquestionably the lowermost stratum, not the argillaceous sand. From want of specimens, I presume, he has also omitted to insert the names of the Deer, Pig, Glutton, and Field Mouse.

**WEALDEN STRATA AT ELGIN.**—At a meeting of the Geological Society, on the 25th April, a communication from Mr Malcolmson was read, giving an account of the occurrence of Wealden Strata at Linkfield, near Elgin. The country around consists principally of old red sandstone, but at Linkfield, about a mile south of the town, that formation is overlaid by a series of beds, formerly considered to be lias, but ascertained by their organic remains to belong to a fresh-water deposit of the age of the Wealden of England. The succession of the strata in descending order is as follows:—1. Blue clay with thin beds of compact shelly limestone. 2. Bands of limestone and clay. 3. Blackish clay. 4. Compact grey limestone with shells. 5. Green clay. 6. Red sandy marl, enclosing rolled pebbles of granite, gneiss, &c., also angular fragments of old red sandstone. Among the fossils are *Cyclus medius*, a common shell in the fresh-water strata of Essex; an *Avicula*, which occurs in the lower purple beds at Swanwich, also remains of fishes, and great abundance of a new species of Cypris. Strata equivalent to the Wealden of England were discovered in the Isle of Skye by Mr Morchison, in 1827. The Rev. G. Gordon has recently found the Linkfield fossils at Lhanbryde, three miles to the eastward of that locality; also a Pinna, considered by Mr James Sowerby as closely resembling a species belonging to the Portland sand; and, in making the canal by which a great part of the Loch of Spynie was drained, fossils were found belonging to the coral rag and the lias of England. Mr Malcolmson, therefore, hopes that many of the formations above the old red sandstone, hitherto undetected in that part of the kingdom, will be discovered. He also announced, that Mr Martin of Elgin has found in the old red sandstone of that neighbourhood, among other remains of fishes, scales identified with those of the old red sandstone of Clackbennie.

### CHEMISTRY.

**DR TRAILL'S INDELIBLE INK.**—On the 19th February last, Dr Traill read to the Royal Society of Edinburgh a paper on the composition of a new ink, which, by resisting chemical deletion, promises to diminish the chances of the successful falsification of bills, deeds, and other documents. The author was led to the investigation of this subject by its connection with that branch of medical jurisprudence which treats of the prevention and detection of forgery. It is well known that common writing ink may be totally effaced from paper by certain chemical agents, and that several others so impair its colour, that the characters traced with it become illegible. To the first class of chemical agents belong chlorine, and substances containing it, as well as oxalic acid; to the second diluted solutions, or the vapours of the mineral acids, and of the caustic alkalis. These agents were applied to written specimens of a great number of different inks, and the degree of resistance to their effects was considered as the criterion of the durability of each. These views engaged the author in an extensive series of experiments on coloured metallic preparations, suspended in different vehicles, the results of which were not satisfactory. He then attempted the composition of a carbonaceous liquid which should possess the qualities of good writing ink. The inks used by the ancients were carbonaceous, and have admirably resisted the effects of time; but the author found that the specimens of writing on the Herculæanum and Egyptian papyri were effaced by washing with water; and on forming inks after the descriptions of Vitruvius, Dioscorides, and Pliny, he found that they did not flow freely from the pen, and did not resist water. The carbonaceous inks with resinous vehicles, rendered fluid by essential oils, though they resisted water and chemical agents, had the disadvantages of not flowing freely from the pen, and of spreading on the paper, so as to produce unseemly lines. Solution of caoutchouc in coal-naphtha, and in a fragrant essential oil, lately imported from South America, under the name of *acete de sassafras* (the natural produce of a supposed Laurus), were subject to the same objections.

The author tried various animal and vegetable fluids as vehicles of the carbon, without obtaining the desired result, until he found, in a solution of the gluten of wheat in pyroligneous acid, a fluid capable of readily uniting with carbon into an ink possessing the qualities of a good, durable writing ink. To prepare this ink, he directs gluten of wheat to be separated from the starch as completely as possible, by the usual process, and when recent to be dissolved in pyroligneous acid with the aid of heat.

This forms a saponaceous fluid, which is to be tempered with water until the acid has the usual strength of vinegar. He grinds each ounce of this fluid with from eight to ten grains of the best lamp black, and one and a half grain of indigo. The advantages of this ink are:—1. It is formed of cheap materials; 2. is easily made; 3. has a good colour; 4. flows freely from the pen; 5. dries quickly; 6. when dry is not removable by friction; 7. is not affected by soaking in water. Lastly, slips of paper written on by this ink have remained immersed in solutions of various chemical agents, capable of immediately effacing or impairing common ink, for seventy-two hours, without change, unless the solutions be so concentrated as to injure the texture of the paper.

Dr Traill offers this composition as a writing ink, to be used on paper, for the drawing out of bills, deeds, wills, or wherever it is important to prevent the alteration of sums or signatures, as well as for handing down to posterity public records, in a less perishable material than common ink.

### OBITUARY.

On the 11th of May, in the 80th year of his age, died in London, Thomas Andrew Knight, Esq., of Downton Castle, in Herefordshire, the President of the Horticultural Society of London. A correspondent in the *Athenæum* gives the following account of his life.

Mr Knight was born at Worsley Grange, near Hereford, on the 10th of October 1758. He was the youngest son of the Rev. Thomas Knight, a clergyman of the Church of England, whose father had amassed a large fortune as an iron-master, at the time when iron-works were first established at Colebrook Dale. When Mr Knight was three years old, he lost his father, and his education was in consequence so much neglected, that at the age of nine years he was unable to write, and scarcely able to read. He was then sent to school at Ludlow, whence he was removed to Chiswick, and afterwards entered at Balliol College, Oxford. It was in the idle days of his childhood, when he could derive no assistance from books, that his active mind was first directed to the contemplation of the phenomena of vegetable life; and he then acquired that fixed habit of thinking and judging for himself, which laid the foundation of his reputation as an original observer and experimentalist. He used to relate an anecdote of his childhood, which marks the strong original tendency of his mind to observation and reflection. Seeing the gardener one day planting beans in the ground, he asked him why he buried those bits of wood. Being told that they would grow into bean plants and bear other beans, he watched the event, and finding that it happened as the gardener had foretold, he determined to plant his pocket knife, in the expectation of its also growing and bearing other knives. When he saw that this did not take place, he set himself to consider the cause of the difference in the two cases, and thus was led to occupy his earliest thoughts with those attempts at tracing the vital phenomena of plants to their causes, upon which he eventually constructed so brilliant a reputation.

It was about the year 1795 that Mr Knight began to be publicly known as a vegetable physiologist. In that year he laid before the Royal Society his celebrated paper upon the inheritance of disease among fruit-trees, and the propagation of debility by grafting. This was succeeded by accounts of experimental researches into vegetable fecundation, the ascent and descent of sap in trees, the phenomena of germination, the influence of light upon leaves, and a great variety of similar subjects. In all these researches, the originality of the experiments was very remarkable, and the care with which the results were given was so great, that the most captious of subsequent writers have admitted the accuracy of the facts produced by Mr Knight, however much they may have differed from him in the conclusions which they draw from them.

The great object which Mr Knight set before himself, and which he pursued through his long life with undeviating steadiness of purpose, was utility. Mere curious speculations seem to have engaged his attention but little; it was only when facts had some great practical bearing that he applied seriously to investigate the phenomena connected with them. For this reason, to improve the races of domesticated plants, to establish important points of cultivation upon sound physiological reasoning, to increase the amount of food which may be procured from a given space of land, all of them subjects closely connected with the welfare of his country, are more especially the topic of the numerous papers communicated by him to various societies, especially the Horticultural, in the chair of which he succeeded his friend Sir Joseph Banks. Whoever calls to mind what gardens were only twenty years ago, and what they now are, must be sensible of the extraordinary improvement which has taken place in the art of horticulture during that period. This change is unquestionably traceable in a more evident manner to the practice and writings of Mr Knight, than to all other causes combined. Alterations first suggested by himself, or by the principles which he explained in a popular manner, small at first, increasing by degrees, have insensibly led, in the art of gardening, to the most extensive improvements, the real origin of which has already, as always happens in such cases, been forgotten, except by those who are familiar with the career of Mr Knight, and who know that it is to him that they are owing. Of domesticated fruits or culinary vegetables there is not a race that has not been ameliorated under his direction, or immediate and personal superintendence; and if henceforward the English yeoman can command the garden luxuries that were once confined to the great and wealthy, it is to Mr Knight, far more than to any other person, that the gratitude of the country is due.

The feelings thus evinced in the tendency of his scientific pursuits were extended to the offices of private life. Never was there a man possessed of greater kindness and benevolence, and whose loss has been more severely felt, not only by his immediate family, but by his numerous tenantry and dependants. And yet, notwithstanding the tenderness of his affections for those around him, when it pleased Heaven to visit him, some years since, with the heaviest calamity that could befall a father, in the sudden death of an only and much-loved son, Mr Knight's philosophy was fully equal to sustain him in his trial.

Mr Knight's political opinions were as free from prejudices as his scientific views; his whole heart was with the liberal party, of which he was all his life a strenuous supporter. It is no exaggeration to add, that great as is the loss sustained by his country and his friends, it will be equally difficult to fill his vacancy in science. No living man now before the world can be said to rank with him in that particular branch of science to which his life was devoted.

DIED, at his house in Ridley Place, Newcastle, on the 5th of May, aged 69, Nathaniel John Winch, Esq., greatly respected. Mr Winch was well known as an excellent botanist. He was author of an "Essay on the Geographical Distribution of Plants through the Counties of Northumberland, Cumberland, and Durham," which has passed through two editions; also of "Observations on the Geology of Northumberland and Durham, 4to, 1814;" and of a very elaborate "Flora of Northumberland and Durham," printed in the Transactions of the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne. He has bequeathed the whole of his very extensive Herbarium and his Library of Natural History to the Linnæan Society, of which he was a member, and has left a legacy of £200 to the Newcastle Infirmary, to which he acted as secretary for 21 years.

### MISCELLANEOUS.

MANGANESE MINE AT GRANDHOLM, NEAR ABERDEEN.—We are informed, says the Editor of the *Edinburgh New Philosophical Journal*, by Dr Fleming, that the ore occurs in a rock of mica-slate, which stretches in a northerly direction, and has an easterly dip, varying from 30° to 50° and upwards. In some places it is thin, slaty, even, or wavy, while at other parts thin beds of gneiss and granite make their appearance. When the mine was opened upwards of twenty years ago, an excavation, or opencast, was made across the stretch of the strata, at the eastern termination of which a mass of felspar porphyry makes its appearance, the relations of which are not seen at present. The ore, which is the Grey Manganese ore, or Hydrous Binoxide of Manganese, occurs in irregular thin beds, rounded concretions, or anastomosing films in the rock, accompanied by small quantities of sulphate of barytes. As the working has but recently commenced, little more than a dozen of tons of the ore have been obtained; but as the undertaking is in hands possessing abundance of capital and enterprise, Messrs Cookson, of Newcastle, the mine will have a fair trial, and it is hoped that a new branch of trade will thus be added to those already so successfully carried on at Aberdeen.

PHOSPHORESCENCE OF THE OCEAN.—The naturalists of *La Bonita*, in her late voyage round the globe, have made many observations respecting marine phosphorescence, which are thus reported to the French Academy of Sciences. Numerous observations made upon phosphorescent water, by means of reagents, of filtration, boiling, simple examination, and with the help of the microscope, have led us to the following conclusions:—The phosphorescent property of sea-water is not inherent in the nature of this liquid, but is essentially owing to the presence of organized beings. The animals which produce the phosphorescence belong to different classes. In the first rank we find the minute species of crustacea which swarm in the sea, but especially a very small species having two valves, which possess this remarkable property in the highest degree. All these species have been collected, and are carefully preserved in alcohol. Many mollusca, principally small Pelagic Cephalopoda, Biphora, &c., also many zoophytes, among which we remark Diphyes, Medusæ, &c., possess the phosphorescent property. Lastly, in certain localities we also find, on the surface of the ocean, very small yellowish bodies, which are, nevertheless, extremely phosphorescent. We encountered these small bodies in immense abundance, when landing at the Sandwich Isles, and in crossing from that archipelago to the Marianne Islands. We met with them in such vast quantities in the Straits of Malacca and on the coasts of Pulo Penang, that the whole surface over a great extent seemed as if covered by a thick yellowish dust. These small bodies have been examined with the microscope; but although they have been for a long time submitted to our notice, we have never been able to detect the slightest movements connected with them. At the same time, the experiments we have made on them, through the means of various reagents, lead us to the conclusion that they are organized and living bodies. They appeared somewhat different as taken at the Sandwich Islands, and in the Straits of Malacca. The former were globular and transparent, with a yellowish point in the centre, the latter were rather oval, with a depression in the centre, so that they were somewhat kidney-shaped; they also were entirely yellowish.

In all the animals which possess phosphorescence, the property has appeared to us to depend upon a particular principle, probably a secretion. Some of them, as the small phosphorescent crustacea, can distinctly emit it in streams, especially when irritated. Others did not appear to possess the power of emitting this matter, and in them it was developed only in certain circumstances, as when they struck a body, or were irritated. In others again, as in the Cephalopoda, and in some Pteropoda, the phenomenon showed itself in a nearly passive way: the phosphorescent matter in their nucleus, or other parts of their bodies, shone constantly and uniformly as long as the animal was in the enjoyment of life, and along with this disappeared their light. Lastly, in the yellowish corpuscles above described, the phosphorescent matter shines almost uniformly, but if brought into contact with any reagent, their lustre is first increased, and then insensibly vanishes away. The phosphorescent matter which we collected on the sides of the vessel was yellowish, slightly viscous, and very soluble in the water, which it rendered luminous at the moment it was projected by the animal.—*Comptes Rendus*, 5 Avril. ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE HOGS.

IN the order of Pachydermata, the Hogs constitute a family distinguished by having the feet cleft, with two hoofed toes, and two additional smaller ones behind, which do not reach the ground; as well as a moveable prolongation of the muzzle, supported upon a bone, and which enables them to dig into the soil in search of roots. This family is composed of the Hogs properly so called, the Ethiopian Hogs, and the Peccaris.

Fig. 1. THE CHINESE HOG (*Sas Scrofa*, var. *Sinensis*) is a small variety of the Common Hog, with the ears erect, the upper parts blackish, the lower white.

Fig. 2. THE CAPE HOG (*S. capensis*) is similar to the Chinese in form, and generally of a black colour.

Fig. 3. THE BABYRUSSA (*S. Indicus*) is distinguished by the elongation of the tusks of both jaws, which are curved backwards. Its ears are short, its feet comparatively long, its colour brownish-grey. It inhabits the Indian Islands.

Fig. 4. THE BABYRUSSA. Female. Of a brownish colour, with the tusks not projecting.

Fig. 5. ÆLIAN'S HOG (*Phacochoerus Æliani*). The Phacochoeri are distinguished from the Hogs by their grinders, which are composed of cylinders connected by cortical matter. Their tusks are of enormous size and spread outwards. This species, of which the head is furnished on each side with a large fleshy lobe, is peculiar to Africa.

Fig. 6. THE COLLARED PECCARI (*Dicotyles torquatus*). The Peccaris, which are peculiar to South America, resemble our Common Hog in form, but have no outer toe on the hind feet, and their tusks are not protruded. The present species has a band of white on the shoulder and lower part of the neck.

Fig. 7. THE WHITE LIPPED PECCARI (*D. labiatus*) is brownish-black, with the lower lip and the throat white.

DESCRIPTION OF THE PLATE.—THE JAYS.

THE JAYS constitute a genus of birds very nearly allied to the Crows, from which they differ chiefly in having the bill less strong, the tail more elongated, their colours more gaudy, and their habits approximating to those of the Titmice, to which also they are nearly allied. They reside chiefly in woods and thickets, occasionally betaking themselves to the open country in the neighbourhood, and feed on fruits, seeds, insects, worms, sometimes eggs and young of other birds, as well as small quadrupeds, and carrion. They are, in short, as omnivorous as the Crows. They are generally dispersed, and some of the species are spread over a vast extent of country. The species represented on the plate are American, with the exception of the first, the Common Jay, which belongs to Europe and Asia.

Fig. 1. THE EUROPEAN JAY (*Garrulus Glandorius*). This bird, which is remarkable for the beautiful blue barred patch on the wings, although its colours are not otherwise fine, is not uncommon in many parts of Britain and the Continent of Europe. Like several other species, it imitates the notes of birds and the cries of quadrupeds.

Fig. 2. THE FLORIDA JAY (*G. Floridanus*), although a native of Florida, as its name implies, occurs also in Louisiana, Kentucky, and other parts of the United States.

Fig. 3. THE BLUE JAY (*G. cristatus*) is the most extensively distributed and best known of the North American Jays. It is with the description of this species that our countryman Wilson commences his celebrated "American Ornithology;" and its manners have with equal felicity been described by his successor, our esteemed friend, the enthusiastic Audubon.

Fig. 4. STELLER'S JAY (*G. Stelleri*) is peculiar to the north-western coast of America, and was first described by Lathan from a specimen obtained, on Cook's Expedition, at Nootka Sound.

Fig. 5. THE CANADIAN JAY (*G. canadensis*) inhabits the northern parts of the United States, and the British settlements in North America.

BRITISH BIRDS.—THE KINGFISHER.

THE Kingfisher, although one of the least elegantly formed of our native birds, is among the most distinguished for the beauty of its plumage, which is such as at once to recall to mind the splendour of the feathered denizens of the tropics. Its large body, short and thick neck, disproportionately long bill, diminutive feet, and abbreviated tail, give it a peculiar appearance, so that the least observant cannot mistake it for any other bird. The bill is considerably longer than the head, straight, rather slender, higher than broad in its whole length, four-sided, its outlines almost straight, and its tip pointed. The very short tarsi are roundish, and destitute of defined scales; the first toe shorter than the second, the third slightly longer than the fourth; the claws arched, slender, compressed, and acute. The plumage is soft and blended; the feathers generally long, especially on the hind neck and rump; of an oblong form, without plumules. The wings are rather short, but very broad, the secondary quills being of great length; the tail very short, a little rounded, of twelve rather narrow, rounded feathers. The upper mandible is dark-brown, as are the margins and tip of the lower, the remaining part being pale orange. The tarsi and toes are orange-red, the claws dark-brown. The upper part of the head is dull green, each feather with a transverse bar of light greenish-blue near the end; the hind neck, sides of the back, scapulars, and wing-coverts, are of a similar dull green, tinged with purple in a different light, the latter feathers tipped with light blue. The middle of the back, the rump, and tail-coverts, are of a beautiful glossy light blue, the tail of a duller purplish-blue. The quills are brown, with the outer webs dull green. A band of yellowish-red from the nostril to the eye; the loreal space dusky; behind the eye a similar yellowish-red band; below which, and extending from the lower mandible, is a band of greenish-blue, terminating behind in a yellowish-white patch. The throat is of the latter colour, and the rest of the lower parts yellowish-red, of a richer tint anteriorly. The length is  $7\frac{1}{4}$  inches. The female is somewhat smaller, but similar in the colour, the tints being only a little less bright.

Let us now imagine ourselves on the banks of the Esk, the woods resuming their green mantle, and the little birds chanting their summer songs. From afar comes the murmur of the waterfall, swelling and dying away at intervals, as the air becomes still, or the warm breezes sweep along the birchen thickets, and ruffle the bosom of the pebble-paved pool, margined with alders and willows. On the flowery bank of the stream, beside his bole, the Water-Rat nibbles the tender blades; and on that round white stone in the rapid is perched the Dipper, ever welcome to the sight, with his dusky mantle and snowy breast. Slowly along the pale blue sky sail the white fleecy clouds; as the lark, springing from the field, flutters in ecstasy over his happy mate, crouched upon her eggs under the shade of the long grass, assured that no rambling urchin shall invade her sanctuary. But see, perched on the stump of a decayed willow jutting out from the bank, stands a Kingfisher, still and silent, and ever watchful. Let us creep a little nearer, that we may observe him to more advantage. Be cautious, for he is shy, and seeks not the admiration which his beauty naturally excites. There he is grasping the splint with his tiny red feet, his bright blue back glistening in the sunshine, his ruddy breast reflected from the pool beneath, his long dagger-like bill pointed downwards, and his eye intent on the minnows that swarm among the roots of the old tree that project into the water from the crumbling bank. He stoops, opens his wings a little, shoots downwards, plunges headlong into the water, reappears in a moment, flutters, sweeps off in a curved line, wheels round, and returns to his post. The minnow in his bill he beats against the decayed stump until it is dead, then tossing up his head swallows it, and resumes his ordinary posture, as if nothing had happened. Swarms of insects flutter and gambol around, but he heeds them not. A painted butterfly at length comes up, fluttering in its desultory flight, and as it hovers over the hyacinths, unsuspecting of danger, the Kingfisher springs from his perch, and seizing it returns to his post. There, swift as the barbed arrow, darting straight forward, on rapidly moving pinions, gleams his mate, who alights on a stone far up the stream, for she has seen us, and is not desirous of our company. He presently follows, and our watch being ended, we may saunter a while along the grassy slopes, inhaling the fragrance of the primrose, and listening to the joyous notes of the Blackbird, that from the summit of yon tall tree pours forth his soul in music.

It is chiefly by the still pools of rivers and brooks that the Kingfisher is met with. Although not plentiful in any part of this country, nor any where gregarious, it is generally dispersed in England, and occurs in the southern and part of the middle division of Scotland, but has not, I believe, been met with beyond Inverness, for the Kingfishers, so called, of the North, are merely Dippers. It remains with us all the year, shifting its station on the streams, and in summer selecting some place having a steep bank, in a hole in which it deposits its eggs. Mr Henry Turner states, in London's Magazine of Natural History, Vol. IV. p. 450, that at Bury St Edmund's in Suffolk, "some boys watched an old one into a hole in the bank of the river Lark, and attempted to capture it on its exit; but without success in this case. They then with a crooked stick pulled out a portion of the nest, consisting of a few feathers, old dried roots, and hay. I subsequently examined the hole," he continues; "it was in a low meadow 300 yards east of Northgate Street, and on the bank of a small stream. The entrance to the hole was about three feet from the water, and one foot beneath the level of the meadow. Hole nine inches in diameter, and about five feet in length, straight, and somewhat larger at the end than at the entrance." Various other individuals have alleged that the nest is formed of dry grass, roots, and feathers; but Montagu gives a different account of it.

"The hole chosen to build in is always ascending, and generally two or three feet in the bank; at the end is scooped a hollow, at the bottom of which is a quantity of small fish-bones, nearly half an inch thick, mixed in with the earth. This is undoubtedly the castings of the parent birds, and not of the young, for we have found it even before they have eggs, and have every reason to believe both male and female go to that spot for no other purpose than to yield this matter for some time before the female begins to lay, and then they dry it by the heat of their bodies, as they are frequently known to continue in the hole for hours long before they have eggs. On this disgorged matter the female lays to the number of seven eggs, which are perfectly white and transparent, of a short oval form, weighing about one dram. The hole in which they breed is by no means fouled by the castings; but before the young are able to fly it becomes extremely fetid by the fæces of the brood, which is of a very watery nature, and cannot be carried away by the parent birds, as is common with most of the smaller species. In defect of which, instinct has taught them to have the entrance to their habitation ascending, by which means the filthy matter runs off, and may frequently be seen on the outside. We never could observe the old birds with any thing in their bills when they went in to feed their young; from which it may be concluded they eject from their stomach for that purpose."

This account of the nest, however, is very improbable; and accordingly Mr Rennie, in his edition of Montagu's Dictionary, doubts its accuracy. "In the bank of a stream at Lee in Kent, we have been acquainted with one of those nests in the same hole for several successive summers, but so far from the exuviae of fish-bones ejected, as is done by all birds of prey, being dried on purpose to form the nest, they are scattered about the floor of the hole in all directions, from its entrance to its termination, without the least order or working up with the earth, and all moist or fetid. That the eggs may by accident be laid upon portions of these fish-bones is highly probable, as the floor is so thickly strewn with them, that no vacant spot might be found, but they assuredly are not by design built up into a nest. The hole is from two to four feet long, sloping upwards, narrow at the entrance, but widening in the interior, in order, perhaps, to give the birds room to turn, and for the same apparent reason the eggs are not placed at the extremity. I am not a little sceptical as to its sometimes selecting the old hole of a Water-Rat, which is the deadly enemy to its eggs and young; but it seems to indicate a dislike to the labour of digging. It frequents the same hole for a series of years, and will not abandon it, though the nest be repeatedly plundered of the eggs or young."

The question as to its nestling in a Water-Rat's hole can be decided only by observation. Its bill is certainly adapted for digging into earth or sand, but its feet, one might suppose, would prove very inadequate instruments for scraping out the debris along a tunnel of three or four feet. On the other hand, its hole is often at a greater height from the water than we ever find that of the Water-Rat; in one case it has been seen twelve feet above it; and all accounts agree in describing it as straight and sloping upwards, whereas the holes of Water-Rats are usually tortuous. It is possible enough that sometimes the Kingfisher may take possession of a Water-Rat's hole, or even that of a Common Rat or Mole, and enlarge it, as the Starling has been known to do, and that it may also dig a hole for itself, like the Bank Swallow. At all events, we have certain evidence that the American Kingfisher, *Aleedo Aleyon*, digs its hole. Mr Audubon states that "the male and female, after having fixed upon a proper spot, are seen clinging to the bank of the stream in the manner of Woodpeckers. Their long and stout bills are set to work, and as soon as the hole has acquired a certain depth, one of the birds enters it, and scratches out the sand, earth, or clay, with its feet, striking meanwhile with its bill to extend the depth. The other bird all the while appears to cheer the labourer, and urge it to continue its exertions; and, when the latter is fatigued, takes its place. Thus, by the co-operation of both, the hole is dug to the depth of four, five, or sometimes six feet, in a horizontal direction, at times not more than eighteen inches below the surface of the ground, at others eight or ten feet."

In the second volume of the Naturalist, p. 274, Mr Allington gives the following account of it:—"A friend of mine, while fishing on a small trout stream, near Louth, called the Crake, in the early part of June, observed a Kingfisher with a fish in its mouth, flying several times near his hat with a whirling noise. He watched it until it entered a hole in the bank, the entrance to which was strewn with fish-bones. On digging into the hole (which commenced low down in the bank, and ran upwards in a slanting direction for about two feet), he found the nest, containing seven young birds just hatched. The bottom of the nest was excessively thick, and mixed up with small bones of the Stickle-back. Its structure, excepting the mixture of fish-bones, was not very unlike that of a Thrush. It crumbled to pieces on being touched, and I could procure no portion worth preserving. Near the nest was another hole, which had all the appearance of having been the Kingfisher's last residence, the bones at the entrance being dry and crumbling; but in this the parent bird again commenced laying, and on opening the nest six eggs were found on the fragments

of the structure. They were white, and beautifully transparent, showing the yolk through, which gave them a pinkish hue at the larger end. I have now in my collection one of the eggs, which, though so transparent, I was surprised to find thicker and stronger than the generality of eggs, and rounder in its form, the circumference being two inches and a half, the length eight-tenths of an inch."

The flight of the Kingfisher is direct and rapid, performed by quick beats of the wings, and very similar to that of the Dipper, which it, however, excels in speed. The movements of the wings are indeed so rapid that one can scarcely perceive them, and the flight of this bird, the Dipper, Auks, Gullmots, and other short-winged birds, might induce the closet-naturalists to revise their opinions as to flight, founded merely upon the length and breadth of wings; for a long wing is not always so well adapted for speed as a short one, and a Guillemot can easily outstrip a Gull. Its feet are not adapted for walking or hopping, and therefore it takes its stand on a stone, a stump, a rail, or a branch overhanging the water, waits with patience, and when a minnow or a stickle-bat comes near the surface, darts upon it and secures it. In like manner it sallies forth in pursuit of the larger insects. Although very shy, inasmuch that one can very seldom get within shot of it when perched, it does not shun the vicinity of human habitations, but, on the contrary, often breeds at no great distance from them. It does not associate with any other birds, and it is seldom that even two of its own species are seen together. Being highly prized by collectors and others, it is much harassed, and although nowhere plentiful, may be obtained in almost any district to the south of the Forth and Clyde. In some places they leave the larger streams in autumn, and betake themselves to the brooks, so that a person not aware of their habits in this respect might suppose them to be migratory. Even in the more northern parts, however, they remain all the year, and many individuals have been shot near Edinburgh in December and January.

#### ON THE MOVEMENTS OF THE MOTACILLA IN SOUTH DEVON.

BY J. C. BELLAMY, ESQ. YEALMPTON.

THE Grey Wagtail, *Motacilla Boarula*, visits us without deviation yearly in the month of September, and remains until the end of March or the first of April, frequenting rivers, brooks, spring-heads, and the sea-coast. Some circumstance determines a slight irregularity of a few days, both in their arrival and departure,—most probably it is their food; but in respect of number there is apparently little difference. They seem to come in a body, and attract immediate attention by their tameness, and the briskness of their motions. Their retreat, however, is accomplished in a straggling manner: suddenly we lose the bulk of the party, and hear only the twit of a solitary bird or so, on the bank of a river, or at a spring-head; in a few days these are gone, and we see no more of them for a season. But though I am not able to bear testimony to the fact, this species has been known to remain all summer and breed. In 1831 I saw one frequenting a pond near Tavistock on the second of September. This may have been an unusually early arrival, or one of a pair that had stayed through the season. Their chief resorts are rivers and streams, but some repair to the sea-coast, and fare with the Pied Wagtail. In hard weather they seem all to frequent the roads, and seek support from the droppings of cattle, frost seeming to cause a general retirement of the insects on which they feed, or sealing down the soil and stones beneath which they harbour. I believe that if any precise dates for their arrival and departure could be ventured on, they would be September 15th and April 8th; yet in 1835 I saw a flock arrive at a small village on the sea-coast on August 13th. In their retreat also, in the spring preceding, I observed an unusual tardiness, and they disappeared gradually. No phenomena that we know of can enlighten us respecting these irregularities, any more than concerning the cause of their migrations: we see that the Pied Wagtail haunts the same situations, feeds similarly, and is content to remain with us the year through; but some impulse carries the Grey hundreds of miles northward to rear its young. It is now clearly made out that in the spring our flocks retire to the northern counties, it being there a stationary bird also; but, independently of Selby's authority for this, a paper which I possess, written by a naturalist living at Kendal, tallies so well in its account of the transits of this bird there with its movements in this county, as to have led me to suspect the nature of their retreat before I read Selby's statement. This gentleman, Mr Gough, thus writes:—"The Grey Wagtail is a partial migrator; a few remain about the town through the winter, and these are joined by great numbers from the south in March, when they all retire to the rugged banks of the river Muilt to spend the season of incubation." A remarkable feature in the habits and economy of birds is their adaptation of appetite to a variety of food, both as regards one season or time, and as regards various seasons, in which we frequently notice a change in their food. But few of the class confine themselves to one particular species of food, whereas a very large proportion partake of a variety, but still not similar in character. Thus, the Grey Wagtail searches out various insects, and is content to feed on such as are found on the shore, which necessarily must differ widely from those inhabiting the sides of rivers, or the streamlets. Very many birds, again, have appetites still more accommodating, and will devour food quite incongruous. This portion of the economy of the Grey Wagtail permits the extension of the species much more than would otherwise be effected, and we see also that it even protects the species to a great extent from death, for if it could not on emergency betake itself to the food afforded by the roads, when frost deprives it of more genial supplies, it must necessarily be the victim of want. We conclude also, that it is this principle of accommodation in the appetites and digestive powers of birds, and other creatures, which fits and enables them to live in the midst of alterations in their ordinary provender, effected by the operations of man, and which permits us to avail ourselves of their services in a domesticated or reclaimed state, without much trouble or inconvenience, their appetites shortly becoming adapted to an unaccustomed diet. And so, in their habits and actions, we must not fail to note a principle of accommodation of the same description. A little reflection must bring to our minds a thousand alterations in the face of Nature, wherever man has fixed his abode, or extended his domains; and as, on the one hand, we might *a priori* imagine the actions and habits of animals to be as undeviating and determinate

on all points, as are the fundamental laws of their organizations and constitutions, so, on the other, we find a corresponding alteration and conformity of action in them, to suit our intrusions on their territories, our planting, our tillage, our building, and all our various operations on and perversions of Nature. In civilized and cultivated territories scarce an animal moves but it encounters alterations of our making; and, though the lower tribes can experience but slight impediments, and can have to adapt themselves thereto only in a very minor degree, yet the higher tribes must certainly employ some portion of thought at times to overcome these hinderances; and, as before said, if instinct were so confined and constrained a power, as usually conceived, these alterations in Nature would infallibly disarrange all their proceedings. Judging by the analogy of a vast number of instances of departure from accustomed actions, and by the anomalies of individual cases, as contrasted with the proceedings of species taken in the aggregate, we conclude that the instances of the Grey Wagtail's breeding in Devon are determined purely by choice, and are not dependent on any human causes or interferences, and that these are also cases showing that instinct is not so very constrained a faculty, but involves a certain portion of thought and volition. If the instincts implanted in the Grey Wagtail were of a definite, precise, constrained, and unalterable nature, they would necessarily pervade every member of the species; and so far from any pair of birds choosing to stay the summer with us, while all their fellows were preparing to migrate, no inducements of food ever so great, nor even any accidents or ailments impairing their bodily power, would prevent their essaying a flight ever so short and feeble; in fact, they would be compelled to exert themselves to the very utmost, and to sacrifice every feeling to this one object.

The Yellow Wagtail, *Motacilla flava* of Ray and other English writers, offers an illustration of the same diversity of operations among individuals of one species. This summer Wagtail arrives here about the very time the Grey Wagtail leaves us, and it also quits us about the period the winter species comes. Still stragglers are seen on to November, according to some remarks I made in 1831, frequenting both the coast and inland stations; and in October 1833, and other years, they have been noticed haunting the beaches near Plymouth, so that, without contending for their stay through the whole winter, I have reason to infer that, like the Grey sort, they are occasionally induced to act differently from the aggregate of their kind. Facts of the same nature as those I have above recorded, relative to these two birds, are also named by Mr Markwich in Linnæan Transactions, I. 126. The Yellow Wagtails congregate in August and September, and abide for several days on the beaches and shores, feeding among the sea-weed. They likewise affect open fields. The number collected at these times is disproportioned to our summer stock, so that probably this species approaches the southern parts of the kingdom previously to departure.

The Pied Wagtail, *Motacilla alba* of most English writers, appears to be a bird of more enduring constitution than the other kinds, because it suffers the alterations of our seasons without removing to other situations. It is resident with us all the year. Its actions, however, clearly indicate the possession of powers of accommodating itself to circumstances of necessity; not that the species acts in concert, or that the movements and operations of the individuals are simultaneous and uniformly similar; on the contrary, each bird seems intent on its own peculiar interests, and its having been ordained that the appetite of this species of bird should not be restricted or very limited in capacity, some individuals are found to diet on the sea-shore, whereby greater space is allowed to other individuals to procure food. In summer, however, when the supply of food is so ample for the generality of creatures, the number of Wagtails haunting the beaches is very small, whereas, toward winter, they augment greatly. Although I have said that the individuals appear to have separate and exclusive interests, yet it seems that some portion of the kind congregate and depart, we know not whither, some thinking they remove to other countries, and some contending that they merely take up fresh quarters in this same kingdom. However, this removal in August must act beneficially towards the remainder, both of that species and also towards the Grey sort. During summer they may be found distributed by the sides of rivers and ponds, on roads and in gardens, besides being also on the shores and inlets, as before said. In June I have seen them both in that situation, and in my own garden, and before the house on the road, searching for insects. About September, they are more particularly noticed arriving in the vicinity of houses and stable-yards. From that time, on through the winter, they obtrude themselves greatly in gardens, where they pick up the insects disturbed by the spade of the gardener, which had secreted themselves, and been wrapt in their winter's sleep, or in temporary torpor.

**BRITISH SHREWS.**—The Reverend Leonard Jenyns, in a paper published in the last number of the Annals of Natural History, presents the following synopsis of British Shrews:—

**Sorex, Linn.**—Two middle incisors much produced; the upper ones curved, with a spur behind more or less prolonged; the lower ones almost horizontal; lateral incisors or false grinders small, from 3 to 5 above, 2 below, on each side; true grinders 4 above, 3 below, on each side; fur short and soft; snout attenuated; tail long.

**Sect. I.**—*Amphisorax*, Duvernoy.—Middle incisors in the lower jaw with the edge denticulated; the upper ones forked, the spur behind being prolonged to a level with the point in front; the lateral incisors which follow in the upper jaw five in number, and diminishing gradually in size from the first to the last; all the teeth more or less coloured at their tips.

1. *S. rusticus*, Jen., *Common Shrew*.—Snout and feet slender; tail moderately stout, nearly cylindrical, not attenuated at the tip, well clothed with hairs, which are very divergent in the young state, and never closely appressed. Appears principally to frequent dry situations, gardens, hedgebanks, &c.

2. *S. tetragonurus*, Herm., *Square-tailed Shrew*.—Snout broader than in the last species; feet, fore especially, much larger; tail slender, more quadrangular at all ages, and slightly attenuated at the tip; clothed with closely appressed hairs in the young state, in age nearly naked. More attached to marshy districts than the last species, though not confined to them.

**Sect. II.** *Hydrosorex*, Duv.—Middle incisors in the lower jaw with an entire edge; the upper ones notched, or with the spur appearing as a point behind; the lateral

incisors which follow in the upper jaw four in number; the first two equal, the third somewhat smaller, the fourth rudimentary; the tips of all the teeth a little coloured.

3. *S. fodiens*, Gmel., *Water Shrew*.—Deep brownish-black above; nearly white beneath; the two colours distinctly separated on the sides; feet and tail ciliated with white hairs. Marshes and banks of ditches; but it is occasionally met with at a distance from water.

4. *S. ciliatus*, Sowerby, *Ciliated Shrew*.—Black above; greyish-black beneath; throat yellowish-ash; feet and tail strongly ciliated with greyish hairs. Found in the same situations as the preceding.

**HORNS OF THE ARNEE.**—A skull with the horns of an old bull of this species, which inhabits the plains and jungles of the upper parts of India, has lately been presented to the Edinburgh College of Surgeons by Dr James Smith. The length of the skull is 2 feet, and the forehead, which is slightly convex, measures  $10\frac{1}{2}$  inches across, opposite to the middle of the horns. In young animals, the horns rise obliquely, but in very old ones, as in this individual, they spread out nearly horizontally, curve upwards and backwards, and have the points slightly incurvate. They are compressed and somewhat triangular, flattened in front, with numerous transverse broad rugæ, excepting towards the point, which is more rounded. The length of each horn, measured on the outer edge, is 4 feet 2 inches, its breadth at the base 7 inches, its circumference there 18 inches, and the space between the tips of the horns is 5 feet.

**THE GOATSUCKER.**—Of the birds which abound in the Maremma of Patria, says Colonel Maceroni, in his Memoirs, in which I frequently used to pass weeks together, many varieties of the Bittern and of the Goatsucker abound. Of the Bitterns, one very small variety is remarkable for its Mephistopheles-like appearance, and accounts for the frequent appearance of its representation upon Egyptian obelisks and monuments; its body is not so large as a Pigeon, but the beak is a foot long, and the usual attitude of the bird mounted on its equally long legs, is with the sharp sword-like beak pointed vertically upwards. Of Caprimulgi, I have shot a very great variety; the most remarkable of which is one that has the exact representation of a white moth depicted on each side of the expanded tail of the bird, so that when flying about in the night, the moths, which constitute its principal food, seeing the moths upon the tail, come fluttering round their devourer, instead of avoiding him. I forget whether it is in this same specimen of the Goatsucker or in another, that I have remarked a very curious arrangement for the purpose of enabling the bird to see into its own mouth when extended wide open; and their mouths are enormous, so that they cannot easily miss their flying prey. Upon opening the mouth of this kind of Goatsucker, which they can do so as to place each half of their beaks at a straight line with the other, a large portion of the skin beneath the eyes becomes stretched and quite free of feathers; is as transparent as glass, so as to allow the eyes to see directly through it into the mouth, or farther on in that direction. The operations of the Caprimulgi being carried on during the darkness of the night, have not been so much noticed by naturalists as they deserve.—This extract affords a good example of the ridiculous fancies which authors indulge in when they choose to imagine themselves physiologists.

**MALAY ALBINO.**—On landing at Gressik I was struck by the singular appearance of a Malay lad, an albino, standing under the shade of a tree on the river-bank. His skin was of a reddish-white, with blotches here and there, and thinly covered with short white hairs. The ears were small and contracted; the iris of a very light vascular blue; the lids red, and fringed with short white lashes; the eyebrows scanty, and of the same colour; the pupil much contracted from the light. On calling him to come near he appeared to be ashamed. He evinced an extreme sensibility to the stimulus of light, from which he almost constantly kept his eyes guarded by shading them with his hands. He told me he could see better than his neighbours in imperfect darkness, and best by moonlight, like the "moon-eyed" albinos of the Isthmus of Darien. He is morbidly sensitive to heat; for this reason, and on account of the superstitious respect with which the Malays regard him, he is seldom employed by his friends in out-door labour, although by no means deficient in physical strength. The credulous Malays imagine that the Genii have some furtive share in the production of such curiosities, though this they tell as a great secret. To this day the tomb of his grandfather, who was also an albino, is held sacred by the natives, and vows are made at it. Both his parents were of the usual colour. His sister is an albino like himself. Albinos I believe are not common on the Peninsula, nor are there any tribes of them, as according to Voltaire, existing in the midst of Africa. In the only two instances I recollect observing, the eyes were of a very light blue; the cuticle

roughish, and of a rosy blush, very different from that of the two African albinos seen and described by Voltaire, and quoted by Lawrence.—*Journal of Asiatic Society of Bengal.*

### METEOROLOGY.

OBSERVATIONS ON THE EFFECTS OF A REMARKABLE STORM OR TORNADO. BY WALTER R. JOHNSON, A.M. Abridged from Vol. VII. of the Journal of the Academy of Natural Sciences of Philadelphia.

CONSIDERED as a meteorological phenomenon, the calamity which, on the 19th of June 1835, desolated a part of the city of New Brunswick in New Jersey, is worthy of the most attentive investigation. All accounts concur in representing the air of the morning, and, indeed, of the whole day up to the time of the tornado, as unusually sultry. At four o'clock the sun was still unobscured at Princeton; but within half an hour, a cloud from the north-west had reached that place, and a shower of rain, accompanied by a brisk wind from the south-west, had commenced. Before five o'clock the rain had ceased, and the air was less oppressive. The evening continued tranquil until ten o'clock, when another shower of rain fell, accompanied by some wind; but within half an hour the sky was once more cloudless, and the wind began to rise with much force from the west or north-west. Between eleven and twelve a sensible depression of the dew-point was noticed, as indicated by the action of the air on the lungs, as well as on the surface of the body. From twelve at night to five the next morning the wind was boisterous; and a great change in the state of the atmosphere had obviously taken place. An electrical machine, which it had on the day previous been found impossible to excite, was, at nine or ten o'clock, A.M., able to yield sparks an inch and a half or two inches long, between balls three-fourths of an inch in diameter, a sure indication of an increased distance between the dew-point and the temperature.

Intelligence of the occurrence at New Brunswick having been received during the forenoon, it was resolved to visit the spot, and endeavour to ascertain such facts as might explain the mode of action of the tornado. On arriving within six miles of the city, we were informed that it had been seen about a mile and a half to the north-east, and that the dense black cloud was, by the junior observers, conceived to be filled with crows; an appearance afterwards explained by the fact that shingles, boards, &c., had been carried upward by the tempest from buildings destroyed in that vicinity. On reaching the height about half a mile from the dense portion of the city, the first buildings which had been damaged were passed. A barn had been completely demolished, and most of the lighter materials scattered to a great distance. The house was not thrown down, but left leaning with no part of the roof remaining, except some of the rafters; and the fact here witnessed was repeatedly observed in the town below, where several houses within the path of the tornado were deprived of their shingles, and the ribs which had held them to the rafters, but the latter still continuing partially or entirely undisturbed. In a few cases, in which the ridge of a building lay in a northerly and southerly position, the eastern slope of roof was observed to be removed, or at least stripped of its shingles, while the western slope remained entire. Many buildings were likewise observed with holes in their roofs, whether shingled or tiled, but otherwise not much damaged, unless by the demolition of windows. These appearances clearly demonstrated the upward tendency of the forces by which they were produced, while the half unroofed houses, already mentioned, prove that the result out of all the forces in action at the moment was not in a perpendicular to the horizon, but inclined to the east. Such a force would apply to the western slope of the roof some counteracting tendency, or relieve it from some portion of the upward pressure. Had there been no other facts to shew the powerful rushing of currents upward, the above would, it is conceived, have been sufficient to settle the question, but taken in connection with the circumstance that roofs so removed were carried to a great height, and their fragments distributed over a large extent along the subsequent path of the storm—that beds and other furniture were taken out of the upper stories of unroofed houses—that persons were lifted from their feet, or dashed against walls; and that, in one instance, a lad, of eight or nine years old, was carried, upward and onward with the wind, a distance of several hundred yards; and, particularly, that he afterwards descended in safety, being prevented from a violent fall by the upward forces, within the range of which he still continued. In connection with these and similar facts, it seems impossible to doubt that the greatest violence of action was in an upward and easterly direction.

The next point to which attention was called by the appearances around, was the manner in which this upward current had been supplied from below; and for the solution of this question, it was necessary to compare objects throughout the whole breadth of the track left by the storm. A peach orchard on the slope of the hill descending to the town, gave the first indication in regard to this matter, but the larger fruit and ornamental trees, in some gardens in the neighbourhood, together with an inspection of the forest on the east side of the river, shewed conclusively that on the extreme borders of the track, the forces were nearly or quite at right angles to its general direction. Uprooted trees along the southern border lay with their tops towards the north, those on the northern border to the south; thus pointing to a common object in the central line of the current. From the outer edges, however, towards this central line, the trees were observed on both sides to have a gradually increasing inclination towards the east, and in the middle to be entirely in that, as a general direction. None were seen with the tops from the centre of the path. A frame-building, which was on the southerly part of the track, was unroofed, and the remaining part of the structure, with its contents, removed hoidly three or four feet to the northward. All the herbage, shrubs, and trees, in its immediate vicinity, and the trees in a garden, were found lying with their heads in a northerly or north-easterly direction. A stone near the river, and on the northern border of the path of the tornado, was lifted from its foundation about four or five feet towards the south. A row of poplars, which had been prostrated in the lower part of the city, and on the northern part of the path, fell southward. Another evidence of lateral inward currents was

found in the appearance of many forest trees, east of the river, which, though too far removed from the central line of the path to be uprooted, were still so much within the range of the lateral forces as to have their outside limbs, or those most remote from the central line, broken off by the effect of cross strain; while no similar fracture was seen on limbs turned towards the centre of the path. This result will be easily understood when we consider the well known difference between breaking a limb by cross strain, and that of drawing it asunder by simple longitudinal tension.

Another fact, indicative of the direction of currents from the sides inward, was noticed on the plain east from the Baritan, where the shingle and fragments of boards lay with their longitudinal direction generally towards the point to which the storm was moving. Many of them were found far beyond the belt of ground on which the violence of the wind had been exerted. Their position may be explained by referring to the three forces in action at the moment they reached the ground:—First, the force of gravity, which, if the air had been motionless, and the bodies descending perpendicularly, would probably, from the unequal density of the parts of the several masses, have caused most of them to descend endwise; and then the position, subsequently taken by them respectively, would have been a matter of indifference, and we might have expected to find them lying promiscuously. But, second, they were, while in the air, moving onwards with the storm in an easterly direction, and when the lower end struck the ground, the composition of this force with gravity would naturally have thrown the centre of gravity over to the east, and we should have expected to find the lighter end of every piece of timber in that direction. But, third, if a current of wind were encountered near the ground, running towards the centre of the path, we should, on the north side of the path, expect to find the lighter ends of each piece directed to the south-east, and on the south side to the north-east; precisely what appeared to be the case, so far as could be judged from the general appearance of the masses.

The next set of facts observed had reference to the course of the materials projected upwards after they had arrived at a considerable elevation. All accounts agree that the appearance of the cloud was that of a funnel or inverted cone, with the apex resting on the ground. The falling rafters, scantlings, and other parts of the ruined buildings, generally indicated that they were, subsequently to the upward action, carried outward by the gradual enlargement of the current into which they had been drawn. The shingles and boards, just described, were cases in point, being found far beyond the trail of the tornado as marked upon the surface. Bafters, which penetrated buildings south of the track, entered them on the north side, and in a direction inclining to the south-east. Their descent in some instances was with great violence, contrary to what happened in the ravage of the upward motions; where a lad, already referred to, was deposited in safety after an aerial journey of one-fourth of a mile. A window-frame and brick wall were, in one instance, penetrated by a rafter twenty feet in length, eight inches wide, and from four to six inches thick. In the passage of the storm from the city to the opposite bank of the Raritan, no indications were, of course, left to mark its action upon the waters; but it was stated that it had laid the bed of the channel bare, and it is probable that had it traversed a great extent of water, it would have assumed the character, as it certainly had the form, of a water-spout. The upper edge of the opposite bank was marked by two well-defined stripes, each from ten to twenty feet wide, and one hundred or more feet asunder. Here, it was supposed, must have been the outer edge of the aerial trunk, or funnel, through which the air rushed upwards, and as the tornado, in its onward movement, advanced against the bank, the air coming in on every side to fill up the partial vacuum would exert the greatest force at the moment when it changed its horizontal for a vertical motion. The surface of the ground beyond this point seemed, in some places, to have been raised, as if the air beneath, by its sudden rarefaction, had thrown up small portions of the soil, which was rather dry and porous; and it is perhaps worth consideration, whether this cause may not, in this and similar occurrences, have facilitated the overturning of trees themselves.

In conclusion, it may be remarked, that the directions and intensities of the forces in this occurrence, together with the hygrometric states of the air, preceding and following the meteor, and the inverted conical form of the moving column, as confirmed by several witnesses, not less than the fall of hail, and the distribution of fragments of materials beyond the path of the ground current, seem most satisfactorily accounted for, on the supposition that a disturbance of atmospheric equilibrium results from a deposition of moisture in the higher regions of the atmosphere giving out a great amount of latent heat, which, in turn, expands the cold dry air above the forming cloud, and creates an ascending movement; the expansion of pure air by an addition of heat, being in such cases much greater than the contraction of this atmospheric mixture by a condensation of its moisture. In this effect is, of course, involved the well-known principle, that the capacity of air for heat is augmented as its volume expands, but the increase of capacity for heat being less rapid than the supply of heat from aqueous depositions, an ascending current is maintained with a force due to the difference of these two causes. The origin of this view of the subject, with which the writer had been made acquainted previously to the examination above detailed, is due to Mr J. P. Espy.

FALL OF METEORIC STONES IN BRAZIL.—On the 11th December 1836, about half-past eleven o'clock, P.M., the sky clear, and the wind south-west, a fire-ball, of uncommon size and brilliancy, appeared over the village of Macoa, at the entrance of the river Assu. It immediately burst with a loud crackling noise, and a shower of stones fell within a circle of ten leagues. They fell through several houses, and buried themselves some feet deep in the sand, but they did not occasion any further damage than killing and maiming a few oxen. The weight of those picked up varied from one to eighty pounds.—*Poggendorf's Annalen.*

ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE CATS.

THE characters of the extensive family of predaceous quadrupeds usually designated by the name of Cats have already been given.

Fig. 1. THE BLACK LEOPARD (*Felis Leopardus, var.*) is a melanitic variety similar to that of the Jaguar.

Fig. 2. THE MANED HUNTING LEOPARD (*F. jubata*), which is of a light yellowish-red colour, covered with small roundish black spots not confluent, is a native of various parts of Asia, and has been tamed so far as to be sometimes used in hunting.

Fig. 3. THE RED-EARED LYNX (*F. caligata*), of a light-red colour, and with the tail of moderate length and banded with dark-grey, belongs to the section in which the ears are pointed and terminated by a tuft of hairs.

Fig. 4. THE SERVAL (*F. Serval*) is very similar in form to the last, but wants the tufts on the ears, and is spotted with black. It inhabits Southern Africa.

Fig. 5. THE NEPAUL CAT (*F. torquata*) bears a great resemblance in colour and markings to the Wild Cat of Europe.

Fig. 6. THE COLLARED CAT (*F. armillata*), of the same general form as the Serval, is marked with longitudinal elongated bands of light red, unadorned with black.

DESCRIPTION OF THE PLATE.—THE SHRIKES.

THE SHRIKES, which are small birds, generally of rapacious habits, with the bill strong, and having a prominent tooth or projection on each side of the upper mandible, near the decurved tip, are generally distributed over the globe; but certain groups are in a great measure confined to particular regions, and differences of form, combined with geographical distribution, indicate the propriety of a more extended division of this family than that adopted by the older systematic writers. The species of which the bill is strong, with the point curved, constitute the genus *Lanius* of Cuvier, while those whose bill approaches to that of the Thrushes are referred by Vieillot to the genus *Laniarius*.

Fig. 1. THE BUFF-BREASTED SHRIKE (*Lanius icterus*), olivaceous above, and yellow beneath.

Fig. 2. THE CRUEL SHRIKE (*L. pendens*), bluish-grey above, white beneath, with the fore neck black.

Fig. 3. THE SUPERCILIOUS SHRIKE (*L. superciliosus*), light red above, whitish beneath, with a white frontal band extending over the eyes.

Fig. 4. THE WHISKERED SHRIKE (*L. mystacens*) is one of the handsomest species of the genus, and moreover remarkable for the vivid red of its lower parts and tail.

Fig. 5. THE BOUBOU (*L. Ethiopius*), dusky above, and white beneath.

WILD CATTLE OF CHILLINGHAM PARK.—The following account of the Wild Cattle kept at Chillingham, and which are supposed to be the descendants of a species which formerly inhabited this country, is extracted from a letter addressed by Lord Tankerville to Mr Hindmarsh, who read a paper on these animals at the recent meeting of the British Association. His lordship supposes that "they were the ancient breed of the island, inclosed long since within the boundary of the park," but states that he is not in possession of any documents respecting them, or the period at which the park was first inclosed. "They have pre-eminently all the characteristics of wild animals, with some peculiarities that are sometimes very curious and amusing. They hide their young, feed in the night, basking or sleeping during the day; they are fierce when pressed, but, generally speaking, very timorous, moving off on the appearance of any one, even at a great distance. Yet this varies very much in different seasons of the year, according to the manner in which they are approached. In summer, I have been for several weeks at a time without getting a sight of them, they, on the slightest appearance of any one, retiring into a wood, which serves them as a sanctuary. On the other hand, in winter, when coming down for food into the inner park, and being in contact with the people, they will let you almost come among them, particularly if on horseback. But then they have also a thousand peculiarities. They will be feeding sometimes quietly, when, if any one appear suddenly near them, particularly coming down the wind, they will be struck with a sudden panic, and gallop off, running one after another, and never stopping till they get into their sanctuary. It is observable of them as of Red Deer, that they have a peculiar faculty of taking advantage of the irregularities of the ground, so that, on being disturbed,

they may traverse the whole park, and yet you hardly get a sight of them. Their usual mode of retreat is to get up slowly, set off in a walk, then a trot, and seldom begin to gallop till they have put the ground between you and them in the manner that I have described. In form they are beautifully shaped, short legs, straight back, horns of a very fine texture, thin skin, so that some of the bulls appear of a cream colour; and they have a cry more like that of a wild beast than that of ordinary cattle. With all the marks of high breeding, they have also some of its defects. They are bad breeders, and are much subject to the *rush*, a complaint common to animals bred in and in, which is unquestionably the case with these as long as we have any account of them. When they come down into the lower part of the park, which they do at stated hours, they move like a regiment of cavalry in single files, the bulls leading the van, as in retreat it is the hells that bring up the rear. Lord Ossulston was witness to a curious way in which they took possession, as it were, of a new pasture recently opened to them. It was in the evening about sunset; they began by lining the front of a small wood, which seemed quite alive with them, when all of a sudden they made a dash forward altogether in a line, and charging close by him across the plain, they then spread out, and after a little time began feeding. Of their tenacity of life, the following is an instance. An old bull being to be killed, one of the keepers had proceeded to separate him from the rest of the herd, which were feeding in the outer park. This the bull resenting, and having been frustrated in several attempts to join them by the keeper's interposing (the latter doing it incautiously), the bull made a rush at him and got him down; he then tossed him three several times, and afterwards knelt down upon him and broke several of his ribs. There being no other person present but a boy, the only assistance that could be given him was by letting loose a deer hound belonging to Lord Ossulston, who immediately attacked the bull, and by biting his heels drew him off the man, and eventually saved his life. The bull, however, never left the keeper, but kept continually watching and returning to him, giving him a toss from time to time. In this state of things, and while the dog, with singular sagacity and courage, was holding the bull at bay, a messenger came up to the castle, when all the gentlemen came out with their rifles, and commenced a fire upon the bull, principally by a steady good marksman, from behind a fence at the distance of twenty-five yards; but it was not till six or seven balls had actually entered the head of the animal, one of them passing in at the eye, that he at last fell. During the whole time he never flinched nor changed his ground, merely shaking his head as he received the several shots. Many more stories might be told of hair-breadth escapes, accidents of sundry kinds, and an endless variety of peculiar habits observable in these animals, as more or less in all animals existing in a wild state: but I think I have recapitulated all that my memory suggests to me as most deserving of notice."

THE BLACK-TAILED GANNET.—*SULA MELANURA*. TEMM.

A SPECIMEN of this supposed species, which, however, seems to us to be merely a variety of the Common Gannet, is in the Museum of the University of Edinburgh. It was caught on the Bass Rock, in May 1831, and was submitted to our inspection while it was recent. The notes taken at the time are as follows. Apparently adult. The principal differences between this and the common are these:—

The bill is shorter, and at the base thicker.

The space from the eye to the base of the bill is shorter.

The black line of bare skin is extended down the neck to more than half its length, whereas in the common it is only about two inches long.

The secondary quills are dark purplish-brown; white in the common; but dark brown in the second year.

The tail is dark brown; white in the common; but dark brown in the second year.

Length 36 inches; extent of wings 64; bill along the ridge  $3\frac{3}{4}$ , along the edge of lower mandible  $5\frac{1}{2}$ ; tarsus  $2\frac{3}{4}$ ; middle toe  $4\frac{1}{2}$ ; primaries 10; secondaries 26; tail-feathers 12.

The size and proportions are thus nearly the same as those of the Common Gannet; from which it differs, as stated, more especially in having the bill shorter and thicker, and the naked longitudinal band on the throat more extended. Should these differences occur in other individuals resembling the adult of the common kind, but with the secondary quills and tail dark brown, the Black-tailed Gannet may be in reality a distinct species. A few individuals have been seen on the Bass Rock, but the people who rent it do not consider them of a different kind. This notice, it is supposed, is the first account of the occurrence of the black-tailed variety or species of Gannet in Scotland.

## HARES OF THE UNITED STATES AND CANADA.

OUR highly esteemed friend, the Rev. Dr Bachman, of Charleston in South Carolina, has recently published, in the Journal of the Academy of Natural Sciences of Philadelphia, an elaborate monograph on the different species of *Lepus* inhabiting the United States and Canada, of which we here present a very brief abstract.

The Hares constitute the genus *Lepus*, of the order *Glires* or *Rodentia*, characterized by having four small teeth placed behind the two upper incisors, two incisors below, six grinders on each side in the upper and five in the lower jaw, in all twenty-eight; by having the ears and eyes large; five toes to the fore feet, four to those behind, with claws slightly arched; the interior of the cheeks covered with hair, as well as the soles of the feet; the tail short; the mammae from six to ten.

1. *Lepus glacialis* (Leach). Polar Hare. Larger than *L. Virginianus*; colour in winter white; hair of a uniform white to the roots; in summer of a light-grey above; ears black.

This species is the largest at present known in North America. It has a wide range in the northern portions of America, having been found on both sides of Baffin's Bay, on the Banen Grounds, as far north as the country has yet been explored; in the North Georgian Islands; and in Newfoundland and Nova Scotia. It shelters itself among large stones, or in the crevices of rocks, feeds in winter on the Labrador Tea plant and the berries of the Alpine Arbutus, produces several young at a birth, and affords excellent eating, its flesh having a finer flavour than that of any other American Hare.

2. *L. Virginianus* (Harlan). Northern Hare. Larger than the American Hare, less than the Polar; white in winter, the roots of the hairs blue, then yellowish-fawn, tipped with white; in summer, reddish-brown above, white beneath; ears a little shorter than the head.

This species is plentiful in the Northern States, in Canada, in the fur countries as far north as lat. 64° 30', and has been seen on the Columbia River, the plains of the Missouri, and in the eastern states as far south as Virginia. It is supposed to be the fleetest species known, and Lewis and Clarke ascertained by measurement that it could leap 21 feet at a bound. It confines itself to the densest forests or to prairies overgrown with tall grass, feeds principally at night on grasses, bark, leaves, and buds of shrubs and trees, but as an article of food is inferior to the other species.

3. *L. aquaticus*. Swamp Hare. Larger than the American Hare, being nearly the size of the Northern Hare; tail, ears, and head, long; feet long, narrow, less covered with hair than those of the American Hare; general colour nearly black above, white beneath.

This species, now first described, is numerous in all the swamps of the western parts of Alabama, and still more abundant in the State of Mississippi and in the lower parts of Louisiana. It differs from all the other species in frequenting marshy places, occasionally resorting to the water, and swimming with ease.

4. *L. Americanus* (Harlan). American Hare. In summer the fur above yellowish-brown, on the outer surface of the fore and hind legs rufous; beneath, and under surface of the tail, white. In winter the upper surface considerably lighter, being grey or greyish-white, intermixed with black and brown hairs.

It is very widely diffused in the United States, and is very prolific, producing from five to seven at a birth. Its principal enemies, besides Man, are the Ermine, Canada Lynx, Wild or Rufous Cat, Foxes, and various birds of prey. It is fond of frequenting plantations, conceals itself by day in a brush-heap or a tuft of grass, and often commits havoc in the gardens.

5. *L. palustris* (Bachman). Marsh Hare. Smaller than the American Hare; ears much shorter than the head; eyes rather small; tail very short; feet small, thinly clothed with hair; upper surface yellowish-brown; lower grey.

It confines itself to marshy places near the coast, in Carolina, Georgia, and Florida; produces from five to seven young at a birth, and is superior to the American Hare as an article of food.

6. *L. Nuttallii* (Bachman). Nuttall's Little Hare. Very small; tail of moderate length; general colour above, a mixture of light-buff and dark-brown; beneath, light yellowish-grey; ears broad and rounded; lower surface of tail white.

Mr Nuttall, who discovered it, states that it is met with to the west of the Rocky Mountains, inhabiting thickets by the banks of several small streams which flow into the Shoshonee and Columbia rivers.

7. *L. campestris* (Nuttall). Prairie Hare. In summer the head, neck, back, shoulder, and outer parts of the legs and thighs, lead colour; the belly, breast, and inner parts of the legs and thighs, white. In winter it is pure white, except the black and reddish-brown of the ears, which never change.

It occurs in the northern and western parts, especially on the plains to the west of the Rocky Mountains.

8. *Lepus (Lagomys) princeps* (Richardson). Little Chief Hare. Head short and thick; ears rounded; legs short; no tail; colour above blackish-brown; beneath greyish-fawn.

It inhabits the Rocky Mountains from lat. 52° to 60°.

Dr Bachman concludes with the following general observations:—"The *Lepus glacialis* is an inhabitant of the polar regions, having been seen as far north as our discoveries have as yet extended, ranging across the whole of the northern part of our continent, and found as far south, at least, as Newfoundland, where it is abundant, occupying a range of more than 30° of latitude. There are, no doubt, wide intermediate spaces, where it is not found. Professor McCulloch, residing at Picton, Nova Scotia, has not observed it in his vicinity. It generally avoids swampy situations, preferring high grounds, and is often seen along the sides of hills, and in rocky situations. The *Lepus Virginianus*, according to Richardson, is found as far north as lat. 68°, and is known to exist as far south as the mountains of Pennsylvania. The *Lepus Americanus* is believed to exist in all the settled parts of the United States. The *Lepus aquaticus* has not yet been discovered to the east of the State of Alabama, nor to the west of the Mississippi river, or the south of New Orleans, although it will probably be found to extend considerably beyond these limits. The *Lepus palustris* has not yet been seen north of the maritime districts of South Carolina, nor to the west of Georgia, but extends to the southernmost portions of East Florida. The *Lepus Nuttallii* seems peculiar to the district west of the Rocky Mountains. The *Logomys princeps* has been found from lat. 42° to 60°, and probably extends along the whole range of the Rocky Mountains, especially in the most elevated regions.

"These different species, although they have a strong general resemblance during a period of the year, may yet, by a little attention, be easily distinguished from each other. *L. glacialis* may be known by its black ears in summer, and by its hair being snowy white, even to the roots, in winter. *L. Virginianus* may be recognised in summer by its reddish-brown colour, and in winter, by its fur being white at the tips, and plumbeous at the base. *L. aquaticus* may be distinguished from the Northern Hare by its never becoming white in winter; from the American Hare, by its larger size, by its fur becoming black in winter, instead of whiter, as is the case with the former, and by its aquatic habits; and from the Marsh Hare, by its being one-third larger, by its much longer head, ears, and tail, and by its swiftness of foot. *L. palustris* may at any time be distinguished by its short tail, which is never white beneath, by its small hind feet, resembling in this respect the Cavy, and by its aquatic habits. *L. Nuttallii* may be known by its diminutive size, and differs from *Lagomys princeps* by the presence of a tail. *L. campestris* may be distinguished from the Polar Hare, by the fur on the back never becoming pure white to the roots, in winter."

## GEOLOGY.

ON THE SLATE OF SOUTH DEVON. BY J. C. BELLAMY, ESQ. YEALMPTON.

SLATE, in its varied appearances, occupies the generality of South Devon southward of Dartmoor, a granitic tract, being, as it were, diffused in all directions, the other strata, lime trap, &c., being intruded between its courses and hills. Under the term slate I here include every kind of rock popularly so called, and in consequence, for the sake of convenience, confound together rocks both "primitive and transition." However perfect systems and tables as set forth in books may seem to be, and however desirable it might be for me to present definite terms and divisions of the strata under examination, I am so clearly satisfied of the immature condition of this science, simply from the fact that local phenomena have not yet been narrowly investigated and compared, that I think it highly probable a few years will once more remodel existing opinions and classifications, and that, consequently, it can be no great outrage to consider provisionally all our rocks of a slaty nature under one head, though I do not mean to exclude conjecture and classification altogether. Thus, while under the term slate I comprise mica-slate, gneiss-slate, clay-slate, roofing slate, dunstone, greywacke-slate, flinty-slate, and greywacke, with perhaps some other minor kinds, I believe it would be unphilosophical to disregard the principle of separation between the fossiliferous and the nonfossiliferous rocks, or the principle of arrangement derived from the occasional alternation, and intimate blendings of certain strata, together with the truly natural association of deposits by the occurrence of the same description of animal remains, and other structures in their substance. But who, in the midst of conflicting statements of authors, will undertake to explain what is clay-slate, and what is not, particularly as this is generally ranked amongst the primitive (nonfossiliferous) rocks, and with us contains indubitable proofs of being fossiliferous, besides being apparently in union with a mass of other slate containing no such demonstrations? In a popular work now before me, giving a succinct statement of strata, primitive formations are described as being destitute of petrifications; then the rocks so classed under this head are briefly described, and amongst them stands "clay-slate." It is added, "the clay-slates of Switzerland are celebrated for their impressions of fishes. Mont Pilate consists of thin laminae, and in almost every plate is impressed a fish!" Thus it would be gratuitous and presumptuous in me to draw a line of demarcation between the clay-slate and the other kinds of slate, supposing a natural distinction to exist, which I am not sure is the case, for, as respects a distinction founded on the occurrence of fossils, the dunstone and greywacke contain no fossils, and are, it is well known, in immediate connection with patches of fossiliferous slate, and consequently the hills of slate connected with the fossiliferous slate above named may, for aught I see, be equally regarded as coeval in its deposition. If, therefore, it were demanded of me to state what I regarded as clay-slate, and to draw a line of demarcation between it and other kinds, I should say, either that the separation must be dependent on the presence or absence of organic relics, presuming on the possibility of making a separation by that means, or that the entire mass of our slate not evincing the characters of mica, or of gneiss-slate, on the one hand, or betraying none of the characters of flinty-slate or of greywacke-slate on the other; in short, all that rock which amongst amateurs and persons loosely informed on the matter is termed clay-slate, and which I have above recognised in a general way as being fossiliferous, must receive this appellation. From what I have just stated, it might be gathered that the interruptions to the courses of the different varieties of slate were not sudden, but rather the reverse. This circumstance, indeed, is remarkable amongst the features of this rock considered as a whole. Mica-

slate and gneiss-slate, however, hold a station quite apart from the others, and are certainly altogether distinct. On the other hand, clay-slate (used in a limited sense), roofing-slate, dunstone, and greywacke-slate, are observed to pass gradually into one another, and to reciprocate each other's qualities. Again, greywacke-slate, flinty-slate, Lydian-stone, (?) and greywacke, graduate into one another. Roofing-slate is found sparingly, and in small patches. It obviously passes into the general mass of clay-slate, of which, notwithstanding its containing organic remains, I have above surmised that it may in propriety be ranked apart. The general body of clay-slate assumes a great variety of aspects, which are manifestly graduated, sometimes approximating the typical roofing-slate, and sometimes degenerating into a loose brown debris, or becoming indented, or closely impacted, constituting "dunstone;" not unfrequently also running into decided greywacke, either in small patches, or even in extensive beds. Altogether, these last named rocks form the generality of our hills which are round-backed. In situations where the slate is in tolerably-sized fragments, fossils are found in plenty. Greywacke, flinty-slate, and Lydian-stone? are found in one situation, in close approximation to greywacke-slate, this last being itself the staple rock of that spot, and passing with great freedom into greywacke, and rather less so into the others. It and the flinty-slate are fossiliferous. Although I have mentioned certain kinds of slate as being fossiliferous, I believe that no fixed rule can be laid down on this subject, for the same kind of slate will in one place exhibit these remaining, and in another be destitute of them. Greywacke-slate is most constant in this respect. The rubbly and loose kinds of clay-slate, and the best kinds of roofing-slate, seldom contain them. The generality of our slate, that, namely, to which I presume the term clay-slate may be applied, is found assuming for the most part the appearance of small and loosely joined fragments of a light-grey colour, sometimes bluish-grey, much tinged with iron, and frequently intersected by seams of quartz. At intervals, these hills of clay-slate give good quarries of roofing-slate, of a bright lead colour, in which fossils are freely distributed. These quarries are in general soon worked out, the stone soon becoming dense with greywacke, or degenerating into a rubbly state, or a dunstone, which is an indurated form of clay-slate. The course and dip of our slate vary greatly, even at times within a small space. I have understood that near Exeter is a bed of slate horizontal in its course. This, it was thought, was a rare circumstance, but in this neighbourhood it is far from being an uncommon appearance, though only observed in small patches. From a level it varies to a close approximation to verticality. It faces usually from about south-west to about south-east, but likewise at times looks southwardly, eastwardly, and westwardly, or thereabouts; but though it is thus prone to variation, even repeatedly within a small distance, I am not aware that it ever faces northwardly of east and west. Its solidity varies sometimes within very confined limits, and this often depends on the sudden presence of greywacke, which is seen to pervade the slate with great freedom in some spots. At times there is reason to believe that access of air determines the decomposition of slate, though in the cases where this is supposed to have happened, I should consider from its brown and powdery appearance, that some peculiarity of chemical composition had existed previously. Generally, however, the loose rubbly condition in which we observe a deal of our slate to exist, cannot have been owing, at least in the first instance, and principally, to atmospheric influences; for in some places, as at the slate quarries, this presumed decomposition shews itself throughout the whole depth to which the rock has been worked—at one spot the rubbly and loose state of the rock gradually disappearing, and the substance by degrees getting closer, until it is fairly of the character of dunstone, or at the least of ordinary slate. Indeed, this transition from loose to indurated slate is exemplified most freely in this neighbourhood, and seems to be inconsistent with a supposition of decay from the agency of air. The oxide of iron occasionally stains our slate in fantastic shapes. It seems also to occur in greatest plenty in the immediate neighbourhood of fossils, and in their composition. I occasionally find fragments of slate in the quarries on which are marked dark, broad, concentric lines, in the manner of the layers of wood in the boles of trees, of which appearances I can offer no explanation. There is one fact in the history of our slate worthy of notice, and worthy of being further investigated with a view to some explanation. This is the bendings or reflexions in the slope of the rock observed in very many places. In one spot in particular I have observed it to be bent four times in the depth of as many feet, so as to assume a perfectly zig-zag appearance. It must be recollected that this occurrence is not limited to loose and disconnected kinds of slate, but may be seen on larger scales in good solid sorts also, though the repeated reflexions may not be here so remarkable or perfect. At Crab-Tree, near Plymouth, there is a hill of slate, which towards its summit turns off at an obtuse angle, which gives this rock a peculiar aspect. Mr Hennah, in a work before named, records an instance where the slate seems as if thrust up by some violent impulse from below, between two beds of lime. I am of opinion that several similar instances, as regards this appearance of the rock, can be shown in our neighbourhood, though as to the cause of this, as well as of the reflexions above specified, I can offer no satisfactory notion.

Greywacke-slate assumes a very different appearance from all others. It is harder, and not so extensively tabular, is of a dark lead colour, and passes very freely, and very suddenly, into greywacke, at numerous points. Viewing it as it appears on the coasts, it displays itself in large flat cakes, having thin and rounded edges between which other cakes are in their turns inserted. It passes also with freedom into flinty-slate, and also I suspect into Lydian-stone, but here I want the opinion of some competent judge. In the flinty-slate are found the turbinolias formerly alluded to. Beneath the water these are dislodged by the action of that element from their bed, and thrown up in more or less perfection of form on the beach, a fact corroborative of the general rule of fossils exceeding in density the matrix in which they occur. Dr Leach reports that at Buckfast in this county the lime is seen covering the slate, and that they both at this spot contain a quantity of flinty matter. Now, it is singular that close to the place where I reside, there is seen a small quantity of lime overlaid by the slate, and both containing flinty matter!—a fact seemingly confirming amongst others before named, the contemporaneous deposition of these strata, or at least their close relationship with respect to the convulsions which have disturbed the crust of our globe. "The circumstance of strata at their points of junction being more or less

cemented, blended together, and intermixed, appears to me to have attracted too little notice, for though in some cases their admixture seems rationally accounted for by the previous well-founded conjecture, that their deposition was coeval, there are other instances in which we have no ground for imagining that their depositions were coetaneous. Lime and slate are most freely intermixed at their points of junction; and we see the same thing occurring between the slate and sandstone in spots where these meet, the latter frequently being wedged into the other; and in some places there being a union of qualities. But then, there are other reasons for imagining the contemporaneousness in the deposit of these strata. On the other hand, where slate abuts against granite or trap, we find that in some spots the former is cemented freely to the latter. This is seen in numerous blocks scattered profusely through the valley at Joybridge, but I am not sensible of any cases where there is a thorough intermixture, as seen between slate and limestone.

Amongst the varied relations assumed by slate in its before named general diffusion, there is one which seems to indicate that even the oldest (allowing for argument that they are of different ages) kinds of slate were not contemporary with granite, for this rock not only extends into contact with granite at our north, but even spreads between the hills of that primitive formation, assuming, I presume, in its run a lengthened three-sided figure. Whatever be the actual relations between lime and slate (or at least certain sorts of the latter), and whatever may be the depth to which the lime as a whole, or in some parts, descends, I must not omit to furnish an additional proof of the intimate connexion subsisting between these two strata, namely, that "Lime appears in masses on the north, south, and west sides of the Dart, insulated in schistus." (Carrington's Dartmoor, Preface.)

The most common fossils in our slate are the encrinurites, of which there seem to be several species, and all different from those in the limestone. Perhaps the next kind most generally diffused is a sort of coral, or rather, more properly certain species of corallites, for the specimens differ very greatly. One which I have is thick, separate, and fan-shaped; another is fixed in relief, and of a loose powdery texture; while a third sort is like the last alariform, and appears as a mere impression in roofing-slate. They are all small in size. The turbinolias seem limited to the flinty-slate at Bovisand, but are there most plentiful. My brother procured from the slate at Crab-tree a species of "trilobus." Madreporites are found, though rarely, in slate. They seem to be very similar to, if not identical with, those so common in lime. In the flinty-slate at Bovisand, Miss Hook has found two anomalous specimens. One has the appearance of a Turbo, and the other bears a considerable similarity to a crab; but these are highly ambiguous. There are also various other fossils, of which I can render no definite account.

Decomposed and comminuted slate from old buildings, is used with benefit as a manure, for besides acting mechanically in separating tenacious clots of soil with which we may combine it, its composition shews that it is no despicable ingredient, of a productive soil. Shoemakers use what I conceive to be Lydian stone as "lap-stones," they being found on the shore of the required rounded shape, and possessing great density and tenacity.

## VARIETIES.

INSTINCT OF ANIMALS.—The following curious statement is copied from a letter which the late William Fischbein, the well known animal painter, wrote in explanation of one of his most beautiful coloured sketches, now in possession of M. Meyer, of Hildburghausen. It represents five little red mice, in the presence of a young cat. "That instinct is an inherent or innate quality of animals, is clearly proved by experience. The cat possesses the instinct of catching and eating mice, and the mouse that of shunning the cat as its most dangerous enemy. Once, in Rome, I happened to open a drawer which I seldom had occasion to use, when I saw a mouse jumping out of it, and found among the papers a nest with five young mice, naked and blind, and of a pale flesh colour. I placed them on a table, handled them, &c., and they evinced no symptoms of fright, nor any inclination to get away, but only appeared eager to approach each other for the sake of warmth. There happened to be in the house a very young cat, which had never tasted anything but milk. I placed it near the little mice, by way of experiment, but to my astonishment it did not even look at them, nor perceive them, even when I turned its eyes in the proper direction, until at last, when I had repeatedly approached its nose to the mice, it suddenly caught a scent which made it tremble with desire. The propensity became more and more violent, and the cat smelled at the mice, touching them with its nose, when all at once, the pale-coloured like creatures became suffused with blood, and began to make great exertions to get out of the way of imminent danger, whilst the cat as eagerly followed them."—*Dr Weissenborn, in Mag. of Nat. Hist.*

THE VAMPIRE BAT OF SOUTH AMERICA is often the cause of much trouble by biting the Horses on their withers. The injury is generally not so much owing to the loss of blood, as to the inflammation which the pressure of the saddle afterwards produces. The whole circumstance has lately been doubted in England; I was therefore fortunate in being present when one was actually caught on a horse's back. We were bivouacking late one evening near Coquimbo in Chile, when my servant, noticing that one of the horses was very restive, went to see what was the matter, and fancying that he could distinguish something, suddenly put his hand on the beast's withers and secured the Vampire. In the morning, the spot where the bite had been inflicted was easily distinguished, being slightly swollen and bloody. The third day afterwards we rode the horse without any ill effects. Before the introduction of the domesticated quadrupeds, this Vampire Bat probably preyed on the Guanaco or Vicugna, for these, together with the Puma and Man, were the only terrestrial Mammalia of large size which formerly inhabited the Northern part of Chile.—*Darwin, in the Zoology of the Voyage of H. M. S. Beagle.*

PRESERVATION OF CORN.—Thinking that all granaries are but imperfect shelter from the vicissitudes of weather, General Demarcay has made use of an ice-house situated on his estate, but no longer used as such. Its depth was sufficient to render it impervious to atmospheric changes, and he lined it with wooden planks so as to form a large case, but which was at some little distance from the bottom and the sides of

the ice-house, so that it was not liable to the damp of the surrounding earth, and allowed a free circulation of air around its exterior. The corn was placed so as to fill the case to within a yard of the top; three layers of loose planks were placed at a third of a yard distance between each, and the roof was then formed of thatch, and in a conical shape. The experiment has lasted twelve years, and been constantly attended with satisfactory results. The same grain has remained there for three years, without the slightest alteration, and, what is remarkable, some newly-threshed corn which had been completely wetted while it was measured in the open air, having been placed in the case, was three weeks afterwards found to be as dry and glossy as flaxseed.—*Athenæum*.

**CHANGES OF COLOUR IN BIRDS.**—In an excellent paper on the Hares of the United States and Canada, by the Rev. Dr Bachman of Charleston, S. C., are the following observations on this subject:—"In birds, as well as in quadrupeds, there are some species in which great changes of colour take place from the young to the adult state, and also at different seasons of the year; the question is often asked, whether this is effected by a gradual change of feathers, or of hair, or by a sudden moult in birds, and a shedding of the hair in animals. I am inclined to the belief, from many experiments on animals and birds in captivity, that Nature, in effecting these changes, does not proceed with uniformity in all the species. I have observed in the Yellow-crowned Warbler, *Sylvia coronata*, that the change occurs by a sudden moulting in spring; and in a very few days it changes its homely dress, with which it came to us in autumn, for its bright nuptial livery of spring and summer. The *Sylvia petechia* is, during autumn and winter, so nearly of the colour of the *S. coronata*, that they cannot, without careful examination, be known from each other. In spring, this bird becomes olive-green on the back, beneath yellow; the head at the same time becomes of a bright chestnut-bay colour. In this state of plumage, Bonaparte has described it as a different species, *S. palmarum*. In this bird also the change is effected, as I have observed on an examination of more than fifty specimens, by a moulting of the feathers from the 1st to the 15th of March, in Carolina; and it, in the course of two weeks, receives its bright summer plumage. On the other hand, there are many birds in which these changes take place slowly, and by a somewhat different process: the gradual fading or brightening of the feathers immediately after a moult. Thus I have seen the young of the Whooping Crane, *Grus Canadensis*, undergoing its mutations. A pair of these birds, when nearly two years of age, as they increased in size, began gradually to change their colours. I was in the habit of visiting them every two or three days during four or five months. They had just moulted; many of their new feathers were still sheathed. I could, at every renewed visit, perceive that the plumage was continually becoming lighter, till at last they were nearly pure white; and I was gratified to find my previous conjectures correct, that the birds I had so anxiously watched were Whooping Cranes, *Grus Americanus*. A male of the Summer Duck, *Anas Sponsa*, which I have preserved in an aviary for some years, loses its brilliant plumage at the time of moulting in summer, and continues for several weeks afterwards in the plain livery of the female, when the feathers begin to brighten gradually; from day to day the change continues, until, after the expiration of a few weeks, the bird assumes all its bright and beautiful plumage.

All our birds that assume one set of colours during six months of the year, and different ones during the other six months, appear to moult in spring as well as in summer. My examinations have extended to the *Sylvia coronata*, *Fringilla savanna*, *Fringilla Pennsylvanica*, *Sylvia petechia*, *Charadrius Helicticus*, *Streptilas interpres*, and several species of *Sterna* and *Larus*.

**ORNITHOLOGICAL LOGIC.**—In his remarks on Gould's Birds of Europe, Mr Wood, the Editor of the Naturalist, has the following note:—"Red Ptarmigan, *Lagopus Britannicus*, Tétris rouge, Fr. The British ornithologist feels a peculiar interest in this species, as it has never been known to occur out of the British Islands; but since, as every sportsman knows, it is so abundant on the heaths of Cumberland, Westmoreland, Yorkshire, Wales, and many parts of Ireland, surely we cannot encourage the monopoly of our northern brethren by continuing the name *L. Scoticus*." The original name of *Tetrao Scoticus* was not given to the bird in question by the "northern brethren;" but having been imposed and received as genuine, and being moreover correct as the species is a native of Scotland, although also of England and Ireland, it must be retained, the species however being referred to its proper genus, *Lagopus*. Is *Pandicilla Suecica*, so named by Mr Wood, as well as others, peculiar to Sweden; or *Plectrophanes Lapponica* to Lapland; or *Sterna Anglica* to England; or are a hundred and fifty other birds named after particular sections of the world peculiar to those spots? If not, let the catalogue be revised, and we will consent to adopt the proposed alteration in the name of our Ptarmigan; but, in the meantime let it be honoured with the name of a country abounding in that feather in which it delights to dwell.

**HYBERNATION OF SWALLOWS.**—M. Isidore Geoffroy, in his zoological instructions drawn up for the new scientific expedition to the north, calls upon naturalists to observe any facts which they may meet with concerning the hibernation of Swallows. In consequence of this, M. Dutrochet communicates to him, that he found two of these birds in a state of torpor, in a recess, formed in the wall of a building. On being warmed by the hand they flew away, proving thereby that Swallows are occasionally capable of wintering in a northern climate.

**GALVANIC TELEGRAPH.**—The highly scientific mode of making instantaneous telegraphic communications by galvanic power, which has so long been considered attainable, has already been put to the most decided test on the London and Birmingham railway, under the direction of Professor Winston and Mr Stephenson, the engineer to the Company. Four copper wires, acted upon at each end of the line at pleasure, by the agency of very simple galvanic communicators, have been laid down on the line of the London and Birmingham railroad, to the extent of twenty-five miles. They are inclosed in a strong covering of hemp, and each terminus is attached to a diagram, on which the twenty-four letters of the alphabet are engraved in relative positions, with which the wires communicate, by means of moveable keys, and indicate the terms of the communication. The gentlemen are fully satisfied that com-

munications to almost any extent may be made instantaneously by the agency of galvanism.—*Quarterly Journal of Agriculture*.

**ATHOL FOREST.**—It is said that there are 7000 Red Deer in the Athol Forest, and the number is not over-rated, if the extent of ground, of which they have the undisturbed possession, be any criterion. The Roe Deer also are numerous in the different plantations of the country. The Fox, the Wild Cat, the Marten, the Polecat, the Weasel, and the Alpine Hare, are common. The Rabbit, the Squirrel, and the Rat, have lately made their way into the country, and have increased so rapidly as to become troublesome and destructive.—*New Statistical Account of Scotland*.

## REVIEWS.

*A History of the British Zoophytes.* By GEORGE JOHNSTON, M.D. W. H. Lizars, Edinburgh; S. Highley, London; W. Curry, Jun. and Co., Dublin.

THIS important work is recommended to the lovers of Natural History, not less by the very pleasing manner in which it is written, than by the scrupulous accuracy of description which it displays. An accomplished scholar, as well as an acute observer, the author has so illustrated what is technical by the choicest selection of what is common to the affections of all persons of cultivated faculties, that his work, while it affords a clear view of a class of animals hitherto little studied on account of the want of sufficient guides, is calculated to interest even those who satisfy themselves with a vague contemplation of the beauties of Nature, or derive pleasure from the familiar exposition of her wonders.

The first part is devoted to a history of Zoophytology, and the structure, physiology, and classification of Zoophytes. Restricting the term Zoophyte to those creatures "which in their form, or most remarkable characters, recall the appearance of a vegetable or its leading properties," he defines the class thus.—Animals avertibrate, inarticulate, soft, irritable and contractile, without a vascular or separate respiratory or nervous system; mouth superior, central, circular, edentulous, surrounded by tubular, or more commonly by filiform tentacula; alimentary canal variable; where there is an intestine the anus opens near the mouth; asexual; gemmiparous; aquatic. The individuals (*Polypes*) of a few families are separate and perfect in themselves, but the greater number of Zoophytes are compound beings, viz. each Zoophyte consists of an indefinite number of individuals or polypes, organically connected and placed in a calcareous, horny or membranous case or cells, forming, by their aggregation, corals or plant-like *Polypidoms*. The arrangement which he adopts, or rather elaborates, is as follows.

**Subclass I. RADIATED ZOOPHYTES.** Body contractile in every part, symmetrical; mouth and anus one; gemmiparous and oviparous.

Order I. *Hydroïda*. Polypes compound, the mouth encircled with roughish filiform tentacula; stomach without proper parietes; reproductive gemmules pullulating from the body and naked, &c.

Order II. *Asteroida*. Polypes compound, the mouth encircled with eight fringed tentacula; stomach membranous, with dependent vasculiform appendages; reproductive gemmules produced interiorly, &c.

Order III. *Helianthoida*. Polypes single, free or permanently attached, fleshy, naked or encrusted with a calcareous Polypidom, the upper surface of which is crossed with radiating lamellæ; mouth encircled with tubulous tentacula; stomach membranous, plaited, oviparous, &c.

**Subclass II. MOLLUSCAN ZOOPHYTES.** Body non-contractile, and non-symmetrical; mouth and anus separate; gemmiparous and oviparous.

Order IV. *Ascidïoida*. Polypes aggregate, the mouth encircled with filiform ciliated retractile tentacula; a distinct stomach, with a curved intestine terminating in an anus near the mouth; ova internal. Polypidoms horny and fistulous, or calcareous, membranous, &c.

The second part of the work, necessarily more extended, is composed of a history of all the British species, including characters of the orders, families, genera, and species. Besides the technical descriptions, we are favoured with numerous and often highly interesting historical notices, referring to the structure and physiology of the animals described, their uses, discoverers or describers, and other points. Sometimes quaint, and frequently antiquarian, although never obscure or antiquated, some of our author's scientific friends, if consistent with themselves, must deem him an affected imitator. We, on the contrary, are delighted with those peculiarities of style and manner which contrast so strongly with the dry didactic details, and awkward attempts at freedom of speech, of persons who do not always succeed in spelling their names, much less in constructing a sentence according to rule. It is pleasant, too, to be reminded of "the charming Hippothoa and rosy-armed Hipponee," Nereids of old Hesiod; or of Drayton's

"Antheia, of the flowers that hath the general charge,  
And Syrinx of the reeds, that grow upon the marge."

The descriptions are illustrated by forty-four plates, and numerous engravings on wood, for all which the drawings were made by the author's accomplished consort, "by Mrs Johnston, who is herself the engraver of fourteen of them. The naturalist who may have attempted similar illustrations will appreciate the labour, perseverance, and skill that has been bestowed upon them, and will not harshly censure any errors of detail which a minute criticism may discover." The discovery of these errors we leave to the envious, and conclude our brief notice of a work that deserves all commendation, by expressing our wish that it may quickly be dispersed over the land, and inspire in those who peruse it some of that spirit of unaffected piety which has dictated many of its most beautiful passages.

ZOOLOGY.

DESCRIPTION OF THE PLATE.—THE DEER.

THE Ruminantia, so named on account of the singular faculty which they possess, of subjecting to mastication a second time the food which they have hastily bruised and deposited in the stomach, may be primarily divided into two groups: those destitute of horns, as the Camels, Lamas, and Musks; and the horned species, which again arrange themselves into two distinct families or sections, those with caducous bony horns or antlers, and those with hollow persistent horns of the same texture as hoofs, and moulded upon a bony core. The antlered Ruminantia constitute the family of *Cervida* or Deer, of which there are numerous species, some of which are found in all the continents and large islands, excepting New Holland. The Deer are generally remarkable for elegance of form, and rapidity of motion. Their body is of moderate bulk, their limbs long and slender, their tail very short, their eyes and ears large; and the males or Stags are furnished with branched horns or antlers, which are shed and renewed annually. The female of one species, the Rein Deer, is also horned. These appendages, varying in size and form, afford good distinctive characters for the species, taken in conjunction with the stature, colour, and other circumstances. The Stags represented in the accompanying plate belong to a section characterized by having the branches of the horns round, and generally tapering, not flattened.

Fig. 1. THE WAPITI DEER (*Cervus Canadensis*) is much larger than the Stag of Europe, but very similar in form. It differs in not having the horns forked or branched at the extremity, as well as in other particulars. The northern parts of America are inhabited by this species, whose range is daily becoming more limited on account of the increase of population.

Fig. 2. THE RED DEER (*C. Elaphus*). This beautiful and stately animal, once generally distributed over Europe, still occurs in a wild state in many of the hilly and wooded districts of that continent, as well as of the northern and temperate parts of Asia. In Britain it is confined to some tracts of the Highlands of Scotland, where it is fostered by the land proprietors.

Fig. 3. THE BENGAL DEER (*C. Bengalensis*) is about the same size as our Red Deer, and inhabits various parts of India.

Fig. 4. THE PORCINE DEER (*C. porcinus*) is a small species, so named from its comparatively large body and short legs, giving it somewhat of the aspect of a hog. Its horns are very slender, with two very small antlers, one of which is placed near the summit.

Fig. 5. THE TIMOR DEER (*C. Timorensis*), of larger size, is somewhat similar in form and colour, and has also two short branches on the horns, which are proportionally stronger.

DESCRIPTION OF THE PLATE.—THE PIGEON.

THE extensive family of Pigeons, *Columbida*, characterized by a more or less tumid soft space at the base of the bill, a large double crop or dilatation of the œsophagus, a strong gizzard, and two very small cœca, together with other circumstances, such as their laying two white eggs, emitting a cooing or murmuring sound, and feeding their young by disgorging the food partially macerated in their crop, and mixed with a milky secretion, is divided into several groups or genera, to one of which, *Columba*, with slender bill, the birds represented in the plate belong.

Fig. 1. THE DWARF PIGEON (*Columba nana*) is a very beautiful small species, in the colouring of which green and yellow predominate.

Fig. 2. THE PEARLY PIGEON (*C. perlata*) is also green on the upper parts, with the fore-neck red, and the wing-coverts marked with oblong reddish spots.

Fig. 3. THE RED-HEADED PIGEON (*C. ruficeps*), light red, with the feathers of the hind-neck edged with green.

Fig. 4. THE BANDED PIGEON (*C. leptogrammica*), having the upper parts light-brown and green, transversely banded with dusky.

Fig. 5. THE ASH-COLOURED PIGEON (*C. cinerea*), female; and

Fig. 6. THE FEMALE OF THE DIADEM PIGEON (*C. Diadema*).

There is little of particular interest known of these beautiful birds, which do not require to be technically described here, as they will be the subject of extended description in a subsequent part.

BRITISH BIRDS.—THE CORN CRAKE.

THE Corn Crake, which, although it seldom comes under the observation of unprofessional admirers of Nature, is yet familiarly known by its cry, insomuch, that to most people it is "*vox et præterea nihil*," is a small bird intermediate in size between the Quail and the Partridge, having the body much compressed, the neck rather long and slender, the head small and oblong. The bill is somewhat shorter than the head, stout, tapering, and much compressed; the tongue rather short, fleshy, emarginate, and papillate at the base, flattened above, and pointed. The œsophagus is six inches long, of nearly uniform diameter and narrow, the stomach roundish, compressed, large, with strong lateral muscles; the intestines twenty-five inches long, and of moderate width; the cœca three and a quarter, being large, and, like those of the Gallinules, approaching in form to the cœca of the Gallinaceous birds. The eyes are bare for nearly half an inch; the tarsus is of moderate length, compressed, but stout; the toes very long, slender, and compressed; the first very small; the claws of moderate length, slender, and slightly arched. The plumage is blended; the wings short, concave, and rounded; the first quill much shorter than the second, which is slightly longer than the third; the tail extremely short, arched, much rounded, of twelve very weak feathers. The bill is light brown, the lower mandible whitish at the end; the iris light hazel, the feet bluish flesh-colour. The upper parts are light yellowish-brown, each feather marked with an oblong central spot of brownish-black, and laterally tinged with grey; the wing-coverts are light red, some of them imperfectly barred with white; a broad band of ash-grey passes over and behind the eye and ear, and the cheeks are tinged with the same; the face, fore-part and sides of the neck, are light yellowish-brown, tinged with grey; the sides and breast barred with light red and white; the lower wing-coverts and axillary feathers light red; the chin and abdomen brownish-white; the quills and primary coverts light brown, the outer webs tinged with light red; the edge of the wing, and outer web of the first alular feather and first quill, reddish-white; the inner secondaries, and the tail-feathers, like the back. The length is 10½ inches, the extended wings measure 18, the bill is eleven-twelfths, the tarsus 1½, the middle toe 1½, its claw three-twelfths.

Were we to betake ourselves on some beautiful summer morning to one of the pastures that skirt the sandy shores of the remote Hebrides, anticipating the rising of the sun, and listening as we proceed in the grey twilight to the cries of the distant gulls, and the loud crash of the little wavelet, whose fall on the beach produces a louder noise than the rush of the mighty billow would do in a storm, we should not fail to see as well as to hear the Corn Crake. Here let us crouch behind the turf wall, in view of that thicket of iris, and watch. There already, dimly seen, one is quietly walking along the grassy ridge, lifting high foot after foot, and sometimes stooping as if to pick up something. Now it stops, stands in a crouching posture, but on unbent legs, and commences its curious but monotonous song. Another is observed threading its way among the short grass of the adjoining piece of meadow land. The ruddy streaks in the east betoken the sun's approach to the horizon. There, along tide-mark, some dark-coloured bird approaches; it perceives us, wheels round, and comes up, announcing itself by its croak as the Hooded Crow. The Crakes seem to understand the warning, and immediately betake themselves to the thicket, whence we can easily start them. Yet they sometimes allow you to come within a yard or two before they rise, and so closely do they sit, that I have once or twice seen a small pointer, which I had trained to bird-nesting, spring upon and seize one.

The Corn Crake visits us early in May. It may seem strange that a bird apparently so ill adapted for continued flight, should yet be capable of performing the long journeys necessary for its annual visits. Its ordinary haunts are fields of corn and grass, and in the less cultivated parts of the country the large patches of flags and other tall herbaceous plants, which occur in moist places. It runs with great celerity, so much so, that I think a man could hardly overtake it, and it seems extremely averse from flying, for it seldom rises until one gets quite close to it. When it has started, it flies heavily, with considerable speed, allowing its legs to hang, and soon alights.

In an oat field in Harris, I once shot at a Rail that suddenly rose among my feet, when, apparently not having been hit, it flew off in a direct course to the sea, about four hundred yards distant, where, to my surprise, it alighted and floated motionless, sitting lightly on the water, like a Coot or Gallinule. Soon after, a Black-backed Gull coming up, spied it, and, uttering a loud chuckle of delight, descended with rapidity, and carried it off in its bill. In this case, I think the bird was so

frightened, although not hurt, that it entirely lost its presence of mind, as the Water Hen sometimes does under similar circumstances.

At all times of the day, but more especially in the early morning, and towards twilight, it utters its singular and well-known cry, resembling the syllables *crek, crek*, repeated at short intervals, and often continuing for many minutes, probably a quarter of an hour or more, if the bird is not disturbed. It has the reputation of being an expert ventriloquist, and whether or not it deserves that title, it is certain that one is very apt to be mistaken as to the spot in which the bird is when he listens to its cry, which is at one time loud, at another low, now seems to indicate a close proximity, now a remote position, and even appears to come from various directions. I have heard the Thrush and the Robin so sing, close at hand, that I imagined them to be far away, and it is probable that other birds have the same faculty, which seems to depend upon the elongation or contraction of the trachea. When uttering its cry, the Corn Crake usually remains still, standing with its neck considerably drawn in. I have watched it so employed through a hole in a wall. But I have also often seen it walk leisurely along at the time. As to its neck being "stretched, perpendicularly upwards," as alleged by Mr Selby, it may perhaps sometimes be so, but not usually. At the period when the nights are shortest, I have heard it commence its cry so early as one in the morning.

Although not gaudily attired, the Corn Crake is richly coloured, and when observed in its wild haunts, has an appearance of great elegance. It moves in a graceful manner, and when proceeding leisurely, walks with what might be called sedateness, lifting its feet rather high, jerking up its short tail, and bending its neck backwards and forwards at every step, like the Water Hen. If alarmed, either while walking, or while uttering its cry, it instantly ceases, stands still or crouches, and if it judges it expedient, starts off, throwing its neck out and its body forward. It is not gregarious at any period of its residence with us, although in favourable situations, such as extensive meadows, many individuals may sometimes be found not far from each other. Its food consists of worms, testaceous mollusca, and insects, especially lepidoptera.

Soon after its arrival, it begins to form its nest, which is composed of a few straws, laid in a slight hollow, among corn, or herbage of any kind. The eggs, which are of an elongated oval form, and of a light or cream-colour, pale greyish-yellow, patched, spotted, and dotted with umber or brownish-red and light purplish blue or grey, are generally about ten, or from eight to twelve. In colour they bear a remarkable resemblance to those of the Missel Thrush. Their average length is two inches and one-twelfth; their greatest breadth an inch and five-twelfths. The young are at first covered with long hair-like down of a blackish colour, and leave the nest immediately after they burst the shell, to follow their mother among the grass or corn. When only a few days old, they run with amazing celerity, and scatter about, so that when one falls in with a flock, it is very difficult to catch more than one or two of them. On such an occasion, I have seen the old bird come up and run about in great distress.

Towards the middle of July, the Crake ceases to utter its cry, and one might suppose that it then leaves the country; but the period of its departure is protracted to the beginning of September. I have seen young birds in the end of that month, and instances of their having been shot in winter have occurred in various parts of the country.

The flesh of this bird is white, and affords delicate eating; but this sort of game is not easily obtained in the more highly cultivated tracts. In the Hebrides and West Highlands, however, few birds are more common, insomuch that there is hardly a patch of yellow iris or meadow-sweet, of the nettle, dock, or other tall weed, in which a Crake or two may not be found. Its cry may be so successfully imitated by drawing an edged stick along the teeth of a comb, or a thin piece of bone along another which has been notched by a saw, that by this artifice the bird will sometimes be induced to come up. Pennant and Montagu state that on its first arrival it is very lean, but before its departure becomes excessively fat. I have never, however, seen any great difference in this respect, birds obtained early in the season being in as good condition as afterwards.

The young, when fully fledged, differ from the old birds chiefly in wanting the bluish-grey markings on the head and neck. Individuals are often seen so late as the end of September, and a very few instances of their having been shot in winter have occurred.

#### THE PARROT GROSEBEAK.

HAVING in our possession specimens of this very rare bird, which has not yet been minutely described, we have thought it may prove interesting to our ornithological readers to present an account of it. The genus *Psittirostra* is composed of a single species, about the size of *Loxia curvirostra*, which it resembles in form and proportions, differing, however, in the bill, which approximates more to that of *Corythus Enucleator*. It is precisely intermediate between the genera *Loxia* and *Corythus*.

The bill is short, and very robust; the upper mandible has its dorsal line curved from the base into the fourth of a circle, the ridge narrow, the nasal sinus short and rounded, the sides convex and much declined, the edges sharp, overlapping, inclinate at the base, decurved, destitute of notch, the tip descending much beyond that of the lower mandible, trigonal, and acute; the lower mandible with the angle rather short and rounded, the dorsal line ascending and very convex, the sides of the crura erect, towards the end convex, the edges sharp and somewhat inclinate, the tip broad and rounded, but with a narrowed slightly ascending point.

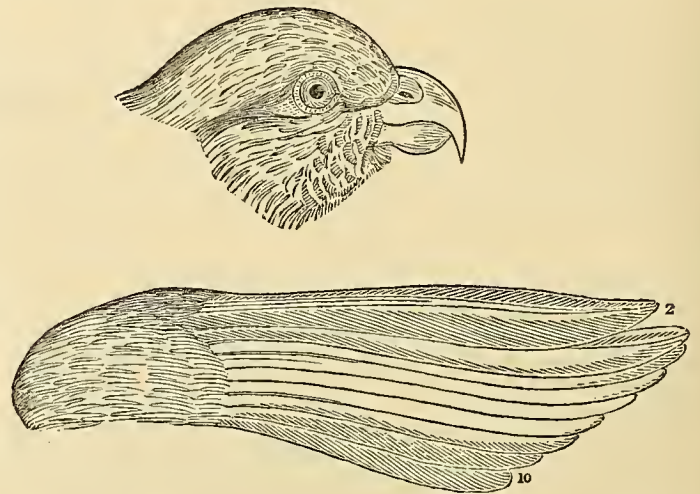

The nostrils are basal, small, half closed by a horny operculum, and partially concealed by short feathers. Aperture of eyes of moderate size; eyelids feathered. Aperture of ear rather large, and roundish.

The head is large, and roundish-ovate; the neck short; the body moderately stout. The feet are rather short, and of moderate strength; the tarsus short, compressed, with seven scutella in front, and two lateral plates meeting behind so as to form a sharp edge; toes four, moderate, compressed; the first stout, the lateral about equal,

the third much longer; the third and fourth united at the base; claws rather large, arched, much compressed, very acute, laterally grooved.

Plumage soft and blended; the feathers ovate and rounded; those on the fore part of the head very short. Wings of moderate length, broad, somewhat rounded; primary quills nine, the first being obsolete, the second longer than the sixth, the third longest, but scarcely exceeding the fourth, the fifth considerably shorter; secondary quills ten, broad and rounded, the inner short. Tail rather short, emarginate, of twelve moderately firm, obliquely rounded feathers.

This genus differs from *Corythus* in having the bill larger and higher, with the upper mandible more elongated, and the lower more convex and rounded; from *Loxia* in not having the tips compressed and laterally divaricate. It was instituted by Temminck, from *Loxia psittacea* of Gmelin and Latham, and is appropriately named, the bill having a great resemblance to that of a Parrot.

#### *Psittirostra psittacea*. Parrot Parrotbill.

Male.—The bill and feet are light brown. The head and neck yellow; the upper parts olive-green, tinged with grey; the wings and tail blackish-brown; the first row of small coverts, and the secondary coverts, tipped with whitish, the quills and tail-feathers margined with light greenish-grey. The throat is greyish-white, the sides of the neck and body light brownish-grey, the middle of the breast and abdomen yellow; the lower wing-coverts and tail-coverts white.

Length to end of tail 7 inches; bill along the ridge  $7\frac{1}{2}$  lines, along the edge of lower mandible  $7\frac{1}{2}$  lines; wing from cubitus  $3\frac{3}{4}$  inches; tail  $2\frac{1}{4}$ ; tarsus  $10\frac{1}{2}$  lines; hind toe  $4\frac{1}{2}$  lines, its claw 5 lines; middle toe 8 lines, its claw 4 lines.

Female.—The bill and feet are as in the male; all the upper parts are olive-green tinged with grey; the throat whitish; the cheeks, sides of the neck and body, light grey; the other parts as in the male. The size is somewhat smaller.

M. Temminck having stated that the first quill is wanting, Mr Swainson, not having a specimen, remarks that this requires explanation. The Parrotbill is not singular in this respect, for all those passerine birds of which the outer quill is as long as the next or nearly so, are equally destitute of the first quill, these species having only nine primaries. I am not aware of this fact having hitherto been observed.

#### GEOLOGY.

LAKE OF ARENDSEE.—Near Arendsee, in the circle of Magdeburg, there is a remarkable lake of the considerable extent of about a German square mile, or about eighteen English square miles. It has been formed in a flat country, within the historical times, probably by the superficial strata sinking into an immense cavern excavated by subterranean currents of water. According to Aimoinus, this event appears to have taken place about a thousand years ago. The lake was considered as unfathomable, and within the memory of man it never had been frozen, the great depth of its water preventing the latter from taking a sufficiently low temperature through that severity and duration of frost which the winters of Northern Germany commonly present. Last winter, however, this rare phenomenon did occur, long after the greatest rivers had been covered with a solid crust; and after having spent its free caloric in large rasses of vapour, which for many days hovered over its surface and banks, the morning of the 31st of January exhibited it all covered with one smooth and polished plate of ice. The thickness of the latter was nine inches, and in a few places not above four or five inches. This was a convenient opportunity for taking accurate measurements of the depth of the lake, and it was then first ascertained that the opinion of its being unfathomable is unfounded. The general depth does not exceed 157 feet, only near the ruins of an old convent, at a distance of 400 steps from the bank, it was found as deep as 161 feet, which may be taken for its greatest depth. Beginning from the south bank, at a place where a large piece of ground sunk in 1685, the depth increased within distances of 400 steps each, at the following rate:—42½ feet, 87, 116, 137, 157. Among the many remarkable phenomena presented by this lake, the one that it throws out *yellow amber* is, perhaps, the most striking. This substance is only found on its eastern bank, and the more violently the west winds blow, the more yellow amber is there collected. The size of the fragments does not, however, generally exceed that of a French bean. As the whole tract of Magdeburg to the Baltic Sea is pretty uniform, we may conclude that in one of its strata it contains an almost continuous bed of yellow amber, which on the shores of the Baltic is exposed in a great part of its length, whereas near Arendsee it has been accidentally opened by the sinking of the ground. Many petrifications of wood and

other substances are likewise thrown out. Innumerable fish, as Eels, Pike, Tench, Perch, &c., inhabit its waters. The fishery is, however, comparatively little productive, on account of the great depth of the lake. Pikes of the enormous weight of 50lb., and Eels of 15lb., are not unfrequently caught.

#### DEER HUNTING IN THE TEXAS.

We have been favoured by a friend, who has recently visited Texas, with the following notice respecting one of its principal islands, and the habits of a species of Deer found there.

It has seldom happened to me to see a more interesting island than that named Galveston, which lies in the inner curvature of the Bay of Mexico. It is flat, somewhat sandy, in places cut up by numerous diverging bayous, between which are marshes of a brackish nature. Its sandy shores produce perhaps the best Oysters in the world, while around it, in the deep waters of Galveston Bay, are found numerous species of fish, not less pleasing to the palate of the epicure, than interesting to the curious ichthyologist. There too are Prawns of finer quality than any found along the Atlantic Coast of North America.

This island, besides being celebrated for Oysters, Prawns, and fine fish, in which respect, however, it does not differ from many others in the same country, is still more so on account of its having been the great place of rendezvous of the ruffians commanded by the famous Pirate Lafitte, a man who, twenty years ago, was looked upon with terror even by the superior authorities of the countries around. There was a time, indeed, when this reprobate had entire possession of Galveston Island, on which he erected his fortresses, raised his numerous huts, and could conceal within the harbour the whole of his curious fleet in the most perfect state of security, for as I can well assure you, the entrance of Galveston Harbour or Bay is most intricate and difficult of access. However, this atrocious villain was at last secured, and, I believe, suffered the punishment which his vile deeds so much merited.

If ever there was a spot where game might be found in abundance, it is Galveston Island. There the common American Deer, *Cervus virginianus*, or perhaps a species not yet portrayed or described, exists, not as Deer are seen in the parks of England, by hundreds, but by thousands. Leave your grassy couch at dawn, see that your rifle is in good order, that your pouch contains fifty bullets, and your horn a sufficient quantity of powder, be a good marksman, calm, steady, and perfectly adept in the work of destruction, and then tell me, when you return towards the setting of the sun, if you have not procured more venison than would suffice for a hundred of the most hungry and voracious flesh-eaters.

Methinks now I am on that loved spot, that I have risen a little before the appearance of the orb of day, that, clothed like a true hunter, I stand in the midst of my companions, who are similarly equipped. We are landed from our vessel at the distance of some eight or ten miles from the Town of Galveston, say, if you choose, at the "Eagle's Nest." Then here we all are, quite ready for a frolic. Our guns are in trim, our sailors, as sailors generally are, gay and sprightly, and towards you cover of small bushes we proceed with some caution. The shooters take their stations at pretty regular distances, under the lee of the thicket, and at such spots as we conceive to be those at which the game will probably issue. Our sailors, now well trained, for we have no dogs, enter the bush windward, and now their loud shrieks announce to us their willingness to perform their duty faithfully. "Halloo! Halloo! Halloo!" these sounds come pleasantly on our ears, however much terror they may inspire in the timid deer. Up starts,—not a Stag, but a Galveston Owl. "Quite a stranger!" quoth the sportsman in advance; but, as it proves somewhat of a curiosity, in the way of feathers and flesh, no sooner has it come within range of my "Long Tom," than aim I take, pull the slick trigger, and down to the earth falls the bird. Think not that such an incident tends to mar the main sport. No; Deer, such at least as those of Galveston Island, on such occasions shrink into their form, lay down their ears, and perhaps, for aught I know, indulge in the thought of their being quite safe. But hark!—"Watch! Watch! Watch!" Ah! how delightful the sound! The Deer is a-coming; the guns are all instantly cocked, and every shooter has crouched close down. There!—the antlered, smooth, and sleek-skinned Buck emerges, bounding violently at first, but now advancing timorously, for you see it crouching almost to the ground as it enters the plain; its tail nevertheless goes this way and that way, and again and again waves, like the flag of some party willing to come to a parley. But, alas for thee, thou forlorn Buck! I have heard the report of a gun. I see the beautiful animal stagger; his tongue is out, his eye becomes dim. There he lies at our mercy extended on the ground! The shouts of the sailors are repeated. All the Deer in the thicket are now truly alarmed. Out and in again bound some of the most timorous; now they are hard pressed by the tars, and many are forced to take to the open plain; but before they have sped fifty yards toward another cover, the agonised bleatings of several are heard amidst the noise of the shots.

"Enough for a week's food," says one. "Agreed," say all. And now the sailors are called. "Bring your oars, brave fellows;" these most useful implements have been used in beating the bushes. The Deer are now fastened so as to swing by their four feet, three or perhaps four on the same oar. Two sturdy fellows shoulder the bending sticks; others follow, laden in the same manner; and toward the sandy shore we return.

Did you ever see a Deer skinned in a trice, and cooked in sixty minutes? I have. It is done thus. Imagine first that the game and all have reached the inner margin of the bay, and that the venison "in the skin" lies on the ground. Our encampment is prepared, by which I mean you to understand, that four oars have been put up, and the sail of our craft attached to them, so as to keep the sun's rays from parching our eyes. A fire has been kindled, to chase away the myriads of mosquitoes, now fully as hungry as ourselves. The Deer are dragged to the water, and there skinned *sans ceremonie*; that is to say, by cutting and tearing off their hide in a manner which an Edinburgh "flesher" would hold most unbutcherly. Then the carcase is washed in the brine, partially salted, if you please to call it so, and hung in front of the augmented blaze. There let it roast a while. "Turn it again, John." "Aye, aye, sir;" and so it fizzes and drips. Each hunter, who, in the meantime, has collected along the shore his

hundred or so of Oysters, now watches them as they gasp in the agonies of death, hissing and opening their shells wider and wider, in the midst of the burning embers. "Done, sir, quite done!" "Thank you, John." Now, every man, his own carver, cuts and slashes according to his own taste; the juicy meat allays our hunger, the Oysters follow as a dessert; and should we apprehend an apoplectic attack, we guard against it by washing all down with a glass of grog.

My opinion, that the Deer which are so abundant on Galveston Island, as well as in all the maritime parts of the Texas, is different from the Virginian Deer, is founded on the following facts. The latter, which is common and well-known, not only in Virginia, but throughout the whole of our Atlantic states, from Maine to South Carolina, is a much larger animal. It differs also materially in its general colour at all seasons, being more red in summer, and of a darker grey in winter. Its average weight, when in good condition, may be estimated at about a hundred and fifty pounds. Its antlers are much larger, more bent forwards, and considerably less palmated than those of the Texian or Floridan species. In its movements, the Virginian Deer, though extremely swift and graceful, differs from the Deer of Galveston Island, in exhibiting a certain *je-ne-sçai-quoi* in its bound, which resembles in this respect that of the Roe-Buck of Scotland and of Europe generally. The Galveston Deer is also wont to congregate in immense numbers at all times, so much so, indeed, that I and my companions have passed through spaces on Galveston Island where their tracts were as thick as those in a sheep-fold. In spring and summer, the general colour of the pile is in some individuals almost white, and in winter red, instead of dark-grey or brown. Whether this may be owing to the influence of climate or not I cannot positively say, although I think not. At Galveston, their principal enemy, besides Man, is a small wolf, probably of a species yet unknown to Naturalists, which hunts in packs, and has been known to chase the Deer even into the town.

#### THE HYDRA, OR FRESH-WATER POLYPUS.

LEEUWENHOEK discovered the Hydra in 1703, and the uncommon way its young are produced; and an anonymous correspondent of the Royal Society made the same discovery in England about the same time, but it excited no particular notice until Trembley made known its wonderful properties, about the year 1744. These were so contrary to all former experience, and so repugnant to every established notion of animal life, that the scientific world were amazed; and while the more cautious among Naturalists set themselves to verify what it was difficult to believe, there were many who looked upon the alleged facts as impossible fancies. The discoveries of Trembley were, however, speedily confirmed; and we are now so familiar with the outlines of the history of the Fresh-water Polype, and its marvellous reproductive powers, that we can scarcely appreciate the vividness of the sensation felt when it was all novel and strange; when the leading men of our learned societies were daily experimenting upon these poor worms, and transmitting them to one another from distant countries, by careful posts, and as most precious gifts, and when even ambassadors interested themselves in sending early intelligence of the engrossing theme to their respective courts.

The Hydræ are found in fresh, and, perhaps, also in salt waters, but the former species only have been examined with care, and are the objects of the following remarks. They prefer slowly running or almost still water, and fasten to the leaves and stalks of submerged plants by their base, which seems to act as a sucker. The body is exceedingly contractile, and hence liable to many changes of form. When contracted it is like a tubercle, a minute top, or button, and when extended it becomes a narrow cylinder, being ten or twelve times longer at one time than at another, the tentacula suffering changes in their length and diameter equal to those of the body. "It can lengthen out or shorten its arms, without extending or contracting its body; and can do the same by the body, without altering the length of its arms; both, however, are usually moved together, at the same time and in the same direction." The whole creature is apparently homogeneous, composed of minute pellucid grains cohering by means of a transparent jelly, for, even with a high magnifier, no defined organization of vessels and fibres can be detected. On the point opposite the base, and in the centre of the tentacula, we observe an aperture or mouth which leads into a larger cavity, excavated as it were in the midst of the jelly, and from which a narrow canal is continued down to the sucker. When contracted, and also when fully extended, the body appears smooth and even, but "in its middle degree of extension," the sides seem to be minutely crenulated, an effect probably of a wrinkling of the surface, although from this appearance Baker has concluded that the Hydra is annulose, or made up of a number of rings capable of being folded together or evolved, and hence in some measure its extraordinary ability of extending and contracting its parts. That this view of the Hydra's structure is erroneous, Trembley has proved; and the explanation it afforded of the animal's contractility was obviously unsatisfactory, for it was never pretended that such an anatomy could be detected in the tentacula, which, however, are equally or more contractile. These organs encircle the mouth, and radiate in a star-like fashion, but they seem to originate a little under the lip, for the mouth is often protruded like a kind of small snout; they are cylindrical, linear, or very slightly tapered, hollow, and roughened, at short and regular intervals, with whorls of tubercles which, under the microscope, form a very beautiful and interesting object, and I have thought when viewing them, that every little tubercle might be a cup or sucker similar to those which garnish the arms of the Cuttle-fish. Trembley has shown us that this is a deception, and that there is really no exactness in the comparison. The tentacula are amazingly extensible, from a line or less to one, or, as in *Hydra fusca*, to more than eight inches; and "another extraordinary circumstance is, that a Polype can extend an arm in any part of its whole length, without doing so throughout, and can swell or lessen its diameter, either at the root, at the extremity, in the middle, or where it pleases; which occasions a great variety of appearances, making it sometimes terminate with a sharp point, and at other times blunt, knobbed, and thickest at the end, with the figure of a bobbin. We naturally inquire how this wonderful extension is made,—by what power a part without muscularity is drawn out until it exceeds by twenty or even by forty times the original length? The dissections of Trembley have proved beyond all doubt that the body is a hollow cylinder or bowel, and that the tentacula are tubular, and have a free communication with its

cavity; and in this structure, combined with the loose granular composition of the animal, we find an answer to the question. Water flows, let us say by suction, into the stomach, through the oral aperture, whence it is forced by the *vis a tergo*, or drawn by capillary attraction, into the canals of the tentacula, and its current outwards is sufficient to push before it the soft yielding material of which they are composed, until at last the resistance of the living parts suffices to arrest the tiny flood, or the tube has become too fine in its bore for the admission of water attenuated to its smallest possible stream,—how inconceivably slender may indeed be imagined, but there is no thread fine enough to equal it, seeing that the tentacula of *Hydra fusca* in tension can be compared to nothing grosser than the scarce visible filament of the gossamer's web."

The Hydra, though usually found attached, can nevertheless move from place to place, which it does either by gliding with imperceptible slowness on the base, or by stretching out the body and tentacula to the utmost, fixing the latter, and then contracting the body towards the point of fixture, loosening at the same time its hold with the base; and by reversing these actions it can retrograde. Its ordinary position seems to be pendant or nearly horizontal, hanging from some floating weed or leaf, or stretching from its sides. In a glass of water the creature will crawl up the sides of the vessel to the surface, and hang from it, sometimes with the base, and sometimes with the tentacula, downwards; and again it will lay itself along horizontally. Its locomotion is always very slow, and the disposition of the zoophyte is evidently sedentary; but the contractions and mutations of the body itself are sufficiently vivacious. While in seizing and mastering its prey it is surprisingly nimble; seizing a worm, to use the comparison of Baker, "with as much eagerness as a cat catches a mouse." It is dull, and does not expand freely, in the dark, but enjoys light, and hence undoubtedly the reason why we generally find the Hydra near the surface and in shallow water.

The Hydræ are very voracious, feeding only on living animals, but when necessary they can sustain a fast of many weeks without other loss than what a paler colour may indicate. Small larvæ, worms, and entomostracous insects, seem to be the favourite food, and to entrap these, they expand the tentacula to the utmost, and spread them in every direction, moving them gently in the water to increase their chances, and when a worm, &c., touches any part of them, it is immediately seized, carried to the mouth by these flexible and contractile organs, and forced into the stomach. "Tis a fine entertainment," says Baker, "to behold the dexterity of a Polype in the mastering its prey, and observe with what art it evades and overcomes the superior strength or agility thereof. Many times, by way of experiment, I have put a large worm to the very extremity of a single arm, which has instantly fastened on it with its little invisible clasps. Then it has afforded me inexpressible pleasure to see the Polype poising and balancing the worm with no less seeming caution and judgment than a skilful angler shows when he perceives a heavy fish at the end of a single hair-line, and fears it should break away. Contracting the arm that holds it, by very slow degrees, he brings it within the reach of his other arms, which eagerly clasping round it, and the danger of losing it being over, all the former caution and gentleness is laid aside, and it is pulled to the Polype's mouth with a surprising violence." Sometimes it happens that two Polypes will seize upon the same worm, when a struggle for the prey ensues, in which the strongest gains of course the victory; or each Polype begins quietly to swallow his portion, and continues to gulp down his half until the mouths of the pair near, and come at last into actual contact. The rest which now ensues appears to prove that they are sensible of their outward position, from which they are frequently liberated by the opportune break of the worm, when each obtains his share; but should the prey prove too tough, woe to the unready! The more resolute dilates the mouth to the requisite extent, and deliberately swallows his opponent, sometimes partially, so as, however, to compel the discharge of the bait, while at other times, the entire Polype is engulfed! But a Polype is no fitting food for a Polype, and his capacity of endurance saves him from this living tomb, for after a time, when the worm is sucked out of him, the sufferer is disorged with no other loss than his dinner. This fact is the more remarkable when it is contrasted with the fate which awaits the worms on which they feed. No sooner are these laid hold upon than they evince every symptom of painful suffering, but their violent contortions are momentary, and a certain death suddenly follows their capture. How this effect is produced is mere matter of conjecture. Worms, in ordinary circumstances, are most tenacious of life even under severe wounds, and hence one is inclined to suppose that there must be something eminently poisonous in the Hydra's grasp, as it is impossible to believe, with Baker, that this soft toothless creature can bite and inject a venom into the wound it gives. "I have sometimes," says Baker, "forced a worm from a Polype the instant it has been bitten, (at the expense of breaking off the Polype's arms,) and have always observed it to die very soon afterwards, without one single instance of recovery." To the Entomostraca, however, its touch is not equally fatal, for I have repeatedly seen Cyprides and Daphniæ entangled in the tentacula, and arrested for some considerable time, escape even from the very lips of the mouth, and swim about afterwards unharmed; perhaps their shell may protect them from the poisonous excretion. The grosser parts of the food, after some hours' digestion, are again ejected by the mouth; but, as already mentioned, the stomach is furnished with what, in one sense, may be called an intestine, to which, according to Trembley and Baker, there is an outlet in the centre of the base, and the latter asserts that he has, "several times, seen the dung of the Polype, in little round pellets, discharged at this outlet or anus."—*Dr Johnston's British Zoophytes.*

#### MISCELLANEOUS.

**BLINDWORM.**—Mr Ryland has the following notice respecting this animal in the last number of the Naturalist. "I am led to suppose from Mr Salmon's remarks, that a prejudice against these inoffensive reptiles exists in his neighbourhood, similar to the belief prevalent in Lancashire. The notion of the lower orders here respecting this Snake is curious, and will be best shown by a conversation I once had with a turf-cutter:—'Well, my man, you have other kinds of Snakes here (Woolston Moss)

besides the Viper?' 'Aye, sir, we sometimes light on Blindworms and Edders.' 'Indeed!' 'Aye: but the Blindworms are the worst, and desperate hard to kill.' 'Who, if you were to cut one into half a dozen pieces, they 'ud join together again!' A medical friend informs me that a belief in the power of separated parts of this Snake reuniting is prevalent amongst the lower classes in Scotland. How can it have originated?"

In Scotland, the "lower classes" imagine the Blindworm to be as poisonous as the Viper or Adder, and geographically do not distinguish the one species from the other. Knowing that Serpents have often bitten (or, as they think, stung) persons, as well as cattle, and as they are thus dangerous, they naturally on falling in with one kill it, and to make sure work, usually cut it into pieces with a knife, it being a prevalent belief among them, that a Serpent, if merely bruised, will or may come alive again. Their abhorrence of the animal, and their apprehension of the possibility of reviving, even leads them to separate the pieces to a distance; but the belief of a reunion of the parts, if left in proximity, is merely the result of fear carried to excess. The Blindworm is a very harmless creature, but, like many other innocuous Snakes, participates in the bad character of those which are venomous. I knew a gentleman in Harris, who, when a child, carried home a great number of them in his lap, to the great terror of his friends, as well as his own, after he came to be informed of their nature. A very slight blow with a stick is sufficient to disrupt this animal, and individuals are often seen with part of the tail wanting, in which respect it resembles the Lizards.

**MAGNIFICENT AURORA BOREALIS.**—Happening to be at Loch Achray on Sunday the 16th October, I was gratified by the sight of a more splendid display of the Aurora than I have ever witnessed. About nine o'clock, having gone out with a friend to enjoy the pure air, and the stillness of a most lovely night, I observed an arch extending from N.E. to S.W., its highest part being about 20° below the zenith. At nine, the arch broke up, and numberless streams of light, issuing from the horizon, shot upwards, and converged in a point a few degrees to the east of the zenith. At one time these streams rose from every part of the horizon, being, however, broader and brighter in some places. From behind Benvenue, in particular, rose a vast sheet of yellowish light, which changed into dim red and purple, and showed the outlines of the mountain as distinctly as they could have been seen on the clearest day, while its black mass, in which no feature could be distinguished, added greatly to the sublimity of the phenomenon. To the eastward, in the direction of the arch, which had disappeared, sheets of light shot across the sky, some apparently proceeding from the N.W., others meeting them from the S.E. This continued some time; the sheets then broadened, and finally were converted into thin streamers, shooting towards the zenith. The magnificence of the spectacle then gradually diminished, and the Aurora assumed a more ordinary appearance. Next day, the weather was fine, as also on Tuesday; but on Wednesday it rained at Glasgow from nine in the morning until late at night. This I mention, because it has been alleged that the more brilliant the Aurora, the sooner it is succeeded by rain or a tempest. In this case, after the most gorgeous exhibition imaginable, no rain fell for sixty hours.

**MUSK DEER.**—The Musk Deer, *Moschus moschiferus*, is found in Thibet, Western Tartary, and the adjacent provinces of China. It is a species of Antelope, about the size of a moderate Hog, with a small head, a round hind quarter, delicate limbs, and without a tail. From the upper jaw two long curved tusks project downwards. Long bristles, not unlike the quills of a Porcupine, cover the body. The musk is a secretion, formed in a little bag resembling a wen, near the navel, which is found only upon the males. Its flesh is eatable. In Thibet it is considered the property of the state, and can be hunted only by permission of government. It delights in the coldest regions of the mountains, and bids defiance to the pursuit of man. In taking the musk from the animal, when still alive, it is necessary to bind up the bag instantly, for otherwise it is absorbed in the flesh, and retains no smell.—*Gutzlaff's China.*

**CHINESE CORMORANTS AND QUAILS.**—The Fishing Cormorant, which is trained to dive and catch the unwary fish, proves very useful. To prevent it from swallowing its prey, an iron ring is put around its neck, so that it is obliged to deliver its quota to its owner. It is as well trained as the Falcon in Europe, and seldom fails to return to its master, who rewards its fidelity by feeding it with the offals of the fish it has caught.—Quails, which are to be met with in great quantities in the north, are greatly valued by the Chinese, on account of their fighting qualities. They carry them about in a bag, which hangs from their girdle, treat them with great care, and blow occasionally a reed, to rouse their fierceness. When the bird is duly washed, which is done very carefully, they put him under a sieve with his antagonist, and strew a little millet on the ground, so as to stimulate the envy of the two Quails. They very soon commence a fight, and the owner of the victor wins the prize. Good fighting Quails sell at an enormous price, and are much in request.—*Ibidem.*

**POLYGONUM TINCTORIUM.**—This plant is now cultivated with success in the experimental gardens of M. Vilmorin, near Paris. Attention was called to it by M. Jaume St Hilaire, in consequence of its being used in China for dyeing a deep blue. M. Chevreul has examined it, and ascertained that it owes its properties to the true Indigotine, of which it yields a greater proportion than the *Isatis tinctoria*.—*Athenæum.*

**PROGNOSTICS OF WEATHER.**—If the sound of the rapid or cataract descend with the stream, it foretells such rainy weather to be at hand as will swell the brook or river to its margin; whereas, if the sound ascend along the stream, and die away in the distance, it is an omen of the continuance of dry weather. If, during a storm of frost and snow in winter, the Ptarmigan, the hardiest among the feathered tribes of the Grampians, be repeatedly heard in the face of the mountain, an additional fall of snow may soon be expected.—*Rev. Robert Macdonald, in Stat. Account.*

### ZOOLOGY.

#### DESCRIPTION OF THE PLATE.—THE HOWLERS.

THE Monkeys of America are distinguished from those of the Old Continent by having four additional grinders, and by being destitute of cheek-pouches as well as callosities. Some of them have an elongated prehensile tail, and of these the first group is that composed of the *Howlers*, constituting the genus *Mycetes* of Illiger. They are so named on account of the frightful noises which they are enabled, by a peculiar inflation of the hyoid bone and larynx, to emit.

Fig. 1. THE RED OR ROYAL HOWLER (*Mycetes Seniculus*), which is of the size of a Fox, and somewhat similar in colour, inhabits the forests of Guiana.

Fig. 2. THE URSINE HOWLER (*M. ursinus*) is very similar to the last, and occurs in the same country.

Fig. 3. THE GOLDEN-TAILED HOWLER (*M. chrysurus*) is also similar in size and colour, but with the upper part of the body and the terminal portion of the tail bright yellow.

Fig. 4. THE BLACK HOWLER (*M. niger*), of a blackish colour, paler beneath, inhabits Brazil.

Fig. 5. The female is of a yellowish-grey tint.

Fig. 6. Represents a variety of the same species of a yellow colour.

#### DESCRIPTION OF THE PLATE.—THE SHRIKES.

THE Shrikes are in a manner intermediate between the Thrushes and the Falcons, resembling the former in their general appearance and in the form of their feet, while their notched and curved upper mandible indicates their affinity to the latter, which they also imitate in their predatory habits, although they also feed on insects and fruits. Most of the species represented in the plate are such as may be called typical.

Fig. 1. THE CAPE SHRIKE (*Lanius capensis*), variegated with white and black, inhabits southern Africa.

Fig. 2. THE SHARP-TAILED SHRIKE (*L. pyrronotus*), with an elongated and graduated tail, and variegated with ash-grey, light red, white and brownish-black, is from the same country.

Fig. 3. THE RED-BACKED SHRIKE (*L. Collurio*) is pretty similar to the last, but smaller and with a shorter tail. It is a regular summer visitant in most parts of Europe, and is not uncommon in some portions of England, chiefly frequenting copses and commons.

Fig. 4. THE BLUE SHRIKE (*L. bicolor*) has the upper parts bright blue, the lower white.

Fig. 5. THE GREAT CINEREOUS SHRIKE (*L. Excubitor*) is common to Europe and North America, although some ornithologists have alleged that the Shrike of the latter country differs from ours. It is a rare visitant in Britain, coming late in autumn and departing in spring.

Fig. 6. THE COLLARED SHRIKE (*L. collaris*), which inhabits Africa, is described by Vaillant as transfixing its prey on a thorn, which is a habit common to many other species.

Fig. 7. THE RUFOUS SHRIKE (*L. rufus*) has been seen in England, where, however, it is extremely rare, although it occurs in summer in many parts of the continent.

#### BRITISH BIRDS.—THE CURLEW.

WITH the history of the Curlew might be connected, and not inappropriately, much of the wild scenery of our land, for, during the breeding season, its retreats are the barren heath and the mountain side. Let it be now the middle of October. We are traversing the mud flat that extends from the village of Cramond to near Queensferry, on the southern shore of the Frith of Forth. Many Gulls are scattered over the sands, small flocks of Ducks are swimming in the river, straggling bands of Terns hover and scream along the edge of the water, here and there may be seen a solitary Gannet gliding past, and far out at sea are some dusky birds, which may be Cormorants or Red-throated Divers. On that shoal is a vast assemblage of small birds, probably Duolins; farther on are some black and white Waders, which we may conjecture to be Oyster-catchers; and here, scattered over the miry flat, are very many grey-backed, long-legged, long-necked, and long-billed stragglers, the very birds of which we are in search. They observe us, one utters a loud shrill cry, to which an-
