The navigable waters of California affected by hydraulic mining consist of the bays of Suisun, San Pablo, and San Francisco, forming the great estuary of California, and of the rivers, the Sacramento, the San Joaquin, and the Feather. The Sacramento River rises in the north and flows in a southerly direction through the great valley, flanked on the east by the Sierra Nevada, and on the west by the coast range. The Feather is a tributary of the Sacramento. The San Joaquin has its source in the south and flows in a northwesterly direction through the valley, uniting with the Sacramento at the upper or eastern end of Suisun Bay. The strait of Carquinez connects Suisun Bay with San Pablo Bay which opens into San Francisco Bay, and, taken as a whole, these separate bays and rivers afford a continuous channel, connecting with the Pacific Ocean through the Golden Gate. The auriferous drift deposits which are worked by the hydraulic process lie on the western slope of the Sierra, in a belt 40 or 50 miles wide, extending from the plains or edge of the valley to altitudes of 4,000 or 5,000 feet. The length of this deposit, measured in a northwesterly direction, parallel to the crest of the Sierra, is about 150 miles, and extends from the Merced river on the south to Chico Creek in the north, with some exceptionally placed deposits lying both north and south of these limits. It may be remarked that in addition there are, on the Klamath and Trinity, one of its branches, quite important places, which are now worked. The detritus is lodged in the rivers, which are neither navigable or tributaries of navigable rivers, so that this separate mining district is not thought to come within the limits of this investigation. The Klamath empties into the Pacific Ocean at a few miles south of the northern boundary of California. The tributaries of the San Joaquin, coming from the Sierra Nevada, and affected by mining, either past or present, are the Merced, the Tuolumne, the Stanislaus, the Calaveras, the Mokelumne, and the Cosumnes. Each of these rivers has small tributaries, which, for the sake of clearness, need not be mentioned by name, but which are to be understood as being included in the designation of the larger tributaries.

The Feather and American are the principal tributaries of the Sacramento, which drain the mining districts. The Feather is a large river draining 3,400 square miles, and includes as its tributaries the Yuba, with its three forks, and the Bear, which rivers are noted as the seat of the principal hydraulic mining operations of California. The Sacramento and San Joaquin rivers near their mouths flow through a delta of considerable extent, the surface of which is below the level of flood waters. The connecting channels surround a number of islands. The soil is extremely fertile, and great efforts have been made, thus far with limited success, to reclaim the land. Insecurity in foundations and the absence of a proper material for making levees, have been the chief difficulties in the way of complete reclamation. On the east side of the Sacramento, close to the river, between the American and Feather, is a basin the level of which is a number of feet below the banks of the main river. This basin is overflowed in every freshet. A similar and more extensive basin lies in the angle between the Sacramento and Feather rivers, extending from the Marysville Butte to the mouth of the Feather, a distance of about 30 miles. This basin is also overflowed at high stages of the river. Its great area and capacity for storage gives it an important influence in determining the flood flow of the river. These features are here mentioned that a future reference to them may be intelligible. Several small streams—the principal of which is Auburn Ravine—carrying mining detritus, and natural tributaries of the Sacramento river, do not reach it directly, but discharge into the basin between the American and Feather. The drainage from the Spring Valley Mine, on the waters of Butte Creek, enters into the Sutter Basin between the Sacramento and Feather rivers, and, therefore, does not reach the Sacramento directly. The lower portions of the Cosumnes, Mokelumne, and Calaveras, all tributaries of the San Joaquin, lie in the delta lands, which receive a part of the mining detritus of these streams, and to this extent relieve the San Joaquin from injury.

Ancient Drainage.—The existing drainage system of the auriferous gravel belt is geologically recent. Mining operations have unveiled an older system, lying higher and oblique to the existing drainage, obliterated during the Pliocene period, by deposits of sand, gravel, clay, and bowlders with gold intermingled. The ancient drainage lines are the loci of modern hydraulic mining operations. Subsequent to the destruction of the ancient channels the whole country was covered by a flow of lava and kindred substances, which yet remains in many places a complete bar to effective mining; when hydraulic mining is practicable the basalt has disappeared or is replaced by volcanic ashes. The existing rivers flow through the mountains in canyons cut down to depths varying from 1,000 to 2,500 feet below the ridges which bound them on either side. The portions of the old drainage lines which remain are on these ridges, and therefore are at considerable elevations above the present river beds. This feature is generally true of the northern portion of the auriferous belt, while in the southern portion of the levels the two systems do not present such marked differences. A considerable elevation above existing river beds is indispensable in hydraulic mining in order to give a good clearance of the tailings. This feature is presented most favorably in the mine on the Yuba, and it is one of the reasons for the great development of the hydraulic industry in that part of the country.

The ancient river beds are again distinguished from the modern by greater width and steeper slopes. In position they are generally oblique to the existing drainage system. So far as mere surface indications are concerned, the old system was completely obliterated. Occupying in the aggregate many square miles in area, the whole surface was filled to the rim rocks with gravel, and over these to a depth often of many hundred feet by a plain of eruptive material, extended from the summit of the Sierra to the valley. The capping of lava has since been lost in many places. In others it is thin, exposing the top surface of the gravel. Under these circumstances it has been impossible to trace out the old drainage system, and it is only by comparison of altitudes and directions of the small portions that have been uncovered by the miner, and tracings here and there of the rim rock, that any inferences can be drawn as to the courses of the ancient rivers. In consequence there are many opinions as to the directions of the drainage. The modern rivers cutting across the old drainage lines swept the gravel and gold down their own beds, and thus formed the bars which so richly repaid the labors of the early miners. Deposits of this kind, whether in the beds or on the banks, or in gulches at small elevations above the beds are workable without much aid from capital. Water can be secured by storage in reservoirs close at hand or be brought by short canals, the construction of which is practicable by the labors of the miners themselves. These river or placer deposits were worked out in a few years, and it was only as they were being exhausted that attention was directed to the higher and larger deposits in the old river beds.

The extent of these deposits is not known. A great part of them is hidden under the lava cap which covers the flanks of the Sierra with more or less continuity. Definite information exists only where the mines have been opened to a considerable extent. When this is the case, the depth of the gravel deposit has been found to be as much as six hundred feet. This is, however, an unusual depth. One hundred and fifty or two hundred feet depth is frequently found. While the deposit is known among the miners as gravel, it is not by any means all gravel, nor is the deposit homogeneous as a rule in any mine or in any district. The vertical section of a mine may show sand on top, with pipe clay, then gravel, first fine and afterwards coarse, generally white, often colored; and in the bottom a large proportion of bowlders, sometimes tons in weight. Stratification on planes either horizontal or inclined may be observed in some cases. The variety in the components and in their arrangement forbids, in a sketch of this kind, any other conclusion than the general one, that the material becomes coarser and heavier as you descend from the surface to the bed-rock. The accepted theory now is that these river beds were filled by detritus brought down by their own currents. If this be true it would follow that the lighter materials, the only ones transportable in the slight slopes of the river when nearly extinct, should be found on top. The different grades of materials are not, however, clearly segregated in their places of deposit. Sand is found everywhere in the vertical section, mixed in greater or less abundance with coarser material. It often happens that the components are found to be cemented, by iron-oxides and silica in solution, into conglomerates that need powder or stamp-mills to disintegrate them. Gold is generally found everywhere in the gravel, but not in equal proportions. The gravel on top is generally poor, and the best pay is near the bed-rock. In cases where the pay is concentrated in a streak four or six feet thick near the bed-rock, it may be secured by stopping out this stratum, leaving the upper mass undisturbed. This is drift mining. Generally, however, the pay is not concentrated, but diffused throughout the gravel in increasing proportion from the top to the bottom. The only way to get the gold in this general case is by the hydraulic process.

The Hydraulic Mining Industry.—The first engineering problem presented in an attempt to work deposits lying at high altitudes is to introduce a sufficient supply of water at an adequate height. The head of a canal fulfilling the necessary conditions must be placed on the river, where its bed is some hundreds of feet higher than the gravel to be worked. The canal must be built for many miles on the steep flanks of the ridges which extend from the main vertebra of the mountains toward the plains. When canals were built, it was found in many cases that the supplying rivers did not in the low stages afford an adequate amount of water. This deficiency was remedied by the construction of reservoirs still higher in the mountains, which retained in storage enough water collected in the season of abundance to supplement the supply during the period of inadequate river flow. In order to apply the water supply to hydraulic mining, a conveyance of detritus from the mines to the dumps has to be provided. This, in the general case, requires the construction of one or more tunnels in bed-rock, the upper end under the lowest point of the gravel to be worked, and the lower end opening if possible into a deep cañon, with room for holding the accumulations of one or more seasons. These sluice tunnels form one of the most expensive adjuncts to hydraulic mining. The longest and most costly single tunnel is that for the North Bloomfield mine, which is nearly eight thousand feet in length, its cost being $500,000. A permanent and sufficient water supply, a good bank of gravel, and a suitable outfall are the conditions for success. The extent and boldness of the engineering operations just referred to are calculated to excite surprise and admiration. Tables follow which give statistics as to the reservoirs, canals and tunnels in a part of the mining field.

Table of Reservoirs on the Yuba, Bear, Feather and American rivers, constructed for Mining purposes.

Name of Company.	*Capacity.*	*Authority.*
	Cubic feet.	
North Bloomfield	1,050,000,000	Hamilton Smith, jr.
Milton Company	650,000,000	Do.
Eureka Lake	1,130,000,000	Do.
South Yuba	1,800,000,000	Do.
Omega and Blue Point	300,000,000	Do.
Spring Valley	300,000,000	Do.
California	600,000,000	Do.
El Dorado	1,070,000,000	Do.
Other small reservoirs on the Feather, Yuba, and American rivers	700,000,000	Do.
Total storage	7,600,000,000	

Incomplete statistics of mining ditches in California, from Mint Report, 1881.

Name.	*Length.*	*Capacity.*	*Grade by feet.*	*Cost.*	*Dim'nsn's in ft.* *Top.*	*Btm.*	*Depth*
	Mls.	*In.*	*Per ml.*				
North Bloomfield, including reservoirs	157	3,200	12 to 16	$708,841	8⅓	5	3½
Milton, including reservoirs	80	3,000	12 to 25	391,579	6	4	3½
Eureka Lake and Yuba ditches	163	5,800	....	723,342	.	..	...
South Yuba ditches	123	7,000	8 to 13	....	6	..	4 to 5
Smartsville ditches	113	5,000	9	1,000,000	8	5	4
Spring Valley and Cherokee	52	2,000	....	....	5	..	3½
Hendricks	46¼	...	6 to 12	136,150	5	..	2
La Grange	20	2,700	7 to 8	500,000	9	6	4
Blue Tent	32	1,800	10	150,000	8	6	4

NOTE.—The length of Smartsville ditches is taken from reports on the mines by Professor Poupelly.

Hydraulic mining, as it is understood in California, is that process by which a natural bank is excavated by a jet of water and conveyed by the same water through the sluices to the dumps. Water does all the work; manual labor is needless in a perfect bank; when bowlders are found too large to pass through the sluice they are sometimes blasted into smaller pieces suitable for the sluices. Where the bank is cemented or contains masses of pipe clay it is shattered by charges of powder. The scale of blasting corresponds to the other features of this kind of mining, 30,000 or 40,000 pounds of powder being on occasions exploded to break up a bank. The method is similar to that used at Lime Point in 1868. In a certain sense all mining is hydraulic. Water is indispensable for the separation of gold in all the processes of mining. But before the introduction of existing appliances water was used for this purpose only. Now water under pressure excavates, water transports the detritus, and with the aid of quicksilver collects the gold. The very moderate amount of human labor required is the secret of the cheapness of this kind of mining. The hydraulic method dates from about 1855. The first efforts in using water under pressure were in rubber or canvass hose, with nozzles of an inch or less diameter. Now nozzles vary from 4 to 9 inches, and pressures are as high as 400 feet. An 8-inch nozzle at North Bloomfield discharges 185,000 cubic feet in an hour, the velocity being 150 feet per second.

This is the culuminating instance of this kind of force. There are, however, frequent instances of one-half or one-third of this hose power being applied. The excavating power of a force of this extent on a bank of gravel is enormous, and in general unless the gravel is very heavy or cemented is much in excess of the transporting power. The latter depends on the grade of the sluice, so that really the latter factor becomes in great part the measure of the quantity of gravel that can be handled, for it is not desirable to excavate more gravel than can be sluiced away. Grades of sluices vary from mine to mine. The topography generally determines the fall of sluices. It is desirable to have a grade of 4 or 5 per cent., very often the grade is necessarily much lower, and in some cases 8 or 9 per cent. The following table, taken from a paper entitled Hydraulic Mining in California, by Augustus J. Bowie, mining engineer, volume vi., Transactions of the American Institute of Mining Engineers, gives the grades of the tunnels of the principal mines on the Yuba River.

Name of mine or tunnel.	*Locality.*	*Length of tunnel.*	*Average grade of tunnel.*	*Reported cost.*
			ft. per 100	$40,000 500,000
Boston	Wolsey's Flat	1,600	7¼	Not complete
North Bloomfield	Humbug Canon	8,000	4½	140,000
Farrel	Columbia Hill	2,200	3½	62,000
English mine	Badger Hill	1,400	7	90,000
American	Below San Juan	3,900	6¼	
Manzanita	Sweetland	1,740	4⅛	165,000
Sweetland Creek	...do.	2,200	4⅔	
Bed-Rock	Below Sweetland	2,600	5¼	
French Corral	French Corral	3,500	4⅔	
Babb	Timbuctoo	1,200	3.80	
Pactolus	do.	1,700	4.16	
Rose's Bar	do.	1,600	4.16	
Blue Gravel	Succor Flat	1,100	4.50	
Pittsburg	do.	900	4.16	
Blue Point	do.	2,250	4.16	
Enterprise	do.	1,200	4.16	
Deer Creek	Mooney's Flat	2,200	3.40	

If the inclination of the sluice be increased, the quantity of material carried off by a given amount of water will increase more rapidly. This fact is well understood; the law has not yet been fully developed. Sometimes it is claimed that the quantity worked will vary with the square of the inclination, that is, if the inclination be doubled the quantity worked will be four-fold. The quantity which an inch of water will handle is its duty. The duty depends on the kind of material. In light gravel, 10 or more yards may be moved to an inch of water taken to be 2,250 cubic feet. In the heavy material of the bed-rock, the same water and grades may not move one-eighth or one-tenth of the former volume. The differences in material, grades, and other circumstances give for each mine a particular duty and thus far have prevented the deduction of the law of change in quantities moved, due to changes in inclination. In particular instances water in sluices of an average grade, the material being of moderate quality, carried 10 or 11 per cent. of gravel in weight otherwise expressed, 2,250 cubic feet of water carried 14,000 pounds of gravel, which in volume is about 4 cubic yards. It may be remarked that when the material is heavy it is carried on the bottom of the sluice, and as a rule only the slightest material is in suspension. So the duty varies in the same mine from the top to the bottom, and from mine to mine. A mean duty adopted by the State engineer is given with the next table, which is assumed as the basis for this report. The quantities of water used in 1880 in the Sacramento Basin were returned by the county assessor and published as an appendix to the report of January 10, 1881. This report not being complete is supplemented by information collected by the State Engineer Department.

Summarized the table is as follows:

Name of stream.	*Quantity of water used in mining and discharged into bed of river in twenty-four hours.*	*State engineers estimate of duty per inch.*	*Amount moved.*
	Inches.	*Cubic yards.*	*Cubic yards.*
Table Mountain or Dry Creek	833.250	3½	2,916,375
Butte Creek	24,000	3	84,000
Feather River	1,259,363	3½	4,407,770
Yuba River	5,458,171	3½	19,103,598
Bear River	1,117,082	3	3,351,246
Dry Creek, No. 2	44,229	3	132,687
American River	1,914,500	4½	8,615,250
Total	10,650,505	......	38,610,926

The amount of material discharged, as found from this computation, and the amount of water used are both less than previous estimates. The quantity of water used in 1880 was about 870,000,000 cubic yards, of which 281,500,000 were stored in reservoirs, as will appear by the preceding table. The following table gives information collected by Lieutenant Payson in regard to rivers south of the American:

Estimate of material moved annually.

River.	*Mine.*	*Ditch.*	*Water used, twenty-four hours.*	*Cubic yards moved per twenty-four hours per inch.*	*Total number cubic yards moved.*	*Summary.*	*Remarks.*
			Inches.			*Cub. yards*	
Cosumnes	Hill Top	American and Sacramento.	456,000	2½	1,140,000	. . .	Much heavy material stored in ravine.
	Various placers	Jordan	48 000	. . . .	40,000	1,180,000	Part of water used for power.
Dry Creek	Irish Hill	American and Sacramento.	162,000	2½	405,000	405,000	Little now reaches any river.
Mule Creek	Various small placers	Johnson's	38,000	1	38,000	38,000	
Sutter Creek	Various placers and hydraulic	Amador Canal	54,750	1	54,750	.	
	Volcano hydraulic	Volcano	365,000	2½	912,500	. .	Not now working dump in bed of dry creek.
	Various placers	Johnson's	38,000	1	38,000	1,695,250	
Jackson Creek.	Various placers and hydraulic M	Amador Canal Company	127,750	1	127,750	. . . . .	
	Near Buena Vista, at head of Jackson Creek.	Dougherty	43,400	1	43,400	171,150	
Mokelumne	Near Campo Seco, Camache and Stockton Ridge.	Mokelumne	61,000	2	122,000	. . .	Bulk of heavy material stored in ravines. Parts of water used for power.
	Railroad Flat, head South Fork	Clark's	45,000	2	90,000	. . . .	
	Near Lancha Plana and Camache	Murray & Dougherty's	118,500	. . .	60,000	272,000	
Calaveras	Near Jenny Lind	Salt Spring Valley Reservation and Union.	365,000	2	730,000	. . .	Formerly in main stream. Heavy material now mostly stored.
	Chile Gulch and Jesu Maria Fork of Calaveras.	Mokelumne	200,750	2½	501,875	. . . .	
	Juniper, at Dogtown, San Domingo Creek.	Union	365,000	2½	912,500	. . .	In bed of streams.
	Near Mokelumne Hill	Cook Brothers	45,000	2	90,000	2,234,375	
Stanislaus	Near Knight's Ferry	(small)	38,720	2	77,440	77,440	In main rivers.
Tuolumne	La Grange and Patricksville	La Grange	812,500	2½	2,031,250	2,031,250	
	Total at present		3,384,370	. . . .	7,414,465	.	

Quartz and drift mining contribute a considerable quantity of detritus, none of which can be exected to remain where discharged from the mines. The product of the quartz mill is impalpable sand. The drift miner leaves the bowlders in the mine and brings out only the gravel. The Chinese mine quite extensively in the beds of the rivers in low stages. They take the water out of the bed in a flume and sink shafts or run drifts in the gravel. While this makes no additional contribution to the amount of gravel in the river bed, it disturbs the equilibrium and facilitates the movement down stream. There are no means of estimating the amount of detritus due to these causes, although they contribute in a sensible degree to the evils due to mining. Professor Price estimates that in the year 1881 two thousand five hundred and forty-six stamps in quartz mills contributed to the drainage lines of the State 1,500,000 tons, otherwise expressed as 1,000,000 cubic yards of detritus. Drift mines are numerous, but there are no statistics of the detritus furnished by them. The Bald Mountain drift mine is reported as coutributing 106,160 cubic yards in a year. There are a large number of quartz mines in the State. Lieutenant Payson found south of the American River in 1880 eight hundred and forty-two stamps running, producing an estimated yearly amount of 567,575 cubic yards of tailings. There is no report in regard to the number in operation north of the American. There are also a large number of drift mines in Sierra and Plumas counties, the production of which either in gold or detritus is not ascertained.[1]

The Economic Aspect of Mining.—It is stated in the testimony in the case of the State of California *versus* The Gold Run Mining Company that the Capital invested in mining in California is about $160,000,000, of which $100,000,000 is in gravel mining. This appears to be a generalized opinion, based upon a partial knowledge of investments. It is not based on detailed information, and is not claimed to be more than an approximation. So far as it applies to gravel mining, the amount is probably in excess. Perhaps it is quite as well for the purposes of this report to be able to say that the invested capital is large as to be able to give the specific amount. This kind of information for a majority of mining properties is quite out of the question. The natural secrecy of business operations and the varied and complicated circumstances of the different properties forbid any attempts in this direction. The assessed valuations might be a guide, but these are now much depressed by litigation, present and prospective. In the cases of the principal hydraulic properties held by incorporated companies information can be obtained.

The following list is believed to be quite accurate, as in most cases the information is taken from books of the companies.

Excelsior Company, of Smartsville	$2,857,166 65
North Bloomfield and Milton	4,079,321 62
Gold Run Company	433,335 00
Blue Tent	755,000 00
El Dorado Deep Gravel	1,008,611 60
Eureka Lake (approximate)	2,500,000 00
South Yuba Company	2,000,000 00
Spring Valley Company	2,000,000 00
La Grange (about)	650,000 00
	$16,283,434, 77

This list includes a number of the principal hydraulic mines of the State, but there is a much larger number of smaller properties not included, in reference to which no information is at hand. A considerable amount of capital is understood to be invested in mining ground acquired for mining purposes. The most important single group of mines not included in the list is that at and about Dutch Flat and tailing into Bear River. Referring to the table next to come, it will be found that there are seventeen counties in California in which mining is a principal industry and in some it is the basis for all industries, in the sense that if it did not exist, the population would mainly disappear. So far as hydraulic mining is concerned Nevada is the county which produces the most gold, two-thirds of its production being credited to hydralic mining. Trinity County production is believed to be nearly all due to earth washing, and the same is true of Shasta and Sierra Counties. Mono County production comes from vein-mining. Attention is invited to the column of remarks in the table, which describes the resources of each county in a general way, and discriminates partially between the different forms of mining. It may be said that the belt of country on the flank of the Sierra Nevada, from the Merced River to Chico, is interested to such an extent in mining interests of one kind or another, that its abandonment would change the condition from prosperity to extreme depression, which might be expected to last until new resources are developed. The table may be used for the purpose of reaching an approximate relation between the production from earth-washings and

[1] Those who desire to obtain a full account of the hydraulic system are referred to a paper on the subject by Augustus J. Bowie, Jr., published in Volume VI, Transactions of the American Institute of Mining Engineers. The geological relations of the gravel will be found fully described in a work by Prof. J. D. Whitney, entitled the Auriferous Gravels of the Sierra Nevada of California, printed for the Museum of Comparative Zoology at Harvard College. These works have been consulted in the preparation of this report, as may be noticed by the references.

that due to the quartz industry. The items are not segregated in sufficient detail to enable one to establish an exact relation, but it cannot be far from one of equality. The table is made from returns to the mint and other official departments, and so far as the production of the precious metals is concerned is apparently incomplete, and perhaps necessarily so. The production stated for the fiscal year ending June 30, 1880, is $15,148,505. It appears from Wells, Fargo & Co.'s estimate that the production of California in 1879 was $18,190,973, and for 1880 $18,276, 166. The production for the fiscal year ending June 30, 1880, embracing half of each of the calendar years of 1879 and 1880, may well be assumed to be the mean production of those two years, which is $18,238,567, an amount $3,098,062 in excess of the tabular statement. It may be supposed that the production from gravel-washing forms a greater proportion of this unreported sum than the quartz production. This supposition is justified by the fact that there are a great number of small properties of this kind, the aggregate production of which is considerable, which would be more likely to be unreported than the quartz industry, which generally involves the investment of considerable capital. Giving weight to this consideration, it appears fair to say that earth-washings may be credited with an annual production of nearly $10,000,000, the quartz-industry being credited with the remainder.

hydraulic mining does not exceed, if it equals, two-thirds of the gross amount credited to earth washings. On the other hand it is proper to remark that somewhat different views are held, as will be observed from the following quotation from Prof. J. D. Whitney, page 368, Auriferous Gravels:

> At the beginning of the present decennium it [the gold production] was probably about $20,000,000 in value, and since that time has slowly and irregularly decreased, the present production being about $18,000,000. Considerably the larger portion of this comes from the hydraulic and tunnel mines, chiefly from the former. The best authorities estimate the present yield from this source at from $12,000,000 to $14,000,000.

While these results are to some extent indefinite, they are nevertheless sufficient to limit error of judgment within bounds compatible with the purposes of this report. The following tables are compiled by Hamilton Smith, jr. They are believed to be the most reliable existing estimate of the production of the precious metals in California.

Products of precious metals in California, 1848 *to December* 31, 1881.—[The figures from 1848 to 1857, inclusive, are based upon estimates made by Mr. Louis A. Garnett, late manager San Francisco Refinery. The estimates from 1858 to 1870, inclusive, are made by Professor Raymond, Official Report as Mining Commissioner, 1874, page 543; from 1871 to December 31, 1881, from the official estimates of Mr. John J. Valentine, superintendent of Wells, Fargo & Co.]

Tabular statement showing condition of mining in California for the fiscal year ending June 30, 1880.

[Compiled from Mint Bureau Returns, United States Census, and State Reports.]

Counties.	*Number of quartz mills.*	*Number of mining ditches*	*Miles of mining ditches.*	*White population in mining counties.*	*Chinese population in mining counties.*	*Gold bullion produced.*	*Silver bullion produced.*	*Total production.*	*Remarks.*

*No returns.

The production of the San Juan ridge in the year 1881 was $1,705,019, of which $144,351.97 was from drift mining. The North Bloomfield, Milton, and American Companies, which produced nearly one-half of the whole hydraulic output, were idle four of the best months of the year under an injunction of Judge Keyser. It is thought that but for the injunction the production of the ridge would have been $2,000,000. The production from washings is nearly all due to deep placer mining, including in this term both hydraulic and drift mining, but no attempt is here made to apportion the production to its various sources. The information at hand leads to the conclusion that the annual production of

1858-1870, Raymond	424,800,000	
1871-December 31, 1881, Valentine	189,537,337	$15,470,191
	1,162,437,337	15,470,191

The diminished product of gold for the last six months of 1881 was largely due to stoppage of several important mines by injunction, being an aggregate of about $1,178,000,000 since California belonged to the United States. Much the greater portion has been derived from gravel found in ancient river beds or eroded from them and afterwards deposited in modern streams or on their banks. It is altogether to be supposed hundreds of millions yet remain untouched and buried in the pliocene gravel. This branch of the subject is here closed with the following extract from an article of Mr. Skidmore, in the Mint report of 1880, which gives information in regard to the yield from gravel:

The following tabular statement of the average yield of auriferous gravel, worked on a large scale by the hydraulic method, has been compiled from the returns of companies who have acquired extensive and exclusive water rights and large areas of ground, embracing the principal enterprises included in the table on page—:

Name of company.	Average height of bank.	Yield per cubic yard.
	Feet.	*Cents.*
Smartsville claims, Yuba County	112	19½
Blue Tent, Nevada County	180	15
North Bloomfield, Nevada County	180 to 260	4 to 6½
Gold Run, Placer County	200	4⅘
Columbia Hill, Milton County	100	4⅓
La Grange, Stanislaus County	18 to 100	2½ to 15½
Patricksville, Stanislaus County	40 to 60	4⅓ to 18½
Dardanelles, Placer County	150	13

But the profits of hydraulic mining do not depend so much upon the contents per cubic yard as upon the facility and economy with which the auriferous material may be moved, cost of water, means of outlet, &c. It is within the personal knowledge of the writer that a claim near Iowa Hill, Placer county, yielded cost of outfit and a fair profit in the season of 1879, when the product was only three cents per cubic yard. In this case the owner possessed a water-right and ditch.

With a view to the presentation of some statistics of the operations of hydraulic companies, with a record of production less than the average, I have selected the data of several claims in Stanislaus county, California. The figures are compiled from a paper on hydraulic mining in California, by Aug. J. Bowie, jr., mining engineer, which will be found in the Transactions of the American Institute of Mining Engineers for 1879. The period covers the operations of two seasons.

Name of claim.	Average height of bank.	Pressure of water.	Cubic yards washed.	Cubic yards of gravel moved per miner's inch.	Yield per miner's inch water.	Yield per cubic yard.
	Feet.	*Feet.*			*Cents.*	*Cents.*
French Hill claim	30	50 to 70	676,968	1.08	14	13
Light claim	45	60	683,244	1.80	12	6⅔
Chesnan claim	28	70	284,932	1.37	23	16
Johnson	30	80	196,632	1.76	8	4
Licard	90	90	155,347	2.89	37	13
For a corresponding period the North Bloomfield of Nevada County, showed the following results	180 to 260	. . . . .	4,104,700	4.5	23	5⅓

Name of claim.	Cost of water per cubic yard.	Cost of labor material, &c., per cubic yards.	Total cost per cubic yard.	Total expenses.	Total yield.
	Cents.	*Cents.*	*Cents.*		
French Hill claim	1.000	5	6	$42,655 83	$90,186 19
Light claim	.006	3	3⅔	25,962 82	45,444 65
Chesnan claim	.008	4	4⅗	15,923 71	47,781 73
Johnson	.006	3	3⅔	7,466 00	9,148 27
Licard	.004	3½	3 9/10	6,205 40	20,197 07
For a corresponding period the North Bloomfield, of Nevada County, showed the following results	.0755	2¼	3	147,912 58	267,007 50

The examples above cited have been selected exclusively from the record of companies who have washed gravel of low grade by hydraulic method with a steady profit. The average yield per cubic yard on the above exhibit would be 7½ cents. In the case of the claims in Stanislaus county, if we take 7½ cents per cubic yard as the average yield, and 45 feet as the height of bank, each acre of gravel washed would yield $5,263.50. In Weaver Basin, Trinity county, the yield has been from $8,000 to $12,000 per acre, where the height of the bank has varied from 30 to 50 feet. These examples are quoted for the purpose of showing the minimum rates of profitable operations where the depth of the gravel is less than 100 feet. The average of the deep washings on the ancient channel claims, where the banks are more than 100 feet in height, would be but little over 10 cents per cubic yard, if we make the estimate from the basis of the returns of the past five years. At the North Bloomfield mine, Nevada county, the yield has not averaged 10 cents per cubic yard. The yield of this company per miner's inch of twenty-four hours for the past ten years has varied from 13½ to 27½ cents, but this has been from top dirt, the bed-rock bench not being reached. But we should not assume from the foregoing statement of the operations of companies hydraulicking low-grade dirt that the richer ground of the deep placers is exhausted. A recent examination of the yield of the Paragon claim, Placer county, California, by F. Von Leight, mining engineer, shows the following results for six seasons (from 1874 to 1879), by the hydraulic method only:

Total production for period	$243,075 85
Dividends paid	119,670 14
Average yield per miner's inch, calculated on a basis of twenty-four hours' inch, under 6-inch pressure	2 54

In this case the lower stratum was washed and the bed-rock stripped. The highest yield per inch was in the season of 1874 and 1875, when $4.04 per inch was realized; the lowest was in season of 1878-'79, when 86½ cents per inch was realized. The largest yield of any season was that of 1875-'76—$90.04, or 3.43 per inch. The company are also engaged in drifting, but the yield and value of ground from that source will be noticed under the head of drift-mining. The system of valuation of ground per cubic yard has long been in disuse in California, by reason of the disparity of conditions of a hydraulic bank, both in respect to its material (whether composed largely of pipe-clay or gravel) and its depth. Thus, several successive hydraulic benches in deep placers may yield, from grass roots to a depth of 100 feet or more, from 5 cents to 20 cents per cubic yard, while the lower or bed-rock stratum will yield from $2 to $6 per cubic yard. In many cases surveys are not made, and the returns are the results of "guessing." The highest returns of the past season by the hydraulic method, where measurement was made, are stated, on the authority of Mr. James Arnott, of Brandy City, Sierra County, to be $1.50 per cubic yard. In this case the bank was 24 feet in height, and the yield included the lower stratum and the bed rock. The product per miner's inch has come to be accepted as the standard of value or hydraulic ground.

Among the defendants enjoined were a number of parties engaged in mining by the drifting process. The language of the decree so far as it relates to fouling or corrupting the waters of the rivers, applies to quartz-mining as well as to all other descriptions of mining. In this case, none of the defendants were vein miners. The decree was overruled by the supreme court of the State on a technical point which did not affect the merits of the case. The distinctions between different kinds of mining so far as they relate to the beds of water-courses as places of deposit, are distinctions of degree and not of principle. As practiced at present they all foul the waters of streams. The impalpable sand products of quartz mines are borne by currents with the greatest facility and are deposited in places where currents are reduced to little or nothing. The detritus from drift mines differs in quality from that of the hydraulic mines in that the former is composed mainly of gravel of ordinary sizes mixed with sand, while the latter contains in addition considerable amounts of large stones and of pipe-clay. To what extent mining can be prosecuted under the conditions expressed in this decree, remains to be seen. Quartz tailings may certainly in some cases, perhaps in many, be impounded in reservoirs near the mills in a way to conform to the conditions. In drift mines the difficulty will be considerably greater owing to the large volume of detritus, while the existence of hydraulic mining is quite inconsistent with the terms of the decree.

Table showing the yield of gravel per cubic yard of hydraulic mines in California, from Mint report, 1880.

Name of claim.	*Location.*	*Cents yield per cubic yard.*	*Authority.*
American Company	Sebastopol, Nevada County	24.0	Hamilton Smith, jr.
Blue Tent	Nevada County	15.0	R. W. Raymond.
Blue Point (1870)	Smartsville, Yuba County	123.0	Hamilton Smith, jr.
Gold Run (1870)	Placer County	04.8	William H. Pette.
Dardanelles and Aro	Forest Hill, Placer County	13.1	Joseph McGillivray.
McCarty's Diggins	Columbia Hill, Nevada County	43.3	J. D. Hague.
Smartsville Mine	Sucker Flat, Yuba County	19.5	Amos Boman.
Union Gravel Mine	Empire Hill	15.0	. . . do
Pactolus Gravel Mine	Yuba County	20.8	. . . do
Blue Gravel Mine	. . do	63.0	. . do
Pittsburg	do	41.0	. . . do
Pactolus	. . . do	44.0	William Ashburner and J. D. Hague.
North Bloomfield	. . . do	12.0 to 16.3	Hamilton Smith, jr.
Spring Valley	Cherokee, Butte County	28.0	R. H. Stretch.
French Corral	Nevada County	33.4 to 47.4	Hamilton Smith, jr.
Manzanita	do	27.4 to 33.3	. . do

The above table extends over a period of ten years' operations, but the yield is not averaged, as it has varied from year to year.

Reference may here be made to the civil and social aspects of the controversy between mining and other interests as developed by the litigation which has been in progress for several years, with a prospect of a long continuance. A very important suit is now in progress before a State court of justice. It is entitled the State of California versus the Gold Run Mining Company. It has occupied the attention of the court for two months, and enlisted the services of some of the ablest counsel in the State. Many of the witnesses are among the ablest and best informed citizens of the State. No case could be watched with more interest by all persons concerned with the prosperity of the State. The issue is the right of miners to discharge detritus into beds of streams. A decision can hardly be expected for several months. In 1878 the case of Keyes versus Little York Gold and Water Company and others, was tried in the tenth judicial district of California. The decree enjoined the defendants in this language, namely, that they—

Be and they are each of them hereby perpetually enjoined and restrained from using the bed of Bear River, or the beds of any or either of its branches, tributaries, ravines, or gulches, as a place of deposit, or as a dump or place of discharge for the tailings or debris of their said mines or mining claims or either of them, and especially from using said beds of said streams or either of them as a place of deposit of the tailings from those mining claims known as the Empire, Christmas Hill, etc. * * * ; and they and each of said defendants are further hereby perpetually restrained and prohibited from fouling and corrupting the water of Bear River, and its branches, tributaries, streams, ravines, and golches, with the tailings or debris from their said mines, or either of them.

Natural Denudation.—A comparison of artificial denudation in mining with that due to natural agencies, if it could be fully made, would be a profitable and interesting step in this investigation. Unfortunately, the data for the determination of natural denudation in the Sacramento basin do not exist. A few observations of the quantities of sediment carried by the Sacramento River have been made, but they are hardly in sufficient numbers to form a basis for calculation. As they exist, the portion due to mining and the portion due to natural agencies cannot be segregated. The physical characteristics of the Sacramento basin affecting the question are condensed from the report of the State engineer, 1880. The total area of the Sacramento basin is 24,708 square miles, of which 4,709 square miles are plains of the main valley. The rainfall in the valley may be averaged at 18 or 20 inches. The Sierra Nevada flanks the valley on the east, with an area of 8,298 square miles, the height of range varying from 7,000 to 11,000 feet. In seasons of ordinarily heavy rainfall this region receives from 24 to 102 inches of rain. The Coast Range flanks the valley on the west, with an area of 3,075 square miles. The Range has considerably less height than the Sierra, and the rainfall is much lighter. At the northern end of the plains lies a mountainous district 5,616 square miles in area, within which lies Mount Shasta, 14,400 feet in height. The rainfall here is larger than in any other part of the districts ranging from 30 to 110 inches.

The area drained by Pit River is stated approximately as 2,950 square miles. The rainfall is unknown, but less than on the Sierra. Three-fourths of the area is thus shown to be mountainous, and the greater part of the mountain area is subject to a very considerable rainfall, which perhaps may be averaged for the whole area of mountains at 35 or 40 inches, and for the area of the basin at about 30 inches. The fall of rain is confined to four or five months, and the greater part usually falls in two months. The precipitation in the higher portions of the Sierra is in the form of snow, which is melted in the months of April, May, and June. The Sierras were originally covered with timber. Along the line of the railroad the hills have been stripped; a young growth is taking its place. Along the whole range there is a large destruction of timber, used for mining and other purposes. Much of it finds its way when manufactured to the valley and other markets in Arizona, being floated from the mountains by V flumes. The Coast Range is comparatively without timber. The mean slope of the basin is, by reason of the great mean altitude, very much in excess of that of most rivers, and particularly of large rivers. In Vol. III of the transactions of the Geological Society of Glasgow, Professor Geikie states the times required by natural agencies to remove an average thickness of one foot of rock in each of several drainage basins, as determined by the amount of sediment carried by the rivers which drain them. They are as follows:

	Years.
Danube basin	6,846
Mississippi basin	6,000
Nile basin	4,723
Ganges basin	2,350
Rhone basin	1,528
Hoang Ho basin	1,464
Po basin	729

Applying the Mississippi rate of one foot of rock removed in 6,000 years to the Sacramento basin, which has an area of 24,708 square miles, it will be found that in one year, 4,250,000 cubic yards of rock will be removed. Converting this volume of specific gravity of 2.5 into sediment having specific gravity of 1.9 it becomes 5,592,110 cubic yards. If we apply the rate of the Po, the yearly denudation of the Sacramento basin would be in rock 34,300,000 cubic yards, or in sediment 43,000,000. The Rhone rate would give 21,950,000 cubic yards of sediment, and the Ganges 13,230,000 cubic yards, as the natural denudation of the Sacramento basin. This comparison would be more satisfactory if we could know that the sediment assumed to be carried by the rivers had been carefully obtained. In the case of the Mississippi, the amount carried in suspension was the subject of more than two years' careful observation, the details of which are to be found in the Physics and Hydraulics of the Mississippi River, page 136. The only statement in regard to the sediment carried by the Po, that is accessible to the writer, is that Lombardini assumes the ratio of sediment to water in volume to be $\frac{1}{300}$, this rate having been determined by Ludini. The extent of the observations upon which the statement is based is unknown; the same is more or less true of the other rivers mentioned in the table.

In the case of the Mississippi, the amount carried on the bottom and not suspended does not result from observation. In area and topography there is a noticeable likeness between the basins of the Po and the Sacramento. The areas are 24,700 for the Sacramento and 26,800 for the Po. The Sierra Nevada and the Coast Range correspond to the Alps and the Apennines, both in the fact that they respectively flank the rivers through a great part of their courses, and also in that the Sierra approaches the Alps in altitudes, and resembles them in heavy deposits of snow; while the Coast Range, like the Apennines, delivers its floods with rapidity, and is comparatively free of snow. The Sierra is distinguished from the Alps by greater breadth, owing to which the proportion of mountain to plain is considerably greater in the Sacramento than in the Po. The lacustrine rivers of the Alps have, however, no adequate counterparts in the Sierra. In point of rainfall the basin of the Po probably surpasses the Sacramento. The slopes of the two basins have a fair correspondence. The denudation of timber on the Sierra is in all probability considerably less than that of the Alps. The average rainfall in the basin of the Mississippi cannot differ much from that of the Sacramento, although the mode of occurrence is altogether different,—the downfall in the Sacramento being confined to a few months in the year. The mean slope of the Sacramento basin is very much in excess of that of the Mississippi. This discussion is altogether of too general a nature to lead to a conclusion more definite than this, namely, that the rate of natural denudation in the basin of the Sacramento is in all probability in excess of that of the Mississippi, and probably less than that attributed to the Po. But whatever may prove to be the position of the Sacramento between these limits of 5,592,110 cubic yards of sediment, representing the Mississippi rate, and 43,000,000 cubic yards, representing the Po rate, we cannot, in any event, help being impressed by the comparison which shows the relations existing between the respective powers of natural forces acting in nature's way, and a part of the same agencies controlled and directed by man, both applied in degradation of the earth's surface. The comparison is more striking when, instead of being applied to the whole area of the Sacramento basin, it is confined to the limits of the field of the Yuba, Bear, and American rivers, where mining exists on the greatest scale. The area of the basins of these tributaries is 3,520 square miles, which is one-seventh of the whole area of the Sacramento basin. Under any rate that we can be justified in assuming for natural denudation, even that of the Po, it will easily be seen that the annual mining denudation in these basins is several times in excess of that due to natural causes. To place this in a more specific light, we may recall that the mining detritus annually placed in the three rivers is quite 31,000,000 cubic yards; while the Po rate of denudation applied to the area of the basins would afford little more than 6,000,000 cubic yards per year. These general considerations are calculated to convey to the minds of those familiar with the natural circumstances of rivers as clear a conception of the magnitude of the problem as would be afforded by a study of its details. They explain the accumulations in the river beds, by making it evident that mining operations contribute more material per year than the floods of that year are able to carry. It also becomes plain that if the mining were to cease now, the floods, being able to transport considerably more material than that due to natural erosion, would then be in a condition to attack deposits in the beds, which are comparatively safe so long as the floods are overloaded as they now are.

Changes in Navigable Waters.—The navigable waters are the channels of the Great Bay, and the Feather, the Sacramento, and San Joaquin rivers. So far as the rivers are concerned, we are not in possession of charts of old date, which compared with recent maps would afford an accurate record of the changes that have occurred in the past generation. Nevertheless, the partial records that exist, and well-established facts developed by inquiry and by comparison of statements made by those who by reason of occupation or residence must be supposed to have knowledge of certain facts, are sufficient to enable a fair general comparison to be made of the present and former conditions of the Sacramento River below the entrance into it of mining detritus. As for the San Joaquin River, no evidence is known to exist showing any change of importance in its channels. A gauge has been observed at the city of Sacramento with more or less continuity, since and including the year 1849, which was the date of the great influx of people into California. The gauge readings of the low stage of the river are here given to include the year 1881:

	Feet.
1849, low-water reading	zero.
1869 . . . do	2.9
1874 . . . do	4.9
1875 . . . do	4.5
1876 . . . do	7.1
1877 . . . do	5.3
1878 . . . do	5.5
1879 . . . do	5.8
1880 . . . do	7.4
1881 . . . do	6.5

It may be observed that the low-water plane was raised 2.9 feet in the twenty years succeeding the beginning of mining, and that the next ten years, from 1869 to 1879, doubled the rise of the plane. The table shows a continuous rise, with some anomalies, which may in part at least be accounted for by the different volumes of the river in its low stages. The difference in volume may be accounted for by difference in rainfall, and also by the influence due to the amount of water contributed from the storage reservoirs of mining companies. A local change in the slope of the river may also be due to variations in the amount of detritus deposited in the Sacramento by the American, which joins the main river at Sacramento. Notwithstanding these variations, the conclusion is plain that the low-water plane at Sacramento has been raised about 6 feet since 1849. As a consequence of the elevation of the bed, the tidal influence which in 1849 extended at least as high as the mouth of the Feather, 25 miles above Sacramento, and was quite 2 feet at Sacramento, is now no longer noticeable above Heacock Shoals, 9 miles below Sacramento.

The tide within the past thirty years rose on these shoals as much as 3 feet. Corroborative evidence of the rise of the bed is afforded at the Russian Embarcadero, 10 miles below Sacramento, which in old times was 3 feet out of the water in the low stage. In 1878, it was found to be 1½ feet under water, showing a rise of surface of about 4½ feet. This is confirmed again by the level of the low-water of 1852, which was fixed at Greene's Ferry, 3 miles above Courtland, by the level at which the branches of a tree were cut off in that year for the accommodation of the ferry boat. This level is 4 feet below low water of 1878. Confirmation of like character is afforded by trustyworthy circumstances needless to record, occurring at the Hog's Back and at Ida Island. The State engineer gives the changes of level in 1880 as 5 to 5½ feet at Sacramento; mouth of Feather, 3 or 4 feet; head of Steamboat Slough, 1½ to 2½ feet. The rise of the low-water plane indicates filling not so much in the pools of the river as on the shoals. All of the shoals below Sacramento have been bored, and samples have been collected under the direction of this office. The deposits are found to be chiefly mining detritus. We may fairly assume that the filling in the pools has at least kept pace with the rising in the low-water plane. This assumption, which is much within probability, and within facts so far as they are known, would make a general filling of the bed between the Feather and Sacramento, a distance of 25 miles, to be 5 feet, and for the 60 miles below Sacramento an average of about 3 feet, to which is to be added the deposit in Steamboat Slough. The State engineer compared a survey of 1854, made by direction of the town council, by the city surveyor, of a portion of the river 2 miles in length in front of the town of Sacramento, with the condition of the river in 1879.

The maximum filling was 25 feet and the average 15 feet. (State Engineer's report 1880, page 31.)

Specific information of this kind for the river as a whole is lacking, therefore no means exist for obtaining an estimate in any detail of the aggregate deposits in the Sacramento River made during the last thirty years. They can only be generally inferred from known facts. Twenty-five miles below Sacramento the river divides into two delta channels, which unite below, the intermediate distance by two channels being 18 miles by Old River, and 12 miles by Steamboat Slough. In the earlier days of navigation and until six or eight years ago, Steamboat Slough was the channel used by all boats and vessels. It is now obstructed by shoals and at low tide carries only about 4 feet, so that its navigation is now for the most part abandoned. Old River is now the navigable channel. The depth on the bars of the river at low water does not appear to have been diminished to a great extent, but the expulsion of tidal influence in whole or in part has resulted in a decrease of effective depth. As the slope of the river increases, it is plain that the low-water discharge will afford a constantly diminishing depth. The decrease on the bars produced to this time has been masked by the absence of tide. As the scouring influence of the tide is diminished, the tendency to deposit is increased. Above the city of Sacramento as far as the Feather, although the deposits have been large, the effective depth appears not to have suffered to any great extent, if at all. The slope in this reach has probably not been much changed. It would not be changed if we supposed the elevation of the surface at the mouth of the Feather to be just equal to that at the mouth of the Sacramento. This may be the case, for although the Feather is the outlet of a more extensive mining field, the main Sacramento into which it empties is at and above this point free of mining detritus. For this reason the minor output of the American may be able to maintain at Sacramento a rise of bed equal to that produced by the Feather. However this may be, the best accessible testimony indicates that there has been no change of effective depth between Sacramento and the mouth of the Feather worthy of notice. The width, however, of portions of this stretch of the river has been considerably diminished. Large deposits of fine mining detritus 10 or more feet above low water, and covered with willow growths, now form the banks for considerable distances, the old banks in rear being indicated by the growth of heavy timber. This is a regulation of the river-bed by the influences of nature, which could not have occurred except for the loads of sediment in the river. The Feather River low-water level at Marysville, the head of navigation, has been raised about 15 feet. The rise in level at the mouth, 30 miles below, is given by the State engineer, already quoted, 3 or 4 feet. The description of the mouth of the Feather, given by the Wilkes exploring expedition, indicates more filling at the mouth. Investigations made by this office in comparing present with former depths on Fish Slough bar and the middle ground, both being in the Sacramento River above the mouth of the Feather, prove quite satisfactorily that in 1878 the filling at the mouth of the Feather was fully 5 feet. At present it can be no less. Taking 15 feet at Marysville, and 5 feet at the mouth, the difference, 10 feet, is to be added to the old fall. This increases the slope of the Feather in its navigable part 4 inches to the mile. This increase has impaired the depth of water and the practicability of navigation to a considerable extent.

Applying to the navigable portion of the Feather the rule adopted for the minimum deposited in the Sacramento, namely, that the average filling is equal to the elevation of the plane of low water, we will have for the thirty miles, from Marysville to the mouth, an average depth of ten feet over the bed of the river. This estimate is thought to be here, as in the Sacramento, considerably below the fact. As a consequence of these changes a higher flood line and greater exposure to overflow now exists for all riparian lands on both these rivers. This is an element of considerable loss to the country, but its description and discussion do not come within the limits of this investigation. The steepening of the slopes when they are low, as they necessarily are in navigable streams, is in the direction of the fulfillment of the condition essential to enable the river to carry the material delivered to it. The steady increase of elevation of the lower water-plane at Sacramento indicates that the relation now existing between slopes and sediments is not that of stable equilibrium, and for the present we must look for the continued increase of slope. If we suppose the weight of sediment presented to the river for transportation to be increased, an increased rate of steepening in slopes must be anticipated. The elevation of the bed of the river is not accompanied by an equal rise in the river banks. The level of the beds approaches more and more the level of the bank. In the cases of the Yuba and Bear, non-navigable streams yet to be described, the level of the beds has risen from a depth a number of feet below the banks to an elevation of several feet above the banks. These instances may be taken to illustrate the ultimate condition of the Sacramento and Feather rivers, under a continuance of the influences to which they are now subjected. The abandonment of existing channels is a consequence to be apprehended. The information that has been obtained in regard to the channels of the bay, results from a study in obedience to a resolution of the House of Representatives, of the 12th of June, 1880, which called for a report upon the causes tending to diminish the tidal area of the bay and the commercial value of the harbor of San Francisco. The report made in obedience to this resolution was published by the House of Representatives, Forty-sixth Congress, third session, Ex. Doc. No. 93. The main facts are here reproduced:

1. A careful comparison of the charts of San Francisco entrance bar, made in 1855 and 1873, shows that the bar had suffered no injury in that interval.

2. A comparison of surveys of the ship's channel of a portion of San Pablo bay, made in 1855, 1863, 1878, shows that between 1855 and 1863, no deposits of much importance were made in the channels. The surveys of 1863 and 1878 are distinguished by a deposit of 76,025,000 cubic yards made in the interval. The depth of deposit averaged over the area of comparison 24⅓ square miles, would be 3.1 feet. The deposit, however, did not occur in the shape of a layer of uniform thickness. It occurs mainly on the flanks of the channel, and has the effect to narrow the channel without

affecting to any noticeable extent the ruling depth. The mean reduction in width of channel between the 18-foot contours obtained by comparison of six cross-sections, is 2,820 feet, which is 22 per cent. of the mean width of 1855. This comparison includes only the channel. The shoal-water areas were necessarily excluded from comparison, owing to the fact that no survey of them has been made since 1855.

3. A comparison of maps of three and a half miles on the Sacramento near its mouth and one mile at the mouth of the San Joaquin, shows a deposit of 2,000,000 cubic yards in the Sacramento, and 500,000 in the San Joaquin between 1867 and 1878. The comparison of charts of Suisun Bay made in 1867 and 1878, shows an extension in area of the shoals, which have not yet been measured in a detailed way. A comparison of charts of Carquinez Straits, during different dates indicates the formation of large deposits in recent years. No opportunity has offered as yet for the investigation of the origin of the deposits in the bays. It would be possible to determine by a sufficient number of samples taken from each locality, whether the deposits are mainly due to either of the two great sources of erosion, the artificial due to mining or the natural. It is to be presumed that both causes are represented in these effects.

Deposits of Detritus in Tributaries of Navigable Waters.—The Yuba and Bear tributaries of the Feather, and the American, a branch of Sacramento, present to inspection large deposits of detritus in their beds and on adjoining alluvial lands. These are in places of temporary lodgment, where they are left by one flood and removed in greater or less degree by the succeeding one. Each movement carries a quota into the navigable streams and maintains the features of these rivers that have been described. The loci of these deposits are determined by the circumstances of the case, among which may be mentioned the character of the detritus as to size and weight, the volume of flood waters and the natural grades of the river beds. Differences of circumstances correspond to widely different localities of deposit. The cañons of the three forks of the Yuba are distinguished by heavy natural grades. The mines on the Yuba afford a large supply of fine material, and the flood discharge is large; consequently we find the upper cañons quite free from deposit, which begins to be important only where the three forks unite to form the main Yuba. On the Bear a great proportion of heavy material is deposited near the head of the river, about and above Dutch Flat. The river does not head in the high Sierra, and, therefore it has not the same flood characteristics as the Yuba. We find a very large and increasing deposit in the vicinity of the mines themselves. In 1879 Professor Pettee found the bed of the Bear, at the crossing between Dutch Flat and Little York, to be 97 feet higher than 1870, and that in the same interval Steep Hollow, between Little York and You Bet, had risen 136 feet. (Volume II., page 425, Auriferous Gravels, by Prof. J. D. Whitney.) The best information available leads to the opinion that the Bear River here is filled 150 feet in depth; Steep Hollow, 250 feet; and the Greenhorn, at the crossing of Nevada and Dutch Flat Road, 200 feet deep. Where the detritus, consists, in part, of heavy cobbles or larger stones, it is supposed to remain where deposited, or at least to be moved slowly. It thus forms a barrier which serves to impound above it a mass of gravel, which otherwise would have traveled further down stream. The steep grade of the Bear River bed below the Dutch Flat dump may be taken to be that which the floods in this stream require to give motion to the heavy material there deposited. The average grade from Dutch Flat, for 10 miles below, to Nevada Railroad bridge is 55 feet to the mile, being about 30 feet at the lower end, and presumably 80 feet at the upper. Over all this distance the cañon is filled and graded—cobbles and large stones above, with diminished sizes below. With the exception of about 11 miles, the river bed is filled from Dutch Flat to the mouth. Below the Nevada Railroad bridge, wherever the grades are in the neighborhood of 25 and 30 feet to the mile, there are large deposits; and where the grade is 40 feet, the amount is noticeably decreased, while in the 11 miles already mentioned as free from deposits, the grade varies between 80 and 140 feet in the mile. On any such grades as have been mentioned, the deposits are mainly of gravel and cobbles, with comparatively little sand. The great reservoirs of sand lie at the exit of the river from the foothills and on the plains below, where the deposit is widened in resemblance to, but not to the same extent as on the Yuba, with grades of from 8 to 5 feet to the mile. Attempts have been made by various parties to estimate the volumes of these deposits. Such attempts must be regarded in the light of conjectures. The circumstances do not permit estimates in the true sense to be made, except with great outlay of time and money. In the case of Keyes *vs.* Little York Gold Washington and Water Company evidence was given by several experts, placing the amount of deposits in the Bear River, above the plains, as 86,000,000 cubic yards, and below the foothills to the mouth 36,000,000 cubic yards; total, 122,000,000. This was in 1878. Similar estimates by Mr. Manson, reported to the State engineer, give the estimated deposits, in 1879, on the Yuba above the foothills as 48,462,100 cubic yards, the great bulk in 8 or 10 miles; and below, 23,284,000; a total of 71,746,100 cubic yards. In the light of later information, it seems probable that this estimate is altogether too low, the deposits in small tributaries not having been taken into account, and the amount in the lower river having been much underestimated. The actual amount is not capable of being ascertained, and the statements are given merely for purposes of illustration. At its escape from the mountains, where the foothills recede and give width to the plain, the Yuba spreads out its load of sand and gravel over a plain of 15,000 to 16,000 acres, which has risen until it now stands above the level of the adjoining country on either side. This plain has a slope of about 10 feet to the mile, varying above and below this limit as you ascend or descend the river bed, being 15 feet at the foothills and 5 feet at Marysville, 10 miles below. The sizes of material have some correspondence to the grades. Ascending the stream one passes to a continually increasing average size of material. While it is nearly all sand below, above it becomes nearly all gravel, with, however, considerable admixtures of different sizes everywhere. This eruption from the mountains has destroyed thousands of acres of alluvial land. The State engineer, in 1880, estimated that 15,220 acres had been seriously injured by these deposits from the Yuba. On the Yuba the great deposits of gravel are found on a grade of 30 feet to 20 feet to the mile. The sands predominate greatly in slopes of 10 feet and below. On grades greater than 40 feet to the mile the cañons are generally quite clear of material, unless it be stones of considerable size. The forks which have been alluded to as quite free from deposits have grades generally exceeding 50 feet to the mile. Mr. Manson supplies the following information in reference to the American River:

The American, a tributary to the Sacramento, presents the following general features and characteristics:

Its water-shed extends to the summit of the Sierra Nevada, and is drained by three principal forks. The northern one of these is the recipient of a large amount of detritus and is much filled up, down to its junction with the Middle Fork. The depth of this deposit is variously estimated; the maximum depth is probably as much as 100 feet. The volume is, as in other instances, a matter of conjecture, but probably does not fall far short of 20,000,000 or 25,000,000 of cubic yards.

The grades upon which this material has found lodgment vary from 46 feet per mile in the upper reaches, where coarse material is lodged, to 23 feet per mile where finer material has been carried. This latter grade is found in a portion of the canyon some 20 miles in length. In this there is economical storage.

After the North and Middle forks join the grade is about 22 feet per mile; the large volume of flood-water sweeps all material out of the canyon of the American, only the coarsest finding lodgment in protected places, and equalizing the inequalities in the original grades. These grades, although lighter than those above, upon which material has lodged, have a larger volume of flood-water passing down them, and hence no deposits of moment have occurred.

The Middle Fork is not so much filled as the North Fork, as hydraulic mining is not so extensive upon it.

The grades in its lower reaches are somewhat less than upon the North Fork, and the canyon is of greater lateral dimensions. Although this portion of the river is suitable for storage, such use is entirely prohibited by the existence of valuable mines in and near the bed of the river, whose destruction would be caused by the storage of debris in this portion of the river. The upper portions of this stream have not been examined for more than 8 or 10 miles farther; here the grades are about 45 feet per mile, and the canyon narrow. Storage is available here for the coarsest material from above.

The South Fork is practically clear of debris; that which has been discharged into it has been of a different character from the bulk of that discharged into the rivers farther north.

The application of the hydraulic process to the ancient river gravel is limited, owing to the lava covering the greater portions of the ancient channels; those portions which were exposed under the edges of this lava cap have been nearly exhausted. Decomposed slate, carrying quartz veins, is extensively mined by the hydraulic process, but the hardness of this material limits the quantity moved in a given time, and the shape of the particles of slate prevents them from being easily transported; hence a larger proportion of the waste products remains on the dumps and in the small tributaries. The finer detritus from the mines in the basin of the South Fork forms an excellent soil, as is shown by the deposits intentionally caused by parties owning land upon which this material can be diverted; its desirable quality can be easily predicated, from the fact that there is a great deal of the surface soil washed.

From the mouth of the canyon to the Sacramento River there have been some 6,000 acres of land covered, and 25 or 30 miles of river-bed, from 200 to 400 feet wide, raised from 5 to 30 feet.

The deposits in the Lower American do not admit of being restrained in the bed of the stream by means that are considered practicable under present circumstances. The amount cannot be specifically stated, but from what precedes it may be conjectured to be twenty or more million yards. The deposits in the upper cañons of the Feather appear from Mr. Manson's account to be very limited. At and below Oroville, however, they become very extensive, in positions where it is difficult if not impossible to exercise control over them. They are a constant injury to the navigable waters below. Being beyond the range of practicable restraints they are foreign to the purposes of this report. Lieutenant Payson estimates the volume of deposits in the bed of the Cosumnes River to be 6,000,000 cubic yards, and the maximum depth of filling to be 20 feet. Reference to his report will show that the same state of affairs exists in all the rivers south of the Cosumnes to the Merced, the degree, however, being very much less than that shown to exist on the Yuba, Bear, and American.

Gravel Workable by Hydraulic Process.—The quantity of auriferous gravel now remaining on the flanks of the Sierra Nevada is practically unlimited. If it were all workable its exhaustion would task the energies of miners for many generations. No practical end could be served by an attempt to estimate the aggregate mass. For several good reasons only a comparatively small portion of the whole can be regarded as workable under existing conditions. The workable quantity in several basins is in a certain sense subject to estimate between limits in an approximate way. Such an estimate is very desirable in order to give a basis for an opinion as to the extent, cost, and duration of any system which may be adopted for the purpose of remedying evils consequent upon mining. The estimates that follow are thought to be sufficient for the present purpose, and any considerable errors that may be found in them can be corrected in the future by more accurate information. All the gravel which will pay a profit under hydraulic processes may be regarded as workable.

Under the most favorable circumstances it is Professor Whitney's opinion that gravel yielding $4\frac{3}{4}$ cents per cubic yard may be worked at a profit. Abundance and cheapness of water are essential, as well as favorable outfall. (Page 371, Auriferous Gravels.) This, however, must be understood to apply only to the light top gravel, which is readily moved. The yield must be much greater to give a profit in the lower portions where bowlders and cemented gravel are frequently encountered. The hydraulic process may be unprofitable, because the gravel does not contain sufficient gold, or because it is overlaid with too much or too hard a capping, or because the outfall is insufficient, or because the supply of water is not at hand. If the gold is found in a pay streak close to the bed rock, it may be more profitable to stope out the pay gravel than to wash the whole superincumbent mass by hydraulic process. Generally speaking, working is a question of richness. If there is no outfall the hydraulic process cannot be applied. If the gravel is rich enough, and there is an outfall, capital can supply all that is required to apply the hydraulic process. Keeping this in view, the approximate estimates of gravel tributary to the Bear River and to the North Fork of the American, contained in Appendix 3, will be intelligible. It will be observed that the material in each of the mines is classified particularly as to size, as cobbles, gravel, sand, lava, ashes, &c. The object of this classification is to afford a basis for calculating amount to be stored, it being generally assumed that the cobbles and bowlders will not be carried far from the mines. It is thought to be safer under our present knowledge, or rather want of knowledge, to regard the whole mass requiring storage, including both the portion which by reason of its fineness is incapable of storage and the heavier portion, which, perhaps, may never reach the reservoirs. We thus make compensation for any error in the underestimation of material. The estimates for the Bear River and the North Fork of the American are based upon an inspection of each mine, but not on the instrumental measurements, which the funds available did not permit to be made.

It appears that the territory tributary to the North Fork of the American contains of workable gravel 75,190,010 cubic yards. In the first-named district are the Gold Run and Iowa Hill Mines. In illustrations of differences that throw more or less discredit on all the estimates of this kind, which, at best, are rude approximations, reference is made to Professor Pettee's conclusions in regard to Gold Run Mine in 1870. (Page 147, Auriferous Gravels.) He estimates the amount washed off south of the railroad at 43,000,000, and the amount remaining at 86,000,000 cubic yards; and adding other claims not yet touched, the gross amount to be mined becomes 125,000,000 cubic yards. In the testimony recently given in the case now under trial at Sacramento, The State of California *vs.* The Gold Run Mining Company, the State engineer gives the amount washed off to date as 52,440,000 cubic yards. Other witnesses estimate the amount remaining in the Gold Run Mine variously from 18,000,000 to 22,000,000 yards. In 1870 Mr. Goodyear estimated gravel to be mined at Iowa Hill at 26,000,000 yards. (Page 119, Auriferous Gravels.)

Mr. Larson's estimate in 1881 is 6,388,800 cubic yards, which allows for nearly 20,000,000 washed between 1870 and 1881. On the ridge south of the American and between it and the Cosumnes, Mr. Manson reports that practicable hydraulic mining is about exhausted. The gravel deposit from Placerville to Sportsman's Hall, 14 miles in length, is lava-capped to depths of 20 to several hundred feet, and the mines are now worked up to the edge of the lava. The lava is regarded as a bar to further use of the hydraulic process. There is, however, a large field for drift mining. In 1870 Mr. Goodyear estimated the quantity remaining subject to the hydraulic process near Placerville, at about 50,000,000 cubic yards. (Page 120, Auriferous Gravels.) Mr. Manson supplies the following information in regard to the gravel deposits on the Georgetown divide, which lies between the South and Middle Forks of the American. Gravel deposits worked on the Georgetown divide are—

(1.) Volcanoville.
(2.) Mount Gregory.
(3.) Rubicon.
(4.) Mount Hope.
(5.) Mount Ross.
(6.) Jones Hill.

All discharge directly or indirectly into the Middle Fork.

Of those *Mounts Hope* and *Ross* have not been worked for four years although belonging to a company having an abundance of water. This deposit is lava-capped. *Jones Hill* has exhausted its claim on the south side of the deposit, and the water has been turned to the north side and preparations made for opening work; claim to have from 400 to 500 inches for nine months in the year. Deposit limited, and lava-capped. The amount on the Forest Hill divide tributary to the Middle Fork of the American has not been ascertained, even approximately. The yearly contribution of detritus is stated by Mr. Manson to be about 2,500,000 cubic yards, and includes that from the south side of the Middle Fork.

The deposit on the San Juan Ridge, between the South and Middle Yuba, is, for several reasons, the most important in the State. It is much the largest deposit, and it lies very favorably for working, the beds of the ancient rivers being elevated some hundreds of feet above the beds of modern streams. The floods in the Yuba may be relied on to carry away the gravel, which is generally light in character. The canal and reservoir systems are more developed than in any other portion of the State, and the yield of gold is greater than that derived from any other equal area. An approximate estimate of the quantity of workable gravel on this ridge was made in 1876 by James G. Hague. The quotation is from a printed report on the water and gravel mining properties belonging to the Eureka Lake and Yuba Canal Company:

The linear extent of the gravel channel and its branches on this ridge is about 25 miles. Deducting liberally for the portion already worked and for that too deeply covered by lava to be available for hydraulic mining, there remain probably not less than 14 miles of channel available for washing, from which only a comparatively small portion of the top gravel has been removed. Below San Juan the gravel body has a surface width of over 1,000 feet, and is, say, 140 feet deep. From Badger Hill to Bloomfield it is for the greater portion very much wider and deeper. At Columbia Hill its surface width varies from 3,000 or 4,000 to 8,000 feet, and it is from 300 to 600 feet deep. The gravel at Lake City is probably 300 or 400 feet deep. At North Bloomfield it is opened to the bed-rock, showing a depth of more than 300 feet. Roughly estimating the average width of the remaining gravel range at 400 yards, and after allowing for the portion worked off, placing its average depth at 70 yards, the sum is an average of, say, 50,000,000 yards per mile, or for 14 miles, say, 700,000,000 yards.

Allowing for the amount washed since 1876, 100,000,000 yards, there remains 600,000,000 to be removed. The working of the lower lying deposits at Columbia Hill will, however, require the driving of a tunnel between two and three miles in length. It may be regarded as doubtful whether under existing circumstances a work of this magnitude will be undertaken. The terms used in the description indicate that it is only approximate, but, while this is the case, no one has attempted a correction, and in the treatise on the Auriferous Gravels, by Prof. J. D. Whitney, Mr. Hague's estimate is adopted. The best information in regard to the extensive mining property of the Excelsior Water and Mining Company, at Smartsville, is derived from reports made in 1879. This property consists of 525 acres of mining ground, which contained, according to Professor Pumpelly, 76,500,000 cubic yards of gravel. Mr. Janin's estimate was 75,000,000 cubic yards. This is expected to produce per cubic yard 25 cents by Mr. Janin's estimate, and 34 cents according to Professor Pumpelly. The lower of these estimates being fulfilled will make the working very profitable. There are other deposits about Smartsville, in regard to which no definite information has been obtained. There are also deposits in the basin of the North Fork of the Yuba, which are noticed in Mr. Manson's appended report, the cubical contents of which we have not the means of stating. They are, however, of much smaller dimensions than those already enumerated. Seven hundred millions of cubic yards may be assumed to represent the amount of gravel, workable by hydraulic process, tributary to the Yuba.

By the estimate carefully considered the quantity of gravel workable by the hydraulic process is, in the Bear and tributaries, in round terms, 50,000,000 cubic yards, which is a comparatively small proportion of the whole amount. The choking of the beds of the river and the tributaries, which are the outfalls of the mines, explains the small amount of the estimate. The debris from the Dutch Flat Mines is unusually heavy, and forms barriers in the river beds which impound a large amount of detritus above. In the Quaker Hill mines the lower gravel can only, under present circumstances, be worked by drifting, there being no outfall for sluices. The top gravel is stated (page 425, Auriferous Gravels) to yield 6⅝ cents per cubic yard. This rate will yield a profit. When the hydraulic process is not applicable, mining may in special cases be continued by drifting. This method is followed in some of these mines. The amount of detritus thus produced is a small percentage of that due to the hydraulic process.

Mr. Manson refers in his report to the prospect of new properties being opened on the Upper Feather, in positions where it will be difficult, if not impossible, to provide restraint for detritus. As for the existing mines on the Feather, it appears that the groups on the upper waters already find natural storage for their detritus in great part, and so long as this condition is fulfilled, the magnitude greater or less of the operations need not be considered.

On the Lower Feather, near Oroville, there are considerable bodies of gravel, the amount of which is not known. It will be seen by Mr. Manson's report that he was unable to find storage for the product of these mines. Lieutenant Payson furnishes the following information in regard to the Cosumnes and rivers south of it. At "Hill Top," on the Cosumnes, the superintendent told me that an estimate had been made, based on their previous rate of working; that they had gravel enough remaining to last from ten to eleven years. I was able to make here a very close estimate of the duty of an inch, stated in my report of last year as 2.4 yards. This, with the water supply of the mine, would indicate for the remaining gravel between 11,000,000 and 12,000,000 yards. From its source this is probably a liberal estimate for the mine, and since it is the only one of any consequence on the river, will probably cover the remaining supply for it; also Jenny Lind mine on the Calaveras. The water supply now is 550 inches for six months in the year. They expect to get soon 1,000 inches throughout the year. The superintendent estimates the gravel remaining as sufficient for twenty-five years at their present rate of progress, or fifteen years with their expected increase in facilities. From the circumstances of the case I think this estimate is made with care. As they probably move from 800,000 to 1,000,000 yards per annum now, this would correspond to a remaining supply of say 22,500,000 yards. This will probably all be worked, and can be safely said to include the total remaining supply for the lower river which lies in such a position that it can be worked. There remain enormous additional amounts in the deposits about Mokelumne Hill, but as described elsewhere they are not favorably situated for working, and the cessation of hydraulic operations for this reason will precede by a long time the exhaustion of the gravel supply. No approximation can be given by me to the quantity now available. The remaining deposit of consequence is found in the newly opened mine at Dogtown (Juniper County). This has not been developed, but promises to be extensive, and has good facilities for working. The only other large mine now in operation on the southern rivers is that at La Grange. This has probably, since it began, moved over 16,000,000 yards. The space left by this removal seems but a small fraction in the area of the remaining deposits. The superintendent told me they considered their supply of gravel as "inexhaustible," but the facilities for working it very bad. The Golden Rock Deposit on the upper Tuolumne I did not see. Its owner told me that the deposit was 10 miles in length and the beds 100 feet deep in places. The aggregate amount of gravel not subject to the hydraulic process, but workable by drift mining must be considerable, and the development of this kind of industry promises to take greater proportions as wages of miners become less. It is probable that this description of mining will continue for several generations.

Remedial Measures.—The statement of the case presented in the preceding pages seems to establish the necessity of measures of remedy or alleviation, even in the event that no further contribution be made to mining detritus in the beds of streams. We may now inquire whether any remedy is practicable and general for all mines and all circumstances, or whether there are mines producing detritus or existing deposits of detritus, so situated as to be beyond the application of a remedy. Mention has been made of basins lying near the Feather and American rivers, the surfaces of which are below the level of average stages of the rivers. It is in some cases possible to direct streams from their present courses and turn them into the low-lying lands, with the effect to make a place of deposit for mining material. Diversion of the rivers in all their stages is essential to this project. Partial diversion or separation of seams into parts, by lessening the transporting power, would aggravate present evils. The present objections on account of expense and other considerations are sufficient to make us defer further reference to the project. If, however, in the future it shall become desirable to undertake a fuller consideration of the scheme, account must be taken of the fact already established that the mining streams are not generally able to carry to these basins in a year anything like the full amount of detritus which they receive. It is in consequence of this fact that their beds when inclosed by high banks are rising year by year, and when not so inclosed are undergoing obliteration. The preservation of river beds and routes of drainage requires that effective restraint be imposed upon mining detritus. Otherwise these drainage lines may be expected to suffer the fate which overtook their prototypes, the Pliocene rivers, which are obliterated by enormous deposits brought down by their own currents. It may be added that the conservation of existing facilities for navigation equally requires restraint of the flow of sand and gravel and that no important improvement of the channels can be expected until this result shall be secured. Under all circumstances, restraint is the first and essential step to any projects whether of alleviation, conservation, or improvement. It has been shown that in the beds of the American, Bear and Yuba there are now lying many millions of cubic yards of material, in positions where it is comparatively harmless, and that each year as a rule adds something to the volume of these deposits, but that whether anything is added or anything subtracted, which is sometimes the case, depends upon the volume and power of the floods. As a rule the mines supply more material annually than the floods are able to transport over the grades in the lower portions of the rivers. If the floods were of sufficient duration, the accumulations would be formed lower down, and in more dangerous positions. Instead of lying in the bed of the Yuba, they would be in the Feather. Taking the Yuba as an instance, the great deposits of finer grades of material are near and below the foot-hills on slopes of 10 feet or less to the mile. The heavier classes of material are found in greater abundance higher up the streams on grades of 20 or 30 feet to the mile. Now if we place across the river beds barriers some feet in height, the slope of the bed above will be reduced, and with it the transporting power of the water. The deposits now taking place will be aided and increased. When the material is gravel and sand, the river bed will be filled to the crest of the dam and be graded back on a slope determined by the nature of the material, the width of the channel, and the volume of the floods. This proposition is not only in harmony with principles of hydraulics, but it is abundantly proven by results of experience on the Bear and American rivers.

When the banks are sloping, as is the case generally in the cañons of the mountain streams, the elevation of the bed increases the width. These slopes are more generally 35°, and an elevation of the bed of 50 feet adds 140 feet to the width. This extended width reduces the heights of floods, the cubes of the heights being proportional to the squares of the widths. Doubling the width reduces the height one-third. The reduction in heights of floods is an important gain in two respects. It reduces the suspending power of the water, and in this way and to some extent favors the deposition of material. It also reduces the exposure of the structure in floods. Another important feature is the increase of the storage volume, consequent upon this increase of width. A permanent structure will make permanent storage, for the reason that it will prevent the river at any time from eroding the deposits to the original bed, which otherwise would take place sooner or later. It may be asked whether the protection afforded in this way will be complete, and include all grades of mining tailings. This cannot be claimed. The suspensory matter of fine sands and clay cannot be restrained in this way or by any other method which does not provide a settling basin in which the water can be maintained in a quiescent state for some time. It may also be expected that during the flood stages in the early period of development, a certain portion of material of every grade may be suspended, and thus pass the crest of the barrier, but it is to be remarked that as the width is increased the suspensory power is diminished, so that the degree of protection becomes greater as the system is developed. We can imagine a condition of a river when comparatively little is carried suspended, and nearly the whole of the material transported is rolled in waves on the bottom. This condition is more and more approached as the dams are raised. It seems therefore to be good policy to give the first dam in the cañons considerable height. It will be understood that permanent protection can be attained only by building dams in proportion to the amount of detritus turned out by the mines. The system must be continued at least as long as the mines are worked. If this system of restraint had proceeded *pari passu* with mining during the past thirty years it can hardly be doubted that the condition of the country affected would to-day have been much better than it is. A system begun now is obliged to deal not only with the current action of the mines, but is also compelled to contend with the accumulated difficulties of thirty years. The same principles apply to the large deposits of finer materials that are found in the plains, particularly on the Yuba and Bear. A considerable mass of detritus has, however, reached positions in which no control can now be exercised, but so far as barriers can be applied to hold the sands in their present position it is thought that they ought to be constructed. In particular mines it is impossible to store all the detritus before it reaches the river-beds, and perhaps in many cases partial storage is possible. It is needless to remark that this kind of storage ought to be insisted on whenever it is practicable. The amount of storage that will be secured by a barrier of given height is in our present state of knowledge to some extent indeterminate. It depends in any case directly upon the grade of equilibrium which the material takes behind the barrier, and this cannot be regarded as constant, for it must depend upon the violence of floods, in which respect there is much variation. It cannot be doubted that as the bed is widened and the height of floods thereby reduced, material of a given size will be found to be in equilibrio on a grade steeper than that of equilibrium in the original bed. This secondary effect of width shows that the storage prism will grow in a greater than arithmetical ratio as the dams are raised and the widths increased. The barriers or dams, to be permanent, must be made of stone in all exposed parts. If wood is used it must be in circumstances where it will be kept wet. In the canyons the dams will consist of a mass of stone blasted from the side hills and deposited with only sufficient care of arrangement that no continuous currents can be established through the structure, and that the velocity of the water shall be broken by repeated falls. For purposes of estimate, the dams are protected with slopes of 1 upon 1, and one upon 4, above and below, respectively, but an arrangement of stones on the lower face to an uniform slope would be a serious error in construction. The more this slope can be broken by falls and the rougher its outline, the more effectually will the destructive action of the water in severe floods be counteracted. In order to fulfill these necessary conditions, it is essential that the quarry shall supply large stones, the larger the better, for exposed positions, and smaller grades to measurably fill the interstices of the larger. Where the foundation is natural rock, it is proposed to use only stone, but in cases where the foundation is gravel or sand, a grillage or mattress of timber or brush will be required to prevent settlement. The purpose of barriers or dams being to restrain sand and gravel, and not to impound water, it is not essential that they shall be impervious, nor can they be water-tight. Being unable to store water, it is impossible to conceive them, in the event of breach, as capable of inflicting disaster upon riparian inhabitants below. Nor could a breach cause an unusual flow, to any great distance, of detritus in a given flood, for the reason already established, that floods are now fully loaded with all the material they are able to carry. The result of a breach, however serious, could therefore be only to restore conditions now existing. Moreover, it is impossible to conceive sudden and wholesale disaster overtaking one of these structures. They may settle, and their usefulness may be impaired, but being simply a mass of large rubble stone without bond, disaster cannot take great proportions or be an element of sudden danger to persons or property. In cases where brush or timber is much cheaper than stone, it will be permissible to use it more freely and make a considerable part of the structure of this material—after covering it with stone. The moisture below the surface of the river-bed may be relied upon to keep the wood wet, and the covering will protect it from the rays of the sun. It may be well to say that while structures for the same purpose have been used in the Alps and Appennines, there has been no occasion elsewhere to require dams of the same dimensions. They are to this degree novel, and their exposure in floods may require attention and expense in repair. The site for the dams ought to be such as will give the maximum storage above, and to this end, the larger the area and the lighter the grade of the river the better will be the position. This system of restraint has been put in operation in a partial and insufficient way by the State of California, in the construction of two brush dams, one in Bear and the other in the Yuba, at the edge of the foot-hills. They were described in the report of January 10, 1881. On this date they were standing intact and doing good service. Later they both met misfortune, and considerable portions of each were carried away. A report of their condition in the summer of 1881 will be found in Appendix 3. They have not been repaired, the State having relinquished any attempt to deal with the engineering features of the case, owing to the unconstitutionality of the act of the legislature under which it was acting.

By a comparison of survey in 1880 and 1881, it was found by the office of the State engineer that 4,851,000 cubic yards were impounded above the Yuba dam. Above the Bear River dam 961,000 cubic yards were impounded. These dams serve the purpose of controlling deposits on the plains to a certain and beneficial degree, and it is thought that good policy requires them to be repaired and raised. Perhaps, subsequently, they ought to be covered with stone. In the application of this system it will be plain, from what precedes, that the Yuba presents the case, of greatest necessity, and requires the greatest storage volume. The American and Bear also require the system. As to the Feather, it appears from the report of Mr. Manson, hereto appended, that the canyons of the Feather are unsuitable for storage, and, what is quite satisfactory under the circumstances, that the extent of mining on its upper waters, and the amount of injury resulting therefrom, are not of such a character as to require remedial measures. It is not so, however, with the mines on the lower Feather, in the neighborhood of Oroville. These mines discharge into the Feather at points below which there is no opportunity to store the detritus.* A group of mines 12 miles north of Oroville, at Cherokee, the principal of which is the Spring Valley mine, at present need no attention, for the reason that they do not contribute to the navigable water any material capable of being stored. The heavier material is stored below the mines, at the edge of the foot-hills, and the remainder is deposited on lands lying between the mines and the Sacramento River. It is thought that no considerable quantity reaches the Sacramento River. In regard to the Cosumnes, and the rivers to the south, the damage done thus far is comparatively insignificant, and the prospects of mining are not very favorable. Reservoir sites have been examined which will serve when the occasion arises for their use. The Calaveras, it is now thought, may be the first of the southern streams to require the application of the system, and an excellent site exists for the purpose. For special information in regard to these rivers, reference may be made to the report of Lieutenant Payson, hereto appended. The following statements embrace the measures and constructions which are recommended for the Yuba, Bear, and American rivers, with estimates of cost of the system maintained for a series of years. It is recommended to occupy at once two sites for storage, and after several years a third. The first and upper site is at the narrows just above the mouth of Deer Creek, which enters the Yuba about 12 miles above the plains. The next two sites are below on the edge of the plains, one at De Guerre Point, and the other the brush barrier built by the State of California. The features of the upper site are these: The width of the river-bed is 270 feet; the banks slope at angles with the horizon between 32 and 50 degrees for a height of 200 feet. There is an abundance of stone in convenient positions, and favorable as to quality and sizes. Mr. Manson observes that it will quarry in pieces varying from 2 to 30 tons. The river for 44,500 feet above has an average width of 300 feet, with a fall of 22 feet per mile. The banks have inclinations of 30 to 35 degrees. The South Yuba joins the river 8 miles above the site. In the future development of the system this stream will afford considerable additional storage. The height of floods is 12 feet. The storage is calculated on a grade behind the dam of 14 feet per mile. The grade of the top surface of the prism is held constant in the calculation. We know that the grade for given material must become steeper as the river-bed is widened. The probable storage is therefore in excess of the tabulated amount. No allowance is made for material necessarily escaping, or for that which may remain stored above the reservoir. Both of these points are assumed at the worst. The estimates are therefore larger than they would have been if allowance had been made for these considerations. The Deer Creek site is below all mining dumps except those of the Smartville Group and the minor output at Sicard Flat and Dry Creek. The length of river-bed taken by the reservoir, formed by a dam 75 feet high on a grade of 14 feet, will be 9 miles, obtained by dividing the height of the dam by the difference between the present grades and that assumed for the future grade. The lower site may be either De Guerre Point, or that of the Brush Barrier, erected by the State in the year 1880. This structure was much injured by natural causes in 1881. Since the date of that report the dam has been injured by fire, applied, it is supposed, by design. Its present condition is worse than when examined, but to what extent is not known. The advantage of restoring this structure is that by its position it exercises restraint of considerable amounts of sand and gravel already in the plains, which otherwise will be free to move below to navigable waters, and serve to threaten the town of Marysville still more. The project consist in repairing the breaks in the dam and restoring it to the original height in the first year, at a cost of $80,000. In the second year to cover it with stone to the depth of 4 feet, raising the height of the dam 4 feet. The estimate contemplates, first the construction of a dam at the Narrows, then the restoration of the Brush Dam and covering it with stone, the De Guerre Dam being the last undertaken. The yearly expenditures for a series of years are given in the accompanying table, as nearly as they can be foreseen.

* This group of mines is in a position to do special injury to Feather River, as may be seen from Mr. Manson's report, Appendix 2, to which reference is made.

Table showing estimates and order of structure upon Yuba River for ten years.

Year.	Structure erected or raised.	Annual cost.	Total cost.	Storage provided by each structure.	Total storage provided.
				Cub c yds.	Cubic yds.
1	Build the Narrows Dam to a height of 75 feet . . .	$224,779	. . . .	. . . . . .	. . . . .
	Repair the Brush Dam	80,000	$325,000	30,000,000	30,000,000
2	Cover Brush Dam with stone .	137,000	462,000	10,000,000	40,000,000
3	Raise the Narrows Dam 25 feet	113,807	576,000	25 000,000	05,000,000
4	Erect De Guerre Dam 5 feet .	100,000	076,000	10,000,000	75,000,000
5	Raise De Guerre Dam 5 feet .	110.000	786,000	15,000,000	90,000,000
6	Raise Narrows Dam 25 feet . .	90,734	876,000	31,000,000	121,000,000
7	No expenditures				
8	Raise De Guerre Dam 5 feet .	74,000	950,000	20,000,000	141,000,000
9	Raise Narrows Dam 25 feet . .	122,000	1,072,000	36,000,000	177,000,000
10	Raise De Guerre Dam 5 feet .	63,000	1,135,000	17,000.000	194,000,000
	Total	1,135,000	. .	194,000,000	. . .

Average yearly cost for ten years, $113,500.
Average yearly storage provided, 19,400,000 cubic yards.

The site elected for a dam in the Bear River Cañon is at or near Van Giesen's Dam. The width of the river-bed averages 53 feet at the site; the side slopes are 15 degrees and 20 degrees. The rock is trap, and the foundation will be on rock. The reservoir space above consists of the river-bed, which in some places is flanked by low banks, which increase the area for storage. The bed for 11 miles above the site is covered to a considerable depth with sand and gravel, on a slope of 25 feet to the mile, the average width being 350 feet. The storage prism is calculated on a grade of 19 feet per mile, being the observed line of deposit due to a dam once occupying the site, and carried out in the past few years. The first structure is estimated at 30 feet in height. The successive additions, with cost and storage capacities thereby acquired, and that due to the repair of the brush structure erected by the State at the débouch of the rivers on the plains, are shown in the following table. A further examination of the levels on the plains needs to be made to settle definitely whether storage after two or three years cannot be secured more thoroughly by occupying lands which lie further down the river, and which have been injured in a greater or less degree by deposits of sand and slickens.

It is recommended to occupy two dam sites on the American, one on the North and one on the Middle Fork. The site on the North Fork is about 1½ miles above the junction of the North and Middle Forks. The width of the river-bed at the site is 75 feet. The banks are hard trap, with slopes of 32 and 42 degrees. The river-bed above the site for about 20 miles has a mean width of 250 feet, and a slope of about 23 feet to the mile, with side slopes of 25 to 30 degrees. The contents of the prism are calculated on a slope of 18 feet to the mile. On the Middle Fork, the site selected is about 12 miles above the junction of North and Middle Forks, and about 2 miles above the mouth of the Cañon Creek. The width of the river-bed is 90 feet, and the slide slopes 42 and 55 degrees. The river-bed above is 125 to 150 feet in width, and the slope 45 feet to the mile. The slopes of the bank vary from 30 to 35 degrees.

Table showing the order recommended for structures on Bear River.

Year.	Structure erected or raised.	Annual cost.	Total cost.	Storage provided by each structure.	Total storage.
				Cubic yds.	Cubic yds.
1	Erect the Van Giesen's Dam 30 feet	$34,600	. . . .	6,700,000	. . . . .
	Repairs, Brush Dam	45,500	$80,100	5,300,000	12,000,000
2	Cover Brush Dam with stone	75,000	155,100	5,000,000	17,000,000
3	No expenditures.				
4	Raise Van Giesen's Dam 10 feet	12,500	167,600	5,800,000	22,800,000
5	Raise Van Giesen's Dam 10 feet	16,400	184,000	9,200,000	32,000,000

8	No expenditures				
	Total	177,200	. . . .	. . . .	.

Average yearly cost for eight years, $22,150.
Average yearly storage provided, 5,200,000 cubic yards.

The estimate for the first year's operations on the Yuba, Bear, and American Rivers is $511,600.

The Gold Run Suit.—A matter of such great importance as has been disclosed in the preceding pages could not, of course, keep out of the courts. The State of California brought suit against the Gold Run Mining Company, a company operating the hydraulic process, not only for itself but for others who purchased water for hydraulic mining. The *debris* started by this company found its way into the North Fork of the American River, and so on to the agricultural lands and into the rivers where it blocked the channels. Suit was instituted in 1881, a jury waived, and the trial took place, before Judge Temple of the Superior Bench of California. During the progress of the suit, an Anti-*Debris* Convention was convened at Sacramento, and the following resolutions passed:—

Whereas, At least 100,000 acres of the finest lands in the Sacramento valley have already been destroyed, and hundreds of thousands of acres of such lands are now in imminent danger of destruction by the unrestrained flow of detritus from the hydraulic mines on the headwaters of the several tributaries of the Sacramento and San Joaquin rivers: and, whereas, the said flow of detritus has already filled the channel of many miles of the navigable rivers of the State, and its continuance must result in a very short time in the complete destruction of said rivers and their tributaries, throwing them in broad, shallow, muddy streams over the fairest portion of the State, annihilating not only the productiveness of the lands, but the cities, towns and villages; and,

Whereas, The navigation of the bay is now imperiled, and the harbor itself must at no distant day succumb to this devastating agency, and ruin overtake the metropolis of the Pacific thus completing a picture of desolation never before beheld by the civilized world: and,

Whereas, There are but few individuals or corporations comparatively engaged in this species of mining; and,

Resolved, That it is the duty of the State of California, as a moral person, endowed with rights and resting under obligations, to defend herself against such fearful mutilation, and protect the people of the valleys in the peaceful and undisturbed enjoyment of the fruits of their labor.

Resolved, That we indorse the action of Attorney-general Hart, in bringing suit against some of the hydraulic mining companies, in the name of the State, to test the right of one man in the pursuit of wealth to destroy the property of another, as well as the common heritage of this and future generations—the navigability of the rivers of the state.

Resolved, That as experience has taught us that the water will readily carry off, without serious consequences, the washings of quartz and drift mining, we wish to say in the most emphatic manner to the miners of the State that we have no contest with any one engaged in such mining.

Resolved, That we have no contest with those hydraulic mines which take care of their debris, but are against those, and those only, which wash great areas of earth into our streams.

Resolved, That the political party that does not recognize the just principle that every man must so use his own as not to injure his neighbor, is not worthy the support of the people.

Resolved, That the attention of the press of the State, especially the metropolitan press, is called to the immense importance of this matter, and to the fact that it has, in our judgment, failed to take the comprehensive view of the subject which its importance demands.

Resolved, That the people of Sacramento valley demand of the executive, legislative and judicial branches of the State that just protection of our property for which governments are established and maintained.

Resolved, That the contest already begun against this system of desolation and destruction of our State is a sacred cause, which should enlist the sympathies and active co-operation of all her people; that the burden of the conflict should not be borne by the few who have heretofore struggled to stay this great destroyer, but should be shared by all the people of our great valley; that in order to reinforce those who are now at the front to concentrate all efforts in united action, we do most earnestly recommend that the several Boards of Supervisors present on this occasion meet together and take such action in the premises as will enable their several counties to contribute that aid and encouragement which only united action can bring, and we hereby pledge ourselves to the support of such action.

Resolved, That the action of the Board of Supervisors of Sacramento county in calling this convention together, meets the unqualified approval of the people of this valley.

The testimony at the trial developed some interesting facts. Mr. G. G. Blanchard was examined as to the number of persons engaged in mining along the American and its tributaries, the quantity of material displaced by their operations, etc., and testified: They all tailed into the most convenient places; each miner displaced about 10 cubic yards of material per day; think there were from 15,000 to 20,000 miners at work in Placer county in 1851-52-53; the displacement by each miner would be about 15 cubic yards per day; there is considerable seam mining now done in El Dorado county; in 1861 there were about 15,000 persons depending on mining in that county; there are now perhaps 10,000; prior to 1862 there was probably 50 times as much matterial removed as since; then the earth removed between 1848 and 1862 was light and of vegetable mold; most of the heavy material mined in later years is still in the vicinity of the mines; no man can tell how far any particular kind of material would be carried in suspension in the South Fork; ten per cent. of the material mined in El Dorado county would not go thirty miles from the mine; some of the lighter vegetable mold might reach Sacramento; the natural wash of the river in Eldorado county is now more than twenty-five times as much as from all the mines; the tailings from the mines are saved wherever possible; it makes the best land in the county; about one thousand acres of land have been thus made, from two to ten feet deep; it will raise what the natural land will not; the blue cement rock makes the very best sort of land after it decomposes and crumbles.

Among the witnesses was James Marshall, the discoverer of gold in California. He testified that the whole Sacramento valley was flooded in the winter of 1845-46. He was told at that time by the Indians and those who had resided here in 1830, that during the winter of that year the entire valley was deeply submerged, the only land visible in the valley being the Buttes. The highest water he ever saw in the American river, at Coloma, was in the winter of 1861-62.

Evidence along the banks, near that town, shows that prior to 1848 the river at some time had been two or three feet higher than it has been since that time.

Hon. Niles Searls, among other things, said: The great bulk of litigation brought before me while I was District Judge, was what is termed mining litigation. The habit of the miners of Plumas, Placer, Nevada, Yuba and El Dorado counties, where I have lived, is to wash the earth in order to separate the gold, and then dump the water and debris into the most convenient canyon or ravine. This has been the universal practice in those counties, except the miners have impounded their own debris in order to wash it a second time. After impounded tailings were washed, they were then allowed to escape through the most convenient and available natural channels. I have been through the mining counties from Amador to Siskiyou. This custom of discharging from the mines the debris into the most convenient canyons or ravines, has been the universal custom among all the miners of California, as far as my observation goes, from 1849 up to the present time. This mode of mining is the only way in which the mines could be worked profitably. Gold mining cannot be prosecuted except with the use of water. I am familiar with all the streams in Nevada and some adjoining counties, and all, or nearly all, of the canals in those counties. [Witness described the Eureka Lake, South Yuba, Rock Creek, Bloomfield, Milton and other canals, giving their locations, source of supply, and the mines they furnish with water. He also described the large reservoirs that held back large amounts of the winter's water for use in summer mining.] The canal companies I have mentioned all have large reservoirs at their sources and some of them have a great many. Some of these are natural lakes dammed at their outlet, three or four miles in length, and varying in depth from nothing to 100 feet. The North Bloomfield reservoir, with which I am very familiar, having boated upon and fished in it for cat many times, is about four miles in length, and has an average depth of from 50 to 60 feet. The water from these reservoirs is not discharged until the waters in the creeks, ravines and natural channels fail. The amount of water discharged from the Excelsior, South Yuba, North Bloomfield and Milton mines is at least double the quantity of the water flowing in the Yuba during the dry season. During the dry season, those mines discharge of this stored water, at least 20,000 miners' inches. This amount of water would make a stream 100 feet wide and 3 feet deep. This volume of water confined in a canal, would float most any of our up-river steamers. During the winter of 1850 and 1851, within an area of three miles of Nevada City, there was an estimated population of 20,000. At least 15,000 of this population were engaged in mining. There are not 100 men engaged in hydraulic mining within this same area at the present time. There were several thousand men mining in Sierra County in 1850. Nearly all the early mining was in light soil and shallow surface diggings. The reservoirs supplying the canals for these mines are mostly situated near the summit. The Bowman reservoir occupies the whole of a valley. It was dammed up in a narrow gorge, and the whole valley, several miles in length and a mile wide, was thus flooded. I consider that the storing of water in the winter, and sending it down during the dry season, greatly assists in the navigation of the rivers of California.

Witness was examined minutely regarding the flow of water from the reservoirs referred to in his direct examination; the quantity of water used by miners daily along the Yuba must have been more than 17,000 inches. [The report of the County Assessor showed the quantity to be about 17,000 inches, supposing the miners to have worked 300 days per year.] The mining population in Nevada county has been largely reduced within late years. Resuming, witness stated that when he testified that the practice among miners was to dump their tailings in the most convenient places, he simply stated a fact; there was no compulsion in the matter—they were not obliged to do so; sometimes the nearest canyon was not the most convenient one; monitors did not come into use in hydraulic mining until 1865; before that the ordinary goose-neck was used; powder was first used largely in 1853 or 1854, but in the gravel banks it was not generally used until 1865; the Excelsior, the Milton, the Eureka Lake and North Bloomfield companies do, perhaps, on an average, sometimes three-fourths and sometimes one-third of the mining now done along the Yuba; they use perhaps more than one-half of the water brought in by artificial means, but there is a great deal of mining done by aid of the natural water-channels; during the flood season, the water in most of the ravines is used for mining.

The suit took 45 days to try, and on June 12, 1882, Judge Temple rendered his decision as follows:

The Findings of Fact.—In the Superior Court, Sacramento county, California. The people of the State of California, plaintiff, *vs.* the Gold Run Ditch and Mining Company, defendant. This cause was tried by the court, a jury having been waived. Having fully considered the evidence, I now find the facts as follows:

First.—The Sacramento and American rivers are wholly within the State of California; the latter is a tributary of the former, flowing into it about one mile north of the city of Sacramento.

Second.—The Sacramento is navigable, and has been continuously navigated by steamers, barges, schooners and smaller craft, and up to 1862 was navigated as far as the city of Sacramento without difficulty by steamers of deep drift, to wit, by boats drawing nine or ten feet of water. That said river has been declared navigable by law to the mouth of Middle creek, which is above the confluence of the American and the Sacramento. That since 1862 the navigation of said river has been seriously impaired by deposits of mud and sand therein, which have in part come from hydraulic mines; so that now the city of Sacramento can be reached by boats of deep draft during the high stages of the water only, instead of at all times, as formerly.

Third.—That hydraulic mining, as that term is generally understood, consists in washing and removing from their natural positions into the water-courses and rivers, by means of water, high banks of earth and gravel containing gold, and thereby separating the gold from the earth, sending the residue, consisting of bowlders, cobblestones, gravel, sand and clay, into the water-courses, the larger portion of which finds its way into the principal confluents of the Sacramento river, and is deposited along said streams from the place of discharge or dump to San Pablo and San Francisco bays, the heavier material being first deposited.

Fourth.—Hydraulic mining has been practiced for 20 years to some extent in the mountains of the Sacramento basin. It attained great magnitude as an industry before 1875, and is still extensively carried on, principally in the counties of Butte, Yuba, Sierra Nevada and Placer.

Fifth.—The tailings from some of the hydraulic mines are deposited in the North Fork of the American river, and large quantities thereof have been deposited in the channel of said North Fork and of the American river, throughout its entire course, and a large portion thereof has been washed and carried down into the Sacramento river. That the tailings from other hydraulic mines are washed and carried into the Middle and South Forks of said river, and in the Yuba, Bear and Feather rivers, which are tributaries of the Sacramento.

Sixth.—That the tailings and deposits from said hydraulic mines, with other matter carried by the waters of said rivers has filled up and raised the bed and channels of said Sacramento river to a great extent below the mouth of the American river, to wit, from six to twelve feet, and has filled up and raised the American river below Alder creek from ten to twenty feet, and in places even more. Such filling has been materially increased by the tailings from the hydraulic mines. Such fillings have shallowed the channels of the Sacramento river, and materially impaired the navigation thereof and has materially increased the liability of the Sacramento river and of the American river below Alder creek to overflow their banks, and has caused the frequent floods in said rivers to be more destructive than they otherwise would have been. That the debris from mines, including the mine of the defendant, has materially contributed to such filling of the river channel, and thereby has interfered with and obstructed the free and comfortable use and enjoyment of large portions of the land upon the American and Sacramento rivers. The American river is, however, obstructed by the levees and the levee system of the Sacramento, which cause the water to be dammed up and made to flow back into the American river and over the banks thereof, during the stages of high water in the Sacramento, and thereby large tracts of land are submerged and heavy deposits made thereon, which would not exist but for such levee system, or the defects in the same. That one of the principal sources of damage by the overflow of lands on the Sacramento river is from the erosion of the bank nearly opposite the mouth of the American river and the break in the levee at that point. That the more immediate cause of this erosion and break was the change in the course of the American river, which manifestly would have produced the break and much consequent damage although all mining operations had been suspended.

That during the highest stages of the water of the Sacramento the channel of said river is insufficient, and even if it had not been filled up would have been insufficient to carry one half of the volume of water sent down by its various confluents, and at such times would break the present levees, even though no mining were carried on. Still the mining debris does increase and aggravate all these evils, and renders the problem of controlling the streams and protection of the valleys more difficult and expensive, and causes more land to be injured and the free enjoyment thereof to be interfered with than would have been interfered with or injured but for such mining debris.

Seventh.—That defendant is, and since August, 1870, has been, a corporation under the laws of the State of California, for the purpose of mining by the hydraulic process and selling water to miners and others. That it is now, and for several years last past, it and its predecessor have been in possession of certain mines and mineral land situated adjacent to the North Fork of the American river, on the north side thereof, near town of Gold Run, in Placer county, and consisting of about 500 acres of land. The surface of said land is about 1,000 feet above said North Fork of the American river. All the material of said mine is capable of being worked off into said American river, and consists of about 20,000,000 cubic yards of material, composed mostly of sand, gravel, small stones, cobbles and bowlders, mixed with small particles of gold.

Eighth.—Defendant, by means of ditches and iron pipes, has conducted to its aforesaid mines a large quantity of water, which it is using and will continue to use under a vertical pressure of several hundred feet, to mine its said tracts of mining land by the hydraulic process, discharging water through Little Giants and Monitors, and dumping all the tailings from such mines into the North Fork of the American river.

Ninth.—Said defendant has been mining its said tracts of land for about eight years past in the mode and process aforesaid, and up to the time of commencing this action, and during about five months of each year of said period, has been daily discharging into the said North Fork between 4,000 and 5,000 cubic yards of solid material from its said mine—to wit: of bowlders, cobbles, gravel and sand, making a yearly discharge of at least 600,000 cubic yards, and will continue to discharge that quantity annually, if the working of said mine is permitted to continue, and at such a rate, it will require some 30 years to mine out and exhaust said mineral land.

Tenth.—That a large portion of the material so dumped by the defendant into the North Fork of the American river has been washed down said river by the water and com mingling with tailings from other hydraulic mines, and still other material, which is the produce of natural erosion, has been deposited in the beds and channels of the Sacramento and American rivers, but mostly in the American river, and upon the lands adjacent to said rivers; and by said mining of the defendant and other mines the filling up, raising and shallowing of said rivers has been materially increased, to the impairment of the navigation of the Sacramento river, and to the excessive overflow of the land adjacent to said rivers, to the great injury of said land, and damage, discomfort and annoyance of a great number of citizens of the State, owners of said land and residents of said valley.

Eleventh.—That the power of water to preserve its channels and to clear out and to carry off deposits in the same is proportioned—other conditions remaining the same—to the depth of the stream and the freedom of said water from earthy matters. That the beds of said rivers have already become so widened and filled that the depth of the water therein has been greatly lessened; that said water, at all times, is heavily laden with earthy matters, chiefly from mines; therefore, said rivers are likely to fill more rapidly in the future, in proportion to the quantity of hydraulic tailings, than in the past. That thousands of acres of good land in Sacramento valley have already been covered by such debris, and, if some preventive is not applied, much further and greater injury is likely to ensue in the future, and large tracts of land will probably be rendered, within a few years unfit for cultivation and inhabitancy.

Twelfth.—That the discharge from the defendant's and other mines so fouls the water of the American river at all points below, as to render said water unfit for any domestic use by the inhabitants.

Thirteenth.—That the filling of the beds of said rivers has, to some extent, obstructed the natural and artificial drainage of the valleys of said rivers, and has interfered with the percolation and flow of the water through the soil, and has raised the soil water to such an extent as would naturally increase the tendency to malarial diseases; but I do not find that heretofore, it has had any effect on such diseases, and the material carried down by the rivers is singularly free from matter which could ferment and induce malaria.

Fourteenth.—That if the said acts of defendants and others, mining as aforesaid, are allowed to continue, there is imminent danger that the beds and channels of the lower portion of the American river, and of the Sacramento river below the mouth of the American, will be so filled and choked up by tailings and other deposits that said rivers will be turned from their channels, cutting new water-ways, injuring or destroying immense tracts of land, and probably will result in greatly impairing the navigability of the Sacramento river.

Fifteenth.—That the filling in of said rivers below Alder creek has been accumulating from year to year. The largest deposits were made by the floods of 1861 and 1862, since which time there has been a steady increase in deposit and a slow but constant working down in the channels of the rivers of the heavier material; that it is not possible to determine the proportions of such deposits which come from mines now working in other sources, but it is quite prohable—in fact, almost certain—that very much the larger part of that which injuriously fills the rivers is composed of material dumped into the river from mines within ten years previous to the fill in the river.

Sixteenth.—That the waters of the American river and its tributaries, during the recurrence of high water in each year, move and transport portions of the debris then in the river further down the stream, and the most of such matter finds its way ultimately below Alder creek, which is a point in the American river near where said stream emerges from the foothills, about 27 miles above the mouth of said river.

Seventeenth.—The grade of the American river above the Alder creek to Canyon creek is about 30 ft. per mile. The mine of defendant is about 83 miles, by the river, above Sacramento, and is a blue-gravel mine, and constitutes a portion of the ancient river channels which cross the present river system diagonally.

Eighteenth.—That the Gold Run mine, in 1854 was within the mining district known as Gold Run district. That mining rules and regulations were in force in that district, as in all other districts in this State, which prescribed the size of the mining claims, the manner of locating and recording them, and the amount of work to be performed to enable the locators to hold their claims. Miners' rules and regulations had no force beyond the district. Claims in the Gold Run district were in small parcels, about 100,000 square feet, and were taken, held and worked by a large number of persons, commencing such work in some of the claims as early as 1852, and were so held until sold to defendant, which has since acquired title to said lands by means of patents from the United States. That between the years 1854 and 1874, the upper levels of the Gold Run mines were practically all worked off, leaving the lower portions thereof next to the bed-rock to be worked off. Such lower portions now constitute the mines of the defendant, and yield in gold from 5 to 20 cents per cubic yard. The mining ditch property cost the present company $253,000, including tunnels and all improvements in the same.

Nineteenth.—The rules and regulations of miners did not purport to regulate the mannner in which mining claims should be worked, nor the manner or places in which mining debris should be dumped; but the universal practice was to discharge the tailings into the most convenient stream or gulch, even though it should interfere with claims located in the streams or ravines below. It has been a custom, almost universally acquiesced in, in the mining communities of this State, to regard the streams as common ways for the discharge of mining detritus. The exceptions being where such stream has been previously occupied by some works, such as a ditch to convey water. Such right on the part of the mine owners is, in most cases, essential to the economical working of the mine. Such practice is necessarily confined to the mining localities and has not been recognized or acquiesced in elsewhere, except that the waters of the streams throughout the entire course have been rendered turbid and foul without complaint until within the past few years.

Twentieth.—That neither this State nor the United States has licensed the defendant or any miner to dump his tailings into the streams so as to be transported into any navigable river, stream or bay, nor has this State legalized the same. Nor have the Sacramento or American rivers been dedicated to the use of the miners as a place of deposit, or for a way to transport mining material, nor is either cause of action set forth in the complaint barred by the provisions of Secs. 315, 338 or 343 of the Code of Civil Procedure of this State, or of either or any of said sections.

Twenty-first.—That the acts threatened to be performed by the defendant in continuing to prosecute its mining industry in the manner set out in these findings, as it will do, unless restrained, if allowed to be done, will, in connection with like acts by others, obstruct the navigation of the Sacramento river, and fill up, to some extent, Suisun bay, destroy or injure large amounts of land, and constitute an obstruction to the free use and enjoyment of the property of a large number of citizens of this State.

Twenty-second.—Ancient gravel channels exist, at least 200 miles in extent, from Mariposa county to Siskiyou, crossing the present river system diagonally and at higher altitudes. These channels are from 200 to 2,000 ft. wide, and contain gravel sometimes several hundred feet deep. Gold is distributed quite uniformly throughout the length of the channels. The first mining was generally in the present rivers below where they had washed out the old channels.

Competent persons estimate the entire product of gold from California mines at $1,154,689,036 up to June, 1881, $900,000,000 being from the ancient channels. The present yield varies between $15,000,000 and $20,000,000 per annum, and there is no doubt much more gold still remains in these ancient channels than has been washed out. Present investments in California mines are estimated at $150,000,000, $100,000,000 of which is in hydraulic mines. Some portion of this is, no doubt, in mines which cannot be profitably worked. Mining for gold is the principal industry in 15 counties of the State, and the population of the mining counties is over 100,000. In the past eight years the amount of material washed from hydraulic mines has diminished, owing to change from washing light surface gravel with few bowlders to heavy bottom gravel, and from steep grades in the sluices to light grades. The amount washed from a mine will depend upon the amount of water used, the character of material and grade and size of sluices. Late improvements in hydraulic mining do not increase the amount of material mined. The various mines in the drainage area of the Sacramento river have reservoirs in which they store about 7,600,000 cubic feet of water, which is gradually drawn off in the five months after the middle of July, and to that extent increases the flow in the Sacramento river.

General Finding.—To the foregoing findings of fact I desire to add a general finding, explaining, amplifying and perhaps to some extent qualifying them. The case involves the consideration of the operation on natural forces on a large scale, and many conclusions are necessarily to some extent matters of theory or opinion. Conclusions upon such matters when expressed in legal findings often seem to imply a certitude which does by no means exist. The field of observation is so vast that the full case cannot be presented in the findings; much must be left unexpressed, being presumed to be within the judicial knowledge of the Court; as for instance, the geography and generally the geology of the country over which our inquiries have extended; the nature of the ancient river channels and the different forms and methods of mining which have prevailed, as well as the general history of the country—matters which everyone is presumed to know.

The American River.—The drainage area of the American river is 1,889 square miles, mostly on the western slope of the Sierra Nevada mountains. This slope is composed of numerous deep canyons and ravines, high and steep ridges and lofty mountains. The formation is mostly granitic, is largely covered with deep soil, generally of decomposed granite. Originally, there were very extensive forests of immense pine trees. Since the settlement of the country there has been a continuous destruction of these trees for the lumber, although large forests still remain. Numerous roads have been cut and trails made within this area. Considerable industries in fruit raising are carried on in some places, and every summer thousands of sheep are driven from the valleys into the mountains to be pastured. As early as 1852 there were mining in the American river, in Placer county, 20,000 men, and in El Dorado county, 40,000. The earlier mining was in the bars and beds of the river or its tributaries, or in the dry diggings, which were probably older bars made in former geological periods. The work was chiefly in mining, the gravel and sand composing the river bars into the river, generally leaving the heavier cobbles in the claims. The so-called dry diggings were worked during high water. Much of the material being light soil, we sent down the stream, leaving innumerable small pits and piles of debris on the slopes of the mountains. In the winter of 1852-1853 there was a *large flood*, but from that time until the winter of 1861 and 1862—the memorable flood year—there was no flood of moment. Of course, at this time, an enormous amount of material would naturally be exposed to the transporting power of such deluge, and, accordingly, we find that for the first time the inhabitants of the valleys became aware that the water was filled with sediment which menaced the navigability of the rivers, and which left large deposits of sand upon their margins. It is probable that more sediment was brought down by the river during that year than any year since. It is contended by the defendant that most of the sediment in the river is from other sources than mining. Perhaps this is not so important an inquiry as it is deemed. What proportion of sediment is from mining, and what from other sources it is impossible to determine; but it probably may be safely claimed that the greater portion is from mining deposits made within the periods of the recurring high floods, which are from eight to ten years apart. The Sacramento might be expected to bear 19,000,000 cubic yards of sediment, independently of mining debris, per annum. The drainage area of the American river is about one-twelfth of the Sacramento basin. The erosion upon the American river would, however, naturally be much above the average. Let it be placed at twice the average, and then natural erosion cannot be held responsible for half the material which is carried in suspension to the Sacramento, and which is rolled along the bottom of the river, at least below Alder creek. Again the character of the material is *an important consideration.* Generally the wash from other sources than mining is the very lightest material; the exceptions are land slides and sudden cutting of gullies on the hill sides. The wash from such sources, therefore, would be easily managed by the great volume of the lower rivers, and would be carried in suspension to Suisun bay, which is the great settling reservoir of the basin. The damage to the rivers or the adjacent land would be slight. Mining debris, however, is of all degrees of fineness. The question as to what will be carried down will depend upon the size of the rocks which the water has sufficient force to roll along. In other words, it will furnish the heaviest material which can be transported. This is just the material which naturally fills the rivers below the foothills more or less permanently while slowly but constantly creeping further down the stream. It is probably from this source mostly, rather from causes other than mining, that the material has come which has filled the channels of the Yuba, and the Bear, near their confluence with the Feather. It is contended by the defendant that all the debris which it puts into the

American river (save a small per cent). remains permanently above Rice's bridge—a point about nine miles below Canyon creek—and no question in the case has been more minutely examined. This portion of the river is through a rocky gorge with banks sloping at an angle of from 30 to 40 degrees. According to a profile furnished by the defendant, the grade of the original bed from Canyon creek for about two miles, was over 70 feet per mile; then for a distance of over four miles the average grade was a little less than 40 feet per mile, with occasional spaces of several hundred feet each, in which the grade was ascending. The remaining distance the grade was about 21¼ feet per mile. There is a large fill now in the river, commencing about one-half mile below Canyon creek.

The Surface Grade of the present bed for this portion of the first section which contains any fill one and one-fourth miles is 46 feet per mile. The grade of the next four miles is 40 feet, and the remainder over 36 feet per mile—the last quarter of a mile being 25 feet per mile. Prior to the commencement of the work in the present pit, or lower portion of the mine, it is estimated that there had been washed from the upper, or old washings, 67,000,000 cubic yards of material, which also come into the American river through Canyon creek. Also large quantities of material were placed in the same sections of the rivers from the Iowa Hill mines. The surface of the old washings was principally light red earth, with sand and pipe clay. In the channel, however, the old washing was chiefly composed of gravel, sand and cobble stones. The old mines ceased to be operated because, as the miners say, they ran out of grade, and not because of a change in the character of the material. The banks are of a mixed character of sand, gravel and cobbles, from the top to the bottom. In the present pit, however, there is no pipe clay in the ribbon or channel which will be worked, and none of the red earth, and there is a constant increase in the average size of materials as we approach the red rock. There was no clear line of distinction between the present and old washing. The great proportion of material in the lower pit, therefore, cannot reasonably be heavier than 10 per cent. of largest material in the old washing. It seems that, prior to 1875, this portion of the river was filled with this debris to a much greater depth than at present. All the material was washed out and went down the stream, as also vast quantities of material put in from the Iowa Hill mines. The material in the river is naturally graded as to size down stream; the heavier being first lodged, and then the next in size, and so on.

The heavier material, therefore, cannot hold back the light debris which has been separated by the water, and is constantly washed lower down. If all the detritus from the top washing has gone down over the lower grades of the original bed, certainly that portion of the material in the present pit, which is not heavier than the largest cobbles in the old washing, will pass over the present increased grades of the river, if we suppose that the hill now there is so impact that it will remain. But I think it altogether probable that the profile is incorrect. The surveyor who made it is evidently competent and apparently candid, but he did not measure the depth of the fill. The estimate must be very much in excess or considerable of the old fill must still be there. In either event the case must be taken as established against the defendant—that a considerable portion of the material will and does come down the river. It may be added that at high water the current of the river at this point must have a velocity of at least from six to eight miles per hour. There are few cobbles of bowlders which will exceed 10 inches in diameter. Theoretically they would all come down.

The Conditions in the American River differ widely from those at the Polar Star dump in Bear river, aside from the fact that the material at the Polar Star is heavier and the stream of less force. At the Polar Star, if I have rightly understood the evidence, the fill is immediately at the dump, some of the material rolling up the stream above the point of discharge. The larger bowlders, therefore, do hold back the lighter material. At Canyon creek the material, after it reaches the river, is transported by the water from half a mile to six and eight miles before it finds a lodgment, and is, of course, completely graded by the action of the water, it settles on a steep incline and is so distributed as to build up the bed of the river to a uniform grade. It forms nothing like a dam, but at the upper end rests against the steep grade so as to form a continuous incline, over which most of the material passes, even at ordinary stages of the water while the mine is working. I think it may be assumed that the new grade at Pickering's Bar—46 ft. to the mile—is just the grade over which the heaviest material of the mine will not pass at ordinary winter stages of the river. It certainly all passes over the grade from Canyon creek to Pickering's Bar, and will continue to be completely sorted by the water, and therefore, as it seems to me, a large portion of it must inevitably come down.

The Coarser Material will travel very slowly, probably requiring many years before it reaches Alder creek—10, 20 or more, according to the size. No doubt much which was thrown into the river many years ago is still slowly moving down and, though all mining should cease, will continue to come for many years. This is important, as showing to what extent stopping the work at the mines will afford a remedy. It appears that this part of the injury is easily remedied, and at comparatively little expense, by the erection of dams to impound the debris. If the experts are correct in their conclusions—and I am bound to so conclude—all that is very greatly injurious could be so impounded. Of course during its slow journey the detritus is very greatly comminuted; much of it will be be carried off as clay in suspension; the proportion cannot be determined.

On the American river, and its tributaries, a vast amount of mining was done in early times, and up to this time a great deal is being done beside that by the defendant. No other mine contributes annually more detritus to the river than the defendant; still I am unable to say that defendant's mine alone, without reference to the debris from other mines, materially contributes to the evils mentioned; or, in other words, if there were no mining operations save those of the defendant, I am not prepared to say that it would materially injure the valley lands or the navigation of the river. It is the aggregate of debris from all the mines which produces the injuries mentioned in these findings. The lower portion of the American river is very much filled with debris, and has been, in places, much widened. As yet, however, no such state of things exist there as is seen in the Bear and Yuba near their confluence with the Feather. Perhaps if it were not for that instructive lesson we should not be justified in anticipating all the evils which may yet flow from these constant accumulations.

About one thousand acres of valuable farming land have already been covered with heavy sand along the margin of the American river, and the adjacent lands are subject to frequent overflows. The overflows would probably occur to a considerable extent, although there were no mining. Very much of the trouble from this source comes from backwater, from the Sacramento. In flood times, if the rains have been general, the American is the first to rise. The Sacramento then being at its low state, the flood rushes out loaded with sand and mud, and, with very great velocity, is precipitated on the Yolo shore, and there covers large tracts of land with its sediment. At such times the current is much greater than at any other time, and, of course, a great deal of sediment which has accumulated in the river during slack or low water is carried out.

About fifteen hours after the rise of the American, the flood from the Feather, also surcharged with mud, reaches Sacramento, and 36 hours later the floods of the upper Sacramento. By this the current of the American is checked, and considerable land sometimes remains submerged by back water. At such times, of course, sediment is left both on the lands and in the channel of the river, which otherwise would have gone off in suspension.

SACRAMENTO RIVER.

The plane of low water has been raised about six and one-half feet since 1849 in the Sacramento. The rise in the low-water plane has been continuous since 1868, when the low-water mark was about two feet above the low-water plane of 1849, although in some years, probably for special reasons, it has been higher than in the succeeding year. This indicates that the bed of the river at the shoals has been filled at least six and one-half feet, and probably much more. The consequence is that the influence of the tide is not felt above Haycock shoals—nine miles below the city—it formerly being about two feet at Sacramento. As we go down the river there is a less elevation of the low-water level, indicating an increase in the grade of the river, from which will follow additional force to carry off the sediment.

The levees of the river are insufficient to carry one-half the water during the periods of the higher floods. Breaks are therefore, inevitable, and perhaps have caused, in some localities, greater damage than would have occurred had there been no levees. The levees, to some extent, increase the scouring force of the water, but not so much as would be the case if the water were not at its high stages already surcharged with sediment. The levees, also, somewhat prevent the river from wasting its material along the banks and building up the valley as it builds its own bed, and causes it to carry to its mouth more material than it otherwise would do. As to the islands below Grand island, I conclude from the evidence in this case, that at present they cannot be reclaimed by any practical means. Of course, the quantity of sediment in the river makes the problem more difficult and the means more expensive if they are to be reclaimed; but it would seem evident that this cannot be done at any reasonable cost until they are still further built up by the operation of natural causes.

Sacramento City.—I am compelled, by the weight of the evidence in the case, to find against the plaintiff in the charge that the prosecution of its industry by the defendant, with similar operations by others, has impaired, or to a material extent is likely to impair, the sewerage of Sacramento, or injuriously affect the sanitary condition of the city. The sewers of the city are about seven feet above tide water. The drainage was never into the Sacramento river, and perhaps could not rightfully be there. It does not appear that the city has been deprived of any outlets for its sewerage by debris, nor do I see that the drainage has been interfered with, except during the very highest floods, which may be expected about once in eight years. The interference, at all events, is quite inconsiderable. It is said that the soil-water is raised in the city by sipage, so that cesspools are emptied of their contents. It is natural to think that raising the water level in the river will necessarily raise the level of soil-water in the vicinity. That it does so, to some extent, I cannot doubt. The drainage canal from Sacramento to Snodgrass slough, a distance of 25 miles, has a fall of about six feet. There can be no good drainage under such circumstances without pumping, and I do not see how the debris has made matters worse in this respect. The health of the city has been steadily improving for the last 25 years, and during all that time the city has ranked very high in regard to healthfulness with cities of equal population and similarly situated. There has been manifested during late years, however, some tendency to a change in the character of the disease, from those of a purely malarial character to those of typho-malarial character. This seems to be the usual course of disease in all newly settled countries, and according to the testimony in this case, could not have been otherwise. The slight indication of a typhoid epidemic during one year is nothing more than is to be expected in any city. I am entirely satisfied that the question whether the deposits of debris in the vicinity of Sacramento have affected or will injuriously affect the health of the city is altogether too much a matter of theory to be the foundation of a judgment which shall deprive the defendant of the use of its property.

Fouling the Streams.—The first mining in the river bars and channels discolored the waters to some extent as early as 1853, and the rivers have become more and more discolored by sediment since. The early mining was in well-washed sand and gravel, which contained none of the red earth which has since so highly colored the water. The dry diggings were in red earth, but were prospected only during high water, and therefore during the summer the rivers became reasonably clear. As ditches were constructed, and mining in what are called surface diggings, as contra-distinguished from deep gravel mines, commenced, the water began to be colored as at present, red or yellow. This color is from sesquioxide of iron, which is not found in the deep gravel mines. The cementing material, however contains protoxide salts of iron. Peroxidation of this commences upon its exposure to the air and water. This ferruginous clay is readily transported by the water, and probably is not so peroxidized as to discolor the water while being transported. Washing in the red gravel has greatly diminished since 1875; but probably the water still receives its deep color principally from surface washings. There is evidence of considerable filling in the San Pablo Bay, principally along the channels through the bays. Practically there is yet no impairment of navigation in this bay, and is not likely to be for many years to come. Suisun bay is rapidly filling with sediment, but I conclude from the evidence that the volume of water passing through will always maintain channels sufficient for the purposes of navigation.

Conclusions of Law.—*First.*—That the plaintiff's cause of action and its right to relief in this section demanded, is not barred by all or either of the statutes of limitation pleaded by the defendant in this case or otherwise.

Second.—That defendant has not acquired any right to the use of the bed of the American river, or of the Sacramento river, as places of deposit for its mining tailings, nor to choke or fill with such tailings the channels of said rivers in the valleys thereof, nor to flow or overflow the said lands situate along the bank thereof.

Third.—That the said acts of defendant constitute a public nuisance, in that they are an obstruction of the free use by a considerable number of the citizens of this State of their said lands, situate along the banks of said rivers as aforesaid, so as to interfere with the comfortable enjoyment thereof, and in that they unlawfully obstruct the free passage and use in the customary manner of the said Sacramento river.

Fourth.—The mining customs, usages and regulations authorized by the statutes of this State, or recognized by the decisions of its courts, are local in their operation, and have not and are not intended to have any effect beyond a mining bar, diggings or district in which they have been adopted or recognized.

Fifth.—That the mining laws and mining customs or practices of the said Gold Run mining district, in which said defendant's mines are located, mentioned and referred to in the findings of fact herein, were not intended to and did not and cannot protect the defendant in the doing of the acts, matters and things complained in this action.

Sixth.—That the plaintiff is entitled to a decree of this court restraining and enjoining the defendant, its superintendent, agent and employees, from discharging or dumping into said North Fork of the American river, or into Canyon creek, and also from suffering or causing to flow into said rivers any tailings, bowlders, cobble stones, gravel, sand, clay debris or refuse matter perpetually, or until it shall be first known, upon application made to this court for modification of such degree, that dams shall have been built in said American river, which will prevent the heavier portion of said material, including the coarser sands, from coming below Alder creek, or until some other means equally efficacious shall be adopted to impound liquid debris, and which, in the opinion of the court, upon such application, will certainly prevent sand, and all heavier material than sand, from being carried by the water below Alder creek.

J. TEMPLE,
Superior Judge, presiding.

June 12, 1882.

The Opinion.—The people of the State of California, plaintiff, vs. The Gold Run Ditch and Mining Company, defendant.

This action is brought to restrain the defendant from dumping his tailings into the North Fork of the American river. It is charged that these tailings, being washed down by the current, are deposited in and fill up the channel of the American river below Alder creek, as well as the Sacramento, impairing the navigation, increasing the liability of both to overflow, and making each overflow more destructive, causing deposits upon the farming lands, thereby rendering them unproductive, raising the soil water, which also tends to unproductiveness, and producing malarial and other diseases among the inhabitants of the valley. It is substantially found that much of the tailings come down the streams, filling up the rivers, and producing most of the evils charged. Navigation has been obstructed, much valuable land covered with sand, and that the continuation of the practice will probably be productive of still greater damage. The finding may be considered for the defendant, however, upon the charge that the debris adds materially to the malarial influences, or have obstructed, or will obstruct the sewers of Sacramento, or have injuriously affected the sanitary condition of that city. It is found that mining pollutes the water of the rivers with mud, rendering them less suitable for domestic purposes. And that numerous other persons engaged in the same pursuit contribute debris to the same streams, but for which contribution the rivers would be able to maintain their channels without serious obstruction, notwithstanding the detritus from the mine of defendant. The case is quite unusual in some respects, and I have departed from the customary findings by adding a general finding in which are stated some conclusions in a mode less formal, and some deductions from the evidence, hoping that the special findings will be sufficient to sustain the judgment and that the general conclusions may aid the appellate court in a review of the case. The decision has been more or less delayed by other official work, and somewhat by failure to receive in time the promised briefs, and I especially regret that counsel for the defense have not complied with my repeated request that each party would suggest the points upon which special findings were required. There is no possible utility in an elaborate argument on my part in support of the conclusions to which I have arrived; but, in fairness to counsel, I will briefly state some of the conclusions.

The defense—which may be designated by the terms statute of limitations, prescription, dedication and way of necessity—may be passed with the remark that obviously the plea indicated by each term or phrase cannot be a defense in this case. Indeed, it apppeared to be on the argument neither was really relied upon, but were all used as a convenient means of illustrating and enforcing a more plausible proposition, which may be briefly stated as follows: The customs, usages and practice of miners, which have universally prevailed, and which have everywhere been acquiesced in throughout the State ever since its organization, have sanctioned this use of the navigable streams, and in connection with the recognition and approval of the Government, both State and national, for a long series of years. Every one knowing the practice, and no one objecting, has changed the common law upon this subject—or at least the equitable circumstances exist which bind the consciences of both Governments and which cannot be disregarded by them. The equitable circumstanees alluded to are manifest and could hardly be too strongly stated. So great a calamity to so many people as would result from a judgment in this case, were it to be a precedent, has probably never been produced by any case in the country. And the acts which are said to be wrongful have certainly been tolerated so long without objection, if they have not been encouraged, that no shadow of blame can possibly attach to those who have invested their money in it. If the question were in a legislative body, whether some law which had permitted it, and under the sanction of which it had grown into importance, should be repealed, the suggestion would be irresistible. So it would in an action, perhaps, where it involved only the proprietary rights of the Government, or any interest of the Government, simply considered in its corporate capacity. Such were the facts in the cases cited for the defense. But there can be no estoppel which shall prevent the State from exercising its general governmental powers in providing for good government; and certainly no equities can grow up in favor of one set of citizens as against others by the fact that illegal acts have been long tolerated or that they are convenient in the preservation of a great industry the importance of which has been repeatedly recognized. Here are many citizens complaining that their rights are being violated, their property and their health threatened, and their common highway over navigable waters obstructed by the illegal acts of the defendant and others. To constitute equitable circumstances which can bind the Court in such a case they would need to be such as would legalize the acts claimed to be wrongful. Has, then, the national or State Governments licensed the defendant to make this use of the navigable streams, or in any way legalized the practice? Has the common law in that respect been modified, as claimed by the defendants? It is of course not claimed that any action on the part of the Federal Government has changed the common law of this State. That is not within the authority of that Government. So are the authorities, and they were not needed in so manifest a case. And it would seem equally clear that the United States has not licensed this use of the rivers, and that it cannot do so, nor can it dedicate them to the use of the miners.

For the purpose of this inquiry it may be conceded that it has licensed the miners to enter upon the public land, to prospect and dig for gold; to appropriate the waters from the non-navigable streams and conduct them for long distances, discharging them again—perhaps into streams from which they were not taken—corrupted and surcharged with mining debris, washing the hills down into canyons and the channels of the mountain streams. To make every canyon or gulch a common way for the tailings of all. That it has finally sold to them the mines with the right to extract from them the gold, and with the full knowledge of the mode of working them, and with full knowledge that the practice of miners in this respect was universal and under claim of right. These propositions are not admitted on the part of the plaintiff, but do any or all of them imply the consent of the Government to the deposit of tailings in the navigable rivers? Obviously all these are the acts of a landowner. The Government has suffered this occupation and use of the public land. They can imply nothing more, for the United States has no further rights in the matter, or power over it. It was stated on the argument that Congress may, and perhaps has, devoted these navigable waters to this industry, under the power to regulate commerce. But evidently this cannot be so. The reason given was that gold facilitates commerce. The products of most industries promote commerce. Nothing facilitates it more than a good government and security for property. Under such a construction, the power to regulate commerce with foreign countries and among the States would be the Aaron's rod to swallow all others. The reserved powers of the States would only be exercised by sufferance. Mining is not a branch of commerce, and certainly not of commerce with foreign nations or among the States. But, if Congress did possess the power, the intention to permit the destruction of navigable waters, so extensive and important, could not be inferred from any doubtful acts. Such a policy is opposed to the practice of all civilized people, and to our own traditions especially. It is manifest from a simple statement of the proposition, that no such result was or could have been anticipated. Then the evil was not evident immediately. There does not seem to have been any material injury until 1864, and even yet it is stoutly denied that the tailings materially injure navigation. The suggestion as to the intention to be inferred from the acts committed and industry encouraged apply with equal force to the claim that the State has licensed this use of the navigable waters.

The Legislature and the courts have recognized the fact that the United States has licensed this extraordinary intrusion upon the public land and the rights asserted by the settlers. Beyond this it has provided for their governmental wants as it has for other communities, and has done so, in part, by recognizing the rules and regulations adopted by themselves when they practically had no government, save such as sprang spontaneously from the instinct for order and genius for organization which seems part of the nature of people accustomed to self-government. These were principally to settle their possessory rights to the land, and to subject it to what was then a novel use under our system, As has been said, it, by wise judicial decisions, has molded them into a comprehensive system of common law, embracing not only mining law, but also regulating the use of water for mining purposes. Perhaps these customs and the practices of miners have been the chief agency in modifying the law of riparian rights—if it has been modified—as not suited to our climate and civilization. In all this, however. there is no rule or custom which can justify the claim that by common consent the navigable waters were subjected to the use of mining, so as to allow tailings to be deposited in them to the injury of navigation. The only thing that can be said is that, in the prosecution of a great industry by a great many people, the practice of dumping into the mountain affluents of these streams has been followed for a long time, and that a great deal of money has been invested in the business, in the full belief, justified, to some extent, by long toleration, that it would be permitted to continue, and that extensive villages have grown up dependent upon it. The rules and customs of miners and their practices, or the fact that they have become part of the common law, outside and apart from this long tolerated practice of dumping into these navigable streams, cannot affect this question. The practice of dumping directly into the navigable waters has never existed, and it is difficult to see how long submission to the consequent injury differs in any respect from any other case where a community has tolerated a nuisance for a long time. In other words the defense is an ingenious attempt to evade the rules, *Nullum tempus occussit regi*, the evidence of acquiescence is long endurance. The mischief, however, as has been said, was not immediately apparent. An action could not have been maintained, for lack of evidence of injury, for many years. A public wrong is not made legal, and certainly acquires no vested right to be perpetuated from long forbearance. There being no change in the common law, the case would be remitted to the ordinary defense of the Statute of Limitations. I have concluded to so find that when the heavier debris is completely impounded mining may be resumed, virtually refusing to hold that the plaintiff may enjoin such operations as only corrupt the water with mud and render it less suitable for domestic and other uses. Perhaps I am somewhat moved to this by the consideration that mining can never be prosecuted at all. It will probably be impracticable to impound the lighter portion of the sediment. I confess I shrink from a consequence so far-reaching. It seems to be a conceded fact that this is not materially injurious either to navigation or the riparian lands. Counsel denied that there was any intention to assail the prosecution of drift, seam or quartz mining. There was no material injury from that source. The sediment from such mines is of the same character as the material which cannot be wholly impounded. Perhaps this will not materially add to the permitted evil.

The authority of the Attorney-General to bring the action in the name of the people, has been called in question, and may become a serious question in the Supreme Court. Practically, it was made only on the final argument. Under the circumstances, I do not doubt the propriety of my referring that matter to the Supreme Court. If the point were sustained and the case dismissed, in the event of a rehearal, a new trial would be necessary before the vital questions involved in the controversy could be presented to the appellate tribunal. There have been many cases in that Court brought by the Attorney-General, on the presumption that such power exists. No question of authority was made. A trial court, under such circumstances, may well follow the practice until a precedent is formed.

J. Temple,
Superior Judge.

June 12, 1882.

The Decree.—In the Superior Court of Sacramento county, State of California. The people of the State of California, plaintiff, vs. The Gold Run Ditch and Mining Company, defendant.

This cause having been duly called for trial upon the complaint, and answer, and both parties appearing and waiving a jury trial, the said cause was duly tried before court without a jury, and the court having heard the evidence and the argument of counsel, has duly signed findings of fact and conclusion of law therefrom, which said findings are now duly filed in this court;

Now, therefore, by reason of the premises and of the law, it is considered by the court, and it is ordered, adjudged and decreed: That said defendant, and all the officers, superintendents, foreman, agents and employees thereof, be perpetually enjoined and restrained from discharging or dumping into the North Fork of the American river, or into any stream tributary thereto, and especially into Canyon creek, any boulders, cobblestones, gravel or sand from the mines; also from causing any such material to flow or to be washed into said river from its said mines or tracts of mineral land. Subject, nevertheless, to this, that said defendants may at any time, as it shall be advised, apply to this court to have this decree and restraining order modified or vacated and set aside. And whenever, upon such showing, it shall appear that efficient means have been provided to impound, detain and hold back such tailings at any point on said American river above Alder creek, and that such means are sufficient to detain all boulders, cobblestones, gravel and the heavier sand, then said defendant shall be entitled to have said decree vacated and set aside. It is further adjudged and decreed that plaintiff recover costs herein, taxed at ——.

J. Temple,
Superior Judge, presiding.

June 12, 1882.

Upon this decision the *Mining and Scientific Press* made the following criticism: "The decision in the famous Gold Run suit, is a "setback" to the miners; but it is by no means as bad as it might be, or as bad as a mere casual reading would lead one to infer. An analysis of the decision is much more encouraging to the miners than appears at a glance. The immediate effect will be to depreciate the value of gravel deposits temporarily, and to temporarily depress the mining interests of the State. It will bring down the value of the bonds of the mining companies, depreciate their stocks, and cause them more or less embarrassment, in one way or another.

The case will be appealed, of course. A new trial will be applied for, which will be denied, and the case will then go to the Supreme Court of California. There are several technical points to be made in the appeal, among them the question of the competence of the Attorney-General to bring the action.

The decision gives the miners the right to continue mining, *provided* they impound or detain the boulders, cobbles and heavy sand, which can easily be done. As a matter of fact, in the Gold Run mine, none of this sort of material came down at all. The judge says himself it will take twelve to twenty years for the material to reach navigable waters. The miners can soil the waters with lighter mud if they so choose, and they cannot be prevented from doing this. The general conclusions of the decision are perhaps correct. The miners will accept the decision as rendered with fairness by an able judge. The trial lasted many weary days, and an immense mass of contradictory testimony was presented. Experts on both sides testified voluminously. All this the judge had to thoroughly digest, separate the "wheat from the chaff," and there is no doubt, from reading the decision, that the gentleman has given the whole subject close study, careful attention and impartial judgment. Partisan feelings may bring other conclusions, but a careful reading of the decision will convince most persons that, whether right or wrong in the abstract, the conclusions are evolved from arguments duly weighed and considered. Nine out of ten of the mines are prepared to control their heavy gravel, rocks and sand. In fact, nearly all can do it, and will construct such dams as will keep back the heavy material. They will comply with the decision the more cheerfully, knowing that the expenses for so doing will not exceed those of litigation.

The main point of the decision as we understand it, is this: The miners claimed a prescriptive right to dump the tailings into the stream. The effect of the decision is, that no such rights ever existed or were acquired. The miners thought they had this right, and exercised it in good faith. Judge Temple now decides that they had not; but, at the same time, he says they can carry on their industry, provided they restrain the heavy material. Temporarily, capital will be withdrawn from the hydraulic mining industry, until the whole question is settled. We venture to predict, however, that this will not affect the gold product of California for more than one year. During that time such dams will be constructed as will comply with the conditions of the judgment. The judge has tried the whole case on the *known* damage on Bear and Yuba rivers; and he admits that, as far as the Gold Run mine is concerned, he is "unable to say that this mine, without reference to the debris from other mines, materially contributes to the evils mentioned; or, in other words, if there were no mining operations save those of the defendant, I am not prepared to say that it would materially injure the valley lands or the navigation of the river. It is the aggregate of debris from all the mines which produces the injuries mentioned in these findings."

This paragraph shows that if the miners had confined their defense to that particular mine, the suit would probably not have been lost. But the miners have been liberal in this matter and have met the issues broadly and fairly. There is a sort of a panic just at the moment among hydraulic miners, of course, but second thought will convince the most despondent that if the decision says they must impound the heavier material, it also gives them the right to let the lighter material pass on. It is not the heavy material of which the farmers complain so badly. If the miners contended that they had vested rights to dump tailings into the water-courses, and the judgment is that they have not, the same judgment says they can soil and muddy the waters if they choose. There are now some thirty-two of the larger hydraulic mines under injunction, but they are all working. Dams will be built, jointly or separately, and it is not probable the mines will shut down. By taking the proper means, the industry is allowed to proceed, and the radical measures prompted by those who contend that the whole business shall be stopped, are, of course, to be thrown aside, and have received judicial rebuke. The decision is, in effect, a judicial enunciation of the doctrine that the miners cannot empty their sand into the streams. The miners contended they had vested and prescriptive rights to do this. Judge Temple says they have not. The decision not only settles the question as far as this court can settle it, but also does something unusual for a judicial document, viz., suggests the remedy for the evil complained of."

A word more on the subject. The *Mining and Scientific Press* a few days before Judge Temple's decision was given, contained the following,—an evidence of the distinctive importance of the question:—"It would seem, after all the time, trouble and money spent on the famous Gold Run suit, that the Sacramento people might wait until that was settled before bringing new suits. The Gold Run suit has been argued and is now under advisement by the Judge who tried it. The case was well known to be a test one, and is so recognised by both sides. Now, however, new suits are to be instituted, since Sacramento's Supervisors, by a vote of four ayes to three noes, adopted the following:

Resolved, That George Cadwalader, our special legal counsel, institute and take the necessary legal steps to enjoin and restrain all the hydraulic mines and mining corporations from using the bed of the American river and its tributaries as a place for the deposit of their tailings or mining debris, also all the hydraulic mining companies operating on the Cosumnes river, from using the bed of Cosumnes river for the deposit of their tailings and debris in said river.

'The effect of this resolution,' aptly says the Grass Valley *Union*, in commenting on it, 'if injunctions can be obtained, will stop all kinds of mining on the American and its tributaries—bar and bank minings as well as that generally designated as hydraulic, where a large quantity of water under pressure is used. Bank mining on the American has been carried on for 30 years without interruption, and the only way in which such claims can be worked is by tailing into the streams. These are generally owned by individuals or partnership associations, and not by large corporations, and they could not afford, of themselves, to defend in expensive suits. The proposition to bring a series of suits against the miners has a look of maliciousness on the part of the anti-debris people of Sacramento county. An important suit has been tried, and a decision is pending, in which the right of miners to use the streams for tailings is involved. It is an important legal question, and the final decision will establish the rights of all parties. Why not wait for the outcome of this case, instead of bringing a multiplicity of suits that can only result in vexing defendants, proving very expensive, and creating further embittering feelings.'"

FORMS FOR MINING COMPANIES AND OFFICERS.

UNDER this caption we have gathered together many little things that will be of daily value to Mining Companies and the officers and stockholders of the same, as they are of the essentially practical side of mining life.

Mining Company Charter.—We append here, as an illustration of a Western Charter, the Charter, by-laws, &c., of the Hidalgo Town Mining Company.

Whereas, the undersigned citizens of Colorado desire to organize themselves into a company and become incorporated under the provisions of the statutes of the State of Colorado, for the purpose of founding and laying out a town on the public lands in the State of Colorado, and prospecting for and developing mines in said State, we do make, sign and acknowledge the following articles of incorporation, viz: This is to certify:

First.—That the corporate name of this company shall be The Hidalgo Town and Mining Company.

Second.—The objects of this corporation shall be the founding, surveying, platting and laying out a town in the county of Gunnison and State of Colorado, upon the public lands and acquiring title to the land therefor from the United States, under the provisions of law, and prospecting for minerals and developing mines in the vicinity of said proposed town, and to do all other acts and things necessary to be done to carry out the above-mentioned objects.

Third.—The capital stock of said corporation shall originally be fifteen hundred dollars, divided into fifteen shares of one hundred dollars each, provided that the capital stock may be increased to any sum not exceeding one hundred thousand dollars ($100,000) by the vote of a majority of the stockholders at any regular meeting thereof, previous notice of such proposed action having been given by the publication for one month in some newspaper published in the county where the principal place of business is located, said stock to be non-assessable.

Fourth.—This corporation shall exist for the term of twenty years from the date of filing this certificate, subject to termination under the provisions of the laws of Colorado.

Fifth.—The officers of this corporation shall be a President, Vice President, Secretary, Treasurer, and seven Trustees; those appointed for the first year shall be as follows:

H. E. AUSTIN, President.
O. E. HENRY, Vice-President.
M. S. ADAMS, Secretary.
GEORGE W. MCGOVERN, Treasurer.

J. A. Merriam,
N. H. Heath,
P. Churchfield,
Will C. Ferril,
Joseph H. Schlund,
B. F. Baldwin,
Charles A. Smith. } Trustees.

Who shall hold their office for one year, or until the first annual meeting in May, 1882, and until their successors are elected and qualified, and said officers shall constitute the Board of Directors.

Sixth.—The principal office for the transaction of the business of this company shall be at Silver Cliff, Custer County, Colorado, until such time as the Board of Directors shall establish a different place.

Seventh.—"The Board of Directors" and their successors in office shall have power to make all such by-laws as they may deem proper for the regulation and management of the business affairs of the company, not inconsistent with the terms of this charter.

Eighth.—Thirty-three and one-third per cent. of the capital stock of this company shall be paid by the stockholders within five days from the filing of these articles of incorporation, and the balance of said stock to be paid in installments at such times as may be ordered by the Board of Directors at the regular meeting of said Board.

In witness whereof, we, the undersigned incorporators, have hereunto set our hands and seals this 9th day of April, A. D. 1881.

H. E. Austin, (Seal).
O. E. Henry, (Seal).
M. S. Adams, (Seal).
Geo. W. McGovern, (Seal).
N. H. Heath, (Seal).
P. Churchfield, (Seal).
Will C. Ferrill, (Seal).
B. F. Baldwin, (Seal).
Thomas Hookey, (Seal).
Joseph H. Schlund, (Seal).
Charles A. Smith, (Seal).

STATE OF COLORADO, } ss.
COUNTY OF CUSTER, }

On this, the 18th day of April, A. D. 1881, personally appeared before me the undersigned, a Notary Public in and for the county and State aforesaid, H. E. Austin, O. E. Henry, M. S. Adams, George W. McGovern, N. H. Heath, P. Churchfield, Will C. Ferrill, B. F. Baldwin, Thomas Hookey, Joseph H. Schlund and Charles A. Smith, who are personally known to me to be the identical persons who signed the foregoing instrument of writing, and each for himself acknowledged the execution of the same to be his own free act and deed for the uses and purposes therein set forth.

In witness whereof I have hereunto set my hand and affixed my Notarial seal the day and year last above written.

NOTARY SEAL.

W. P. ALEXANDER,
Notary Public.

BY-LAWS.

Sec. 1.—The first annual meeting of the stockholders of this company shall be held at the office of the principal place of business of the company on the first Monday in May, 1882, and thereafter on the first Monday of May of each year, at which time shall be elected the officers named in the charter, each stockholder being entitled to one vote for each share of stock he may own or represent by proxy.

Sec. 2.—If for any cause the stockholders shall fail to meet on the day named in section 1 of these by-laws for the election of officers, the president may call a meeting of the stockholders for the purpose of electing the officers of the corporation, and the transaction of such other business as may properly come before the annual meeting first giving ten days' notice of such meeting by a notice published in some newspaper of the county where such meeting is to be held.

Sec. 3.—Any vacancy occurring in the board of directors of said company, by death, resignation or other cause, may be filled by the board of directors at a regular meeting of said board, or a meeting of said board called specially for that purpose.

Sec. 4.—The regular meetings of said board shall be held on the first Tuesday of each month, and special meetings may be called by the President, or on the request of five members of said board; personal notice of such meeting being given to the members thereof residing in the county where such meeting is to be held, and as far as practicable, to all the members of said board, at which meeting, no business shall be done but such as is named in said notice.

Sec. 5.—A majority of said Board of Directors shall constitute a quorum for the transaction of any business that may properly come before them.

Sec. 6.—The Board of Directors may appoint a Superintendent, to hold his office during the pleasure of said Board, and fix his compensation and prescribe his powers and duties, in accordance with the provisions of these By-Laws.

DUTIES OF OFFICERS.—*President.*—A. Sec. 7.—It shall be the duty of the President to preside at all meetings of the Board of Directors and meetings of the Stockholders, to sign all bonds, deeds or other contracts entered into by, or in behalf of the Company, to sign all certificates of stock and all orders on the Treasurer for the payment of money, and perform such other duties as are incident to such office.

Vice-President.—B. It shall be the duty of the Vice-President to perform the duties of the President in the absence of the President.

Secretary.—C. The Secretary shall give due notice of all the called meetings of the Stockholders or Board of Directors, prepare and keep proper books of record of the business of the company, and such other books as the Board of Directors may prescribe, receive all moneys to be paid to said company, and pay the same over to the Treasurer, taking his receipt for the same. He shall countersign and register all certificates of stock and other papers and documents requiring the President's signature, and attest the same with the company's seal, countersign and seal all contracts, bonds and deeds entered into by and on behalf of the company, which have been signed or are to be signed by the President, and perform such other duties as are incident to his office and be the custodian of the corporate seal, and may receive such compensation for his services as may from time to time be allowed by the Board of Directors.

Treasurer.—D. The Treasurer shall be the custodian of the funds of the Company, receiving the same from the Secretary, and giving his receipt therefor, and pay out the same only on the order of the President, countersigned by the Secretary. He shall give such bond for the faithful performance of his duties, as may from time to time be prescribed by the Board of Directors, and may be paid such compensation as the Board of Directors may order.

Superintendent.—E. The Superintendent shall under the direction of the Board of Directors, have control of the working and development of the company's mines and general direction and control of the construction of all mills and other buildings ordered to be erected, and perform such other duties as may be prescribed for him by the Board of Directors, and shall receive such compensation as may be allowed by the Board of Directors.

Seal.—Sec. 8.—This company adopts as its corporate seal the following design: "Figure of an elk standing erect surrounded by the words, 'The Hidalgo Town and Mining Company, Incorporated April 28th, 1881. Colorado.'"

Finance.—Sec. 9.—The fiscal year shall end on Saturday preceding the annual meeting of the Stockholders, at which meeting the Secretary and Treasurer shall submit their reports in writing, showing all the receipts and disbursements of funds. And at the same time the Superintendent shall submit a report in writing showing his receipts and disbursements, and all his business transactions for the company, and also the general condition of the affairs of the company, and said officers shall also report to the Board of Directors at any time when ordered to do so by said Board.

Dividends.—Sec. 10.—Dividends may be made by the Board of Directors at any regular meeting of said Board, but not in excess of the surplus funds in the Treasury, and shall be apportioned only to the stock subscribed and issued.

Debts.—Sec. 11.—No debt shall be contracted for the company except by order of the Board of Directors, and then not in excess of the funds actually in the Treasury.

Finance Committee.—Sec. 12.—The President shall appoint a Committee of three on Finance to whom shall be referred all bills and accounts for their approval, and to whom shall also be referred all reports of the Secretary, Treasurer, Superintendent, or other officer of the company in any manner connected with the finances of the company, and the Finance Committee and any member of the Board of Directors shall at all times have access to the books of said officers for the purpose of examination.

Bills and Accounts.—Sec. 13.—All bills against the company shall be itemized, and duly presented to the Board of Directors, and shall not be paid until audited by the Finance Committee and ordered paid by said Board, provided that the Board of Directors may order the Treasurer to pay over to the Superintendent, from time to time, such sums of money as may be necessary to pay for assessment work or other developments or improvements ordered to be made by said Board.

Stock.—Sec. 14.—Transfers of stock shall be made only on the books of the company by the owner in person, or by Attorney upon surrender of the certificate transferred, and when made by Attorney, the power of Attorney shall be filed and remain with the Secretary, who shall be entitled to a fee of fifty cents for each certificate issued by him. When any certificate of stock has been lost or destroyed the owner may apply for a new certificate of such stock and shall be entitled to receive such new certificate upon application to the Board of Directors, accompanied by proof to their satisfaction, showing that such certificate has been lost or destroyed, and also in the discretion of the Board, giving a bond of indemnity, with not less than two good and sufficient sureties to be approved by the Board, securing the company, and any person interested, against liability and loss by reason of the issuance of such new certificate, which bond shall be the only recourse for any person subsequently claiming such stock under the certificate so alleged to have been lost or destroyed.

Amendments.—Sec. 15.—These By-Laws may be amended or repealed, or additional sections passed, at any regular meeting of the Board of Directors, by a vote of two-thirds of all the members of said Board, notice of the proposed amendment having been given at a regular meeting of the Board preceding the one at which action is taken thereon.

ORDER OF BUSINESS.

1. Calling the Roll.
2. Reading the Minutes.
3. Reading Communications.
4. Presentation of Bills.
5. Reports of Standing Committees.
6. Reports of Special Committees.
7. Unfinished Business.
8. Miscellaneous Business.

Adopted July 8th, 1881.

AMENDMENTS TO THE CHARTER.

Be it remembered that at a meeting of the Stockholders of the "Hidalgo Town and Mining Company," held at the office of the Secretary of said company at Silver Cliff, Colorado, on the 9th day of August, A. D. 1881, pursuant to the following notice, to-wit:

STOCKHOLDERS' MEETING,
SILVER CLIFF, COLORADO,
July 8th, 1881.

The Stockholders of the "Hidalgo Town and Mining Company" are hereby notified that a meeting of said company will be held at the office of the Secretary of said company in Silver Cliff, Colorado, on the 9th day of August, 1881, at 8 o'clock P. M., at which time a proposition will be submitted to the company to increase the capital stock of said company to $100,000, according to the provisions of the charter.

M. S. ADAMS, Secretary.

H. E. AUSTIN, President.

And it appearing that notice of said meeting had been duly given in accordance with the provisions of the charter of said company, from the affidavit of W. S. Montgomery, duly filed with the Secretary of said company as follows, viz:

STATE OF COLORADO, Custer County. } ss.

W. S. Montgomery being duly sworn says that for the last six months he has been the editor and publisher of the Daily and Weekly Prospect, a newspaper published in the town of Silver Cliff, Custer County, State of Colorado, and that the annexed and foregoing notice of the Stockholders' meeting of the Hildago Town and Mining Company, has been published in said paper for one month next preceding the date of this affidavit, and that said notice has been published four times in said paper, and further this deponent saith not. W. S. MONTGOMERY.

Subscribed and sworn to before me this ninth day of August, 1881.

NOTARY SEAL.

W. P. ALEXANDER,
Notary Public.

And there being present a quorum for the transaction of business either in person or by proxy the following proceedings were had, to wit:

The President being absent, the meeting was called to order by the Vice President, O. E. Henry, who presided over said meeting. M. S. Adams offered the following resolution, to wit:

Resolved, That the capital stock of this company be increased to one hundred thousand dollars ($100,000), and that the stock be disposed of in accordance with the recommendation of the Committee of Ways and Means, under the direction of the Board of Directors.

The vote on the motion to adopt this resolution was taken by ayes and nays, when it appearing that four-fifths of all the capital stock had voted in favor of its adoption, and none having voted against its adoption, the resolution was declared adopted, and the capital stock of said company was declared to be increased to one hundred thousand dollars.

In witness whereof we have hereunto set our hands and seals this 25th day of November, 1881.

CORPORATE SEAL.

H. E. AUSTIN, President. [SEAL]
M. S. ADAMS, Secretary. [SEAL]

STATE OF COLORADO, Custer County. | ss.

H. E. Austin and M. S. Adams being duly sworn each for himself says that he is President and Secretary of the Hidalgo Town and Mining Company, respectively, and that the above and foregoing is a correct record of the proceedings of said company, with reference to the increase of the capital stock of said company at the meeting of the Stockholders thereof, held August 9th, A. D., 1881, as it appears from the records of said company made at the time of said meeting, and further these deponents say not.

H. E. AUSTIN,
M. S. ADAMS.

Subscribed and sworn to before me this 26th day of November, A. D. 1881.

NOTARY SEAL.

SAMUEL LEIGHTON.
Notary Public.

STATE OF COLORADO, Secretary's Office. | ss.

I, Norman H. Meldrum, Secretary of State of the State of Colorado, do hereby certify that the foregoing is a full, true and complete transcript of the certificate of amendments to the original articles of incorporation of the Hidalgo Town and Mining Company which was filed in this office the thirtieth day of November, A. D., 1881, at 9 o'clock A. M., and admitted to record.

In testimony whereof I have hereunto set my hand and affixed the great seal of the State, at the City of Denver, this first day of December, A. D., 1881.

GREAT SEAL OF THE STATE OF COLORADO.

N. H. MELDRUM,
Secretary of State.

The charter of the Chrysolite company, is a good example of an Eastern charter. It is as follows:

State of New York, City and County of New York, ss.:

We, Horace A. W. Tabor, Drake De Kay and Henry C. Gardiner, citizens of the United States, and a majority of whom are citizens of the State of New York, hereby associate together for the purpose of creating a corporation under the laws of the State of New York, authorizing the formation of corporations for mining and other purposes, and in compliance with the provisions of said laws we do hereby state and certify:

First.—That the corporate name of this company is and shall be the CHRYSOLITE SILVER MINING COMPANY.

Second.—That this company is formed for the sole purpose of mining the ores and minerals contained in the mines known as the Chrysolite, Carboniferous, Little Eva, Vulture, Kit Carson, All Right, Fairview, Pandora, Colorado Chief, Solid Muldoon, Silver and Eaton, and no others, situated in the California Mining District, Lake County, State of Colorado, and separating the metals from such ores and minerals. The said company shall have power to purchase the said mines, to wit: The said Chrysolite, Carboniferous, Little Eva, Vulture, Kit Carson, All Right, Fairview, Pandora, Colorado Chief, Solid Muldoon, Silver and Eaton, and to issue full-paid stock in payment therefor.

Third.—That the amount of capital stock of this company is and shall be ten million dollars, divided into two hundred thousand shares of the par value of fifty dollars each.

Fourth.—That the existence of the company shall continue for the term of fifty years.

Fifth.—That the number of trustees who shall manage the concerns and business affairs of said company is and shall be eleven, and John P. Jones, Daniel S. Appleton, Ulysses S. Grant, Junior, Henry A. V. Post, William Borden, Horace A. W. Tabor, William S. Nichols, Leonidas M. Lawson, Edward B. Dorsey, Arthur Sewell, and Charles A. Whittier, are the names of the persons who shall be the trustees of said company for the first year, and all of whom are citizens of the United States, and a majority citizens and residents of the State of New York.

Sixth.—That the principal office and place of business of said company shall and is to be located in the City and County of New York, State of New York; but the mining operations and the separation of the metals from the ores are to be carried on out of the State of New York, viz.: In the County of Lake, State of Colorado, and elsewhere in said State.

In witness whereof, we have hereto set our hands and seals this twenty-ninth day of September, one thousand eight hundred and seventy-nine.

(Signed), H. A. W. TABOR,
DRAKE DE KAY,
HENRY C. GARDINER.

SEAL.

State of New York, City and County of New York, ss.:

On the 30th day of September, 1879, before me personally came Horace A. W. Tabor, Drake De Kay, and Henry C. Gardiner, to me known, and known to me to be the individuals described in and who executed the foregoing certificate, and severally acknowledged that they executed the same for the uses and purpores therein mentioned.

(Signed) WILLIAM H. CLARKSON,
Notary Public for New York County, N. Y.

State of New York, City and County of New York, ss.:

I, Hubert O. Thompson, Clerk of the said City and County, and Clerk of the Supreme Court of said State for said County, do certify that I have compared the preceding with the original certificate of incorporation of the Chrysolite Silver Mining Company on file in my office, and that the same is a correct transcript therefrom, and of the whole of said original, endorsed, filed 3d October, 1879.

In witness whereof I have hereunto subscribed my name and affixed my official seal this 3d day of October, 1879.

SEAL.

(Signed,) HUBERT O. THOMPSON,
Clerk.

State of New York, Office of the Secretary of State, ss.:

I have compared the preceding with the original certificate of incorporation of the Chrysolite Silver Mining Company, with acknowledgment thereto annexed, filed in this office on the 3d day of October, 1879, and do hereby certify the same to be a correct transcript therefrom, and of the whole of said original.

Witness my hand and seal of office of the Secretary of State, at the City of Albany, this third day of October, one thousand eight hundred and seventy-nine.

SEAL.

(Signed,) GEORGE MOSS,
Deputy Secretary of State.

BY-LAWS.

ARTICLE I.—*Officers*, - Sec. 1.—The officers of this company shall consist of a President, Vice-President, Treasurer, Secretary, General Manager, and Financial Agent. The President and Vice-President must be chosen from the Trustees.

ARTICLE II.—*President.*—Sec. 1.—The President shall be the chief executive agent of the company in the management of its affairs, but subject at all times and in all matters to the control and direction of the Board of Trustees. He shall, when present, preside at all meetings of the Board of Trustees, and perform such other duties as may be required of him by the laws of the State, and by the by-laws of the company, and by the Board of Trustees. He shall sign all contracts, certificates of stock, drafts, acceptances and checks.

Sec. 2.—He shall receive such salary as the Board of Trustees may fix and allow.

Sec. 3.—He may be removed at any time by a majority of the Board of Trustees.

ARTICLE III.—*Vice-President.*—Sec 1.—In the absence of the President, the Vice-President shall possess all the powers and perform all the duties of the President, and receive such compensation for his services as the Board may fix and allow.

ARTICLE IV.—*Treasurer.*—Sec. 1.—It shall be the duty of the Treasurer to receive all the money and funds of the company, and deposit the same in such banking-house as the Board of Trustees shall from time to time direct; and, under the direction of said Board, he shall pay out the same by check, countersigned by the President and Secretary, and not otherwise.

Sec. 2.—He shall keep full and correct books of account, which shall at all times be open to the inspection of any member of the Board. He shall make a report in detail to said Board at least quarterly, and make such other reports and statements at such times as said Board may require.

He shall give such bonds as the Board shall require.

Sec. 3.—He shall be entitled to such compensation for his services as the Board of Trustees may from time to time fix and allow.

ARTICLE V.—*Secretary.*—Sec. 1.—It shall be the duty of the Secretary to keep full and accurate minutes of all proceedings of the Board of Trustees and Executive Committee, and of the Stockholders, in a proper book or books. He shall also keep a list of all persons who are or have been Stockholders within the period of one year, with their names alphabetically arranged.

Sec. 2.—He shall perform such other duties as may be required by the laws of the State, the Board of Trustees, and the By-Laws of the company; and he shall receive such salary as the Board of Trustees may fix and allow.

ARTICLE VI.—*General Manager.*—Sec. 1.—The General Manager shall be the general agent of the company in the State of Colorado. He shall have power to enter upon and take possession of all the mines and property of the company in the State of Colorado.

Sec. 2.—The General Manager shall be subject at all times and in all matters, acts and transactions, to the direction and control of the President of the company and of the Board of Trustees.

Sec. 3.—He shall not have the power to contract any debt or incur any liability on the part of the company exceeding at any time ten thousand dollars in the aggregate, unless previously authorized by the Board of Trustees.

Sec. 4.—He shall be subject to suspension at any time at the will of the President, and to removal by the Board of Trustees; and in case of suspension by the President, the President shall forthwith notify the Trustees of such suspension, and call a meeting of the Board.

Sec. 5.—The General Manager shall receive such compensation for his services as the Board of Trustees may from time to time fix and allow.

ARTICLE VII.—*Trustees.*—Sec. 1.—Regular meetings of the Board of Trustees shall be held at the office of the company on the fifteenth day of each and every month. When this falls on a legal holiday, on the next succeeding day that is not a legal holiday.

Sec. 2.—Special meetings of the Board may be held at any time on notice of two days, by mail or personal service, to each member of said Board, stating the time, place and objects of meeting, to be given by the President or by the Secretary at the request of any two members of the Board, and no business except that so stated can be acted on at such meeting.

Sec. 3.—They shall exercise a general supervision over the affairs of the company, receive and pass upon the reports of the Secretary, Treasurer and Superintendent, declare dividends, audit all bills and accounts against the company, and direct the Secretary in correspondence. They shall have power to delegate from time to time such authority as they may deem necessary to the officers or agents of the company, or to any one or more members acting as a committee. They may appoint a managing director or such other agents as they may deem necessary, define their respective duties, fix their compensation, and remove or suspend them for sufficient cause, except for the removal of the President and amendment of the By-Laws; in this case a majority.

Sec. 4.—Five of the trustees shall constitute a quorum of the Board at any regular or special meeting; but, in the absence of a majority of the Board, the minority shall have power to adjourn such meeting, regular or special.

In case of meetings held for the amendment of the By-Laws or the removal of the President, a majority of the Trustees elected shall be necessary to constitute a quorum.

Sec. 5.—Neither the President nor any other officer or agent of this company shall have power to contract any debt or incur any liability exceeding the sum of ten thousand dollars, without the authority of the Board of Trustees or the Executive Committee.

ARTICLE VIII.—*Executive Committee.*—Sec. 1.—There shall be an Executive Committee, consisting of five Trustees, four of whom shall be appointed by resolution of the Board. The President, or in his absence the Vice President, shall act as the fifth member of such committee.

Sec. 2.—The Executive Committee shall have full power to manage all the business affairs of the company when the Board is not in session, and the acts and proceedings of the said committee shall have the same force and effect as the acts and proceedings of the Board of Trustees, unless the action of said committee shall be disapproved by resolution adopted by the Board at the next meeting of the Board held after such act or proceeding of said committee has been reported to the Board of Trustees.

Sec. 3.—Any officer or employee of the company, excepting the President, may be suspended or removed at will by the Executive Committee.

ARTICLE IX.—*Vacancy and Tenure.*—Sec. 1.—In case of a vacancy occurring from any cause in the Board of Trustees, the same may be filled by appointment made by the Trustees in office.

Sec. 2.—The Trustees, and each and every officer of the company, shall hold office until their or his successors shall have been elected or appointed and have qualified; but nothing in this section shall be so construed as to prevent the removal of any officer as hereinbefore provided.

ARTICLE X.—*Certificates.*—Sec. 1.—The capital stock of this company shall be represented by certificates signed by the President and the Secretary.

ARTICLE XI.—*Seal.*—Sec. 1.—The corporate seal shall bear upon its face, within a circle, the corporate name of the company and date of incorporation.

ARTICLE XII.—*Closing of Books.*—Sec. 1.—The stock books of the company shall be closed for five days previous to any election of Trustees or the date of payment of a dividend; and a list of stockholders prepared at that time shall designate who shall vote or receive dividends.

ARTICLE XIII.—*Stockholders' Meeting.*—Sec. 1.—The annual meeting of the Stockholders for the election of Trustees of this company shall be held in the city of New York on the first Tuesday in October, 1880, and yearly thereafter. Twenty days notice shall be given of the time and place of holding such meeting by the Secretary, by public advertisement in one or more daily newspapers published in the city of New York, and by notice sent by mail to each Stockholder at his residence, as it may appear on the books of the company. A majority of the Stockholders present, either in person or by attorney, shall constitute a quorum.

Sec. 2.—At such election each Stockholder shall be entitled to cast one vote for each share standing in his name, as shall appear by stock list at the time of closing the books. No person shall vote as proxy unless he shall produce and deliver to the Secretary a written authority so to do, signed by the Stockholder whom he represents.

Sec. 3.—The polls shall be open at twelve o'clock noon, and shall remain open until two o'clock in the afternoon of the same day, and on the closing thereof the inspectors shall proceed to count the vote and declare the result.

ARTICLE XIV.—*Amendments.*—Sec. 1.—These By-Laws may be altered, amended or repealed by the Board of Trustees, at any regular or special meeting; but in every or any such alteration, amendment or repeal at least a majority of the members of the Board of Trustees must concur.

FORM OF PATENT FOR PLACER CLAIM.—General Land Office, No. 4,458. Mineral certificate No. 448.

The United States of America to all to whom these presents shall come, greeting:

Whereas, in pursuance of the provisions of the Revised Statutes of the United States, chapter six, title thirty-two, there has been deposited in the General Land Office of the United States the certificate of the register of the land office at Helena, in the Territory of Montana, whereby it appears that, in pursuance of the said Revised Statutes of the United States, James D. Hammond did, on the ninth day of June, A. D. 1879, enter and pay for certain placer mining premises, being mineral entry number four hundred and forty-eight (448) in the series of said office, embracing the west half of the southeast quarter and the southeast quarter of the southwest quarter of section twenty-three (23), and the northeast quarter of the northeast quarter of section twenty-eight (28), in township ten (10) north, of range four (4) east of the principal meridian, containing one hundred and sixty (160) acres of land, more or less, as shown by the official survey and plat of said township; said placer mining claim or lot of land being situate in the Summit Valley mining district, in the county of Lewis and Clarke, and the Territory of Montana, in the district of lands subject to sale at Helena, and commonly known as the "Jennie Placer Mine."

Now know ye, that the United States of America, in consideration of the premises and in conformity with said Revised Statutes of the United States, have given and granted, and by these presents do give and grant, unto the said James G. Hammond, and to his heirs and assigns, the said placer mining premises above described as the west half of the southeast quarter and the southeast quarter of the southwest quarter of section twenty-three (23), and the northeast quarter of the northeast quarter of section twenty-eight (28), in township ten (10) north, of range four (4) east of the principal meridian.

To have and to hold said mining premises, together with all the rights, privileges, immunities and appurtenances of whatsoever nature thereunto belonging, unto the said James G. Hammond, and to his heirs and assigns forever; subject, nevertheless, to the following conditions and stipulations:

First. That the grant hereby made is restricted in its exterior limits to the boundaries of said legal subdivisions, as hereinbefore described, and to any veins or lodes of quartz or other rock in place, bearing gold, silver, cinnabar, lead, tin, copper, or other valuable deposits, which may hereafter be discovered within said limits, and which are not claimed or known to exist at the date thereof.

Second. That should any vein or lode of quartz or other rock in place, bearing gold, silver, cinnabar, lead, tin, copper, or other valuable deposits, be claimed or known to exist within the above-described premises at the date hereof, the same is expressly excepted and excluded from these presents.

Third. That the premises hereby conveyed may be entered by the proprietor of any vein or lode of quartz or other rock in place, bearing gold, silver, cinnabar, lead, tin, copper, or other valuable deposits, for the purpose of extracting and removing the ore from such vein, lode, or deposit, should the same, or any part thereof, be found to penetrate, intersect, pass through, or dip into the mining ground or premises hereby granted.

Fourth. That the premises hereby conveyed shall be held subject to any vested and accrued water rights for mining, agricultural, manufacturing, or other purposes, and rights to ditches and reservoirs used in connection with such water rights as may be recognized and acknowledged by the local laws, customs, and decisions of courts.

Fifth. That in the absence of necessary legislation by Congress, the legislature of Montana may provide rules for working the mining claim or premises hereby granted, involving easements, drainage, and other necessary means to the complete development thereof.

In testimony whereof, I, Rutherford B. Hayes, President of the United States of America, have caused these letters to be made patent, and the seal of the General Land Office to be hereunto affixed.

Given under my hand, at the city of Washington, the tenth day of December, in the year of our Lord one thousand eight hundred and eighty, and of the Independence of the United States the one hundred and fifth.

By the President.

[SEAL.] R. B. HAYES,
By WM. H. CROOK,
Secretary.

S. W. CLARK,
Recorder of the General Land Office.
Recorded, vol. 54, pages 41 and 42.

FORM OF PATENT FOR VEIN OR LODE CLAIM.—General Land Office No. 4398.—Mineral Certificate No. 419.

The United States of America, to all to whom these presents shall come, greeting:

Whereas, in pursuance of the provisions of the Revised Statutes of the United States, chapter six, title thirty-two, there have been deposited in the General Land Office of the United States the plat and field-notes of survey of the claim of John W. Roe upon the Brooklyn lode, accompanied by the certificate of the register of the land-office at Salt Lake City, in the Territory of Utah, whereby it appears that, in pursuance of the said Revised Statutes of the United States, John W. Roe did, on the thirty-first day of December, A. D. 1879, enter and pay for said mining claim or premises, being mineral entry No. 419, in the series of said office, designated by the Surveyor-General as lot No. 60, embracing a portion of the unsurveyed public domain, in the Ophir Mining District in the county of Tooele and Territory of Utah, in the district of lands subject to sale at Salt Lake City, containing one (1) acre and eighty-four hundredths ($\frac{84}{100}$) of an acre of land, more or less, and, according to the returns on file in the General Land Office, bounded, described and platted as follows, with magnetic variation at sixteen (16) degrees and thirty-five (35) minutes east, to wit:

Beginning at corner No. 1, a cottonwood post, four (4) inches in diameter, marked "U. S. L. 60, No. 1"; thence north sixty-five (65) degrees thirty (30) minutes west, fifty (50) feet to centre of southwesterly boundary of the claim, from which discovery bears north twenty (20) degrees east, at the distance of four hundred (400) feet, ninety-eight and seven-tenths ($98\frac{7}{10}$) feet to a point on easterly boundary of lot No. 63, made for the Noyes lode, from which corner No. 1 of lot No. 63 bears south fourteen (14) degrees west at the distance of seventeen and seven-tenths ($17\frac{7}{10}$) feet, one hundred (100) feet to corner No. 2, a cottonwood post four (4) inches in diameter, in mound of stones, marked "U. S. L. 60, No. 2," from which U. S. Mineral Monument No. 6 bears south ten (10) degrees west at the distance of nine hundred and ninety-eight (998) feet; thence from said corner No. 2 north twenty-six (26) degrees east, six (6) feet to a point on easterly boundary of said lot No. 63, from which corner No. 1 of said lot No. 63 bears south fourteen (14) degrees west, at the distance of twenty-three and eight-tenths ($23\frac{8}{10}$) feet, eight hundred (800) feet to corner No. 3, a cottonwood post four (4) inches in diameter, marked "U. S. L. 60, No. 3"; thence south sixty-five (65) degrees thirty (30) minutes east, one hundred (100) feet to corner No. 4, a cottonwood post four (4) inches in diameter, marked "U. S. L. 60, No. 4"; thence south twenty-six (26) degrees west, eight hundred (800) feet to the place of beginning, containing one (1) acre and eighty-four hundredths ($\frac{84}{100}$) of an acre of land more or less, and embracing eight hundred (800) linear feet of the Brooklyn lode, to wit, four hundred (400) linear feet northeasterly and four hundred (400) linear feet southwesterly from discovery on said lode, as represented by yellow shading in the following plat: [Here follows diagram of claim, shaded in yellow.]

Now know ye, That the United States of America, in consideration of the premises, and in conformity with the said Revised Statutes of the United States, have given and granted, and by these presents do give and grant unto the said John W. Roe and to his heirs and assigns, the said mining premises hereinbefore described as lot No. 60, embracing a portion of the unsurveyed public domain, with the exclusive right of possession and enjoyment of all the land included within the exterior lines of said survey not herein expressly excepted from these presents, and of eight hundred (800) linear feet of the said Brooklyn vein, lode, ledge, or deposit for the length hereinbefore described, throughout its entire depth, although it may enter the land adjoining, and also all other veins, lodes, ledges, or deposits throughout their entire depth, the tops or apexes of which lie inside the exterior lines of said survey at the surface extended downward vertically, although such veins, lodes, ledges, or deposits in their downward course may so far depart from a perpendicular as to extend outside the vertical side lines of said survey: *Provided*, That the right of possession hereby granted to such outside parts of said veins, lodes, ledges, or deposits shall be confined to such portions thereof as lie between vertical planes drawn downward through the end lines of said survey at the surface, so continued in their own direction that such vertical planes will intersect such exterior parts of said veins, lodes, ledges, or deposits: *And provided further*, That nothing in this conveyance shall authorize the grantee herein, his heirs or assigns, to enter upon the *surface* of a mining claim owned or possessed by another: To have and to hold said mining premises, together with all the rights, privileges, immunities, and appurtenances of whatsoever nature thereunto belonging, unto the said John W. Roe, and to his heirs and assigns forever, subject, nevertheless, to the following conditions and stipulations:

First. That the grant hereby made is restricted to the land hereinbefore described as lot No. 60, with eight hundred (800) linear feet of the Brooklyn vein, lode, ledge, or deposit for the length aforesaid throughout its entire depth as aforesaid, together with all other veins, lodes, ledges, or deposits throughout their entire depths as aforesaid, the tops or apexes of which lie inside the exterior lines of said survey.

Second. That the premises hereby conveyed, with the exception of the surface, may be entered by the proprietor of any other vein, lode, ledge, or deposit, the top or apex of which lies outside the exterior limits of said survey, should the same in its downward course be found to penetrate, intersect, extend into, or underlie the premises hereby granted, for the purpose of extracting and removing the ore from such other vein, lode, ledge, or deposit.

Third. That the premises hereby conveyed shall be held subject to any vested and accrued water rights for mining, agricultural, manufacturing or other purposes, and rights to ditches and reservoirs used in connection with such water rights as may be recognized and acknowledged by the local laws, customs, and decisions of courts.

Fourth. That in the absence of necessary legislation by Congress, the legislature of Utah may provide rules for working the mining claim or premises hereby granted, involving easements, drainage, and other necessary means to its complete development.

In testimony whereof, I, Rutherford B. Hayes, President of the United States of America, have caused these letters to be made patent, and the seal of the General Land Office to be hereunto affixed.

Given under my hand, at the city of Washington, the tenth day of December, in the year of our Lord one thousand eight hundred and eighty, and of the Independence of the United States the one hundred and fifth.

By the President:

[SEAL.] R. B. HAYES,
By WM. H. CROOK,
Secretary.

S. W. CLARK,
Recorder General Land Office.
Recorded, vol. 54, pages 43 to 45, inclusive.

Rules for forming a Mining District. We append for this illustration the rules adopted May 27th, of this year in the formation of the Calico Mining District of the State of California:

By-Laws of Calico Mining District, adopted May 27th, 1882.—

SEC. 1.—Calico Mining District shall be bounded as follows: Commence at a point about two and a half miles west of the Calico Well, (better known as the little red butte), run thence ten miles north, thence ten miles east, thence ten miles south, thence ten miles west to point of beginning.

SEC. 2.—The name of the district shall be Calico.

SEC. 3.—This district shall have one officer, viz: A Recorder, whose office shall be in Calico.

SEC. 4.—The Recorder shall hold his office for one year, beginning the 1st day of June and ending the last day of May, provided, his successor has been previously elected; otherwise he shall hold office until the election of a successor.

SEC. 5.—It shall be the duty of the Recorder to keep a record-book for the purpose of recording claims and affidavits of assessment work.

SEC. 6.—The Recorder shall receive one dollar for recording claims, fifty cents for recording affidavits, and twenty-five cents for furnishing certificates.

SEC. 7.—It shall be the duty of the Recorder to post notices of election, in three public places, ten days before the expiration of his term.

SEC. 8.—At the request of five miners, the Recorder shall call a miners' meeting. The notice of the meeting shall set forth the object for which it is called.

SEC. 9.—Provided the limits of the district are to be changed or the By-laws amended, the Recorder shall give notice of such changes or amendments twenty days beforehand by posting-notices in three public places in the district.

SEC. 10.—It shall be the duty of the Recorder to turn over to his successor all books and papers pertaining to the archives of the district.

SEC. 11.—The width of lode claims shall be three hundred feet on each side of the center of the vein or crevice.

SEC. 12.—The discoverer of a lode shall, within ninety days from the date of discovery, record his claim in the office of the Recorder of this district, which record shall contain: 1st, the name of the lode; 2d, the name of the locator; 3d, the date of the locations; 4th, the number of feet in length claimed on each side of the centre of the discovery shaft; 5th, the general course of the lode as near as may be.

SEC. 13.—Any location certificate of a lode claim which shall not contain the name of the lode, the name of the locator, the date of location, the number of lineal feet claimed on each side of the discovery shaft, the general course of the lode, and such description as shall identify the claim with reasonable certainty, shall be void.

SEC. 14.—Before filing such location certificate the discoverer shall locate his claim by first sinking a discovery shaft upon the lode, to the depth of at least ten feet from the lowest part of the rim of such shaft at the surface, or deeper if necessary to show a well-defined crevice. Second, by posting at the point of discovery or the surface, a conspicuous notice containing the name of the lode, the name of the locator, and the date of the discovery. Third, by marking the surface boundaries of the claim.

SEC. 15.—The surface boundaries shall be marked by nine substantial posts or monuments, three on each end and three on a line running through the centre.

SEC. 16.—Any open cut, cross-cut or tunnel, which shall cut a lode at the depth of ten feet below the surface, shall hold such lode the same as if a discovery shaft were sunk thereon, or an adit of at least ten feet along the lode, from the point where the lode may be in any manner discovered, shall be equivalent to a discovery shaft.

SEC. 17.—The discoverer shall have sixty days from the time of discovering a ledge or lode to do the necessary work on his claim.

SEC. 18.—If at any time the locator of any mining claim heretofore or hereafter located, or his assigns shall apprehend that his original certificate was defective, erroneous, or that the requirements of the law had not been complied with before filing; or shall be desirous of changing his surface boundaries; or of taking in any part of an overlapping claim which has been abandoned, such locator or his assigns may file an additional certificate; provided that such re-location does not interfere with the existing rights of others at the time of such relocation; and the record thereof shall preclude the claimants from proving any such title or titles as he or they may have held under previous location.

SEC. 19.—The relocation of abandoned lode claims shall be by sinking a new discovery shaft, fixing new boundaries in the same manner as if it were the location of a new claim; or the relocator may sink the original discovery shaft ten feet deeper than it was at the time of abandonment, and erect new or adopt the old boundaries, renewing the monuments if removed or destroyed. In either case a new location stake or monument shall be erected. In any case, whether the whole or part of an abandoned claim is taken, the location certificate may state that the whole or any part of the new location is located as abandoned property.

SEC. 20.—No location certificate shall claim more than one location, whether the location be made by one or several locators; and if it purport to claim more than one location, it shall be absolutely void, except as to the first location therein described. And if they are described together, or so that it cannot be told which location is first described, the certificate shall be void as to all.

SEC. 21.—Within thirty days after performing the assessment work on a claim the person on whose behalf such outlay was made, or some person for him, shall make and record an affidavit in substance as follows:

STATE OF CALIFORNIA, }
COUNTY OF SAN BERNARDINO. }

Before me, the subscriber, personally appeared who being duly sworn said that at least dollars' worth of work or improvements were performed or made upon (here describe claim or part of claim), situate in Calico Mining District, County of San Bernardino, State of California. Such expenditure was made by or at the expense of , owners of said claim. (Signature.)

And such signature shall be prima facie evidence of the performance of such labor.

SEC. 22.—These By-laws shall take effect on the tenth day of June, 1882.

FORMS—NOTICE OF LOCATION.

Notice is hereby given that the undersigned having complied with the requirements of the Chapter Six of Title Thirty-two of the Revised Statutes of the United States, and the local customs, laws and regulations, has located linear feet on the lode [twenty acres of placer mining ground], situated in Mining District, County, , and described as follows:

[*Describe the claim accurately (by courses and distances, if possible,) with reference to some natural object or permanent monument, and mark the boundaries by suitable monuments: if a placer claim is located on surveyed land, describe the legal sub-division.*]

Discovered , 188–. , Locator.
Located , 188–. Recorded , 188–.
Attest:

PROOF OF LABOR.

of *County of* , *ss.*

Before me the subscriber personally appeared , who being duly sworn says that at least dollars' worth of labor or improvements were performed or made upon [here describe claim], situated in mining district, county, of , during the year ending , 188–. Such expenditure was made by or at the expense of , owners of said claim, for the purpose of holding said claim.

[Jurat.] —— —— (Signature).

NOTICE OF FORFEITURE.

—— County, , 188–.

To—(names of all parties who have record title to any portion of the mine). You are hereby notified that I have expended dollars in labor and improvements upon the lode (describe the claim), as will appear by certificates filed , 188 , in the office of the Recorder of said county (or district), in order to hold said premises under the provisions of section 2324 Revised Statutes of the United States, being the amount required to hold the same for the year ending , 188 . And if within ninety days from the service of this notice (or within ninety days after this notice by publication), you fail or refuse to contribute your proportion of such expenditure as a co-owner, your interest in said claim will become the property of the subscriber under said section 2324.

(Signature).

AFFIDAVIT OF FAILURE TO CONTRIBUTE.

of , *County of* , *ss.*

, being duly sworn deposes and says that for the year ending , 188 , he expended at least dollars in labor and improvements upon the lode [or placer claim] (here describe the claim), to hold the same under the laws of the United States and of this (district, Territory or State,): that due notice thereof was personally served upon , co-owners, on the day of , 188 , (or was duly published in the , as appears from the affidavit of the publisher thereof): and that of the said) co-owners have failed or refused to contribute their share of said expenditures within the time required by law.

Subscribed and sworn to before me this day of , 188 .

MINER'S LIEN.

Know all Men by these Presents, That I, , of the county of , of , do hereby give notice of my intention to hold and claim a lien, by virtue of the statute in such case made and provided, upon (describe premises), with all improvements and appurtenances, situated in Mining District, County of , of .

The said lien being claimed and held for and on account of *work and labor done by me as for , owner of said premises* in and upon said premises, from the day of , A. D., 188 , to the day of , A. D., 188 .

The total value of the said work and labor being dollars, upon which there has been paid the sum of dollars, leaving a balance of dollars still due, owing and unpaid to me, the said claimant.

(Signature).

of , County of , ss.

On this day of , A. D. 188 , personally appeared before me the above named , and who being by me first duly sworn, on oath states that the abstract of indebtedness mentioned and described in the foregoing notice, is true and correct, and that there is still due and owing to from the said , for the aforesaid, the sum of dollars and cents.

(Signature).

Subscribed and sworn to before me this day of , A. D. 188 .

(Official Signature).

APPLICATION FOR SURVEY.

, 188 .

To , United States Surveyor-General for :

SIR—In compliance with the provisions of Chapter Six of Title Thirty-two, Revised Statutes of the United States, herewith make application for an official survey of the mining claim known as the mine, claimed by , located in Mining District, in the County of , Township No. , Range No. , base and meridian, in the of , and request that you will send to address an estimate of the amount to be deposited, for the work to be done in your office; and that after such deposit shall have been made, you will cause the said mining claim to be surveyed by , United States Deputy Surveyor at .

Respectfully,

, Claimant.

P. O. Address, , county, .

APPLICATION FOR PATENT.

, County of , ss.

Application for Patent for the Mining Claim.

To the Register and Receiver of the U. S. Land Office at .

, being duly sworn according to law, deposes and says, that in virtue of a compliance with the mining rules, regulations and customs, by himself, the said , and his co-claimants (residence of each should be stated), , applicants for patent herein ha become the owner of and in the actual, quiet and undisturbed possession of linear feet of the vein, lode or deposit, bearing , together with surface ground feet in width, for the convenient working thereof, as allowed by local rules and customs of miners; said mineral claim, vein, lode or deposit and surface ground being situated in the mining district, county of , and of , and being more particularly set forth and described in the official field-notes of survey thereof, hereto attached, dated day of , A. D. 188 , and in the official plat of said survey, now posted conspicuously upon said mining claim or premises, a copy of which is filed herewith. Deponent further states that the facts relative to the right of possession of himself (and his said co-claimants hereinbefore named) to said mining claim, vein, lode or deposit and surface ground, so surveyed and platted, are substantially as follows, to wit:

(*Give full history of the lode,*)

Which will more fully appear by reference to the copy of the original record of location and the abstract of title hereto attached and made a part of this affidavit; the value of the labor done and improvements made upon said claim, by himself and his grantors, being equal to the sum of five hundred dollars, and said improvements consist of (*describe fully*). In consideration of which facts, and in conformity with the provisions of Chapter Six of Title Thirty-two of the Revised Statutes of the United States, application is hereby made for and in behalf of said for a patent from the Government of the United States for the said mining claim, vein, lode, deposit, and the surface ground so officially surveyed and platted.

Subscribed and sworn to before me this day of , A. D. 188 , and I hereby certify that I consider the above deponent a credible and reliable person, and that the foregoing affidavit, to which was attached the field-notes of survey of the mining claim, was read and examined by him before his signature was affixed thereto and the oath made by him.

(Official Signature.)

PROOF OF POSTING NOTICE AND DIAGRAM ON CLAIM.

of , County of , ss.

and , each for himself, and not one for the other, being first duly sworn according to law, deposes and says, that he is a citizen of the United States, over the age of twenty-one years, and was present on the day of , A. D. 188 , when a plat representing the , and certified to as correct by the United States Surveyor-General of , and designated by him as lot No. , together with a notice of the intention of and to apply for a patent for the mining claim and premises so platted, was posted in a conspicuous place upon said mining claim, to wit: Upon . where the same could be easily seen and examined; the notice so conspicuously posted upon said claim being in words and figures as follows, to wit:

Notice of the Application of and for a United States Patent.

Notice is hereby given that in pursuance of Chapter Six of Title Thirty-two of the Revised Statutes of the United States, and , claiming linear feet of the vein, lode or mineral deposit, bearing , with surface ground feet in width, lying and being situated within the mining district, county of , and of , ha made application to the United States for a patent for the said mining claim, which is more fully described as to metes and bounds by the official plat herewith posted, and by the field notes of survey thereof, now filed in the office of the Register of the District of Lands, subject to sale at , which field-notes of survey describe the boundaries and extent of said claim on the surface, with magnetic variation at east, as follows, to wit:

(*Give full description by courses and distances.*)

the said mining claim being of record in the office of the Recorder of , at , in the county and aforesaid, the presumed general course or direction of the said vein, lode or mineral deposit being shown upon the plat posted herewith, as near as can be determined from present developments; this claim being for linear feet thereof, together with the surface ground shown upon the official plat posted herewith, the said vein, lode and mining premises hereby sought to be patented being bounded on the by the mining claim.

Any and all persons claiming adversely the mining ground, vein, lode, premises, or any portion thereof so described, surveyed, platted and applied for, are hereby notified that unless their adverse claims are duly filed as according to law and the regulations thereunder within sixty days from the date hereof, with the Register of the United States Land Office at , in the of , they will be barred, in virtue of the provisions of said statute.

(Names of applicants.)

PROTEST AND ADVERSE CLAIM.

United States Land Office, of .

In the matter of the application of , for a United States' patent for the lode or mining claim and the land and premises appertaining to said mine, situated in the mining district, in county, of

To the Register and Receiver of the United States' Land Office at , and to the above-named applicants for patent for the lode .

You are hereby notified that of the city of , county of , and of , and a citizen of the United States of America, is the lawful owner, and entitled to the possession of hundred feet of the said lode or mine described in said application, as shown by the diagram posted on said claim, and the copy thereof filed in the land office with said application, and as such owner this contestant, the said , does protest against the issuing of a patent thereon to said applicant, and does dispute and contest the right of said applicant therefor.

And this contestant does present the nature of his adverse claim, and does fully set forth the same in the affidavit hereto attached, marked Exhibit A, and the further exhibits thereto attached, and made part of said affidavit.

The said therefore respectfully asks the said Register and Receiver that all further proceedings in the matter be stayed, until a final settlement and adjudication of the rights of this contestant can be had in a court of competent jurisdiction.

(Place and Date.)

EXHIBIT A.

of County of , ss.

, being first duly sworn, deposes and says, that he is a citizen of the United States, born in the State of , and is now residing in ; that he is the contestant and protestant named in, and who subscribed the notice and protest hereto annexed. Affiant further says that he is the owner by purchase and in the possession of the (adverse) lode or vein of quartz and other rock in place, bearing and other metals. That the said lode is situated in the mining district, county, of .

[*Full history of the lode should be given as follows* :]

This affiant further says, that on the day of location the premises hereinafter described were mineral lands of the public domain, and entirely vacant and unoccupied, and were not owned, held or claimed by any person or persons as mining ground or otherwise, and that while the same were so vacant and unoccupied and unclaimed, to wit:

On the day of , 18 , (name locators,) each and all of them being citizens of the United States, entered upon and explored the premises, discovered and located the said lode, and occupied the same as mining claims. That the said premises so located and appropriated consist of feet in a erly direction, and feet in a erly direction, as will fully appear by reference to the notice of location, a duly certified copy whereof is hereunto annexed, marked Exhibit B, and hereby made a part of this affidavit. That the locators, after the discovery of the said lode, drove a stake on said lode on the discovery claim, erected a monument of stone around said stake, and placed thereon a written notice of location describing the claim so located and appropriated, giving the names of the locators and quantity taken by each, and after doing all the acts and performing all the labor required by the laws and regulations of said mining district and territory of , the locators of said lode caused said notice to be filed and recorded in the proper books of record in the Recorder's office in said district on the day of , 18 .

Affiant further says, that the said locators remained continuously in possession of said lode, working upon the same and within months from the date of said location had done and performed work and labor on said location in mining thereon and developing the same, more than days work, and expended on said location more than hundred dollars, and by said labor and money expended upon the said mining location and claim, had developed the same and extracted therefrom more than tons of ore.

And Affiant further says, that said locators, in all respects complied with every custom, rule, regulation, and requirement of the mining laws, and every rule and custom established and in force in said mining district, and thereby became and were owners (except as against the paramount title of the United States) and the rightful possessors of said mining claims and premises.

And this affiant further says, that said locators proved and established to the satisfaction of the Recorder of said mining district that they had fully complied with all the rules, customs, regulations, and requirements of the laws of said district, and thereupon the said Recorder issued to the locators of said lode, certificates confirming their titles and rights to said premises.

That the said lode was located and worked by the said locators as tenants in common, and they so continued in the rightful and undisputed possession thereof from the time of said location until on or about the day of , A, D. 18 , at which time the said locators and owners of said lode formed and organized under the laws of the State (or Territory) of , and incorporated under the name of the " ," and on the day of A. D. 18 , each of the locators of said lode conveyed said lode and each of their rights, titles and interest in and to said lode, to said " mining company."

On the said day of , 18 , the said company entered into and upon said lode, and was seized and possessed thereof and every part and parcel of the same, and occupied and mined thereon until the day , 18 , at which time the said mining company sold and conveyed the same to this affiant, which said several transfers and conveyances will fully appear by reference to the abstract of title and paper hereto attached, marked Exhibit D, and made a part of this affidavit.

[*In case of individual transfers.*]

And this affidavit further says, that the said , who located claim northwesterly of the said lode, and the said who located claim northwesterly thereon, was seized and in possession of said claims, and occupied and mined thereon until the day of , 18 , at which time the said and sold and conveyed the same to , and thereupon the said was seized and possessed of said mining claims and locations, and occupied and mined thereon until the day of , 18 , at which time the said sold and conveyed the same to this affiant, as will fully appear by reference to the abstract of title and paper hereto attached, marked Exhibit D, at which time this affiant hereby makes a part of this his affidavit.

Affiant further says, that he is now and has been in the occupation and possession of the said lode since the day of , 18 , and the said lode and mining claims were located, and the title thereto established, several before said (applied for) lode was located.

Affiant furthers says, that said lode, as shown by the notice and diagram posted on said claim, and the copy thereof filed in the United States Land Office at said with said application for a patent, crosses and overlaps said lode, and embraces about hundred feet in length by hundred feet in width of the said lode, the property of affiant, as fully appears by reference to the diagram or map duly certified by , United States Deputy

Surveyor, hereto attached, marked Exhibit C, and which diagram presents a correct description of the relative locations of the said (adverse) lode, and of the pretended (applied for) lode.

Affiant further says that he is informed and believes that said applicant for patent, well knew that affiant was the owner in possession and entitled to the possession of so much of said mining ground embraced within the survey and diagram of said applications, as is hereinbefore stated, and that this affiant is entitled to all the and other metal in said (adverse) lode, and all that may be contained within a space of feet on each side of said (adverse) lode.

And affiant further says, that this protest is made in entire good faith, and with the sole object of protecting the legal rights and property of this affiant in the said (adverse) lode and mining premises.

Subscribed and sworn to before me this day of , A. D. 188 .

SURVEYOR'S CERTIFICATE.

On the diagram marked Exhibit C, the Surveyor must certify in effect as follows:

I hereby certify that the above diagram correctly represents the conflict claimed to exist between the and lodes, as actually surveyed by me. And I further certify that the value of the labor and improvements on the (adverse) lode exceeds five hundred dollars, and said improvements consist of (state in full).

(Place and date.)

, *U. S. Deputy Surveyor.*

TUNNEL CLAIM—LOCATION CERTIFICATE.

Know all men by these presents, that the undersigned, citizens of the United States, have this day of , 188 , claimed by right of location, a tunnel claim, for the purpose of discovering and working veins, lodes or deposits on the line thereof [Cutting the lode, and working the lode]. Said tunnel claim is situated in the mining district, county of , State of , and the location and bounds of said tunnel are staked on the surface at the place of commencement and termination thereof, as well as along the line thereof. Said claim is more particularly described as follows: [*Describe the commencement and termination by reference to natural objects and permanent monuments, and the line by courses and distances.*]

Dated , 188 .

POWER OF ATTORNEY TO LOCATE AND SELL.

Know all men by these presents, that we the undersigned [*names*] , citizens of the United States, have made, constituted and appointed A. B. [*some third person who will locate and stake*], our true and lawful attorney for us, and in our names to locate, stake and record for us each lode claim and placer mining ground in the , county, of , and having located the same, to bargain, sell, grant, release and convey the same, entire or in separate parcels, to make proper deeds, seal, acknowledge and deliver the same to such persons as our attorney may desire; hereby ratifying and confirming all lawful acts done by our said attorney by virtue hereof.

Witness our hands and seals this day of , 18 .

[*Names.*]

of , *County of* , *ss.*

On this day of , 18 , before me in and for the county and State aforesaid, appeared personally known to me as the persons whose names are subscribed to the foregoing power of attorney, and acknowledged the execution thereof as their free act and deed, for the purposes therein mentioned.

Given under my hand and seal the day and year above written.

NOTICE OF RIGHT TO WATER.

The undersigned claims the water running in this stream to the extent of inches for mining purposes, to be conveyed by (ditch or flume) from this point to the placer claim.

Dated , 18 .

,
Locator.

PRE-EMPTION OF RIGHT OF WAY FOR DITCH AND LOCATION OF WATER.

To whom these presents may concern, know ye, that I, , of the county of , in the State of , a citizen of the United States, do hereby declare and publish as a legal notice to all the world, that I claim, and have a valid right to the occupation, possession and enjoyment of all and singular, that tract or parcel of land lying and being in the county of , in the state of , for the exclusive right of way for the purpose of constructing a flume or water ditch from stream to placer claim, more particularly described as follows: Commencing (*here describe the exact route for ditch or flume.*)

I also claim, and have a valid right to the enjoyment and use of inches of water from said stream for mining purposes, to be conveyed through such flume or water ditch to said claim, together with all and singular, the hereditaments and appurtenances thereunto belonging, or in any wise appertaining.

Witness my hand and seal this day of , A. D. 18 .

[*Name.*]

Notice posted on the stream , 18 .
Ditch commenced at claim or at stream , 18 .

of , *County of* , *ss.*

On this day of , 18 , before me, a in and for the county aforesaid, in the state aforesaid, personally appeared , to me personally known to be the person who executed the foregoing written instrument, and acknowledged that he executed the same for the uses and purposes therein set forth.

Witness my hand and official seal.

MINING DEED.

THIS INDENTURE, made the day of , in the year of our Lord one thousand eight hundred and eighty, between , of the county of , and of , party of the first, and , of the county of , and of , party of the second part;

Witnesseth, That the said party of the first part, for and in consideration of the sum of dollars, lawful money of the United States of America, to him in hand paid by the said party of the second part, the receipt whereof is hereby acknowledged, hath granted, bargained, sold, remised, released, and for ever quit-claimed, and by these presents does grant, bargain, sell, remise, release, and for ever quit claim, unto the said party, of the second part, his heirs and assigns, the lode, as located, surveyed, recorded, and held by said party of the first part, situated in mining district county , together with all the dips, spurs, and angles, and also all the metals, ores, gold and silver-bearing quartz rock and earth therein, and all the rights, privileges, and franchises thereto incident, appendant and appurtenant, or therewith usually had and enjoyed: and also, all and singular the tenements, hereditaments, and appurtenances thereunto belonging, or in any wise appertaining, and the rents, issues and profits thereof; and also, all the estate, right, title, interest, property, possession, claim and demand whatsoever, as well in law as in equity, of the said party of the first part, of, in or to the said premises, and every part and parcel thereof, with the appurtenances.

To have and to hold, all and singular, the said premises, together with the appurtenances and privileges thereto incident, unto the said party of the second part, his heirs and assigns for ever. In witness whereof, the said party of the first part has hereunto set his hand and seal the day and year first above written.

SEAL.

of , *County, ss.*

I, Fitzmaurice Langton, a Notary Public in and for said county, in the state aforesaid, do hereby certify that , personally known to me to be the person whose name is subscribed to the annexed deed, appeared before me this day in person, and acknowledged that he signed, sealed and delivered the said instrument of writing as his free and voluntary act, for the uses and purposes therein set forth.

Given under my hand and official seal, this day of , A. D. 188 .

SEAL. FITZMAURICE LANGTON, *Notary Public.*

TITLE BOND.

Know all men by these presents, that I. James Bingham, party of the first part, of the County of Lake, and State of Colorado, am held and firmly bound unto George Boyd, party of the second part, of the County of Lake, and State of Colorado, in the penal sum of ten thousand dollars, lawful money of the United States, to the payment of which the party of the first part hereby binds himself, his heirs, executors and administrators. Witness his hand and seal this 20th day of July, 1880. The conditions of the foregoing obligations are such, that whereas, the above bounden party of the first part, in consideration of the sum of five dollars, in hand paid, has, on the day and year aforesaid, agreed to sell to the party of the second part the following described mining property, viz.: An undivided one-eighth interest in and to the Gilt Edge lode claim, as located, surveyed, recorded, and held, situate, lying and being in California Mining District, Lake County, Colorado, together with all and singular, the improvements, hereditaments, and appurtenances thereto belonging, or in any wise appertaining, for the sum of five thousand dollars, to be paid at the times and in the manner following, viz.: One thousand dollars on or before August 20, 1880; one thousand dollars on or before September 20, 1880; and three thousand dollars on or before October 20, 1880; which sums of money are to be paid to the party of the first part in person, or by depositing the same to his credit at the First National Bank of Philadelphia, at the times aforesaid, and time shall be of the essence of these conditions. And in case of failure of the party of the second part, or his assigns, to make either of said payments at the times mentioned, such sum or sums as may have been paid hereunder, shall be forfeited to and retained by the party of the first part, as a penalty and for liquidated damages, and notice of forfeiture is hereby expressly waived, and also all right, demand or claim for the balance or any of said sum of five thousand dollars, is hereby expressly waived by the party of the first part. The party of the first part, his heirs, executors, administrators, and assigns, shall, on the 20th day of October, 1880, or at any time before, upon payment of said sums of money hereinbefore mentioned, make, execute, and deliver to the party of the second part, or to such person or persons as he shall designate, good and sufficient deed or deeds of all of the above described property, conveying a clear and perfect title (except the fee simple title of the United States), free from all incumbrances, with a covenant, that the annual expenditure has been made thereon as required by law. Now, if the party of the second part shall fail to pay the sum or sums of money as hereinbefore provided, and if the party of the first part shall faithfully perform the covenants herein set forth, then this obligation shall be null and void; otherwise, to be and remain in full force and effect.

SEAL. JAMES BINGHAM.

— 9

State of Colorado, Lake County, ss.

Be it known, That on this 20th day of July, 1880, before me, personally came James Bingham, to me known as the person described in, and who executed the foregoing instrument in writing, and acknowledged the execution thereof to be his free act and deed, for the uses and purposes therein mentioned.

Witness my hand and official seal,

SEAL. ALVIN GARNETT, *Notary Public.*

ESCROW AGREEMENT.

The inclosed deed of the lode is hereby placed in the Bank of , *in escrow.* If A. B. shall place, or cause to be placed to the credit of C. D. and E. F., in said bank of , on or before , 188–, the full sum of dollars, then and in that case the said bank is hereby authorized to deliver the inclosed deed to A. B., or his order. In case the said A. B. shall not place, or cause to be placed, to the credit of said C. D. and E. F., in said bank, the full sum of dollars, on or before , 188–, then the said bank is hereby authorized to deliver the inclosed deed to the said C. D. and E. F., or their joint order.

(Signed) C. D.
E. F.
A. B.

——— ——— ———, 188–, (Place and date).

MINING LEASE.

This Indenture, made this day of , in the year of our Lord one thousand eight hundred and eighty , between lessor and lessee or tenant; *Witnesseth*, That the said lessor for and in consideration of the rents, royalties, covenants and agreements hereinafter reserved, and by the said lessee to be paid, kept and performed, granted, demised and let, and by these presents do grant, demise and let unto the said lessee, all the following described mine and mining property, situated in mining district, county of of , to wit: (Here description of property.) Together with the appurtenances to have and to hold unto the said lessee or tenant for the term of from the date hereof, expiring at noon on the day of , A. D. 188–, unless sooner forfeited or determined through the violation of any covenant hereinafter against the said tenant reserved.

And in consideration of the said demise, the said lessee does covenant and agree with said lessor as follows, to wit:

To enter upon said mine or premises and work the same mine fashion, in manner necessary to good and economical mining, so as to take out the greatest amount of ore possible, with due regard to the safety, development and preservation of the said premises as a workable mine.

(Here insert special covenants for dead work, etc.)

To work and mine said premises as aforesaid steadily and continuously from the date of this lease: and that any failure to work said premises with at least persons employed underground for the space of consecutive days may be considered a violation of this covenant.

To well and sufficiently timber said mine at all points where proper, in accordance with good mining; and to repair all old timbering wherever it may become necessary.

To allow said lessor and agents to enter upon and into all parts of said mine for the purpose of inspection, with use of all passages, ropes, windlass, ladder-ways, and all other means of ingress and egress for such purpose.

To not assign this lease, or any interest thereunder, and to not sublet the said premises or any part thereof, without the written assent of said lessor, and to not allow any person or persons except the said lessee and workmen to take or hold possession of said premises or any part thereof under any pretence whatever.

To occupy and hold all cross or parallel lodes, dips, spurs, feeders, crevices or mineral deposits of any kind, which may be discovered in working under this lease, or in any tunnel run to intersect said lode, or by the said lessee or any person or persons under , in any manner at any point within feet of the centre line of said lode, as the property of said lessor; with privilege to said lessee of working the same as an appurtenance of said demised premises, during the term of this lease; and to not locate or record the same, or allow the same to be located or recorded, except in the name of said lessor.

To keep at all times the drifts, shafts, tunnels, and other passages and workings of said demised premises, thoroughly drained and clear of loose rock and rubbish of all kinds.

To pay and deliver to said lessor as royalty, of all ores to be extracted from said premises during said term, of like assay to that retained by said lessee, delivered at as soon as mined, without offset, deduction, or charge whatever, except lessor's proportion for packing.

To deliver up to said lessor the said premises, with the appurtenances and all improvements in good order and condition, with all shafts and tunnels and other passages thoroughly clear of rubbish and drained, and the mine in all points ready for immediate continued working (accidents not arising from negligence alone excusing), without demand or further notice, on said day of , A. D. 188–, at noon or at any time previous, upon demand for forfeiture.

And finally, upon the violation by said lessee, or any person under , of any covenant or covenants hereinbefore reserved, the term of this lease shall, at the option of said lessor, expire, and the same and said premises with the appurtenances shall become forfeit to said lessor; and said lessor or agent may thereupon, after demand of possession in writing, enter upon said premises and dispossess all persons occupying the same, with or without force, and with or without process of law; or at the option of said lessor, the said tenant and all persons found in occupation may be proceeded against as trespassers from the beginning of said term both as to realty and the ore served therefrom; or as guilty of unlawful detainer.

Each and every clause and covenant of this Indenture shall extend to the heirs, executors, and administrators of all parties hereto; and to the assigns of said lessor: and as said lessor may elect, to the assigns of said lessee.

In witness whereof, The said parties, lessor and lessee, have hereunto set their hands and seals.

Prospecting Contracts.—These are quite common and should be carefully drawn. The following form will answer for a guide:

I, A. B., in consideration of the supplies, tools and general prospecting outfit furnished me by C. D., and for the sum of dollars, to be paid as follows, viz:

Have agreed and do hereby agree with the said C. D. to prospect diligently for lodes and placers in the county, (or counties) of , in the State of , and to locate and develop all discoveries, which in my best judgment, shall be worth locating, in the joint names of myself and the said C. D. in equal undivided shares. All expenses of survey and record shall be paid by the said C. D. And the said A. B. agrees to devote his entire time and attention to prospecting for, locating and developing mining claims as aforesaid.

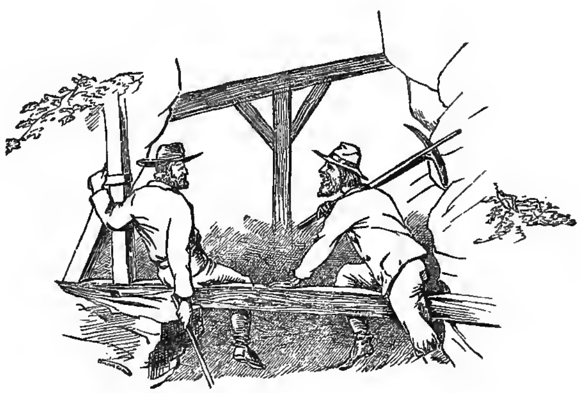
This contract shall be in force from this date until the day of , 188 , or until cancelled by the mutual consent of the parties hereto. (Signed,) A. B.

I agree to the terms above written. C. D.

Dated,

The contract should be recorded in the county, or counties, where the prospecting is to be done, for the purpose of giving notice of the interest of the party furnishing the grubstake in all claims located by the prospector. A contract to prospect for mines on joint account will be enforced; and a decree was given, directing the conveyance to C. of an interest of one-half in a mine located by S. in his own name, upon a finding that the claim was located under the terms of an existing contract that the claim should belong to S. and C. jointly.

An Important Legal Decision.—The Supreme Court of California, in banc, has decided that all mining stocks now issued and in circulation are fully paid up, no matter at what price per share the stock may have been bought. That no stock fully paid up can be assessed. That, under the law, no corporation organized or now in existence can levy any assessment or tax upon said stock; and that any assessment so levied is illegal, and hence null and void; that no stockholder under such circumstance can be divested of his or her rights in and to said stock by any such void proceedings. That partly-paid-up stock may be issued; but that such stock must bear upon its face its fully-paid-up value, and also the exact amount paid per share for said stock. That such partly-paid-up stock may be assessed—but not until 25 per cent. of the company's capital stock shall have been subscribed for; and then only that portion subscribed for can be assessed, and only 10 per cent. of its paid-up-value. This case has been all the more important because of the millions possessed by the contestants—the Santa Craz Railroad Company for and Claus, Spreckels & Co., against. It is believed that those who have paid these illegal assessments in the past can recover the amount paid, with interest. No one has lost or can lose his stock in any company organized in California by refusing to pay his assessments—but only by statute of limitations, which is three years under the present law.—*Chicago Tribune.*



PART VIII.

A GLOSSARY OF MINING TERMS—THE PROPERTIES OF METALS—WEIGHTS AND MEASURES—REFERENCE TABLES.

CALCULATIONS in Mining are the guides of every action. The Miner, the Engineer, the Owner, are slaves of calculation. To accomplish this successfully, reference tables are in constant requisition, as well as that kind of information that may be said to embody cardinal facts. We have therefore in part viii THE MINES, MINERS AND MINING INTERESTS, compiled a set of reference tables that in their liberal scope we trust, will cover every need of the miner, or his employer, or the engineer, or the owners. These are very properly prefaced with Dr. Raymond's admirable Glossary of Mining terms and expressions, a glossary that is of undoubted interest to the professional as well as the non-professional reader; opening up as it does a wide field of thought in the study of the phraseology of a great occupation. The tables are made to include a wide range of information concerning mining and its collateral interests. For the majority of them we are indebted to the "Engineers and Mechanics' Handbook," by Charles H. Haswell, M. E.

A GLOSSARY OF MINING AND METALLURGICAL TERMS.

THE absence of a convenient glossary of terms connected with mining and metallurgy has long been felt by the general public. It is to meet this want, not to furnish a technical manual for experts, that the following glossary has been prepared. In the compilation, the following general principles were adopted:—1. To include the most important technical words and phrases used by American miners and metallurgists, or occurring in English books and periodicals. 2. To exclude Spanish, French and German terms, unless they fall under the rule above given. The Spanish terms included are in use among our miners in the far West and Southwest. 3. To exclude almost all purely scientific terms, such as those which denote the operations of chemical analysis, the chemical names and symbols of elements and compounds, the species of rocks and minerals, the principles of general physics and mechanics, etc. 4. To avoid scientific and technical explanations. 5. To omit, in general, self-explanatory terms, and such as are common to all mechanical and manufacturing trades.

The grounds of these rules are evident. It was neither practicable nor necessary to give in what could be, and must be, sought in technical textbooks or general dictionaries and cyclopædias. But the glossary presents numerous exceptions to the above rules. Many geological terms, for instance, are so common among metallurgists as to render their adoption in this catalogue justifiable. The difficulty has been to "draw the line;" and this has been done, somewhat arbitrarily. An apology should be made for the obscurity of a few of the definitions. Many terms taken from English glossaries were found to be most vaguely defined; and in most cases of this kind, the definitions were improved; but there remain some which it was impossible to amend with certainty.

In many instances, the locality in which a term is believed to have originated or to be peculiarly in use, is indicated by abbreviations which will mostly explain themselves. The principal regions named are England, Scotland, Wales, France, Germany, the United States, Spain (including Mexico), Australia, Cornwall, Derbyshire, Staffordshire, Newcastle, Devonshire, Lake Superior, Pennsylvania, and the Pacific slope (including the mining districts of the Rocky Mountains). It must be understood that the naming, in this connection, of any one locality does not exclude the use of the term in other localities; and particularly that in this country the circulation both of miners and metallurgists, and of books and journals from all the world has brought into use a heterogeneous technical vocabulary. This is especially the case in the gold, silver and lead mining districts of the West, where all the names, phrases, and theories that anybody anywhere at any time has cultivated, together with a crop of indigenous, spontaneous growth, seem to flourish vigorously.

ABSTRICH, GERM. The black or greenish-brown mass (*black litharge*) appearing upon the bath of work-lead early in the cupelling-process, and gradually, as the process advances, giving way to pure litharge.

Abzug, GERM. The first scum appearing (before the *abstrich*) on the surface of molten lead.

Adit. A nearly horizontal passage from the surface, by which a mine is entered and unwatered. In the United States an adit is usually called a *tunnel*, though the latter, strictly speaking, passes entirely through a hill, and is open at both ends.

Adlings, ENG. Earnings.

Adobe, SP. Clay suitable for *adobes* or sun-dried bricks.

Adventurers, ENG. Shareholders or partners in a mining enterprise; in Cornwall, *cost-book* partners.

After-damp, ENG. The irrespirable gas, consisting of nitrogen and carbonic acid chiefly, remaining after an explosion of *fire-damp.*

Agitator, PAC. See *Settler.*

Aich's metal. See *Gun-metal.*

Air-head, or Air-heading, S. STAF. A smaller passage, driven parallel with the *gate-road.* and near its roof, to carry the ventilating current. It is connected with the *gate-road* at intervals by openings called *spouts.*

Air-reduction process. See *Roasting and Reaction process.*

Aitch-piece. See *H-piece.*

Alberti furnace. A continuously working reverberatory furnace for the roasting of quicksilver ores, with condensation of the mercury in iron-tubes and brick chambers.

Alligator. 1. See *Squeezer.* 2. A rock-breaker operating by jaws.
Alloy. A compound of two or more metals fused together.
Alluvium. The earthy deposit made by running streams, especially in times of flood.
Aludel. An earthen condenser for mercury. See *Bustamente furnace.*
Aluminium ores. *Cryolite,* a fluoride of sodium and aluminium, found in Greenland; *bauxite,* a hydrous compound of alumina, ferric oxide and silica.
Amalgamation. 1. The production of an amalgam or alloy of mercury. 2. The process in which gold and silver are extracted from pulverized ores by producing an amalgam, from which the mercury is afterwards expelled. See *Retorting.*
Amalgamator. 1. A machine for amalgamating ores. 2. The workman in charge of such a machine.
American forge. See *Catalan forge.*
Anemometer. An instrument for measuring the rapidity of an air-current.
Annealing. 1. The gradual cooling of glass or metal from a high temperature, to render it less brittle. 2. See *Malleable castings.*
Anthracite. See *Coal.*
Anticlinal. The line of a crest, above or under ground, on the two sides of which the strata dip in opposite directions. The converse of *synclinal.*
Antimony ores. Native antimony; *stibnite,* (sulphide of antimony); *valentinite* and *senarmontite* (oxides).
Apex. In the U. S. Revenue Statutes, the end or edge of a vein nearest the surface.
Apolvillados, Sp. Ores superior in quality to the *azogues.*
Appolt oven. An oven for the manufacture of coke, differing from the *Belgian* in that it is divided into vertical compartments.
Aprons. See *Copper-plates.*
Arch, Corn. 1. A portion of a lode left standing when the rest is extracted, to support the *hanging wall* or because it is too poor for profitable extraction. 2. The roof of a reverberatory furnace.
Arenaceous. Silicious or sandy (of rocks).
Arends' tap. An arrangement by which the molten lead from the crucible of a shaft-furnace is drawn through an "inverted siphon" into an exterior basin, from which it can be ladled without disturbing the furnace.
Arenillos, Sp. Refuse earth.
Argentiferous. Containing silver.
Argillaceous. Containing clay.
Arm. The inclined member or leg of a set or frame of timber.
Arrastre, Sp. Apparatus for grinding and mixing ores by means of a heavy stone dragged around upon a circular bed. The arrastre is chiefly used for ores containing free gold, and amalgamation is combined with the grinding. Sometimes incorrectly written *arraster, arrastra,* or *raster.*
Arroba, Sp. Twenty-five pound avoirdupois.
Arsenic ores. Native arsenic; *mispickel* (*arsenopyrite, arsenical pyrites,* arseno-sulphide of iron).
Ascension-theory. The theory that the matter filling fissure-veins was introduced in solution from below.
Ash-pit. The receptacle for ashes under a fire-place.
Assay. To test ores and minerals by chemical or blowpipe examination; said to be in *the dry way* when done by means of heat (as in a crucible), and in *the wet or humid way* when by means of solution and precipitation or liquid tests. An assay differs from a complete analysis in being confined to the determination of certain ingredients, the rest not being determined. Both assays and analyses may be either qualitative or quantitative; that is, they may determine the presence merely, or also the amount, of some or all of the constituents of the substance examined. The assay value of gold and silver ores is usually determined in Troy ounces (or, for gold, pennyweights) per ton (2000 pounds avoirdupois) of ore. See *Assay ton.* When reported in money value, the ounce of gold is taken at $20.6718. A ton of pure gold would be worth $602,928.51; the value of $6 per ton would be by weight one-thousandth per cent., and so on. Silver varies greatly in market value; but assayers often report their results according to the old U. S. standard, which made the ounce of pure silver worth $1.2929. The ton of silver at this rate, would be worth $37. 710.40; the value of $37 per ton would be by weight one-tenth per cent., and so on. For ordinary gold and silver ores, it is evident that the percentages would be inconveniently small as expressions of value. Assays of lead, copper, iron, etc., are reported in percentages.
Assay-ton. A weight of 29.166⅔ grams. Since one ton of 2000 pounds avoirdupois contains 29.166⅔ troy ounces, it is evident that each milligram of gold or silver obtained from one *assay-ton* of ore represents one ounce troy to the ton of 2000 pounds avoirdupois.
Assessment-work, Pac. The work done annually on a mining claim to maintain possessory title.
Astel. Overhead boarding or arching in a gallery.
Astyllen, Eng. A small dam in an adit or level, to check water.
Atierres, Sp. Refuse ores.
Attle, Corn. Refuse rock.
Auger-nose shell. See *Wimble.*
Auger-stem. The bar to which a *drilling-bit* is attached.
Auget or *Augette.* A priming tube, used in blasting.
Augustin process. The treatment of silver ores by chloridizing, roasting, lixiviation with hot brine, and precipitation with copper.
Auriferous. Containing gold.
Average produce, Corn. The quantity of pure or fine copper in one hundred parts of ore.
Average standard, Corn. The price per ton of pure or fine copper in the ore.
Aviador, Sp. A person who *habilitates* a mine; that is, who furnishes the money for working it by contract with proprietors.
Azogueria, Sp. 1. The amalgamating works. 2. The process of amalgamation.
Azogues, Sp. Common or inferior ores.

BACK, Corn. 1. With reference to an adit, drift or stope, the part of the vein between it and the next working above, or the surface. 2. See *Face.*
Back-casing, Eng. A temporary shaft-lining of bricks laid dry, and supported at intervals upon *curbs.* When the *stone-head* has been reached, the permanent masonry lining is built upon it inside of the *back-casing.*
Back-end, Newc. The part of a *judd* remaining after the *sump* has been removed.
Backing deals, Newc. Planks driven vertically behind the curbs in a shaft from one curb to another.
Back-shift. The second set of miners working in any spot each day.
Back-skin, Newc. A leather covering worn by men in wet workings.
Bait, Newc. A pitman's provisions.
Bal, Corn. A mine.
Balance-bob. A heavy lever ballasted at one end, and attached at the other to the pump-rod, the weight of which it thus helps to carry. When the shaft is deep, and the pump-rods are consequently very heavy, balance-bobs are put in at intervals of 200 or 300 feet, thus relieving the strain on the rods themselves and on the engine.
Balk, Newc. A *hitch* producing a *nip.*
Balland, Derb. Pulverulent lead ore.
Ballast-shovel. A round-mouthed shovel.
Balling. The aggregation of iron in the *puddling* or the *bloomary* process into *balls* or *loups.*
Ball-stamp, Lake Sup. A stamp for crushing rock, operated directly by steam-power, the stem of the stamp being at the same time the piston-rod of a steam cylinder.
Band, Newc. Stone interstratified with coal.
Bank. 1. (Derb. or *Benk*). The face of the coal at which miners are working. 2. An ore-deposit or coal-bed worked by surface excavations or drifts above water-level. 3. Eng. The ground at the top of a shaft. Ores are brought "to bank," *i. e.,* "to grass." See *Grass.*
Banksman, Newc. See *Lander.*
Bar. 1. A drilling or tamping-rod. 2. A vein or dyke crossing a lode. 3. A sand or rock ridge crossing the bed of a stream.
Bar-diggings, Pac. Gold-washing claims located on the bars (shallows) of a stream, and worked when the water is low, or otherwise with the aid of coffer-dams.
Barilla, Sp. Native copper disseminated in grains in copper ores.
Barmaster. Derb. A mining official who collects the dues or royalties, presides over the *barmote,* etc. (From *Germ. Bergmeister*).
Barmote, Derb. A mining court.
Barney. A small car attached to a rope and used to push cars up a slope or inclined plane.
Barranca, Sp. A ravine.
Barrel. 1. The water-cylinder of a pump. 2. A piece of small pipe inserted in the end of a cartridge to carry the *squib* to the powder. 3. A vessel used in amalgamation.
Barrel-amalgamation. The amalgamation of silver ores by revolution in wooden barrels with quicksilver, metallic wire, and water.
Barrel-work, Lake Sup. Native copper occurring in pieces of a size to be sorted out by hand in sufficient purity for smelting without mechanical concentration.
Barrier-pillars. *Pillars* of coal, larger than ordinary, left at intervals to prevent too extensive crushing when the ground comes to be *robbed.*
Barrow, Corn. 1. A heap of *attle* or rubbish; a *dump.* 2. A vehicle in which ore, coal, etc., are wheeled.
Barrow-men, Newc. See *Putters.*
Barrow-way, Newc. A *level* through which coal or ore is wheeled.
Base bullion. See *Bullion.*
Base metals. The metals not classed as *noble* or precious. See *Noble metals.*
Basic. In furnace practice, a slag in which the earthy bases are in excess of the amount required to form a neutral slag with the silica present.
Basic lining. A lining for furnaces, converters. etc., formed of non-silicious material, usually limestone, dolomite, lime, magnesia, or iron oxide.
Basic-lining process. An improvement of the *Bessemer process,* in which by the use of a basic lining in the *converter* and by the addition of basic materials during the *blow,* it is possible to eliminate phosphorus from the pig iron, and keep it out of the steel.
Basin. 1. A natural depression of strata containing a coal bed or other stratified deposit. 2. The deposit itself.
Bass or *batt.* See *Bind.*

Basset. DERB. An outcrop; the edge of a stratum.
Batch, CORE. The quantity of ore sent to the surface by a pare of men.
Batea, SP. A large wooden bowl in which gold-bearing earth or crushed ore is washed in the same way as in a *pan.*
Bath. A mass of molten material in a furnace, or of a solution in a tank.
Batt. See *Bind.*
Battery. 1. A set of *stamps* in a stamp-mill, comprising the number which fall in one *mortar,* usually five. 2. A bulkhead of timber. 3. The plank closing the bottom of a *coal-chute.*
Battery-amalgamation. Amalgamation by means of mercury placed in the mortar.
Battery-assay. See *Pulp-assay.*
Bauxite. See *Aluminium-ores.*
Beans, NEWC. Small coals.
Bean shot. Copper granulated by pouring into hot water.
Bear. 1. See *Salamander.* 2. See *Loup.*
Bearing. See *Strike.*
Bed. A seam or deposit of mineral later in origin than the rock below, and older than the rock above; that is to say, a regular member of the series of formations, and not an intrusion.
Bedded vein. Properly *bed vein* (*Lagergang* of the Germans); a lode occupying the position of a bed, that is, parallel with the stratification of the inclosing rock.
Bede. A miner's pickaxe.
Bed-rock, PAC. The solid rock underlying alluvial and other surface formations.
Bed-way. An appearance of stratification, or parallel marking, in granite.
Beehive oven. An oven for the manufacture of coke, shaped like the old-fashioned beehive.
Belgian oven. A rectangular oven with end-doors and side-flues for the manufacture of coke.
Belgian zinc-furnace. A furnace in which zinc is reduced and distilled from calcined ores in tubular retorts.
Bell and hopper. See *Cup and cone.*
Belly helve, ENG. A forge-hammer, lifted by a cam which acts about midway between the fulcrum and the head.
Bell-metal. A hard bronze, containing sometimes small proportions of iron, zinc or lead, but ordinarily consisting of 78 parts copper and 22 tin.
Bell's dephosphorizing process. The removal of phosphorus from molten pig iron in a puddling furnace, lined with iron oxide and fitted with a mechanical rabble to agitate the bath. Red-hot iron-ore is added. See *Krupp's washing process.*
Bench. 1. One of two or more divisions of a coal seam, separated by slate, etc., or simply separated by the process of cutting the coal, one bench or layer being cut before the adjacent one. 2. To cut coal in *benches.*
Benching up, NEWC. Working on the top of coal.
Bend or *Bind,* DERB. Indurated clay.
Beneficiar, SP. To benefit. To work or improve a mine; to reduce its ores; to derive profit or advantage from working it.
Beneficiation, sometimes used in English, usually means the reduction of ores.
Bessemer iron. Pig iron suitable for the Bessemer process.
Bessemer process. The process of decarburizing a bath of molten cast iron by blowing air through it, in a vessel called a *converter.*
Biche. A tool ending below in a conical cavity, for recovering broken rods from a bore-hole.
Billet. 1. Iron or steel, drawn from a pile, bloom, or ingot into a small bar for further manufacture. 2. A small bloom.
Bind, DERB. See *Bend.*
Biny, NORTH ENG. Eight hundred weight of ore.
Bing-ore, DERB. Ore in lumps.
Bing-hole, DERB. A hole or *shoot* through which ore is thrown.
Bing-tale, NORTH ENG. See *Tribute.*
Bismuth-ores. Native bismuth; *bismuth ochre* (oxide); *bismuthine* (sulphide); also, bismuthiferous cobalt, silver and copper ores.
Bit. The cutting end of a boring implement.
Bituminous coal. See *Coal.*
Black-band. An earthy carbonate of iron, accompanying coal-beds. Extensively worked as an iron ore in Great Britain, and somewhat in Ohio.
Black-copper. Impure copper from smelting, before refining.
Black damp, ENG. Carbonic acid gas.
Black ends, ENG. Refuse coke from coking-ovens.
Black flux. A mixture of charcoal and potassium carbonate.
Black jack, CORN. Zinc-blende; sometimes hornblende.
Black lead. Graphite.
Black litharge. See *Abstrich.*
Black plate. Sheet iron before tinning.
Black tin, CORN. Tin ore prepared for smelting.
Blair process. An improved form of the *Chenot process.*
Blanch. Lead ore, mixed with other minerals.
Blanched copper. An alloy of copper and arsenic.
Blanket sluices. Sluices in which coarse blankets are laid, to catch the fine but heavy particles of gold and amalgam, etc., in the slime passing over them. The blankets are removed and washed from time to time, to obtain the precious metal.
Blast. 1. The operation of *blasting,* or rending rock or earth by means of explosions. 2. The air forced into a furnace to accelerate combustion. 3. The period during which a blast furnace is *in blast,* that is in operation.
Blast furnace. A furnace, usually a shaft-furnace, into which air is forced under pressure.
Blasting-stick. A simple form of fuse.
Bleaching-clay, CORN. Kaolin, used with size, to whiten and give weight and substance to cotton goods.
Bleiberg furnace. See *Carinthian furnace.*
Blende. See *Zinc ores.*
Blick, GERM. The *brightening* or iridescence appearing on silver or gold at the end of the cupelling or refining process.
Blind level. 1. A level not yet connected with other workings. 2. A level for drainage, having a shaft at either end, and acting as an inverted siphon.
Blind-shaft. See *Winze.*
Blister-steel. See *Steel.*
Bloat. A hammer swelled at the *eye.*
Block-coal, U. S. See *Coal.*
Block-furnace. See *Bloomary.*
Block tin. Cast tin.
Bloom. 1. A large steel bar, drawn ftom an ingot for further manufacture. 2. A rough bar of iron, drawn from a Catalan or bloomary ball, for further manufacture. See *Billet.*
Bloomary. A forge for making wrought-iron, usually direct from the ore. The sides are iron plates, the *hair-plate* at the back, the *cinder plate* at the front, the *tuyere-plate* (through which the tuyere passes) at one side (its upper part being called in some bloomaries the *merrit-plate*) the *fore spar plate* opposite the *tuyere-plate* (its upper part being the *skew-plate*) and the *bottom plate* at the bottom.
Blossom. The oxidized or decomposed outcrop of a vein or coal-bed, more frequently the latter. Also called *smut* and *tailing.* See *Gossan.*
Blow. A single *heat* or operation of the Bessemer *converter.*
Blower, NEWC. 1. A strong discharge of gas from a fissure. 2. A *fan* or other apparatus for forcing air into a furnace or mine.
Blow-george. A hand-fan.
Blow-in. To put a blast furnace in operation.
Blow-out. 1. To put a blast furnace out of blast, by ceasing to charge fresh materials, and continuing the blast until the contents of the furnace have been smelted. 2. A large outcrop, beneath which the vein is smaller, is called a *blow-out.* 3. A *shot* or blast is said to *blow out* when it goes off like a gun and does not shatter the rock.
Blow-pipe. A tube through which air is forced into a flame, to direct it and increase its intensity. In the compound blowpipe, two jets of gas (one of which may be air) are united at the point of combustion.
Blue-billy, ENG. The residuum of cupreous pyrites after roasting with salt.
Blue-john, DERB. Fluorspar.
Blue lead. (Pronounced like the verb *to lead.*) The bluish auriferous gravel and cement deposit found in the ancient river-channels of California.
Blue metal. See *Metal.*
Blue peach, CORN. A slate-blue, very fine-grained schorl-rock.
Blue stone. Copper-vitriol; copper-sulphate.
Boards. The first set of excavations in *post-and-stall* work.
Boat level, WALES. A navigable *adit.*
Bob, CORN. A triangular frame, by means of which the horizontal motion imparted from an engine is transformed into a vertical motion of the pump-rods in a shaft.
Bob-station. See *Station.*
Bog-iron-ore. A loose, earthy *brown hematite,* of recent origin, formed in swampy ground.
Boiling. See *Puddling.*
Bonanza, SP. Literally, fair weather. In miners' phrase, good luck, or a body of rich ore. A mine is *in bonanza* when it is profitably producing ore.
Bone. The slaty matter intercalated in coal-seams.
Bonnet. A covering over a cage to shield it from objects falling down the shaft.
Bonney, CORN. An isolated body of ore.
Booming. The accumulation and sudden discharge of a quantity of water (in placer mining, where water is scarce.) See, also, *Hushing.*
Boot. A leather or tin joint connecting the *blast-main* with the *tuyere* or *nozzle* in a *bloomary.*
Bord, NEWC. A passage or *breast,* driven up the slope of the coal from the gangway, and hence across the *grain* of the coal.
Bord. See *Boards, Breast,* and *Post-and-stall.*
Board-and-pillar. See *Post-and-stall.*
Borer. See *Drill.*
Borrasca, SP. The converse of *bonanza.* Barren rock.
Bort. Opaque black diamond.
Bosh. 1. A trough in which bloomary tools (or, in copper-smelting, hot ingots) are cooled. 2. (Or. *Boshes.*) The portion of a shaft furnace in which it widens from above the hearth up to its maximum diameter.
Bottom-lift. The deepest lift of a mining-pump, or the lowest pump.
Bottomer, ENG. The man stationed at the bottom of a shaft in charge of the proper loading of cages, signals for hoisting, etc.

Bottoms, CORN. 1 The deepest workings. 2. In copper-smelting, the impure metallic copper, or cupriferous alloy, which separates from the *matt*, and is found below it, when there is not enough sulphur present to retain in combination all the copper.

Boulder or *Bowlder*. A fragment of rock brought by natural means from a distance (though this notion of transportation from a distance is not always, in later usage, involved) and usually large and rounded in shape. *Cobble stones* taken from river-beds are, in some American localities, called boulders.

Bonds, CORN. A tract of tin-ored ground.

Bout, DERB. A measure of lead-ore; twenty-four *dishes*.

Bowke, S. STAFF. A small wooden box in which iron-ore is hauled underground.

Bowse or *Bouze*, DERB. Lead-ore as cut from the lode.

Box-bill. A tool used in deep boring for slipping over and recovering broken rods.

Box-groove. A closed groove between two *rolls*, formed by a collar on one roll, fitting between collars on another roll.

Box-timbering. See *Plank-timbering*.

Brace, CORN. The mouth of a shaft.

Brace-head. A cross-attachment at the top of the column of rods in deep boring, by means of which the rods and bit are turned after each drop.

Brace-key. See *Bracehead*.

Braize, U. S. Charcoal-dust. See *Breeze*.

Brake-sieve. A *jigger*, operated by a hand-lever.

Brakesman. The man in charge of a winding-engine.

Brances. See *Brasses*.

Branch. CORN. A small vein departing from the main lode, and in some cases returning.

Basque. A lining for crucibles or furnaces; generally a compound of clap, etc., with charcoal-dust.

Brass. An alloy of copper and zinc.

Brasses, ENG. and WALES. Pyrites (sulphide of iron) in coal.

Brat, ENG. and WALES. A thin bed of coal mixed with pyrites or carbonate of lime.

Brattice, ENG., SCOT., and WALES. A plank lining, or a longitudinal partition of wood, brick, or even cloth, in a shaft, level, or gangway, generally to aid ventilation.

Brazil. Iron pyrites.

Breaker. See *Coal-Breaker* and *Rock-Breaker*.

Breast. 1. The *face* of a working. 2. In coal mines, the chamber driven upwards from the *gangway*, on the seam, between pillars of coal left standing for the extraction of coal. 3. That side of the *hearth* of a *shaft-furnace* which contains the *metal-notch*.

Breast-boards. Planking placed between the last set of timbers and the *face* of a *gangway* or *heading* which is in quicksand or loose ground.

Breccia. A *conglomerate* in which the fragments are angular.

Breeding-fire. See *Gob-fire*.

Breeze, ENG. Small coke. Probably connected, perhaps interchangeable, with *Braize*, and both with the FR. *Braise*.

Brettis, DERB. A *crib* of timber filed up with *slack* or waste.

Brettis way. A road in a coal-mine, supported by *brettises* built on each side after the coal has been worked out.

Bridge. See *Reverberatory furnace*.

Bridle-chains. Safety-chains to support a *cage* if the link between the cage and rope should break.

Brightening. See *Blick*.

Broaching-bit. A tool used to restore the dimensions of a bore-hole which has been contracted by the swelling of the marl or clay walls.

Brob. A peculiar spike, driven alongside the end of an abutting timber to prevent its slipping.

Broil or *Broyl*, CORN. See *Bryle*.

Broken coal, PENN. See *Coal*.

Bronze. An alloy of copper and tin.

Brood, CORN. The heavier kinds of waste in tin and copper ores.

Brown coal. See *Coal*.

Browse. Ore imperfectly smelted, mixed with cinder and clay.

Bruckner cylinder, PAC. A form of revolving roasting furnace.

Bryle, CORN. The traces of a vein, in loose matter, on or near the surface.

Bucker, DERB. A flat piece of iron with a wooden handle, used for breaking ore.

Bucket. The piston of a lifting-pump.

Bucking, DERB. See *Cobbing*. The *bucking-hammer* or *bucking-iron* is a broad-headed hammer used for this purpose; and the ore is broken on a flat piece of iron (*bucking plate*).

Buckshot cinder. Cinder from the iron blast furnace, containing grains of iron.

Buckwheat-coal, PENN. See *Coal*.

Buddle, CORN. An inclined vat or stationary or revolving platform upon which ore is concentrated by means of running water. Strictly the *buddle* is a shallow vat, not a platform or *table;* at least not in some localities. But general usage, particularly on the Pacific slope, makes no distinction.

Buggy. A small mine-wagon holding ½ ton to 1 ton of coal.

Buhrstone. A quartz rock containing cellules.

Buitron, SP. A furnace of peculiar construction, in which silver ore is reduced.

Bulkhead. 1. A tight partition or stopping in a mine for protection against water, fire, or gas. 2. The end of a flume, whence water is carried in iron pipes to hydraulic workings.

Bull. See *Clay iron*.

Bulldog. 1. A refractory material used as a furnace-lining, got by calcining *mill-cinder*, and containing silica and ferric oxide. 2. PENN. See *Buckshot-cinder*.

Bullfrog. See *Barney*.

Bullion. Uncoined gold and silver. *Base bullion* (PAC,) is pig lead containing silver and some gold, which are separated by refining.

Bull pump, CORN. A direct single-acting pump, the steam cylinder of which is placed over the top of a shaft or slope, and the piston-rod attached to the pump-rods. The steam lifts piston and pump-rods, and the weight of these makes a down-stroke.

Bull wheel. In rope-boring, a wheel on which is wound the rope for hoisting the bit, etc.

Bully. A pattern of miners' hammer, varying from "*broad-bully*" to "*narrow bully*."

Bunch of ore, CORN. An ore-body, usually a small one.

Bunding. A staging of boards on *stulls* or *stemples*, to carry *deads*. See *stull covering*.

Buntons, ENG. Battens or scantlings placed horizontally across a shaft, to which are nailed the boards forming the *cleading* or *sheathing* of a *brattice*.

Burden, CORN. 1. The tops or heads of steam work, which lie over the stream of tin. 2. The proportion of ore and flux to fuel in the charge of a blast-furnace.

Burning. See *Calcining*.

Burnt iron. 1. Iron which by long exposure to heat has suffered a change of structure and become brittle. It can be restored by careful forging at welding-heat. 2. In the *Bessemer* and *open-hearth* processes, iron which has been exposed to oxidation until all its carbon is gone, and oxide of iron has been formed in the mass.

Burr. Solid rock.

Burrow, CORN. A heap of refuse.

Buscones, SP. Searchers; explorers.

Bushel. The Imperial bushel, of 2218 cubic inches, and the Winchester bushel, of 2150 cubic inches, are divided into 4 pecks. The bushel used in measuring charcoal and coal contains 5 pecks, or 2680 cubic inches, being 20 pounds or less of charcoal, and, in various localities, 80, 76, or 72 pounds of coal.

Bustamente furnace. A cylindrical shaft-furnace for roasting quicksilver ores; divided by perforated arches into two compartments, of which the upper receives the ore and the lower the fuel. The mercury-vapors are condensed in *aludels*.

Butt, ENG. Of coal; a surface exposed at right angles to the *face*. See *End*.

Button. The globule of metal remaining on an *assay-cupel* or in a crucible, at the end of the fusion.

Butty, DERB. and STAFF. A miner by contract at so much per ton of coal or ore.

Cabbling. Breaking up pieces of flat iron to be *piled* or *fagoted*, heated and rolled.

Cable-tools. The apparatus used in drilling deep holes, such as artesian wells, with a rope instead of rods, to connect the drill with the machine on the surface.

Cache, FR. The place where provisions, ammunition, etc., are *cached* or hidden by trappers or prospectors in unsettled regions.

Cage. 1. A frame with one or more platforms for cars, used in hoisting in a vertical shaft. It is steadied by guides on the sides of the shaft. 2. A structure of elastic iron rods slipped into the bore-hole in *rod-boring* to prevent vibration of the rods. 3. The barrel or drum in a *whim* on which the rope is wound.

Cake copper. See *Tough cake*.

Caking coal. See *Coal*.

Cala, SP. A small pit or experimental hole.

Cal, CORN. Wolfram.

Calcine. To expose to heat, with or without oxidation; to *roast*. Applied to ores for the removal of water and sulphur, and the disintegration of the mass; to limestone for the expulsion of its carbonic acid; etc.

Calciner. A furnace or kiln for roasting.

Calicata, SP. A digging or trial pit.

Campaign. The period during which a furnace is continuously in operation.

Canada, SP. A ravine, or small canon.

Canch. A part of a bed of stone worked by quarrying.

Cand or *Cann*, CORN. Fluorspar.

Cank, DERB. See *Whinstone*.

Canon, SP. A valley, usually precipitous; a gorge.

Cannel coal. See *Coal*.

Cap or *Cap-rock*. Barren vein matter, or a *pinch* in a vein, supposed to overlie ore.

Capel. A composite stone of quartz, schorl, and hornblende.

Capella, SP. Cupelling furnace.

Captain, CORN. and WALES. The official in immediate charge of the work in a mine.

Carat. 1. A unit employed in weighing diamonds, and equal to 3⅙ troy grains. A *carat-grain* is one-fourth of a carat. 2. A term employed to distinguish the fineness of a gold alloy, and meaning one-twenty-fourth. Fine gold is 24–*carat* gold. Goldsmith's standard is 22 *carats* fine, *i. e.*, contains 22 parts gold, 1 copper, and 1 silver.

Carbona, CORN. An irregular deposit or impregnation of tin ore, found in connection with a tin lode.

Carbonaceous. Containing carbon not oxidized.

Carbonates. The common term in the West for ores containing a considerable proportion of carbonate of lead. They are sometimes earthy or ochreous (soft carbonates), sometimes granular and comparatively free from iron (sand carbonates), and sometimes compact (hard carbonates.) Often they are rich in silver.

Carbonization. The process of converting to carbon, by removing other ingredients, a substance containing carbon, as in the charring of wood or the natural formation of anthracite.

Carburization. The process of imparting carbon, as in making *cement steel*.

Carga, SP. A mule-load of 300 pounds avoirdupois.

Carinthian furnace. A small reverberatory with inclined hearth, in which lead ore is treated by *roasting and reaction*, wood being the usual fuel.

Car-wheel iron. See *Chill.*

Case. A small fissure, admitting water into the workings.

Case harden. To convert iron superficially into steel by partial cementation.

Casing, CORN. 1. A partition or *brattice*, made of *casing-plank*, in a shaft. 2. PAC. *Casings* are zones of material altered by vein-action, and lying between the unaltered country rock and the vein.

Cast-after-cast, CORN. The throwing up of ore from one platform to another successively. See *Shambles.*

Cast house. The building in which pigs or ingots are cast.

Casting. Pouring or drawing fused metal from a blast furnace, cupola, crucible, converter, or ladle into moulds.

Cast-iron. See *Iron.*

Cast-steel. See *Steel.*

Cata, SP. A mine denounced, but unworked.

Catalan forge. A forge with a tuyere for reducing iron ore, with charcoal, to a loup of wrought iron; a *bloomary.* See *Champlain forge.*

Cat-head. 1. A small capstan. 2. A *broad-bully* hammer. See *Bully.*

Cauf. NEWC. See *Corf.*

Caunter lode, CORN. A vein coursing at a considerable angle to neighboring veins.

Caving. The falling in of the sides or top of excavations.

Cawk. Sulphate of baryta (heavy spar).

Cazo, SP. A caldron in which amalgamation is effected by the *cazo* process, used in Mexico, and South America.

Cement, AUSTR. and PAC. Gravel firmly held in a silicious matrix, or the matrix itself.

Cementation The process of producing a chemical change in a solid substance by packing it in a powder and heating it. See *Cement-steel* and *Malleable castings.*

Cement-copper. Copper precipitated from solution.

Cement-gold. Gold precipitated in fine particles from solution.

Cement-silver. Silver precipitated from solution, usually by copper.

Cement-steel. See *Steel.*

Cendrada, SP. Ashes or smeltings found at the bottom of a furnace, and valuable for use in other smeltings.

Cerro, SP. A hill or mountain.

Chasing. Following a vein by its range or direction.

Chafery. A forge fire for *reheating.* (From the FR. *Chaufferie.*)

Chaldron. Thirty-six bushels. In Newcastle fifty-three hundredweight avoirdupois. *Chaldron-wagons*, containing this quantity, convey the coal from the pit to the place of shipment.

Chalybeate. Impregnated with iron (applied to mineral waters).

Chamber. See *Breast.*

Champion lode. The main vein as distinguished from branches.

Champlain forge or *American forge.* A forge for the direct production of wrought iron, generally used in the United States instead of the Catalan forge, from which it differs in using only finely-crushed ore and in working continuously.

Changing-house, CORN. A room where miners change and dry their underground clothing. See *Dry.*

Charbon roux, FR. Brown charcoal, produced by an incomplete carbonization of wood.

Charge. 1. The materials introduced at one time or one round into a furnace. 2. The amount of explosive used for one blast.

Charger, CORN. An auger-like implement for charging horizontal bore-holes for blasting.

Charring. The expulsion by heat of the volatile constituents of wood, etc., leaving more or less pure vegetable carbon.

Chartermaster, S. STAFF. See *Butty.*

Chats, NORTHUMB. Small pieces of stone with ore.

Cheeks. 1. The sides or walls of a vein. 2. Extensions of the sides of the *eye* of a hammer or *pick.*

Chenot process. The process of making *iron-sponge* from ore mixed with coal-dust, and heated in vertical cylindrical retorts.

Chert. Hornstone; a silicious stone often found in limestone.

Cherry coal, ENG. See *Coal.*

Chestnut coal, PENN. See *Coal.*

Chilian Mill. An improved *arrastre*, in which a heavy stone wheel is rolled around the bed.

Chill. An iron mould or portion of a mould, serving to cool rapidly, and so to harden, the surface of molten iron which comes in contact with it. Iron which can be thus hardened to a considerable depth is *chilling iron*, and is specially used for cast-iron railway car-wheels requiring hardness at the rim without loss of strength in the wheel.

Chimming, CORN. See *Tossing.*

Chimney. An ore-shoot. See *Chute.*

China clay. Kaolin.

Chisel. See *Bit.*

Chock. See *Nog.*

Choke-damp, ENG. Carbonic acid gas.

Chlorides, PAC. A common term for ores containing chloride of silver.

Chloridize. To convert into chloride. Applied to the roasting of silver ores with salt, preparatory to amalgamation.

Chlorination process. The process first introduced by Plattner, in which auriferous ores are first roasted to oxidize the base metals, then saturated with chlorine gas, and finally treated with water, which removes the soluble terchloride of gold, to be subsequently precipitated and melted into bars.

Chrome ore. Chromic iron (*chromite*, oxide of chromium and oxide of iron).

Chute. (Sometimes written *shoot.*) 1. A channel or shaft underground, or an inclined trough above ground, through which the ore falls or is "shoot" by gravity from a higher to a lower level. 2. A body of ore, usually of elongated form, extending downward within a vein (*ore-shoot*). The two forms of orthography of this word are of French and English origin respectively. Under *chute*, the original idea is that of falling; under *shoot*, that of shooting or branching. Both are appropriate to the technical significations of the word. An *ore-shoot*, for instance, may be considered as a branch of the general mass of the ore in a deposit or as a pitch or fall of ore (GERM. *Erzfall*). In England the orthography *shoot* is, I believe, exclusively employed, and this is perhaps the best, the other being unnecessarily foreign.

Cinder, ENG. Slag, particularly from iron blast furnaces.

Cinder-pig, ENG. See *Pig iron.*

Cinder plate. See *Bloomary.*

Cinder tap, *Cinder notch.* The hole through which cinder is tapped from a furnace. See *Lurmann front.*

Cinnabar. Sulphuret of mercury.

Cistern, CORN. See *Tank.*

Clack, CORN. A pump-valve.

Clack-door, CORN. An opening into the valve chamber of a pump.

Claggy, NEWC. Adhesive. When the coal is tightly joined to the roof, the mine is said to have a *claggy top.*

Claim, PAC. The portion of mining ground held under the Federal and local laws by one claimant or association, by virtue of one location and record.

Clanny lamp. The safety-lamp invented by Dr. Clanny.

Clay-iron. A tool for crowding clay into leaky bore-holes.

Cleading, ENG. See *Buntons.*

Clean-up. The operation of collecting all the valuable product of a given period or operation in a stamp mill, or in a hydraulic or placer mine.

Cleat. 1. A joint in coal or rock. 2. A strip of wood.

Cleavage. The property in a mineral, of splitting more easily and perfectly in some directions than in others. The planes of cleavage bear a relation to the crystal form of the mineral. The *cleavage* of rock-masses is more properly a jointing, unless it follows the planes of bedding.

Clinker. The product of the fusion of the earthy impurities (ash) of coal during its combustion.

Clinometer. A simple apparatus for measuring by means of a pendulum or spirit-level and circular scale, vertical angles, particularly *dips.*

Clod. Soft shale or slate, in coal mines, usually applied to a layer forming a bad roof.

Closed-top. See *Cup-and-cone.*

Closed front. An arrangement of the blast-furnace without a *fore-hearth.*

Clotting. The sintering or semi-fusion of ores during roasting.

Coal. (ENG. *Coals*). This term is now applied to *stonecoal* or *pit-coal*, that is, mineral coal, obtained by mining, as distinguished from charcoal. No scientific account of the nature and origin of coal will be given here. The three principal classes recognized by common usage are *anthracite* (hard, black, composed, when pure, almost exclusively of carbon), *bituminous* or *coking coal* (brown or black, containing hydrocarbons, and *lignite* or *brown coal* (brown or black, generally showing a woody or laminar structure, containing much water, and more recent, geologically speaking, than the other varieties). *Semi-anthracites* and *semi-bituminous coals* are gradations between *anthracite* and *bituminous*, based on the increasing percentage of volatile matters. *Hydrogenous* or *gas-coals* are bituminous coals yielding the highest percentage of volatile matters. The English classification of *bituminous coals* distinguishes *coking coal* proper (splintering when heated, but subsequently fusing into a semi-pasty mass), *cherry* or *soft coal* (igniting readily and burning rapidly without splintering or fusion), *splint*, *rough* or *hard* coal (igniting with more difficulty but burning with a clear, hot fire), and *cannel coal* (the *parrot coal* of Scotland, compact, homogeneous, conchoidal in fracture, burning with clear, bright flame). The English call *anthracite* also *stonecoal* or *culm*, and speak of a *semi-anthracite* as *steam-coal*. Any coal advantageously used for generating steam is called a *steam-coal* in the United States. The solid carbon remaining after the expulsion of volatile matters from *bituminous coal* or *lignite* is called *coke*. Commercial *coke*, however, must have a certain coherence and strength; and the coals which furnish it in this condition are called *coking coals*. A peculiar bituminous coal of Indiana and Ohio, which breaks in blocks, and is used raw without coking, to some extent, as a blast-furnace fuel, is called *block coal*. *Anthracite* is divided in the United States according to the color of the ash after burning, into *white-ash*, *red-ash* and *pink-ash coal*. It is also classified for the market according to the size of the pieces (see *Coal-breaker*), as follows: *Lump* includes the largest lumps as they come from the mine. The other sizes pass over and through sieve-meshes of the size named, the figures signifying inches, and thus indicating roughly the average limit of diameter for the pieces in each size, viz.:

Steamboat	through 7	over 4;
No. 1, *Broken* or *grate*,	through 4	over $2\frac{3}{4}$ to $2\frac{1}{2}$;
No. 2, *Egg*,	through $2\frac{3}{4}$ to $2\frac{1}{2}$	over $2\frac{1}{4}$ to 2;
No. 3, *Large stove*,	through $2\frac{1}{4}$ to 2	over $1\frac{7}{8}$ to $1\frac{1}{2}$;
No. 4, *Small stove*,	through $1\frac{7}{8}$ to $1\frac{1}{2}$	over $1\frac{1}{8}$ to 1
No. 5, *Chestnut*,	through $1\frac{1}{8}$ to 1	over $\frac{5}{8}$ to $\frac{1}{2}$;
No. 6, *Pea*,	through $\frac{7}{8}$ to $\frac{1}{2}$	over $\frac{3}{8}$ to $\frac{1}{4}$.

No. 7, *Buckwheat*, is rarely made, except when the coal is washed on the screens, and the *chestnut* and *pea* have the larger dimensions above given. It is the smallest size, and usually included in the dirt or *culm*.

Coal-breaker. A building containing the machinery for breaking coal with toothed rolls, sizing it with sieves, and cleaning it for market.

Coal-pipes. NEWC. Very thin irregular layers of coal.

Cobalt ores. *Cobalt-speiss* (*smaltine*, *chloanthite* when niccoliferous, *safflorite* when ferriferous, an arsenite of cobalt with or without nickel or iron); *cobalt glance* and *cobalt pyrites* (*smaltite* and *linnœrite*, sulphides of cobalt); *cobalt bloom* (*erythrite*, arseniate of cobalt).

Cobbing, CORN. Breaking ore to sort out its better portions. See *Spall*.

Cobble, PENN. An imperfectly puddled ball which goes to pieces in the *squeezer*.

Cobre ores. Copper ores from Cuba.

Cockte, CORN. See *Schorl*.

Cod, NEWC. The bearing of an axle.

Coffer or *Cofer*, DERB. 1. To secure a shaft from leaking by ramming in clay behind the masonry or timbering. 2. (or *Cover*) CORN. See *Mortar* (2). 3. A rectangular plank frame, used in timbering *levels*.

Coffin, CORN. 1. An old open working. 2. The mode of open working by casting up ore and waste from one platform to another, and so to the surface.

Cog. To roll or *bloom* ingots.

Cogs. See *Nogs*; only *Cogs* are not squared, but simply notched where they cross each other. The interior of a structure of this kind and the spaces between the timber are usually filled with *gob*. They are called also *cobs*, *corncobs*, etc.

Coil-drag. A tool to pick up pebbles, bits of iron, etc., from the bottom of a drill-hole.

Coke. The product remaining after the expulsion by heat of the volatile constituents of coal.

Coking coal. See *Coal*.

Coal-bed. A platform in a rolling-mill on which cold bars are stored.

Cold blast. Air forced into a furnace without being previously heated.

Cold short. Brittle when cold. Applied chiefly to iron and steel.

Collar. 1. See *Cap*. 2. The *Collar* of a shaft is the horizontal timbering around the mouth.

Colliery. A coal mine.

Collom washer. LAKE SUP. A variety of *jig*.

Color, SP. 1. Color. The shade or tint of the earth or rock which indicates ore. 2. A particle of Metallic gold found in the prospector's pan after a sample of earth or crushed rock has been "panned out." Prospectors say, *e. g.*, "The dirt gave me so many colors to the panful."

Colorados, SP. Ores impregnated with oxide of iron, and in a state of decomposition. See *Gossan*.

Col-rake. A shovel used to stir lead-ores during washing.

Comb. The place, in a fissure which has been filled by successive depositions on minerals on the walls, where the two sets of layers thus deposited approach most nearly or meet, closing the fissure and exhibiting either a drusy central cavity, or an interlocking of crystals.

Combined Carbon. That portion of the carbon in iron or steel which is not visible as graphite, and is supposed to be alloyed or chemically combined with the iron.

Compass. An instrument like the ordinary nautical or surveyor's compass, though sometimes otherwise marked, and having a *clinometer* attached. Also, *a dip-compass*, for tracing magnetic iron ore, having a needle hung to move in a vertical plane.

Concentration. The removal by mechanical means of the lighter and less valuable portions of ore.

Concentrator. An apparatus in which, by the aid of water or air and specific gravity, mechanical concentration of ores is performed.

Condensor. A vessel or chamber in which volatile products of roasting or smelting (*e. g.*, mercury or zinc vapors) are reduced to solid form by cooling, or in which the fumes of furnaces, containing mechanically suspended as well as volatile metallic matters are arrested.

Conglomerate. A rock consisting of fragments of other rocks (usally rounded) cemented together.

Consume. The chemical and mechanical loss of mercury in amalgamation.

Contact. The plane between two adjacent bodies of dissimilar rock. A *contact-vein* is a vein, and a *contact-bed* is a bed, lying, the former more or less closely, the latter absolutely, along a contact.

Continental process. See *German process*.

Converter. See *Bessemer process*.

Cope. 1. DERB. To contract, to mine lead ore by the *dish* load, or other measure. 2. The upper part of a *flask*, separable from the lower part. See *Drag*.

Coper, DERB. One who contracts to raise lead ore at a fixed rate.

Copperas. Ferrous sulphate.

Copper-ores. Native copper; red copper-ore (*cuprite*, protoxide); green and blue *malachite*) *malachite* and *azurite*, carbonates); *copper glance* (*chalcocite*, sulphide); *purple copper* (variegated or *peacock* ore, *bornite*, sulphide of copper and iron); *gray copper* (*fahl-ore*, *tetrahedrite*, sulphantimonide of copper and other metals); *yellow copper* (*copper-pyrites*, *chalcopyrite*, sulphide of copper and iron); *copper-lead ore*, (*bournonite*, sulphantimonide of lead and copper); *black copper-ore* (an earthy and variable mixture of sulphide and oxide of copper).

Copper-plates, AUSTR. and PAC. The plates of amalgamated copper over which the auriferous ore is allowed to flow from the stamp battery, and upon which the gold is caught as amalgam.

Copper-rain. Minute globules thrown up from the surface of molten copper, when it contains but little suboxide.

Copper-smoke. The gases from the calcination of sulphuretted copper-ores.

Corbond. An irregular mass or "dropper" from a lode.

Cordurie process. The refining of lead by conducting steam through it, while molten, to oxidize certain metallic impurities.

Core, CORN. A miner's underground working-time or *shift*.

Corf, *Corve*, or *Cauf* (the last incorrect). 1. NEWC. A large basket used in hoisting coal; from the GERM. *Korb*. 2. A wooden frame to carry coal. 3. A sled or low wagon for the same purpose.

Cornish pump. A pump operated by rods attached to the beam of a single-acting condensing beam-engine. The steam, pressing down the piston in the vertical steam-cylinder, lifts the pump-rods, and these subsequently descend by their own weight.

Coro-coro. A dressed product of copper-works in South America, consisting of grains of native copper and mixed with pyrite, chalco-pyrite, mispickel, and earthy minerals.

Corroding-lead. Refined lead, sufficiently pure for the corroding process, by which white lead is manufactured.

Cost-book, CORN. A book used to keep accounts of mining enterprises carried on under the *cost-book system*, peculiar to Cornwall and Devon, and differing from both partnership and incorporation. It resembles the mining partnership system of the Pacific States.

Costeaning or *Costeening*, CORN. Discovering veins by pits and open cuts, run on the surface transversely to the supposed course of the veins.

Counter. 1. A cross-vein. 2. (Or *counter-gangway*.) A gangway. driven obliquely upwards on a coal-seam from the main gangway until it cuts off the faces of the workings, and then continues parallel with the main gangway. The oblique portion is called the *run*.

Country, or *country-rock*, CORN. The rock traversed by or adjacent to an ore deposit.

Course. See *Strike*.

Course of ore. See *Chute* (2.).

Coursing. Conducting the air-current of a mine in different directions by means of doors and stoppings.

Cousin Jack. A common nickname for a Cornishman.

Covered-binding, CORN. See *Plank-timbering*.

Cow. A kind of self-acting brake for inclined planes; a trailer.

Cowl. See *Water-barrel*.

Cowper-Siemens stove. A hot blast stove of firebrick on the regenerative-principle.

Coyoting, PAC. Mining in irregular openings or burrows, comparable to the holes of *coyotes* or prairie foxes.

Crab. A machine for moving heavy weights. Specially the engines employed for lowering into place the pumps, rods, pipes, etc., of Cornish *pit-work*.

Cradle, PAC. See *Rocker*.

Cramp. A pillar of rock or mineral left for support.

Cranch. Part of a vein left by old workers.

Craze or *Creaze*, CORN. The tin-ore which collects in the middle part of the *buddle*.

Creep, NEWC. A rising of the floor of a gangway, occasioned by the weight of incumbent strata, in pillar workings. Also any slow movement of mining ground.

Cretaceous. 1. Chalky. 2. See *Geological formations*.

Crevet. A crucible.

Crevice, PAC. 1. A shallow fissure in the bed-rock under a gold placer, in which small but highly concentrated deposits of gold are found. 2. The fissure containing a vein.

Crib. 1. See *Curb*. 2. A structure composed of frames of timber laid horizontally upon one another, or of timbers built up as in the walls of a log cabin. 3. A miner's luncheon.

Cribbing. Close timbering, as the lining of a shaft, or the construction of *cribs* of timber or timber and earth or rock, to support a roof.

Cribble. A sieve.

Crop. 1. CORN. See *Crop-tin*. 2. The *basset* or *outcrop* of strata at the surface. 3. To leave coal at the bottom of a bed.

Cropping out. The rising of layers of rock to the surface. That part of a vein which appears above the surface is called the *cropping* or *outcrop*.

Crop-tin. The chief portion of tin-ore separated from waste in the principal dressing operation.

Cross-course, CORN. An intersecting (usually a barren) vein.

Cross-cut. A level driven across the course of a vein, or, in general, across the direction of the main workings (and to connect two parallel gangways), or across the "grain of coal."

Cross-heading. A heading driven across from one gangway or breast to another, usually for ventilation.

Cross-vein. An intersecting vein.

Crow or *Crow-foot*. A tool with a side-claw, for grasping and recovering broken rods in deep bore-holes.

Crucible. 1. A melting pot. 2. The lower part of a shaft furnace, in which fusion is effected and the molten bath is contained.

Crush. 1. A *squeeze*, accompanied, perhaps, with more violent motion and effects. 2. A variety of fault in coal. See *Fault* (2).

Crusher. A machine for crushing ores.

Cry of tin. The peculiar crackling noise produced in bending a piece of metallic tin.

Culm. 1. ENG. Anthracite. 2. PENN. The waste or *slack* of the Pennsylvania anthracite mines, consisting of fine coal, more or less pure, and coal-dust and dirt.

Cup-and-cone. A machine for charging a shaft-furnace, consisting of an iron hopper with a large central opening, which is closed by a *cone* or *bell* pulled up into it from below. In the annular space around this cone, the ore, fuel, etc., are placed; then the cone is lowered to drop the materials into the furnace; after which it is again raised to close the hole.

Cupellation. The treatment on a hearth or *cupel* (usually formed of bone-ash) of an alloy of lead, gold, and silver, by means of fusion and an air blast, which oxidizes the lead to litharge, and removes it in liquid form, or absorbs it in the cupel.

Cupola. A shaft-furnace with a blast, for remelting metals, preparatory to casting. Sometimes incorrectly pronounced and written *Cupalo*.

Curb. A timber frame, circular or square, wedged in a shaft to make a foundation for walling or tubbing, or to support, with or without other timbering, the walls of the shaft.

Curbing. See *Cribbing*.

Cut. 1. To intersect a vein or working. 2. To excavate coal.

DAM. 1. To keep back water in a stream or mine by means of a dam or bulkhead. 2. S. STAFF. See *Stopping* and *Bulkhead*. 3. The wall of refractory material, forming the front of the *fore-hearth* of a blast furnace. It is built on the inside of a supporting iron plate (*dam-plate*). Iron is tapped through a hole in the dam, and cinder through a notch in the top of the dam. See *Lurmann front*.

Damask. The etched or "watered" surface produced on polished (welded) steel by corrosion.

Damper. A valve in a flue or at the top of a chimney to regulate the draft.

Dam-plate. The plate upon the *dam-stone* or front stone of the bottom of a blast furnace.

Damp-sheet, S. STAFF. A large sheet, placed as a curtain or partition across a gate-road to stop and turn an air-current.

Dan, NEWC. A truck or sled used in coal mines.

Danks puddler. A revolving mechanical puddler. See *Puddling*.

Dant, NEWC. Soft, inferior coal; *mineral charcoal*.

Davy lamp. The safety lamp invented by Sir H. Davy.

Day, WALES. The surface of the ground over a mine. *Day-level*. An *adit*. *Day-water*. Water from the surface.

Dead, CORN. 1. Unventilated. 2. As to a vein or piece of ground, unproductive.

Deadened mercury. See *Floured*.

Dead-plate. Nearly horizontal iron plate, at the mouth of the furnace, under a steam-boiler, on which the bituminous coal charges are laid to be partially coked before they are pushed upon the grate where their solid carbon is consumed. The gases evolved on the *dead-plate* pass over the grate and are burned.

Dead riches. See *Base bullion*.

Dead roasting. Roasting carried to the farthest practicable degree in the expulsion of sulphur.

Deads, CORN. The waste rock, packed in excavations from which ore or coal has been extracted.

Dead work. Work that is not directly productive, though it may be necessary for exploration and future production.

Deal. Plank used in shaft and gallery construction.

Dean, CORN. The end of a level.

Debris, FR. The fragments resulting from shattering or disintegration.

Deep, CORN. The lower portion of a vein; and in the phrase *to the deep, i. e.*, downward upon the vein.

Denunciar, SP. To denounce. To give information that a mine is forfeited for being insufficiently worked, or for a violation of some condition which imposes that penalty. This term is also applied to the giving notice of a discovery, for the purpose of registry.

Deposit. The term *mineral deposit* or *ore-deposit* is arbitrarily used to designate a natural occurrence of a useful mineral or ore in extent and degree of concentration to invite exploitation.

Derrick. 1. See *Whip*. 2. The hoisting-tower over an artesian well-boring.

Descension-theory. The theory that the material in veins entered from above.

Desilverization. The process of separating silver from its alloys.

Desuing, CORN. See *Disuing*.

Desulphurization. The removal of sulphur from sulphuret ores.

Dial, CORN. See *Compass*. To *dial* a mine is to make a survey of it.

Diamond-drill. A form of rock-drill in which the work is done by abrasion instead of percussion, black diamonds (*borts*) being set in the head of the boring tool.

Diamond groove. A groove of V-section in a *roll*.

Die. A piece of hard iron, placed in a mortar to receive the blow of a stamp, or in a pan to receive the friction of the muller. Between the die and the stamp or muller the ore is crushed.

Dig. CORN. See *Gouge*.

Diggings. Applicable to all mineral deposits and mining camps, but in usage in the United States applied to placer-mining only.

Dike. A vein of igneous rock.

Dilluing or *dilleughing*, CORN. An operation performed in tin-dressing upon the slimes of a certain part of the process. It is like the operation of *panning*, only performed with a sieve having a close haircloth bottom, and in a *kieve* of water which receives the tailings of the process.

Diluvium. Sand, gravel, clay, etc., in superficial deposits. See *Drift*. According to some authors, alluvium is the effect of the ordinary, and diluvium of the extraordinary action of water. The latter term is now passing out of use as not precise, and more specific names for the different kinds of material are substituted.

Dinas brick. A refractory brick, almost entirely composed of silica from the Dinas "clay" in the Vale of Neath, England.

Dip. The inclination of a vein or stratum below the horizontal. The dip at any point is necessarily at right angles with the local *strike*, and its inclination is steeper than that of any other line drawn in the plane of the vein or stratum through that point.

Dipping-needle. See *Compass*.

Discovery, PAC. The first finding of the mineral deposit in place upon a mining claim. A *discovery* is necessary before the location can be held by a valid title. The opening in which it is made is called *discovery-shaft, discovery tunnel*, etc.

Dish, CORN. 1. The landowner's or landlord's part of the ore. 2. DERB. A measure of 14, 15 or 16 pints.

Dissuing, CORN. Cutting out the *selvage* or *gouge* of a lode, to facilitate the ore-extraction.

Distillation. Volatilization, followed by condensation to the liquid state.

District. In the States and Territories west of the Missouri, a vaguely bounded and temporary division and organization made by the inhabitants of a mining region. A district has one code of mining laws, and one recorder. Counties and county officers are gradually taking the place of these cruder arrangements.

Ditch. An artificial watercourse, flume or canal, to convey water for mining. A flume is usually of wood; a ditch, of earth.

Divining-rod or *Dowsing-rod*, CORN. A rod (most frequently of witch-hazel, and forked in shape) used, according to an old but still extant superstition, for discovering mineral veins and springs of water, and even for locating oil wells.

Doggy, S. STAFF. An underground superintendent, employed by the *butty*.

Dog-hole. A small *proving-hole* or airway, usually less than 5 feet high.

Dole. A division of a parcel of ore.

Dolly-tub, CORN. A tub in which ore is washed, being agitated by a *dolly*, or perforated board.

Dope. See *Explosives*.

Dotts or *Dott-holes*. Small openings in the vein.

Douglas process. See *Hunt and Douglas process*.

Downcast. The opening through which the ventilating air-current descends into a mine.

Downcome. The pipe through which *tunnel-head* gases from iron blast-furnaces are brought down to the hot-blast stoves and boilers, when these are below the *tunnel-head*.

Dradge, CORN. The inferior portions of ore, separated from the *prill* by cobbing.

Drag. The lower part of a *flask*. The mould having been prepared in the two parts of the flask, the *cope* is put upon the *drag* before casting. After casting, the flask is opened by removing the *cope*.

Drag-twist. A spiral hook at the end of a rod, for cleaning boreholes.

Draught, S. STAFF. The quantity of coal raised *to bank* in a given time.

Draw. To *rob* pillars or the top-coal of breasts before abandoning the ground.

Dredge. Very fine mineral matter held in suspension in water.

Dresser, S. STAFF. A large pick, with which the largest lumps of coal are prepared for loading into the *skip*.

Dressing, CORN. The picking and sorting of ores, and washing, preparatory to reduction.

Drift. 1. A horizontal passage underground. A *drift* follows the vein, or distinguished from a *cross-cut*, which intersects it, or a *level* or *gallery*, which may do either. 2. Unstratified *diluvium*.

Drill. A metallic tool for boring in hard material. The ordinary miner's drill is a bar of steel, with a chisel-shaped end, and is struck with a hammer. See *Rock-drill*, *Diamond-drill*.

Driving. Extending excavations horizontally. Distinguished from *sinking* and *raising*.

Dropper, CORN. A branch leaving the main vein on the *footwall* side.

Dross. The material skimmed from the surface of freshly melted, not perfectly pure metal.

Drowned-level. See *Blind-level*, (2).

Druggon, S. STAFF. A square iron or wooden box, used for conveying fresh water for horses, etc., in a mine.

Drum. That part of the winding machinery on which the rope or chain is coiled.

Druse. A crystallized crust lining the sides of a cavity.

Dry, CORN. See *Changing-house*.

Dry copper. See *Under-poled copper*. Also copper just ready for *poling*.

Dry Puddling. See *Puddling*.

Dry sand. Sand prepared for *moulds* by thorough drying and baking. When special cohesion is required (as for *cores*) other substances, such as flour, molasses, etc., are mixed with it.

Dualin. See *Explosives*.

Dumb-drift. An *air-way* conveying air around, not through, a ventilating furnace to the *upcast*.

Dump. 1. To unload a vehicle by tilting or otherwise, without handling or shovelling out its contents. 2. A pile of ore or rock.

Dumper. A tilting-car used on *dumps*.

Durn, CORN. A frame of timbering, like a door-frame.

Dust-plate. A vertical iron plate, supporting the *slag-runner* of an iron blast furnace.

Dutch metal. An alloy of copper and zinc, containing more copper than ordinary brass.

Duty. A measure of the effectiveness of a steam-engine, usually expressed in the number of foot-pounds (or kilogrammetres) of useful work obtained from a given quantity of fuel.

Duty-ore, CORN. The landlord's share of the ore.

Dyke. See *Dike*.

Dzhu, CORN. To cut ahead on one side of a *face*, so as to increase the efficacy of blasting on the remainder. (Doubtless the same word as *Dissue*. See *Dissuing*.) Also called *to hulk*.

EGG-coal, PENN. See *Coal*.

Egg-hole, DERB. A notch cut in the wall of a lode to hold the end of a *stempel*.

Electrum. An alloy of copper, zinc, and nickel.

Eliquation. Separating an alloy by heating it so as to melt the more fusible of its ingredients, but not the less fusible.

Elutriation. Purification by washing and pouring off the lighter matter suspended in water, leaving the heavier portions behind.

Elvan, CORN. A name given to certain broad granite veins or belts in schistose rocks.

Emery. Impure corundum.

End of coal. The direction or section at right-angles to the *face*; sometimes called the *butt*.

End-pieces, CORN. See *Wall-plates*.

English process. In copper-smelting, the process of *reduction* in a *reverberatory* furnace, after *roasting*, if necessary.

English zinc-furnace. A furnace in which zinc is reduced and distilled from *calcined* ores in *crucibles*.

Engorgement. The *clogging* of a furnace. See *Scaffold*.

Entry. An *adit*. Applied to the main *gangway* in some coal mines.

Estufa amalgamation, SP. A modification of the *patio* process, using heat.

Exploder. A cap or fulminating cartridge, placed in a charge of gunpowder or other explosive, and exploded by electricity or by a fuse. See *Explosives*.

Exploitation, FR. The productive working of a mine, as distinguished from exploration.

Explosives. The principal explosives used in mining are *gunpowder*, a compound of sulphur, charcoal, and potassium nitrate (potash saltpetre) or sodium nitrate (Chili or soda-saltpetre); *nitro-glycerin*, a liquid compound of carbon, hydrogen, nitrogen, and oxygen, produced by the action of nitric acid upon glycerin; *dynamite No.* 1, or *giant-powder*, a mixture of nitroglycerin with a dry pulverized mineral or vegetable absorbent or *dope* (commonly silicious or infusorial earth); *dynamite No.* 2, nitroglycerin mixed with saltpetre, sawdust, or coaldust, paraffin, etc., in lieu of an inexplosive *dope*; *lithofracteur*, nitroglycerin mixed with silicious earth, charcoal, sodium (and sometimes barium) nitrate and sulphur; *dualin*, nitroglycerin mixed with potassium, nitrate and fine sawdust; *rend-rock*, *Atlas*, *Hercules*, *Neptune*, *tonite*, *vigorite*, and other powers, resembling dynamite No. 2, *i. e.*, consisting of nitroglycerin with a more or less explosive *dope*; and *mica-powder*, a No. 1 *dynamite*, in which the *dope* is fine scales of mica. The *chlorate*, *picrate*, and *fulminate* explosives are not used in mining, except the fulminate of mercury, which is employed for the *caps* or *exploders*, by means of which charges of powder, dynamite, etc., are fired.

Eye. 1. The top of a shaft. 2. The opening at the end of a *tuyere*, opposite the *nozzle*. 3. The hole in a *pick* or hammer-head which receives the handle.

FACE. 1. In any adit, tunnel, or stope, the end at which work is progressing or was last done. 2. The *face of coal* is the principal cleavage-plane at right angles to the stratification. Driving *on the face* is driving against or at right angles with the face.

Fagot. See *Pile*.

Fahlband, GERM. A zone or stratum in crystalline rock, impregnated with metallic sulphides. Intersecting fissure-veins are enriched by the *fahlband*.

Famp, NEWC. Soft, tough, thin shale beds.

Fan. A revolving machine, to blow air into a mine (*pressure-fan*, *blower*), or to draw it out (*suction-fan*).

Fanega, SP. A bushel; sometimes half a mule-load.

Fang, DERB. An air-course cut in the side of a shaft or level, or constructed of wood.

Fast-end. 1. The part of the coal-bed next the rock. 2. A gangway with rock on both sides. See *Loose-end*.

Fast shot, NEWC. A charge of powder exploding without the desired effect.

Fathom, CORN. Six feet. A *fathom of mining ground* is six feet square by the whole thickness of the vein, or in Cornish phrase, *a fathom forward by a fathom vertical*.

Fauld. The *tymp-arch* or working-arch of a furnace.

Fathom-tale, CORN. See *Tut-work* (2). This name probably arises from the payment for such work by the space excavated, and not by the ore produced.

Fault. 1. A dislocation of the strata or the vein. 2. In coal-seams, sometimes applied to the coal rendered worthless by its condition in the seam (*slate-fault*, *dirt-fault*, etc.).

Feather. See *Plug and feather*.

Feathered-shot. Copper granulated by pouring into cold water.

Feathering. See *Plugging*.

Feeder. 1. A small vein joining a larger vein. 2. A spring or stream. 3. A *blower* of gas.

Feigh, NEWC. Refuse washed from lead-ore or coal.

Feldspathic. Containing feldspar as a principal ingredient.

Fell. See *Riddle*.

Ferric furnace. A high iron blast furnace, in the upper part of which crude bituminous coal is converted into coke.

Ferromanganese. An alloy of iron and manganese.

Ferruginous. Containing iron.

Fettle, *Fettling*. See *Fix*.

Fillet. The rounded corner of a *groove* in a *roll*.

Fin. The thin sheet of metal squeezed out between the collars of the *rolls* in a *roll-train*.

Fine metal. 1. See *Metal*. 2. The iron or plate-metal produced in the *refinery*.

Finery. A charcoal-hearth for the conversion of cast into malleable iron.

Fining. 1. See *Refining*. 2. The conversion of cast into malleable iron in a hearth or charcoal-fire.

Finishing-rolls. The *rolls* of a *train* which receive the bar from the *roughing-rolls*, and reduce it to its finished shape.

Fire-bars. Grate bars in a fireplace.

Fire-bricks. Refractory bricks of fire-clay or of silicious materials used to line furnaces.

Fire-bridge. The separating low wall between the fire-place and the *hearth* of a reverberatory furnace.

Fire-clay. A clay comparatively free from iron and alkalies, not easily fusible, and hence used for fire-bricks. It is often found beneath coal-beds.

Fire-damp. Light carburetted hydrogen gas. When present in common air to the extent of one-fifteenth to one-thirteenth of volume, the mixture is explosive.

Fire-setting. The softening or cracking of the working-face of a lode, to facilitate excavation, by exposing it to the action of a wood-fire built close against it. Now nearly obsolete, but much used in hard rock before the introduction of explosives.

Fire-stink, S. STAFF. The stench from decomposing iron pyrites, caused by the formation of sulphuretted hydrogen.

Fissure-vein. A fissure in the earth's crust filled with mineral.

Fix. To *fettle* or line with a *fix* or *fettling*, consisting of ores, scrap and cinder, or other suitable substances, the hearth of puddling furnace.

Flang, CORN. A two-pointed miner's pick.

Flange. Applied to a vein widening.

Flap-door, NEWC. A manhole door.

Flask. 1. The wooden or iron frame which holds the sand-mould used in a foundry. 2. An iron bottle in which quicksilver is sent to market. It contains 76½ pounds.

Flat, DERB. and N. WALES. A horizontal vein or ore-deposit auxiliary to a main vein; also any horizontal portion of a vein elsewhere not horizontal.

Flat-nose shell. A cylindrical tool with valve at bottom, for boring through soft clay.

Flat-rods. A series of horizontal or inclined connecting-rods, running upon rollers, or supported at their joints by rocking-arms, to convey motion from a steam-engine or water-wheel to pump-rods at a distance.

Flat-wall, CORN. A local term (in St. Just) for *foot-wall.*

Flintshire furnace. A *reverberatory* with a depression, *well* or *crucible* in the middle of the side of the hearth; used for the *roasting and reaction process* on lead ores.

Float-copper, LAKE SUP. Fine scales of metallic copper (especially produced by abrasion in stamping) which do not readily settle in water.

Float-gold, PAC. Fine particles of gold, which do not readily settle in water, and hence are liable to be lost in the ordinary stamp-mill process.

Float-ore. Water-worn particles of ore; fragments of vein-material found on the surface, away from the vein outcrop.

Flookan or *Flooking*, CORN. See *Fluccan.*

Floor. 1. The rock underlying a stratified or nearly horizontal deposit, corresponding to the *foot-wall* of more steeply-dipping deposits. 2. A horizontal, flat ore-body. 3. A floor, in the ordinary sense, or a plank platform underground.

Floran-tin, CORN. Tin ore scarcely visible in the stone, or stamped very small.

Flosh, CORN. A rude mortar, with a shutter instead of a screen, used under stamps.

Floss. Fluid, vitreous cinder, floating in a puddling furnace.

Floss-hole. A tap-hole.

Floured. The finely granulated condition of quicksilver, produced to a greater or less extent by its agitation during the amalgamation process.

Flowing furnace. A *reverberatory* with inclined hearth, used in Cornwall for treating roasted lead ores by the *precipitation process.*

Fluccan, CORN. Soft clayey matter in the vein; a vein or course of clay.

Flue. A passage for air, gas, or smoke.

Flue-bridge. The separating low wall between the flues and the laboratory of a reverberatory furnace.

Flue-cinder. Iron-cinder from the reheating furnace, so called because it runs out from the lower part of the flue.

Flume. A wooden conduit, bringing water to a mill or mine.

Flux. A salt or other mineral, added in smelting to assist fusion, by forming more fusible compounds.

Foal. NEWC. A young boy employed in *putting* coal.

Fodder, NORTH ENG. A unit employed in expressing weights of metallic lead, and equal to 21 hundredweight of 112 pounds avoirdupois.

Foge, CORN. A forge for smelting tin.

Fondon. A large copper vessel, in which hot amalgamation is practiced.

Foot-piece. See *Sill.*

Foot-wall, CORN. The wall under the vein.

Foot-way. The series of ladders and *sollars* by which men enter or leave a mine.

Forefield, NEWC. The face of the workings. The *forefield-end* is the end of the workings farthest advanced.

Fore-hearth. A projecting bay in the front of a blast-furnace-hearth, under the *tymp.* In *open-front* furnaces it is from the fore-hearth that cinder is tapped. See *Dam* and *Tymp.*

Forfeiture. The loss of possessory title to a mine or public lands by failure to comply with the laws prescribing the quantity of *assessment* work, or by actual abandonment.

Fore-poling. A method of securing drifts in progress through quicksand by driving ahead poles, lath, boards, slabs, etc., to prevent the inflow of the quicksand on the sides and top, the face being protected by *breast-boards.*

Forespar. See *Bloomary.*

Fore-winning. NEWC. Advanced workings.

Forge. 1. An open or semi-open *hearth* with a *tuyere.* 2. ENG. That part of an ironworks where *balls* are squeezed and hammered and then drawn out into *puddle-bars* by grooved rolls.

Forge-cinder. The slag from a forge or bloomary.

Formation. See *Geological formations.*

Fork. 1. CORN. The bottom of the *sump.* 2. DERB. A piece of wood supporting the side of an excavation in soft ground.

Forpale or *Forepale.* The driving of timbers or planks horizontally ahead at the working-face, to prevent the caving of the ground in subsequent driving.

Fossil ore. Fossiliferous red hematite.

Fother, NEWC. One-third of a chaldron.

Foundershaft. The first shaft sunk.

Fox-tail, S. WALES. The last cinder obtained in the *fining* process.

Frame, CORN. See *Tin-frame.*

Free, native, uncombined with other substances, as free gold or silver.

Free fall. An arrangement by which, in deep boring, the *bit* is allowed to fall freely to the bottom at each drop or down-stroke.

Free-milling. Applied to ores which contain free gold or silver, and can be reduced by crushing and amalgamation, without roasting or other chemical treatment.

Freiberg amalgamation. See *Barrel amalgamation.*

Fritting. The formation of a slag by heat with but incipient fusion.

Frontal hammer or *Frontal helve*, ENG. A forge-hammer lifted by a cam, acting upon a "tongue" immediately in front of the hammer-head.

Frue vanner. A variety of continuously working *percussion-table.*

Fulguration. See *Blick.*

Furgen. A round rod used for sounding a bloomary fire.

Furnace. 1. A structure in which heat is produced by the combustion of fuel. 2. A structure in which, with the aid of heat so produced, the operations of roasting, reduction, fusion, steam-generation, desiccation, etc., are carried on, or, as in some mines, the *upcast* air-current is heated, to facilitate its ascent and thus aid ventilation.

Furnace cadmium or *cadmia.* The oxide of zinc which accumulates in the chimneys of furnaces smelting zinciferous ores.

Furtherance, NEWC. An extra price paid to *hewers* when they also *put* the coal.

Fuse. A tube or casing filled with combustible material, by means of which a blast is ignited and exploded.

GAD. 1. A steel wedge. 2. A small iron punch with a wooden handle used to break up ore.

Galemador, SP. A small Mexican furnace for roasting silver ores.

Gale, ENG. (Forest of Dean). A grant of mining ground.

Galiage. Royalty.

Gallery. A level or drift.

Gallery-furnace. A retort-furnace used in the distillation of mercury.

Gallows-frame. A frame over a shaft, carrying the pulleys for the hoisting cables.

Galvanize. To coat with zinc.

Ganister. A mixture of ground quartz and fire-clay, used in lining Bessemer converters.

Gang. 1. A mine. 2. A set of miners.

Gangue. The mineral associated with the ore in a vein.

Gangway. 1. A main level, applied chiefly to coal mines. 2. NEWC. A wooden bridge.

Garland, S. STAFF. A trough or gutter round the inside of a shaft to catch the water running down the sides.

Gas-coal. See *Coal.*

Gas-furnace. A furnace employing gaseous fuel.

Gash. Applied to a vein wide above, narrow below, and terminating in depth within the formation it traverses.

Gas-producer. A furnace in which combustible gas is produced, to be used as fuel in another furnace.

Gas-well. A deep boring, from which natural gas is discharged.

Gate, Gate-way, or *Gate-road*, ENG. 1. A road or way underground for air, water or general passage; a *gangway.* 2. The aperture in a founders' mould, through which the molten iron enters.

Gear, NEWC. 1. The working tools of a miner. 2. The mechanical arrangement connecting a motor with its work.

Geode. A cavity, studded around with crystals or mineral matter, or a rounded stone containing such a cavity.

Geological formations. Groups of rocks of similar character and age are called formations. The different stratified formations have been arranged by geologists according to their apparent age or order of position stratigraphically, and the fossils they contain. While there are minor points of difference in classification, and still more in nomenclature, the general scheme is now well settled. Three tables are given on another page, the first prepared in 1878, by Prof. J. D. Dana, the second by Prof. T. Sterry Hunt, both for the United States, and the third referring to formations found in Pennsylvania only, by Professor J. P. Leslie. They are taken (Professor Hunt's, with later revision by the author), from *The Geologist's Traveling Handbook*, prepared by James Macfarlane, Ph.D. The numbers attached to the different formations in these tables will facilitate the identification of a given formation under different names. A catalogue of the formations is added to the tables, in which the predominant rocks of each are named. The eruptive rocks are not included in these tables, the determination of their age being a more difficult and doubtful matter, the discussion of which cannot be undertaken in this place. For lack of space, also, the enumeration and description of the different species of rocks and minerals must be omitted, the reader being referred for such information to works on lithology and mineralogy.

Geordie. The Miners' term for Stephenson's safety-lamp.

PROFESSOR J. D. DANA'S TABLE OF GEOLOGICAL FORMATIONS.

SYSTEMS OR AGES.	GROUPS OR PERIODS.	FORMATIONS OR EPOCHS.
Age of man.	20. Quarternary.	20. Quarternary.
Age of mammals.	19. Tertiary.	19 c. Piliocene. 19 b. Miocene. 19 a. Eocene.
Reptilian age.	18. Cretaceous.	18 c. Upper Cretaceous. 18 b. Middle Cretaceous. 18 a. Lower Cretaceous.
	17. Jurassic.	17. Jurassic.
	16. Triassic.	16. Triassic.
Carboniferous.	15. Permian.	15. Permian.
	14. Carboniferous.	14 c. Upper Coal Measures. 14 b. Lower Coal Measures. 14 a. Millstone Grit.
	13. Subcarboniferous.	13 b. Upper Subcarboniferous 13 a. Lower Subcarboniferous.
Devonian or age of fishes.	12. Catskill.	12. Catskill.
	11. Chemung.	11 b. Chemung. 11 a. Portage.
	10. Hamilton.	10 c. Genesee. 10 b. Hamilton. 10 a. Marcellus.
	9. Corniferous.	9 c. Corniferous. 9 b. Schoharie. 9 a. Cauda Galli.
Silurian or age of Invertebrates. Upper Silurian.	8. Oriskany.	8. Oriskany.
	7. Lower Heiderberg.	7. Lower Heiderberg.
	6. Salina.	6. Salina.
	5. Niagara.	5 c. Niagara. 5 b. Clinton. 5 a. Medina.
Lower Silurian.	4. Trenton.	4 c. Cincinnati. 4 b. Utica. 4 a. Trenton.
	3. Canadian.	3 c. Chazy, 3 b. Quebec. 3 a. Calciferous.
	2. Primordial on Cambrian.	2 b. Potsdam. 2 a. Acadian.
	1. Archæan.	1 b. Huronian. 1 a. Laurentian.

PROFESSOR T. STERRY HUNT'S TABLE OF GEOLOGICAL FORMATIONS.

AGES.	GROUPS.	AMERICAN FORMATIONS.
Cenozoic.	20. Quarternary.	20. Recent.
	19. Tertiary.	19 c. Pliocene. 19 b. Miocene. 19 a. Eocene
Mesozoic.	18. Cretaceous. 17. Jurassic. 16. Triassic.	18. Cretaceous. 17. New Red Sandstone. 16. New Red Sandstone.
Paleozoic.	13-15. Carboniferous.	15. Permo-Carboniferous.
	8-12. Erian or Devonian.	14. Coal Measures. 13 b. Mississippi (Carb-Limest'e). 13 a. Waverley or Bonaventure. 12. Catskill 11. Chemung and Portage, 10. Hamilton (including Genesee and Marcellus). 9. Corniferous or Upper Heiderb'g 8. Oriskany.
	5-7. Silurian.	7. Lower Heiderberg. 6. Onondaga or Salina. 5 c. Niagara (including Guelph). 5 b. Clinton. 5 a. Medina. 5 a. Oneida.
	4. Upper Cambrian, Siluro-Cambrian, Ordovician, or Ordovian.	4 c. Loraine. 4 b. Utica. 4 a. Trenton.
	3. Middle Cambrian.	3 c. Chazy. 3 b. Levis (Tremadoc and Arenig). 3 a. Calciferous.
	2. Lower Cambrian.	2 e. Potsdam. 2 d. Sillery. 2 c. Acadian (Menevian). 2 b. Taconian. 2 a. Keweenian.
Eozoic.	1. Primary or Crystalline.	1 e. Montalban. 1 d. Norian or Labrador.[1] 1 c. Huronian. 1 b. Arvonian. 1 a. Laurentian.

[1] Professor Hunt says there are many reasons for believing that the Norian may be older than the Arvonian and Huronian.

PROFESSOR J. P. LESLEY'S PROVISIONAL NOMENCLATURE OF THE SECOND GEOLOGICAL SURVEY OF PENNSYLVANIA.

	NAMES PROVISIONALLY ADOPTED.	Nos. used in first survey.
	20. Quarternary. 16. Triassic. 14 c. Upper Barren Measures. 14 c. Monongahela River Coal Series. 14 b. Lower Barren Measures. 14 b. Allegheny River Coal Series. 14 a. Pottsville Conglomerate.	 XIII. XIII. XIII. XIII. XII.
Bernician.	13 b. Manch Chunk Red Shale. (Umbral.) 13 a. Pocono Gray Sandstone. (Vespertine.)	XI. X.
Devonian.	12. Catskill Red Sandstone. (Ponent.) 11 b. Chemung. 11 a. Portage. 10 c. Genesee. 10 b. Hamilton. 10 a. Marcellus. 9. Upper Heiderberg. 8. Oriskany.	IX. VIII. VIII. VIII. VIII. VIII. VIII. VII.
Silurian.	7. Lower Heiderberg. (Lewistown Limestone.) 5 b. Clinton. 5 a. Medina. 5 a. Oneida.	VI. V. IV. IV.
Siluro-Cambrian.	4 c. Hudson River. 4 b. Utica. 4 a. Trenton. 3 a. Calciferous. 2 b. Potsdam.	III. III. II. II. I.
	1. Azoic.	

NOTES.—In the following notes Professor Hunt's classification is sufficiently followed to show the nature of the older groups which he distinguishes.

1a. *Laurentian.* Chiefly massive gneiss, reddish or grayish, sparingly micaceous, often hornblendic Some crystalline limestone, magnetic iron, and other metallic ores.

1b. *Arvonian.* Chiefly petrosilex, often becoming quartziferous porphyry, with some quartzites and hornblendic rocks; magnetic and specular iron ore.

1c. *Norian.* Chiefly a feldspathic rock (norite), which sometimes carries garnet, epidote, etc.; also, great beds of titaniferous iron ore.

1d. *Huronian.* Chloritic schists, greenstone, (diorite or diabase). serpentine, steatite, dolomite, copper, chrome, nickel, and iron ores.

1e. *Montalban.* Fine-grained micaceous or hornblendic gneiss, crysolite rock, serpentine, mica-schist, granite.

2a. *Keweenian.* The copper-bearing series of Lake Superior, made up of sandstones and conglomerates, with much interstratified eruptive rock.

2b. *Taconian.* Granular quartzites, argillites and nacreous or hydro-micaceous schists and great masses of crystalline limestone, marbles, magnetite, siderite, and pyrite changing to limonite.

2c and d. *Acaian* (and *Sillery*). Fossiliferous sandstone and shale.
2e. *Potsdam.* Sandstone conglomerate.
3a. *Calciferous.* Sandy magnesian limestone, calcareous sandstone.
3b. *Quebec.* Sandstone, limestone conglomerate, black slate.
3c. *Chazy.* Limestone, chert.
4a. *Trenton.* Limestone, buff and blue; dolomite carrying lead ore deposits; brown-hematite beds.
4b. *Utica.* Dark carbonaceous slate; impure limestone.
4c. *Hudson River.* Slate, shale, clay, grit.
5a. *Medina.* Conglomerate; argillaceous sandstone.
5b. *Clinton.* Sandstone, shale, conglomerate, limestone, fossiliferous red hematite, or oolitic iron ore bed.
5c. *Niagara.* Clay shale; limestone.
6. *Salina.* Red shale, gypseous, shale, hydraulic lime, salt.
7. *Lower Heiderberg.* Limestone, shaly or compact, and fossiliferous.
8. *Oriskany.* Sandstone.
9. *Corniferous or Upper Heiderberg.* Principally limestone.
9a. *Cauda-galli.* Fine-grained calcareous and argillaceous, drab or brownish sandstone; peculiar fossils.
9b. *Schoharie Grit.* Fine-grained calcareous grit, similar to 9a, but with differing fossils.
9c. *Onondaga,* and 9d. *Coniferous.* Gray, blue, black limestone. At the top of 9d occur the Marcellus iron ore (carbonate.)
10a. *Marcellus.* Black or dark-brown bituminous and pyritiferous shales. In 10a, and 9d occur the petroleum deposits of Canada.
10b. *Hamilton.* Slate, shale, sandstone calcareous and argillaceous.
10b. *Tully.* Impure dark limestone.
10c. *Genesee.* Black clay slate.
11a. *Tortase.* Green and black sandy and slaty shales, sandstone, flagstone.
11b. *Chemung.* Thin-bedded greenish sandstones and flagstones, with intervening shales, and rarely beds of impure limestone.
12. *Catskill.* Red, gray sandstone, grindstone grit, greenish shale, conglomerate.
13. *Lower Subcarboniferous.* Sandstone, limestone, small local coal beds.
13b. *Upper Subcarboniferous.* Red shale, red and gray sandstone, blue limestone.
14a. *Millstone Grit.* White or yellow sandstone, and conglomerate of quartz pebbles.
14b. and 15c. *Coal Measures.* Fire-clay, shale, sandstone, conglomerate, limestone, bituminous coal, anthracite, iron ore, salt.
15. *Permian.* Limestone, sandstone, marl, shale.
16. *Triassic.* Red Sandstone, red shale, conglomerate, lignite, trap dikes, copper ore, coal.
17. *Jurassic.* Marl, limestone, probably the gold-bearing slates of California.
18. *Cretaceous.* Earthy beds of sand, marl, clay, limestone, chalk, lignite.
19. *Tertiary.* Earthy sand, clay, marl, limestone, sandstone.
20. *Quaternary.* Sand, pebbles, boulders, clay, diluvium; gravel and placer tin and gold deposits.

NOTE.—The primary and crystalline schistose rocks contain the larger number of mineral veins. The ancient magnesian limestones (probably Devonian) are characterized in many localities by deposits of argentiferous lead ore and of zinc ore.

German process. In copper smelting, the process of reduction in a *shaft-furnace*, after *roasting*, if necessary.
German Silver. A white alloy of nickel, copper, and zinc.
German steel. See *Steel.*
Gerstenhofer furnace. A *shaft furnace* filled with terraces or shelves, through which crushed ore is caused to fall, for roasting.
Gig. See *Kibble.*
Gin. See *Whim.*
Ginging, DERB. The lining of a shaft with masonry.
Giraffe. A car of peculiar construction to run on an incline.
Girdle. A thin bed of stones.
Girdle, NEWC. A thin stratum of stone.
Girth. In *square-set* timbering, a horizontal brace in the direction of the *drift.*
Glazy. See *Iron.*
Glist, CORN. Mica.
Glut, NEWC. A piece of wool, used to fill up behind *cribbing* or *tubbing.*
Goaf, ENG. An excavated space; also, the waste rock packed in old workings.
Goaves. Old workings.
Gob, S. WALES. See *Goaf.* Both terms are chiefly used in collieries, and are apparently the same word. Local usage seems to give to *goaf* rather the meaning of the space in which the roof has fallen after the *pillars* have been removed, and to *gob* that of a space packed with waste after *long-wall* extraction of the coal.
Gobbing. Packing with waste rock. See *Stowing.*
Gob-up, ENG. Of a blast furnace, to become obstructed in working by reason of a *scaffold* or a *salamander.*
Gob-fire. Fire produced by the heat of decomposing *gob.*
Goffan or *Goffen,* CORN. A long narrow surface-working.
Gold ores. Native gold; *telluric gold ore* (*sylvanite, mullerite, nagyagite,* tellurides of gold, silver, and lead); auriferous lead, zinc, and copper ores.
Good levels, CORN. Levels nearly horizontal.
Good roasting. See *Roasting.*
Gopher or *Gopher-drift.* An irregular prospecting-drift, following or seeking the ore without regard to maintenance of a regular grade or section.
Gossan or *Gozzan,* CORN. Hydrate oxide of iron, usually found at the decomposed outcrop of a mineral vein.
Gothic groove. A groove of Gothic arch section in a *roll.*
Gouge. A layer of soft material along the wall of a vein, favoring the miner, by enabling him after "gouging" it out with a pick, to attack the solid vein from the side.
Grain, ENG. Of coal, the lines of structure or parting parallel with the main gangways and hence crossing the *breasts.*
Grain-tin, CORN. 1. Crystalline tin ore. 2. Metallic tin.
Grapnel. An implement for removing the core left by an annular drill in a bore-hole, or for recovering tools, fragments, etc., fallen into the hole,
Grampus, U. S. The tongs with which *bloomary loups* and *billets* are handled.
Granzas, SP. Small pieces of ore.
Graphite. A crystalline form of carbon.
Graphitic carbon. That portion of the carbon in iron or steel which is present as graphite.
Grass, CORN. The surface over a mine. *Bringing ores to grass* is taking them out of the mine.
Grassero, SP. A slag-heap.
Grate, CORN. See *Screen* (as applied to stamps).
Grate coal, PENN. See *Coal.*
Gravel mines, U. S. An accumulation of auriferous gravel.
Grueso, SP. Lump ore. The term is in use at the quicksilver mines of California.
Green sand. Sand used for moulds without previous drying or mixture.
Gray ore, CORN. Copper-glance. See *Copper-ores.*
Gray slag. The slag from the Flintshire lead furnaces. It is rich in lead.
Griddle, CORN. A miner's sieve to separate ore from *halvans.*
Grip. A small, narrow cavity.
Grizzly, PAC. A grating to catch and throw out large stones from sluices.
Groove or *Grove.* 1. DERB. A mine; from the GERM. *Grube.* See *Roll.*
Ground, CORN. The rock in which a vein is found; also, any given portion of the mineral deposit itself.
Growan, CORN. Decomposed granite; sometimes the granite rock.
Gubbin. A kind of ironstone.
Grundy. Granulated pig iron.
Guard. A support in front of a *roll-train* to guide the bar into the groove, sometimes called a *side-guide.*
Guides. 1. The timbers at the side of a shaft to steady and guide the cage. 2. The holes in a cross-beam through which the stems of the stamps in a stamp mill rise and fall. 3. In a rolling-mill a *guide* is a wedge-shaped piece held in the *groove* of a *roll* to prevent the sticking of the bar by peeling it out of the groove. When the guide is held by a hanger or counter-weight against the under side of the roll, it is called a *hanging-guide.*
Guillotine. A machine for breaking iron with a falling weight.
Gullet. An opening in the Strata.
Gun-metal. An alloy of copper with tin or zinc, and sometimes a little iron. The common formula is nine parts copper to one tin. *Aich's metal* and some other gun-metals contain zinc and iron but no tin.
Gunnies or *Gunniss,* CORN. The vacant space left where the lode has been removed.

HACIENDA, SP. Exchequer, treasury; public revenue; capital; funds; wealth; landed estate; establishment. In mining it is usually applied to the offices, principal buildings, and works for reducing the ores.
Hack. 1. See *Pick.* 2. A sharp blade on a long handle used for cutting billets in two.
Hade, DERB. See *Underlay.*
Hahner furnace. A continuous working shaft furnace for roasting quicksilver ores. The fuel is charcoal, charged in alternate layers with the ores. The *Vall' Alta furnace* is a modification, having the iron tubes of the *Alberti.*
Hair plate. See *Bloomary.*
Half-marrow, NEWC. Young boys, of whom two do the work of one *putter.*
Halvans, CORN. Ores much mixed with impurities.
Hammer-pick. See *Poll-pick.*
Hanging-coal. A portion of the coal-seam which, by the removal of another portion, has had its natural support removed, as in *holding.*
Hanging-guide. See *Guide.*
Hanging-side, or *Hanging-wall,* or *Hanger,* CORN. The wall or side over the vein.
Hazel. Freestone.

Hard head. A residual alloy, containing much iron and arsenic, produced in the refining of tin.

Hard lead. Lead containing certain impurities, principally antimony.

Hasenclever furnace. A roasting furnace, consisting of a long inclined channel (in its first form, a succession of inclined shelves in a shaft) down which the ore slides in a thin sheet, heated from below.

Head-gear. That part of deep-boring apparatus which remains at the surface.

Headhouse. See *Gallows-frame.*

Heading. 1. The vein above a drift. See *Back.* 2. An interior level or air-way driven in a mine. 3. In *long-wall* workings, a narrow passage driven up in a gangway in starting a working in order to give a *loose end.*

Headings. In ore-dressing, the heavier portions collecting at the upper end of a buddle or sluice, as opposed to the *tailings*, which escape at the other end, and the *middlings*, which receive further treatment.

Head-piece. See *Cap.*

Headsman, NEWC. See *Putter.*

Head-stocks. See *Gallows-frame*

Head-tree, NEWC. See *Cap.*

Headway, NEWC. See *Cross-heading.* The *headways* are the second set of excavations in *post-and-stall* work.

Heap, NEWC. The refuse at the pit's mouth

Hearth. 1. The floor or *sole* of a reverberatory. 2 The *crucible* of a blast furnace.

Hearth-ends. Particles of unreduced lead ore expelled by the blast from a furnace.

Heat. One operation in a heating furnace, Bessemer *converter*, *puddling* furnace, or other furnace not operating continuously.

Heating-furnace. The furnace in which *blooms* or *piles* are heated before *hammering* or *rolling.*

Heave, CORN. A horizontal dislocation of a vein or stratum.

Helve. A *lift-hammer* for forging *blooms.*

Henderson process. The treatment of copper sulphide ores by roasting with salt, to form chlorides, which are then leached out and precipitated. Henderson originally proposed to volatilize the chlorides, and the leaching and precipitation are not original with him. *Longmaid* and many other metallurgists have proposed them in various modifications.

Hercules powder. See *Explosives.*

Hewer, NEWC. The man who *cuts* the coal.

Hitch, SCOT. and NEWC. 1. A minor dislocation of a vein or stratum not exceeding in extent the thickness of the vein or stratum. 2. A hole cut in the side rock, when this is solid enough, to hold the *cap* of a set of timbers, permitting the *leg* to be dispensed with.

High explosive. An explosive or detonating compound developing more intense and instantaneous force than gunpowder. Most high explosives in general use contain nitroglycerin. See *Explosives.*

Hog-back. 1. A sharp anticlinal, decreasing in height at both ends until it runs out. 2. A ridge produced by highly titled strata.

Hogger-pipe. The upper terminal pipe of the mining pump.

Hogger-pump. The topmost pump in a shaft.

Holing. 1. The working of a lower part of a bed of coal for bringing down the upper mass. 2. The final act of connecting two workings underground

Hollow-fire, ENG. A kind of hearth with blast, used for reheating the *stamps* produced in the South Welsh process of fining, or the bars of *blister-steel* in the manufacture of *shear-steel.*

Holloway process. The removal of sulphur from iron and copper sulphides by fusion and pneumatic treatment, analogous to the manner in which carbon, etc., are removed in the Bessemer process.

Homogeneous metal. A variety of *ingot-metal* produced by the open-hearth process. See *Steel.*

Hopper. 1. A trap at the foot of a *shoot* for regulating the contents of a wagon. 2. A place of deposit for coal or ore.

Horn. See *Spoon.*

Horse, CORN. 1. A mass of *country-rock* inclosed in an ore-deposit. 2. See *Salamander.*

Horse-back, NEWC. A portion of the roof or floor which bulges or intrudes into the coal.

Horseflesh ore, CORN. Bornite. See *Copper-ores.*

Horse-gin. Gearing for hoisting by horse-power.

Hot-bed. A platform in a rolling-mill on which rolled bars lie to cool.

Hot-blast. Air forced into a furnace after having been heated.

Hotching. NORTH ENG. See *Jigging.*

House of water, CORN. A cavity or space filled with water.

Howell furnace. A form of revolving roasting furnace.

H-piece. That part of a *plunger-lift* in which the valves or *clacks* are fixed.

Hudge. An iron bucket for hoisting ore or coal.

Hulk. See *Dzhu.*

Huel, CORN. See *Wheat.*

Hungry. A term applied to hard, barren vein-matter, such as white quartz (not discolored with iron oxide).

Hunt & Douglas process. The treatment of copper oxide (or roasted sulphide) ores by dissolving the oxides of copper in a hot solution of protochloride of iron and common salt. From the solution thus obtained, metallic iron precipitates metallic copper, at the same time regenerating the protochloride of iron for further use.

Hurdy-gurdy wheel. A water-wheel operated by the direct impact of a stream upon its radially-placed paddles.

Hushing. The discovery of veins by the accumulation and sudden discharge of water, which washes away the surface soil and lays bare the rock. See *Booming.*

Hutch. 1. SCOT. A low car, suited both to run in a level and to be hoisted on a cage. 2. CORN. A cistern or box for washing ore. See *Jig.*

Hydraulicking, PAC. Washing down a bank of earth or gravel by the use of pipes, conveying water under high pressure.

IDRIA furnace. See *Leopoldi furnace.*

Impregnation. An ore-deposit consisting of the country-rock impregnated with ore, usually without definite boundaries.

Inbye or *Inbyeside,* NEWC. Further into a mine, away from the shaft.

Incline. 1. A shaft not vertical; usually on the dip of a vein. See *Slope.* 2. A *plane*, not necessarily under ground.

Indicator. 1. An instrument for showing at any moment the position of the cage in the shaft. 2. An instrument for recording, by a diagram, upon a card the varying pressure of the steam in the cylinder of a steam engine during the stroke.

Infiltration theory. The theory that a vein was filled by the infiltration of mineral solutions.

Ingot. A cast bar or block of metal.

Injection-theory. The theory that a vein was filled first with molten mineral.

In place. Of rock, occupying, relative to surrounding masses, the position that it had when formed.

Inquartation. See *Quartation.*

Intake The passage by which the ventilating current enters a mine. See *Downcast*, which is more appropriate for a shaft; *Intake* for an adit.

Inwalls. The interior walls or lining of a *shaft-furnace.*

Irestone. Hard clay slate; hornstone; hornblende.

Irestone or *Ironstone,* CORN. Greenstone.

Iron. The principal varieties of iron are *wrought-iron* and *cast-iron* (see *Pig-iron*). *Wrought-iron,* also called *bar-iron* and *weld-iron,* is the product of the forge or the puddling furnace, *cast-iron* of the blast furnace. The former approaches pure iron; the latter is an alloy of iron and carbon. Steel except some of the so-called "low" or "mild" steels, which are more nearly wrought-iron (fused and cast) stands between them, having less carbon than cast-iron and more than wrought-iron. Some of the carbon in cast-iron is usually segregated during cooling in the form of graphite, and this determines the grade of the iron as *No. 1 foundry* (the most graphitic, coarsely crystalline, soft and black), *No. 2 foundry* (less open in grain), *gray forge* or *mill-iron* (still closer in grain, suitable for puddling), *mottled* (spotted with *white-iron*), and *white* (hard, brittle, radially crystalline, containing its carbon mostly in alloy with the iron, and showing no visible graphite). These grades are also called simply No. 1, 2, 3, etc. So-called *silver-gray, glazy,* or *carbonized iron* is usually an iron rendered brittle by excess of silicon. *Ingot iron,* see *Steel.* *Anthracite, charcoal* and *coke iron* are names given to pig-iron according to the fuel with which it is made.

Iron hat. See *Gossan.*

Iron-ores: *Magnetic* (*magnetite,* protoperoxide) *specular* (*hematite* proper, *red hematite,* anhydrous peroxide, (*brown-iron ore* (*hematite, brown hematite, limonite,* etc., hydrated peroxides), *spathic* (*siderite,* carbonate), clay ironstone (*black band,* argillaceous *siderite.*) See *Fossil ore.*

Iron-reduction process. See *Precipitation process.*

Ironstone. 1. Iron-ore. 2. See *Ironstone.*

JACKET. A covering to prevent radiation of heat, as the jacket of a steam boiler; also a casing around a furnace hearth in which water is allowed to stand or circulate to keep the walls cool.

Jackhead-pit. A small shaft sunk within a mine.

Jack-head pump. A subordinate pump in the bottom of a shaft, worked by an attachment to the main pump-rod.

Jack-roll, NEWC. See *Windlass.*

Jadding or *Judding.* See *Holing.*

Jagging. A mode of carrying ore to the reduction-works in bags on horses, mules, etc.

Jars. A part of percussion-drilling apparatus for deep holes, which is placed between the *bit* and the *rods* or *cable*, and which by producing at each up-stroke a decided jar of the *bit* jerks it up, though it may be tightly wedged in the hole.

Jig-brow. See *Jinny-road.*

Jig-chain. S. STAFF. A chain hooked to the back of a *skip* and running round a post, to prevent its too rapid descent on an inclined plane.

Jigging, CORN. Separating ores according to specific gravity with a sieve agitated up and down in water. The apparatus is called a *jig* or *jigger.*

Jinny-road. A gravity plane underground.

Joachimsthal process. The extraction of silver from sulphuretted ores by converting into chloride, leaching with sodium hyposulphite, and precipitating the silver as sulphide with sodium sulphide.

Jawl, NEWC. A noise made for a signal by hammering at the faces of two levels expected to meet.

Judge, DERB. and NEWC. A measuring-stick to measure coal work under ground.

Judd, NEWC. In *whole-working*, a portion of the coal laid-out and ready for extraction; in *pillar-working*, (*i. e.*, the drawing or extraction of pillars), the yet unremoved portion of a pillar.

Jugglers. Timbers set obliquely against pillars of coal to carry a plank partition making a triangular air-passage or man-way.

Jump. 1. PAC. To take possession of a mining claim alleged to have been forfeited or abandoned. 2. A dislocation of a vein.

Jumper, CORN. and NEWC. A drill or boring tool, consisting of a bar, which is "jumped" up and down in the bore-hole.

KANN. See *Cand.*

Kast-furnace. A small circular shaft furnace with three or four tuyeres, for lead smelting.

Keckle-meckle. The poorest kind of lead ore.

Keeve. 1. See *Cauf.* 2. A tub used in collecting grains of heavy ore or metal; a dolly tub.

Kernel roasting. See *Roasting.*

Kevil, DERB. A vein-stone consisting of a mixture of carbonate of lime and other minerals.

Kibball or *Kibble*, CORN and WALES. An iron bucket for raising ore.

Kicker. Ground left in first cutting a vein, for support of its sides.

Kieve, CORN. A tub for *tozing* tin-ore.

Killas, CORN. Clay-slate.

Kiln. A furnace for the calcination of coarsely broken ore or stone; also, an oven for drying, charring, etc.

Kind's plug. A wooden plug attached to an iron rod, used in connection with sand for recovering *tubing* from *bore-holes.*

King-pot. The large central pot or crucible in a brass-melting furnace.

King's yellow. Sulphide of arsenic.

Kirving, NEWC. The cutting made at the bottom of the coal by the *hewer.*

Kish. The blast-furnacemen's name for the graphite-segregations seen in pig-iron and in the cinder of a furnace making a very gray iron.

Kit. A wooden vessel.

Kitchen. See *Laboratory* (2).

Knits or *Knobs.* Small particles of ore.

Knobbing-fire. A *bloomary* for refining cast-iron.

Knockings. See *Riddle.*

Knox & Osborne furnace. A continuously working shaft furnace for roasting quicksilver ores, having the fireplace built in the masonry at one side. The fuel is wood.

Knots. Small particles of ore.

Krohnke process. The treatment of silver ores preparatory to amalgamation, by humid chloridization with copper dechloride.

Krupp washing Process. The removal of silicon and phosphorus from molten pig iron by running it into a *Pernot furnace*, lined with iron oxides. Iron ore may also be added, and the bath is agitated by rotation for five to eight minutes only. See *Bell's dephosphorizing process.*

LABOR, SP. Labos; work; a working. This term is applied in mining to the work which is actually going on, and to the spaces which have been dug out. It includes galleries, cavities and shafts.

Laboratory. 1. A place fitted up for chemical analysis, etc. 2. The space between the fire and flue bridges of a *reverberatory* furnace in which the work is performed; also called the *kitchen* and the *hearth.*

Ladle. A vessel into which molten metal is conveyod from the furnace or crucible, and from which it is poured into the moulds.

Lagging. Planks, slabs, or small timber placed over the caps or behind the posts of the timbering, not to carry the main weight, but to form a ceiling or a wall, preventing fragments of rock from falling through.

Lame skirting, NEWC. Widening a passage by cuttng coal from the side of it.

Lander, CORN. The man at the shaft-mouth who receives the *kibble.*

Laundry-box, NEWC. A box at the top of a set of pumps into which the water is delivered.

Lath door-set. A weak lath-frame, surrounding a main *door-frame*, the space between being for the insertion of *piles.*

Lath-frame or *crib.* A weak lath-frame, surrounding a main *crib*, the space between being for the insertion of *piles.*

Laths, CORN. The *boards* or *lagging* put behind the *durns.*

Launder, CORN. A wooden trough, gutter or sluice.

Lazadores, SP. Persons employed to collect work for a mine.

Lazyback, S. STAFF. The place at the surface where coal is stacked for sale.

Leaching. See *Lixiviation.*

Lead (pronounced like the verb *to lead*), PAC. See *Lode.*

Lead-fume. The fumes escaping from lead furnaces, and containing both volatilized and mechanically suspended metalliferous compounds.

Leader, CORN. A small vein leading to a larger one.

Lead-ores. *Galena* (*galenite*, sulphide); *antimonial lead-ore bournonite*, sulphantimonide of lead and copper); *white lead-ore* (*cerussite*, carbonate); *green lead-ore* (*pyromorphite*, the phosphate, or *mimetite* or *mimetesite*, the arseno-chloride); *lead-vitriol* (*anglesite*, sulphate); *yellow lead-ore* (*wulfenite*, molybdate); *red lead-ore* (*crocite*, chromate).

Lead-spar, CORN. Anglesite. See *Lead-ores.*

Leap, DERB. A fault. See *Jump.*

Leat, CORN. A watercourse.

Leath. Applied to the soft part of a vein.

Leavings, CORN. The ores left after the *crop* has been removed.

Ledge, SAC. See *Lode.*

Ledgerwall. See *Footwall.*

Leg. A prop of timber supporting the end of a *stull*, or the *cap* of a set of timber.

Leopoldi furnace. A furnace for roasting quicksilver ores, differing from the *Bustamente* in having a series of brick condensing chambers. Both are intermittent, *i. e.*, have to be charged and fired anew after each operation. The *California intermittent furnace* is a modification of the *Leopoldi*, having the fireplace on the side.

Level. A horizontal passage or drift into or in a mine. It is customary to work mines by levels at regular intervals in depth, numbered in their order below the adit or drainage level, if there be one.

Lewis. An iron instrument for raising heavy blocks of stone.

Ley, SP. Proportion of metal in the ore; fineness of bullion; also an alloy or base metal.

Lid. A flat piece of wood placed between the end of a *prop* or *stamper* and the rock.

Lifters, CORN. The wooden beams used as *stems* for stamps in old-fashioned stamp-mills.

Lift-hammer. See *Tilt-hammer.*

Liftingdog. A claw-hook for grasping a column of bore-rods while raising or lowering them.

Lignite. See *Coal.*

Limp. An instrument for striking the refuse in the sieves in washing ores.

Lining, NEWC. See *Dialling.*

Linnets, DERB Oxidized lead ores.

Liquation. See *Eliquation.*

Litharge. Protoxide of lead.

Lithofracteur. See *Explosives.*

Little giant. A jointed iron nozzle used in hydraulic mining.

Lixiviation. The separation of a soluble from an insoluble material by means of washing with a solvent.

Location. 1. The act of fixing the bou ndaries of a mining claim, according to law. 2. The claim itself.

Loam. An impure potter's clay, containing mica or iron ochre.

Loch, DERB. and WALES. See *Vug.*

Lock-timber. An old plan of putting in *stull-pieces* in Cornwall and Devon. The pieces were called *lock-pieces.*

Lode, CORN. Strictly a fissure in the country-rock filled with mineral; usually applied to metalliferous lodes. In general miner's usage, a *lode, vein*, or *ledge* is a tabular deposit of valuable mineral between definite boundaries. Whether it is a fissure formation or not is not always known, and does not affect the legal title under the United States federal and local statutes and customs relative to lodes. But it must not be a placer, *i. e.*, it must consist of quartz or other rock *in place*, and bearing valuable mineral.

Lodge, WALES. See *Platt.*

Log, S. STAFF. A balance-weight near the end of the hoisting-rope of a shaft to prevent its running back over the pulley.

Longmaid Process. See *Henderson process.*

Long tom, PAC. A kind of gold-washing cradle.

Long-wall. A method of coal mining by which the whole seam is taken out as the working faces progress, and the roof is allowed to fall behind the workers, except where passages must be kept open, or where the *gob* being packed in the space formerly occupied by the coal, prevents caving. According as the work of extraction begins at the boundary of the *winning*, and converges back to the shaft, or begins with the coal nearest the shaft and proceeds outward to the boundaries, it is called *long-wall retreating* or *long-wall advancing.*

Loob or loobs, CORN. The clayey or slimy portion washed out of tin-ore in *dressing.*

Loop. See *Loup.*

Loop-drag. An eye at the end of a rod through which tow is passed for cleaning bore-holes.

Loose-end. A gangway in *long-wall* working, driven so that one side is solid ground while the other opens upon old workings. See *Fast-end.*

Lorry. A hand-car used on mine tramways.

Lost level, CORN. "Level" is "lost" when a gallery has been driven with an unnecessarily great departure from the horizontal.

Loup. The pasty mass of iron produced in a *bloomary* or puddling furnace. See *Puddle-ball.*

Lowe, NEWC. A light. A "piece of lowe" is part of a candle.

Luckhart furnace. A continuously working shaft furnace for roasting quicksilver ores, having the fire-place in the shaft at the bottom, protected by a cast-iron roof. The fuel is wood.

Lum. A chimney over an upcast pit.

Lumpcoal, PENN. See *Coal.*
Lurmann front. An arrangement of water-cooled castings through which iron and cinder are tapped from the blast furnace, thus avoiding the use of a forehearth. See *Closed front.*
Lying-wall. See *Foot-wall.*

MACHINE-WHIM. A rotary steam-engine for windling.
Magistral, SP. A powder of roasted copper pyrites, used in the amalgamation of silver ores.
Main-rod. See *Pump-rod.*
Mainway. A *gangway* or principal passage.
Makings, NEWC. The small coals hewn out in *kirving.*
Malleable castings. Small iron castings made malleable by "annealing" or decarburizing by cementation in powdered hematite or other oxide of iron.
Mallet, CORN. The sledge-hammer used for striking or *beating* the *borer.*
Mandril. See *Maundril.*
Manganese-ores. Gray oxide (*pyrolusite, polianite*, anhydrous peroxide, and *manganite*, hydrated sesquioxide); *black manganese* (*hausmannite*, protoperoxide); *braunite* (anhydrous sesquioxide); *red manganese ore* (*rhodochrosite*, a carbonate, or *rhodonite*, a silicate); also, manganiferous iron ores.
Man-hole, CORN. The hole in a *sollar* through which men pass upon the ladder or from one ladder to the next.
Man-machine or *man-engine*, CORN. and DERB. A mechanical lift for lowering and raising miners in a shaft by means of a reciprocating vertical rod of heavy timber with platforms at intervals, or of two such rods, moving in opposite directions. In the former case, stationary platforms are placed in the shaft, so that the miner in descending, for instance, can step from the moving platform at the end of the down-stroke, and step back upon the next platform below at the beginning of the next down-stroke. When two rods are employed, the miner steps from the platform on one rod to that on the other.
Man-of-war, STAFF. A small pillar of coal left in a critical spot; as a principal support in thick coal workings.
Manta, SP. Blanket; sack of ore.
Mantle. The outer wall and casing of an iron *blast furnace*, above the *hearth.*
Manway. A small passage, used by workmen but not for transportation.
Maquilla, SP. A mill where ore is ground on shares.
Marl. Calcareous clay, sometimes used for the hearths of cupelling-furnaces.
Martin process. Called also the *Siemens-Martin* and the *open-hearth process.* See *Steel.*
Mass-copper, LAKE SUP. Native copper, occurring in large masses.
Massicot. See *Litharge*
Matrix. The rock of earthy material containing a mineral or metallic ore; the *gangue.*
Matt, or *Matte*, FR. A mass consisting chiefly of metallic sulphides got in the fusion of ores.
Maul, DERB. A large hammer or mallet.
Maundril, DERB and S. WALES. A prying *pick* with two prongs.
Mear. DERB. Thirty-two yards of ground measured on the vein.
Measures. Strata of coal, or the formation containing coal beds.
Meat-earth. The vegetable mould.
Meetings, NEWC. The place at middle-depth of a *shaft, slope*, or *plane*, where ascending and descending cars pass each other.
Merceal, SP. A gift. This term is applied to a grant which is made without any valuable consideration.
Merchant-iron. See *Mill.*
Merchant-train. A *train* of *rolls* for reducing iron *piles* or steel *ingots, blooms*, or *billets* to bars of the various round, square, flat or other shapes, known as merchant iron or steel.
Mercury-ores. Native mercury; *cinnabar* (sulphide).
Merrit-plate. See *Bloomary.*
Metal, SP. 1. This term is applied both to the ore and to the metal extracted from it. It is sometimes used for vein, and even for a mine itself. *Metal en piedra*, ore in the rough state. *Metal ordinario*, common ore. *Metal pepena*, selected ore. *Metal de ayuda*, ore used to assist the smelting of other ores. 2. Copper *regulus* or *matt* obtained in the *English process.* The following varieties are distinguished by appearance and by their percentage of copper) here given in approximate figures) *Coarse*, 20 to 40; *red*, 48; *blue*, 60; *sparkle*, 74; *white*, 77; *pimple*, 79. *Fine metal* includes the latter four varieties. *Hard metal* is impure copper containing a large amount of tin. 3. SCOT. All the rocks met with in mining ore. 4. *Road metal*, rock used in macadamizing roads.
Metal-notch. See *Tap-hole.*
Mica-powder. See *Explosives.*
Mill. 1. ENG. That part of an iron works where *puddle-bars* are converted into *merchant-iron, i. e.*, rolled iron ready for sale in bars, rods or sheets. See *Forge.* 2. By common usage any establishment for reducing ores by other means than smelting. More strictly, a place or a machine in which ore or rock is crushed. 3. An excavation made in the *country* rock, by a *cross-cut* from the workings on a vein, to obtain waste for *gobbing.* It is left without timber so that the roof may fall in and furnish the required rock. 4. CORN. A passage through which ore is shot underground. See *Pass* and *Shoot.*
Mill-cinder. The slag from the puddling-furnaces of a rolling-mill.
Mill-run, PAC. 1. The work of an amalgamating mill between two *clean-ups.* 2. A test of a given quantity of ore by actual treatment in a mill.
Mine. 1. In general, any excavation for minerals. More strictly, subterranean workings, as distinguished from *quarries, placer* and *hydraulic* mines, and surface or open works. The distinction between the French terms *mine* and *miniere* results entirely from the law, and depends upon the depth of the working. The former is the more general term, and, ordinarily speaking, includes the latter, which signifies shallow or surface workings. 2. In a military sense, a mine is a subterranean gallery run under an enemy's works, to be subsequently exploded.
Mine-pig, ENG. See *Pig-iron.*
Miner, PENN. The workman who *cuts* the coal, as distinguished from the *laborer* who loads the wagons, etc.
Mineral. In miners' parlance, ore.
Mineral caoutchouc. Elastic bitumen.
Mineral charcoal. A pulverulent, lustreless substance, showing distinct vegetable structure, and containing a high percentage of carbon with little hydrogen and oxygen, occurring in thin layers in bituminous coal.
Mineralized. Charged or impregnated with metalliferous mineral.
Mineral oil or *Naphtha.* A limpid or yellowish liquid, lighter than water, and consisting of hydrocarbons. *Petroleum* is heavier than naphtha, and dark greenish in color when crude. Both exude from the rocks; but naphtha can be distilled from petroleum.
Mineral pitch. Asphaltum.
Mineral right. The ownership of the minerals under a given surface, with the right to enter thereon, mine, and remove them. It may be separated from the surface ownership, but, if not so separated by distinct conveyance, the latter includes it.
Mineral-wool. See *Slag-wool.*
Mine-rent. The rent or royalty paid to the owner of a mineral right by the operator of the mine—usually dependent, above a fixed minimum, upon the quantity of product.
Mineria, SP. Mining. This term embraces the whole subject, including both mines and miners, and also the operations of working mines and of reducing their ores. It, however, is often used in a more restricted sense.
Minero, SP. Miner. This term is not limited to those who work mines, but includes their owners, and all who have the qualifications prescribed in the ordinances, and are enrolled as members of the body or craft. Many of the laborers who work in mines are not, technically speaking, miners. This term is sometimes used in the old laws for *mine.*
Miner's inch, PAC. A local unit for the measurement of water supplied to hydraulic miners. It is the amount of water flowing under a certain head through one square inch of the total section of a certain opening, for a certain number of hours daily. All these conditions vary at different localities. At Smartsville, Cal., the discharge opening is a horizontal slit, 4 inches wide, in a 2-inch plank, with the standing head of water in the feed-box 9 inches above the middle of the slit. Each square inch of this opening will discharge 1.76 cubic feet per minute. A miners' inch in use in Eldorado County, Cal., discharges 1.39 cubic feet per minute. At North Bloomfield, Cal., and other places, the discharge is 50 inches long by 2 wide (giving 100 miners' inches) through a 3-inch plank, with the water 7 inches above the centre of the opening. Each inch is 1.50 to 1.57 cubic feet per minute in practice, or 59.05 to 61.6 per cent, of the theoretical discharge. These figures are taken from the paper of A. J. Bowie, Jr., on "Hydraulic Mining in California," *Trans. Am. Inst. M. E.*, vol. vi, p. 59.
Mineta, SP. A little mine; a chamber, or cavity.
Minium. Protosesquioxide of lead.
Mispickel, GERM. Arsenical pyrites.
Mistress, NEWC. A lantern used in coal-mines.
Mobby, S. STAFF. A leathern girdle, with small chain attached, used by the boys who draw *bowkes.*
Mock-lead, CORN. Zincblende.
Moil or *Moyle*, CORN. A drill pointed like a *gad.*
Monkey-drift. A small prospecting drift.
Monitor, PAC. A kind of nozzle used in *hydraulicking.*
Monnier process. The treatment of copper sulphide ores by roasting with sodium sulphate, and subsequent lixiviation and precipitation.
Monoclinal. Applied to any limited portion of the earth's crust throughout which the strata dip in the same direction.
Montefiore furnace. A peculiar furnace in which *zinc dust* is compressed at a high temperature.
Moorestone, CORN. Loose masses of granite found on Cornish-moors.
More, CORN. A quantity of ore in a particular part of a lode, as a *more* of tin.
Mortar. 2. A heavy iron vessel, in which rock is crushed by hand with a pestle, for sampling or assaying. 2. The receptacle beneath the stamps in a stamp mill, in which the dies are placed, and into which the rock is fed to be crushed.
Mosaic gold. Disulphide of tin.

Mote. See *Squib.*
Mothergate, NEWC. The main passage in a district of working.
Mottled. See *Iron.*
Mouth. The end of a shaft or adit emerging at the surface.
Mountain limestone. The English designation of a limestone of the lower part of the carboniferous age; called also subcarboniferous limestone.
Muck-bar. Bar iron which has passed once through the *rolls.*
Mucks, S. STAFF. See *Smut.*
Muffle. A semi-cylindrical or long arched oven (usually small and made of fire-clay), heated from outside, in which substances may be exposed at high temperature to an oxidizing atmospheric current, and kept at the same time from contact with the gases from the fuel. *Cupellation* and *scorification* assays are performed in *muffles*, and on a larger scale copper ores were formerly roasted in *Muffle-furnaces.*
Muller. The stone or iron in an *arastre*, or grinding or amalgamating pan, which is dragged around on the bed to grind and mix the-bearing rock.
Mun, CORN. Any fusible metal.
Mundic, CORN. Iron pyrites. White *mundic* is *Mispickel.*

NARROW work. The driving of *gangways* or *airways;* also any *dead work.*
Nasmyth hammer. A steam-hammer, having the head attached to the piston-rod, and operated by the direct force of the steam.
Native. Occurring in nature; not artificially formed. Usually applied to the metals.
Nays, CORN. See *Nogs.*
Needle or *Nail*, CORN. A copper or copper-pointed implement, placed in a bore-hole during charging, to make, by its withdrawal, an aperture for the insertion of the *rush* or train.
Negrilo, SP. A silver ore; black sulphuret of silver.
Neptune powder. See *Explosives.*
Neutral. Of slags, neither acid nor basic; or wrought-iron, neither *red-short* or *cold-short;* of iron-ores, suitable for the production of neutral irons.
Niccoliferous or *Nickeliferous.* Containing nickel.
Nickel ores. *Copper-nickel* (*niccolite*, arsenide of nickel); *antimonial nickel* (*breithauptite*, antimonide); *white nickel* (*rammelsbergit*, biarsenide); *nickel pyrites* (*pentlandite*, sulphide of nickel and iron, *millerite*, sulphide); *nickeliferous gray antimony ullmannite*, arsenantimonide): *nickeliferous serpentine* (*refdanskite*, hydrous magnesian silicate); also, niccoliferous ores of copper, cobalt, manganese, etc.
Nicking, NEWC. The cutting made by the *hewer* at the side of the *face.* *Nickings* is the small coal produced in making the nicking.
Nicking-trunk. A tub in which metalliferous slimes are washed.
Nip, NEWC. 1. A crush of pillars or workings. 2. See *Pinch.*
Nipping-fork. A tool for supporting a column of bore-rods while raising or lowering them.
Nitroglycerin. See *Explosives.*
Nittings. The refuse of good ore.
Noble metals. The metals which have so little affinity for oxygen (*i. e.*, are so highly electronegative) that their oxides are reduced by the mere application of heat without a reagent; in other words, the metals least liable to oxidation under ordinary conditions. The list includes gold, silver, mercury, and the platinum group (including palladium, iridium, rhodium, ruthenium, and osmium). The term is of alchemistic origin.
Noddle or *Nodule.* A small rounded mass.
Noger. A *jumper* drill.
Nogs, DERB. and CORN. Square blocks or logs of wood, piled on one another to support a mine roof.
Nose. An accumulation of chilled material around the inner end of a *tuyere* in a smelting shaft furnace, protecting and prolonging the tuyere.
Nose-helve, ENG. See *Frontal hammer.*
Nuts. Small coal.

OCCLUSION. The mechanical retention of gases in the pores of solids.
Ochre. A term applied to metallic oxides occurring in an earthy, pulverulent condition, as iron ochre, molybdic ochre.
Oil-well. A dug or bored well, from which petroleum is obtained by pumping or by natural flow.
Old man. Ancient workings; *goaves.*
Old men. The persons who worked a mine at any former period of which no record remains,
Open cast, SCOT. See *Open cut.*
Open crib timbering. Shaft timbering with *cribs* alone, placed at intervals.
Open cut. A surface working, open to day-light.
Open front. The arrangement of a blast furnace with a *fore-hearth.*
Open hearth. See *Reverberatory furnace.*
Openings. The parts of coal mines between the pillars, or the pillars and ribs.
Opens. Large caverns.
Open sand castings. Castings made in moulds simply excavated in sand without *flasks.*
Open work. A quarry or *open cut.*
Operator, PENN. The person, whether proprietor or lessee, actually operating a colliery.
Ore. 1. A natural mineral compound, of the elements of which one at least is a metal. The term is applied more loosely to all metalliferous rock, though it contain the metals in a free state, as occasionally to the compounds of non-metallic substance, as *sulphur ore.* 2. CORN. Copper-ore; tin-ore being spoken of in Cornwall as *tin.*
Ore hearth. See *Scotch hearth.*
Ore washer. A machine for washing clay and earths out of earthy brown-hematite ores.
Orpiment. Sesquisulphide of arsenic.
Outbye or *Outbyeside*, NEWC. Nearer to the shaft, and hence further from the *forewinning.*
Outcrop. The portion of a vein or stratum emerging at the surface, or appearing immediately under the soil and surface-*debris.*
Outlet. The passage by which the ventilating current goes out of a mine. See *Upcast.*
Output. The product of a mine.
Oval groove. A groove of U-Section in a *roll.*
Overburden. 1. CORN. See *Burden* (1). 2. To charge in a furnace too much ore and flux in proportion to the amount of fuel. 3. The waste which overlies the good stone in a quarry.
Overman, ENG. The mining official next in rank below the *manager*, who is next below the *agent.*
Overpoled copper. Copper from which all the suboxide has been removed by *poling.*
Oxidation. A chemical union with oxygen.

PACK. A wall or pillar built of *gob* to support the roof.
Pair or *Pare*, CORN. Two or more miners working in common.
Pan. 1. See *Panning.* 2. A cylindrical vat of iron, stone, or wood, or these combined, in which ore is ground with *mullers* and amalgamated. See *Amalgamation.*
Pane. The striking-face of a hammer.
Panel. 1. A heap of dressed ore. 2. A system of coal-extraction in which the ground is laid off in separate districts or panels, pillars of extra size being left between.
Panning, AUST. and PAC. Washing earth or crushed rock in a pan, by agitation with water, to obtain the particles of greatest specific gravity which it contains (chiefly practiced for gold, also for quicksilver, diamonds, and other gems).
Parachute. 1. A kind of *safety-catch* for shaft cages. 2. In rod-boring, a *cage* with a leather cover to prevent a too rapid fall of the rods in case of accident.
Parcel. CORN. A heap of dressed ore ready for sale.
Parkes process. The desilverization of lead by treatment with zinc.
Parrot coal, SCOT. See *Coal.*
Parting. 1. A small joint in coal or rock, or a layer of rock in a coal seam. 2. The separation of two metals in an alloy, especially the separation of gold or silver by means of nitric or sulphuric acid.
Parting-sand. Fine dry sand, which is sifted over the partings in a *mould* to facilitate their separation when the *flask* is opened.
Pass, CORN. 1. An opening in a mine through which ore is shot from a higher to a lower level. See *Shoot.* 2. In rolling mills the passage of the bar between the *rolls.* When the bar passes "on the flat" it is called a *flatting-pass;* if "on the edge," an *edging-pass.*
Patent fuel, ENG. The fuel produced by the agglomeration of *coal-slack* into lumps.
Patera process. See *Joachimsthal process.*
Patio, SP. The yard where the ores are cleaned and assorted; also, the amalgamation floor, or the Spanish process itself of amalgamating silver ores on an open floor.
Pattinson process. The process in which lead containing silver is passed through a series of melting-kettles, in each of which crystals of a poorer alloy are deposited, while the fluid bath, ladled from one kettle to the next, is proportionately richer in silver. In *mechanical pattinsonation* the operation is performed in a cylindrical vessel, in which the bath is stirred mechanically, and from which, as the richer alloy crystallizes, the poorer liquid is repeatedly drained out. *Steam pattinsonation* is a variety of the *Pattinson process*, in which steam is conducted through the lead bath to assist the refining.
Pavement. The *floor* of a mine.
Pay-streak. The zone in a vein which carries the profitable or *pay* ore.
Peach, CORN. Chlorite.
Pea-coal, PENN. See *Coal.*
Percussion-table. An inclined table, agitated by a series of shocks, and operating at the same time like a *buddle*, It may be made self-discharging and continuous by substituting for the table an endless rubber cloth, slowly moving against the current of water, as in the *Frue vanner.*
Pernot furnace or *Post-Pernot furnace.* A *reverberatory* puddling or smelting furnace, having a circular, inclined, revolving hearth.
Pershbecker furnace. A continuously working shaft-furnace for

roasting quicksilver ores, having two fire-places at opposite sides. The fuel is wood.

Pertinencia, SP. The extent of a mining location in Mexico, to which a title is acquired by denunciation.

Peter or *peter out.* To fail gradually in size, quantity, or quality.

Pewter. An alloy of tin and lead. Other metals are often added, or the lead is entirely replaced with copper, zinc, antimony, etc.

Pick. A pick-axe with one or two points. The usual miners' pick has but one.

Picker or *Poker.* A hand chisel for *dzhuing*, held in one hand and struck with a hammer.

Pick-hammer. A hammer with a point, used in cobbing.

Pickling. Cleaning sheet-iron or wire by immersion in acid.

Pig. An ingot or cast bar of metal. See *Pig-iron.*

Pig-iron. Crude cast-iron from the blast furnace. When the furnace is tapped the molten iron flows down a *runner* moulded in sand, from which it enters the *sows* or lateral runners, flowing from these again into the *pig-beds*, the separate parallel moulds of which form the *pigs.* In each bed the ingots lie against the *sow* like suckling pigs, whence the two names. See *Iron. Mine-pig* is pig-iron made from ores only; *cinder-pig*, from ores with admixture of some *forge* or *mill-cinder.*

Pike. See *Pick.*

Picking. See *Cobbing.*

Pile. 1. The *fagot* or bundle of flat pieces of iron prepared to be heated to welding-heat and then rolled. 2. To make up into *piles* or *fagots.* 3. *Piles* are long thick laths, etc., answering in shafts, in loose or "quick" ground, the same purpose as *spills* in levels, *piles* being driven vertically.

Pillar-and-stall. See *Post-and-stall.*

Pilz furnace. A circular or octagonal shaft-furnace, maintaining or increasing its diameter towards the top, and having several *tuyeres;* used in smelting lead-ores

Pinch, CORN. To contract in width.

Pink ash, PENN. See *Coal.*

Pipe or *Pipe-vein*, DERB. An ore-body of elongated form.

Pipe-clay, U. S. A fine clay found in hydraulic mines.

Pipe ore. Iron ore (limonite) in vertical pillars, sometimes of conical, sometimes of hour-glass form imbedded in clay. Probably formed by the union of stalactites and stalagmites in caverns.

Piping. 1. PAC. See *Hydraulicking.* 2. The tubular depression caused by contraction during cooling, on the top of iron or steel ingots.

Pit. 1. A shaft. 2. A stack or *meiler* of wood, prepared for the manufacture of charcoal.

Pitch, CORN. 1. The limits of the set to tributers. 2. The inclination of a vein, or of the longer axis of an ore body.

Pitch-bag, CORN. A bag covered with pitch, in which powder is inclosed for charging damp holes.

Pit-coal. See *Coal.*

Pit-eye, ENG. The bottom of the shaft of a coal-mine; also the junction of a shaft and a level.

Pit-eye pillar. A barrier of coal left around a shaft to protect it from caving.

Pit-frame. The framework carrying the pit-pulley.

Pitman. 1. CORN. A man employed to examine the lifts of pumps and the drainage. 2. NEWC. A working miner.

Pitwork, CORN. The pumps and other apparatus of the engine shaft.

Place. See *In place.*

Placer, SP. A deposit of valuable mineral, found in particles in *alluvium* or *diluvium*, or beds of streams, etc. Gold, tin ore, chromic iron, iron ore, and precious stones are found in placers. By the United States Revised Statutes all deposits not classed as veins of rock in place are considered placers.

Plane. An incline, with tracks, upon which materials are raised in cars by means of a stationary engine, or are lowered by gravity.

Plank-timbering. The lining of a shaft with rectangular plank frames.

Plank-tubbing. The lining of a shaft with planks, spiked on the inside of *curbs.*

Plat. The map of a survey in horizontal projection.

Plate-metal. See *metal.*

Plate-shale. A hard argillaceous bed.

Platinum-ores. Mixtures of native platinum in grains with various other metals and minerals.

Platt, CORN. An enlargement of a level near a shaft, where ore may await hoisting, wagons pass each other, etc.

Plattner process. See *Chlorination.*

Plomo, SP. Lead. *Plomo-plata*, lead-silver.

Plug. A hammer closely resembling the *bully.*

Plumb. 1. Vertical. 2. Soft.

Plumbago. Graphite.

Plunger. The piston of a force-pump.

Plush-copper. Chalcotrichite, a fibrous red copper ore.

Pocket. 1. A small body of ore. 2. A natural underground reservoir of water. 3. A receptacle, from which coal, ore, or waste is loaded into wagons or cars.

Podar. See *Mundic.*

Pointed boxes. Boxes in the form of inverted pyramids or wedges in which ores, after crushing and sizing, are separated in a current of water.

Pole-tools. The tools used in drilling with rods. See *Cable-tools.*

Poling. Stirring a metallic bath (of copper, tin or lead) with a pole of green wood, to cause ebullition and deoxidation in the refining process.

Polings. Poles used instead of planks for *lagging.*

Poll, CORN. The lead or striking part of a miner's hammer.

Poll-pick. A *pick* with a head for breaking away hard *partings* in coal-seams or knocking down rock already seamed by *blasting.*

Polroz (pronounced *Polrose*), CORN. The pit underneath a water-wheel.

Ponsard furnace. A furnace in which the escaping combustion-gases, passing through tubular flues, heat the incoming air continuously through the flue-walls.

Poppet-heads, CORN. A timber frame over a shaft to carry the hoisting pulley.

Post. 1. A pillar of coal or ore. 2. An upright timber.

Post furnace. See *Pernot furnace.*.

Post-and-stall. A mode of working coal, in which so much is left as pillar and so much is taken away, forming *rooms* and *thirlings.* The method is called also *bord-and-pillar, pillar-and-breast*, etc.

Potstone. Compact steatite.

Potter's clay and *Pipe-clay.* Pure plastic clay, free from iron, and consequently white after burning.

Power-drill. See *Rock-drill.*

Precious metals. See *Noble metals.*

Precipitation process. The treatment of lead ores by direct fusion with metallic iron or slags or ores rich in iron; performed generally in a *shaft-furnace*, rarely in a *reverberatory.* Often combined with the *roasting and reduction process.*

Prian, CORN. Soft white clay.

Pricker. See *Needle.*

Prill, CORN. 1. The best ore after cobbing. 2. See *Button.*

Pringap. The distance between two mining possessions in Derbyshire.

Produce. 1. The marketable ores or minerals produced by mining and *dressing.* 2. CORN. The amount of fine copper in one hundred parts of ore.

Producer. See *Gas-producer.*

Prop. A timber set to carry a roof or other weight acting by compression in the direction of the axis.

Prop-crib timbering. Shaft-timbering with *cribs* kept at the proper distance apart by means of *props.*

Prospecting. Searching for new deposits; also, preliminary explorations to test the value of lodes or placers. The *prospect* is good or bad.

Proving-hole. A small *heading* driven to find and follow a coal-seam lost by a dislocation.

Pryan. Ore in small pebbles mixed with clay.

Pudding-stone. A conglomerate in which the pebbles are rounded. See *Breccia.*

Puddle-bars. See *Forge.*

Puddle-steel. *Steel*

Puddle-train. A *train* of *rolls* for reducing squeezed *puddle-balls* to *puddle* or *muck-bars.*

Puddling. I. The process of decarburizing cast iron fusion on the hearth of a reverberatory furnace, lined (*fixed* or *fettled*) with ore or other material rich in oxide of iron. The bath is stirred with a *rabble* to expose it to the action of the lining and of an air current. The escape of carbonic oxide causes it to boil, whence the early name of this method of puddling, viz., *boiling. Dry puddling* is performed on a silicious hearth, and the conversion is effected rather by the flame than by the reaction of solid or fused materials. As the amount of carbon diminishes the mass becomes fusible and begins to coagulate (*come to nature*), after which it is worked together into lumps (*puddle-balls, loups*) and removed from the furnace to be hammered (*shingled*) or *squeezed* in the *squeezer*, which presses out the *cinder*, etc., and compacts the mass at welding heat, preparatory to rolling. Silicon and phosphorus are also largely removed by puddling, passing into the cinder. Mechanical *puddlers* (in which the bath is agitated by revolution, or by mechanical *rabbles*, to save hand-labor) are employed to a limited extent. 2. The term *puddling*, now applied in metallurgy exclusively to the above process, originally referred to the *puddling* of clay or clay and charcoal upon the masonry of a furnace hearth, to form a lining. Ditches, reservoirs, etc., are *puddled* with clay to make them water-tight.

Pug-tub. See *Settler.*

Pulley-frame. *Gallows-frame.*

Pulp, PAC. Pulverized ore and water; also applied to dry-crushed ore.

Pulp-assay, PAC. The assay of samples taken from the *pulp* after or during crushing.

Pump-bob. See *Bob.*

Pump-rod. The rod or system of rods (usually heavy beams) connecting the steam-engine at the surface, or at a higher level, with the pump-piston below. See *Balance-bob.*

Pump-station. See *Station.*

Punch or *Puncheon.* See *Leg.*

Punch-prop, NEWC. A short *prop.*

Put, NEWC. To convey coal from the working *breast* to the tramway. This is usually done by young men (*putters*).

Putty-powder. Crude oxide of tin, used for giving opaque whiteness to enamels, or for grinding glass.
Putwork See *Tutwork.*
Pyrometer. An instrument for measuring high temperatures.

QUARRY. An open or "day" working, usually for the extraction of building-stone, slate or limestone.
Quartation. The separation of gold from silver by dissolving out the latter with nitric acid. It requires not less than ¾ silver in the alloy, whence the name, which is also applied to the alloying of gold with silver, if necessary, to prepare it for this method of *parting.*
Quartz. 1. Crystalline silica. 2. PAC. Any hard gold or silver ore as distinguished from gravel or earth. Hence *quartz-mining,* as distinguished from hydraulic, etc.
Quartzose. Containing quartz as a principal ingredient.
Qaere, queere, qwear, CORN. A small cavit or fissure.
Quick. 1. Applied to a productive vein as distinguished from *dead* or barren. 2. PAC. Quicksilver.
Quick ground. Ground in a loose incoherent state.
Quicksand. Sand which is or (becomes on the access of water) "quick," *i. e.* shifting, easily movable or semi-liquid.
Quick-silver ores. See *Mercury ores.*
Quintal. One hundred pounds avoirdupois.

RABBLE. An iron bar bent to a right angle at the end. See *Puddling.*
Race. A small thread of spar or ore.
Rack, CORN. A stationary *buddle.*
Raftertimbering. Timbering in which the pieces are arranged like the rafters of a house.
Rag-burning, CORN. See *Tinwitts.*
Rabbing. A rough *cobbing.*
Rail-train. A *train* of *rolls* for reducing iron *piles* or steel *ingots* or *blooms* to rails.
Raise. See *Rise.*
Rake, DERB. A fissure vein crossing the strata.
Raking-prop. An inclined *prop.*
Ramble. NEWC. A shale bed on the top of a coal seam, which falls as the coal is removed.
Rancho. SP. An estate or property; a farm (PAC. *ranch*).
Rundom. The direction of a *Rake-vein.*
Rapper. A lever or hammer at the top of a shaft or inclined plane, for signals from the bottom.
Raschette furnace. A shaft furnace used in lead, copper, and iron smelting, and having an oblong rectangular or oval horizontal section.
Reaction process. See *Roasting and reaction process.*
Realgar. Sulphide of arsenic.
Reamer. A tool for enlarging a bore-hole.
Record. To enter in the book of the proper officer (usually a district or county officer) the name, position, description, and date of a mining claim or location. See *District.*
Red-ash, PENN. See *Coal.*
Redevance, FR. A tax, duty, or rent. In mining law it means a tax or duty payable to the government or to the surface owner.
Red-lead. See *Minium.*
Red-short. Brittle at red heat. See *Cold-short.*
Reduce. 1. To deprive of oxygen. 2. In general, to treat metallurgically for the production of metal.
Reed, CORN. See *Spire.*
Reef, AUSTR. See *Lode.*
Refinery. See *Run-out fire.*
Refining. 1. The purification of crude metallic products. The refining of "base bullion" (silver-lead) produces pure lead and silver. 2. The conversion of gray into white cast iron in a *run-out fire.*
Refractory. Resisting the action of heat and chemical reagents: a quality undesirable in ores, but desirable in furnace-linings, etc.
Regenerator. A chamber filled with open-work of bricks to take up the heat of the gases of combustion from a furnace, and subsequently impart it to a current of air, the air and gas being conducted alternately through the chamber. See *Siemens furnace.*
Regule, FR. A copper *regulus* from which most of the impurities have been removed by liquidation.
Regulus. 1. The metallic mass which sinks to the bottom of a furnace or crucible, separating itself by gravity from the supernatant *slag* or *matt.* 2. An intermediate product obtained in smelting ores, especially those of copper, lead, silver and nickel, and consisting chiefly of metallic sulphides. In this sense it is synonymous with *matt,* or the GERM. *Stein. Antimony regulus* is metallic antimony.
Rend-rock. See *Explosives.*
Renk, NEWC. The average distance coal is brought by the *putters.*
Rests. The arrangement at the top and bottom of a pit for supporting the shaft-cage while changing the tubs or cars.
Retorting. Removing the mercury from an amalgam by volatilizing it in an iron retort, conducting it away, and condensing it.
Reverberatory furnace. A furnace in which ores are submitted to the action of flame, without contact with the fuel. The flame enters from the side or end, passes upward over a low wall or *bridge,* strikes the roof (*arch*) of the furnace, and is *reverberated* downward upon the charge.

Reversing rolls. See *Three-high train.*
Rib. 1. In coal mining, the solid coal on the side of the gallery or long-wall face; a pillar or barrier of coal left for support. 2. The solid ore of a vein; an elongated pillar left to support the hanging-wall, in working out a vein.
Ribbed. Containing *bone.*
Ribbon-borer. A boring-tool consisting of a twisted flat steel blade.
Rick, PENN. An open heap or pile in which coal is coked.
Riddle, CORN. and SCOT. A sieve. The large pieces of ore and rock picked out by hand are called *knockings.* The *riddlings* remain on the riddle; the *fell* goes through.
Rider. See *Horse.*
Riffle. A groove or interstice, or a cleat or block so placed as to produce the same effect, in the bottom of a sluice, to catch free gold.
Rim-rock. The bed-rock rising to form the boundary of a placer or gravel deposit.
Ring, NEWC. A gutter cut around a shaft to catch and conduct away the water.
Ringe. See *Cowl.*
Rise or *Riser,* CORN. A shaft or winze excavated upward.
Rise-heading. See *Heading in long-wall.*
Rivelaine. A pick with one or two points, formed of flat iron, used to undercut coal by scraping instead of striking.
Roasting. Calcination, usually with oxidation. *Good, dead,* or *sweet roasting* is complete roasting, *i. e.,* carried on until sulphurous and arsenious fumes cease to be given off. *Kernel-roasting* is a process of treating poor sulphuretted copper ores, by roasting in lumps, whereby copper (and nickel) are concentrated in the interior of the lumps.
Roasting and reaction process. The treatment of galena in a *reverberatory,* by first partially *roasting* at a low temperature, and then partially fusing the charge at a higher temperature, which causes a reaction between the lead-oxide formed by roasting and the remaining sulphide, producing sulphurous acid and metallic lead.
Roasting and reduction process. The treatment of lead ores by roasting to form lead-oxide, and subsequent reducing fusion in a shaft-furnace.
Rob. To extract pillars previously left for support; or, in general, to take out ore or coal from a mine with a view to immediate product, and not to subsequent working.
Rock-breaker. Usually applied to a class of machines, of which Blake's rock-breaker is the type, and in which the rock is crushed between two jaws, both movable, or one fixed and one movable. It is common to use a rock-breaker instead of hand-spalling to prepare ore for further crushing in the stamp-mill.
Rock-drill. A machine for boring in rock, either by percussion, effected by reciprocating motion, or abrasion, effected by rotary motion. Compressed air is the usual motive power, but steam also is used. The Burleigh, Haupt, Ingersoll, Wood, and other machines operate percussively; the *diamond drill* (which see) abrasively.
Rocker. A short trough in which auriferous sands are agitated by oscillation, in water, to collect their gold.
Rod-tools. See *Pole-tools.*
Rolley. A large truck carrying two *corves.*
Rolley-way. A *gangway.*
Rolling. See *Roll-train.*
Rolls. 1. Cylinders of iron or steel revolving towards each other, between which rock is made to pass, in order to crush it. 2. See *Roll-train.*
Roll-train. The set of plain or grooved rolls through which iron or steel *piles, ingots, blooms* or *billets* are passed, to be rolled into various shapes.
Rondle or *Rondelle.* The crust or scale which forms upon the surface of molten metal in cooling.
Roof. The rock overlying a bed or flat vein.
Roofing. The wedging of a loaded wagon or horse against the top of an underground passage.
Room, SCOT. See *Breast* and *Post-and-Stall.*
Rosette Copper. Disks of copper (red from the presence of sub-oxide) formed by cooling the surface of molten copper through sprinkling with water.
Rosse furnace. An American variety of hearth for the treatment of galena, differing from the *Scotch hearth* in using wood as fuel, working continuously, and having hollow walls, to heat the blast.
Roughing rolls. The *rolls* of a *train* which first receives the *pile, ingot, bloom.* or *billet,* and partially form it into the final shape.
Roughs, CORN. Coarse, poor sands, resulting from tin-dressing.
Round coal. See *Lump-coal.*
Rounder. See *Reamer.*
Row, CORN. Large, rough stones.
Royalty. The dues of the lessor or landlord of a mine, or of the owner of a patented invention.
Rozan process. An improvement of the *Pattinson process.*
Rubber. A gold-quartz amalgamator, in which the slime is rubbed against amalgamated copper surfaces.
Rullers, CORN. The workmen who wheel ore in wheelbarrows underground.
Run, CORN. 1. The natural falling or closing together of underground workings. 2. Certain accidents to the winding apparatus. 3. *By the run.* A method of paying coal miners per linear yard of breast excavated, instead of *by the wagon* of clear coal produced. 4. A long deep trough in which slimes settle. 5. See *Counter.*

Runner. The channel through which molten metal is conducted from the blast furnace or cupola to the *pig-bed, converter* or *moulds.* See *Pig-iron.*

Run-out-fire. A forge in which cast-iron is refined.

Run-steel. Malleable castings.

Rush, CORN. See *Spire.*

Rusty. Applied to coals discolored by water or exposure, as well as to quartz, etc., discolored by iron oxide.

Rusty gold, PAC. Free gold, which does not easily amalgamate, the particles being coated, as is supposed, with oxide of iron.

SADDLE. An anticlinal in a bed or flat vein.

Safety-cage. A cage with a *safety-catch.*

Safety-car. See *Barney.*

Safety-catch. An automatic device for preventing the fall of a cage in a shaft or a car in an incline, if the supporting cable breaks.

Safety-lamp. A lamp, the flame of which is so protected that it will not immediately ignite fire-damp. There are several varieties, invented by Davy, Stephenson, Clanny and others.

Salamander. A mass of solidified material in a furnace hearth; called also a *sow* and *bear.*

Saline. A salt spring or well; salt works.

Sampson-post. An upright post which supports the walking-beam, communicating motion from the engine to a deep-boring apparatus.

Sand-pump. A cylinder with a valve at the bottom, lowered into a drill-hole from time to time, to take out the accumulated slime resulting from the action of the drill on the rock. Called, also, *Shell-pump* and *Sludger.*

Scaffold. An obstruction in a *blast-furnace* above the *tuyeres* caused by an accumulation or shelf of pasty, unreduced materials, adhering to the lining.

Scal, CORN. A portion of earth or rock which separates and falls from the main body.

Scale. 1. The crust of metallic oxide formed by cooling of hot metals in air. *Hammer-scale* and *roll-scale* are the flaky oxides which fall from the *bloom, ingot,* or *bar* under hammering or rolling. 2. The incrustation caused in steam-boilers by the evaporation of water containing mineral salts. 3. A *scale of air* (NEWC.) is a small portion of air abstracted from the main current.

Scarcement. A projecting ledge of rock, left in a shaft as footing for a ladder, or to support pit-work, etc.

Scarfing. Splicing timbers, so cut that when joined the resulting piece is not thicker at the joint than elsewhere.

Schist. Crystalline rock, usually micaceous, having a slaty structure.

Schlicker, GERM. The skimmings from molten unrefined lead, containing chiefly copper, iron and zinc, with a little antimony and arsenic.

Schorl. Black tourmaline.

Scoria or *Scoriæ.* See *Slag.*

Scorification. A process employed in assaying gold and silver ores, and performed in a shallow clay vessel (*scorifier*), in which ore, lead and borax-glass are exposed to heat and oxidation in a *muffle.* The operation involves roasting, fusion and *scorification* proper, or the formation of a slag, which is not, like the litharge produced in *cupellation,* absorbed by the vessel.

Scotch hearth. A low forge or furnace of cast-iron, with one *tuyere,* in which rich galena is treated by a sort of accelerated *roasting and reaction process.*

Scouring cinder. A basic slag, which attacks the lining of a shaft-furnace.

Scovan lode, CORN. A lode having no *gossan* at or near the surface.

Scraper. A tool for cleaning bore-holes.

Screen. A sieve of wire-cloth, grate bars, or perforated sheet-iron used to sort ore and coal according to size. Stamp-mortars have screens on one or both sides, to determine the fineness of the escaping pulp.

Screw-bell. A recovering tool in deep boring, ending below in a hollow screw-threaded cone.

Scrin or *Skrin,* DERB. A small subordinate vein.

Seam. 1. A stratum or bed of coal or other mineral. 2. CORN. horse-load. 3. A *joint, cleft,* or *fissure.*

Seat, DERB. The floor of a mine.

Seed-bag. A bag filled with flaxseed and fastened around the tubing in an artesian well, so as to form, by the swelling of the flaxseed when wet, a water-tight packing, preventing percolation down the sides of the bore-hole from upper to lower strata. When the tubing is pulled up the upper fastening of the bag breaks, and it empties itself, thus presenting no resistance to the extraction of the tubing.

Segregate, PAC. To separate the undivided joint ownership of a mining claim into smaller individual "*segregated*" claims.

Segregation. A mineral deposit formed by concentration from the adjacent rock.

Selvage or *Selfedge.* A layer of clay or decomposed rock along a vein-wall. See *Gouge.*

Semi-anthracite. See *Coal.*

Semi-bituminous coal. See *Coal.*

Separator. 1. A machine for separating, with the aid of water or air, materials of different specific gravity. Strictly, a *separator* parts two or more ingredients, both valuable while a *concentrator* saves but one and rejects the rest; but the terms are often used interchangeably. 2. Any machine for separating materials, as the *magnetics separator,* for separating magnetic from its gangue.

Set or *Sett,* CORN. 1. A grant of mining ground, as the assignment of a certain part of a mine under contract or *tribute.* 2. A frame of timber for supporting excavations.

Settler. A tub or vat, in which *pulp* from the amalgamating *pan* or *battery-pulp* is allowed to settle, being stirred in water to remove the lighter portions.

Shadd, CORN. Smooth, round stones on the surface, containing tin-ore, and indicating a vein.

Shaft. 1. A pit sunk from the surface. 2. The interior of a *shaft-furnace* above the boshes.

Shaft-furnace. A high furnace, charged at the top and tapped at the bottom.

Shaft-walls. 1. The sides of a shaft. 2. NEWC. Pillars of coal left near the bottom of a pit.

Shake. 1. A cavern, usually in limestone. 2. A crack in a block of stone.

Shaking table. See *Percussion table.*

Shambles. Shelves or benches, from one to the other of which successively ore is thrown in raising it to the level above or to the surface.

Shearing. 1. The vertical side-cutting which, together with *holing* or horizontal undercutting, constitutes the attack upon a *face* of coal. 2. Cutting up steel for the crucible.

Shears, CORN. Two high timbers, standing over a shaft and united at the top to carry a pulley, for lifting or lowering timbers, pipes, etc., of greater length than the ordinary hoisting-gear can accommodate.

Sheathing. A close partition or coverings of planks.

Sheave. The groove-wheel of a pulley.

Shelf, CORN. The solid rock or *bed-rock,* especially under alluvial tin-deposits.

Shell-pump. See *Sand-pump.*

Shelly. The condition of coal which has been so much faulted and twisted that it is not massive, but easily breaks into conchoidal pieces.

Shet, S. STAFF. The broken down roof of a coal-mine.

Shift. 1. The time for a miner's work in one day. The gang of men working for that period, as the *day-shift,* the *night-shift.*

Shift-boss. The foreman in charge of a *shift* of men.

Shingling. Hammering *blooms, billets,* etc.

Shiver. 1. Shale; a hard argillaceous bed. 2. See *Sheave.*

Shoad, CORN. Ore washed or detached from the vein naturally. See *Float-ore.*

Shoading or *Shoding,* CORN. The tracking of boulders towards the vein or rock from which they have come.

Shoe. A piece of iron or steel, attached to the bottom of a *stamp* or *muller,* for grinding ore. The shoe can be replaced when worn out.

Shoot. 1. See *Chute.* 2. See *Blast.* A *Shoot* is a single operation of *blasting.*

Shooting needle. A sharp metal rod, to form a vent-hole through the tamping to a blasting-charge.

Shore-nose shell. A cylindrical tool, cut obliquely at bottom, for boring through hard clay.

Show. 1. The pale-blue, lambent flame of the top of a common candle-flame, indicating the presence of fire-damp. 2. See *Blossom.*

Shute. See *Chute.*

Sicker. See *Zighyr.*

Siddle. The inclination of a seam of coal.

Side-basset. A transverse direction to the line of dip in strata.

Side-guide. See *Guard.*

Side-laning, S. STAFF. Widening a *gate-road* (abandoned for that purpose) so as to make it part of a new *side of work.*

Side of work, S. STAFF. The series of *breasts* and *pillars* connected with a *gate-road* in a colliery.

Siemens furnace. A reverberatory furnace, heated by gas, with the aid of regenerators.

Sigger. See *Zighyr.*

Silesian zinc furnace. A furnace in which zinc is reduced and distilled from calcined ores in muffles.

Silicia. Consisting of or containing silex or quartz.

Sill. 1. A stratum. 2. A piece of wool laid across a drift to constitute a frame with the posts and to carry the track of the tram-way.

Silt. See *Alluvium.*

Silver ores. Silver-glance (*argentite,* sulphide); *horn silver, cerargyrite chloride; dark-ruby silver* (*pyrargyrite,* sulphantimonide); *light-ruby silver* (*proustite,* sulpharsenide); *brittle-silver-glance* (*stephanite,* antimonial sulphide of silver and *polybasite,* arsenical and antimonial sulphide of several metals); *white ore* (argentiferous gray copper, *tetrahedrite,* antimonial sulphide of iron, zinc, copper, lead, and silver); *stetefeldtite* and *partzite* (antimoniates); also, argentiferous lead, copper and zinc ores.

Sinker-bar. A heavy bar attached above the *jars* to *cable-drilling* tools.

Sinking-fire. A force in which wrought iron scrape or refined pig-iron is partially melted or welded together by a charcoal blast.

Siphon-tap. See *Arend's tap.*
Sit or *Sits.* A settling or falling of the top of workings. See *Thrust* and *Creep.*
Sizing. Separating ores according to size of particles, preparatory to *dressing.*
Skep or *Skip,* CORN. An iron box working between guides in which ore or rock is hoisted. It is distinguished from a *kibble,* which hangs free in the shaft.
Skew-plate. See *Bloomary.*
Skimmings or *Skimpings,* CORN. The poorest part skimmed off the *jigger.*
Skull. A crust of solidified steel lining a Bessemer ladle.
Slack. Small coal; coal dirt. See *Culm* (2).
Slag. The vitreous mass separated from the fused metals in smelting ores.
Slag-hearth. A hearth on the principle of the *Scotch-hearth* for the treatment of slags, etc., produced by lead-smelting in the *reverberatory furnace.* The English slag-hearth has one *tuyere;* the Castilian or Spanish, three.
Slag-lead. Lead obtained by a re-smelting of *gray slag.*
Slag-wool. A finely fibrous mass produced by blowing steam or air into molten slag.
Slant. A heading driven diagonally between the dip and the strike of a coal-seam; also called a *run.* See *Run* and *Counter.*
Slate. A sedimentary rock splitting into thin plates. The terms *slate, shale* and *schist* are not sharply distinguished in common use, particularly among older writers. Strictly, according to recent authors, *slate* may be crystalline; *schist* is always so; shale is always (and *slate* most frequently) non-crystalline. There is also a notion of coarser or less complete lamination attached to the term *shale,* as of a rock splitting into thicker or less perfect plates than *slate.* Both may be argillaceous, arenaceous, calcareous, silicious, etc., according to their lithological character. The terms *slaty, shaly,* and *schistose* describe their respective structures.
Sleck, NEWC. Mud deposited by water in a mine.
Sleeper. See *Sill.*
Sleeping-table, CORN. A stationary *buddle.* Now for strict distinction sometimes made between *buddle* and *table.* See *Buddle.*
Slickensides. Polished and sometimes striated surfaces on the walls of a vein, or on interior joints of the vein-material or of rock-masses. They are the result of movement.
Slide, CORN. 1. A vein of clay intersecting and dislocating a vein vertically; or the vertical dislocation itself. 2. An upright rail fixed in a shaft with corresponding grooves for steadying the cages.
Slide-joint. A connection acting in *rod-boring,* like the *jars* in *rope-boring.*
Slimes. CORN. The most finely crushed ores.
Slime-table. See *Buddle.*
Sline. Natural transverse cleavage of rock.
Slip. A vertical dislocation of the rocks.
Slipes, S. STAFF. Sledge runners, upon which a *skip* is dragged from the working breast to the tramway.
Slit. A communication between two levels.
Slitter. See *Pick.*
Sliver, ENG. A thin wooden strip, inserted into grooves in the adjacent edges of two boards of a *brattice,* to make it air-tight.
Slope. See *Incline.*
Sludge. See *Slimes.*
Sludger. See *Sand-pump.*
Sluicing. Washing auriferous earth through long boxes (*sluices*).
Slums, PAC. See *Slimes.*
Slurry, N. WALES. See *Regulus* (2).
Smalt. A blue pigment or glass, consisting of silica, potash and cobalt.
Smeddum, SCOT. The smaller particles which pass through the sieve of the *hutch.*
Smelting. Reducing ores by fusion in furnaces.
Smift. A fuse or slow match.
Smitham or *Smiddan,* DERB. Lead-ore dust.
Smut. 1. S. STAFF. Bad, soft coal, containing much earthy matter. 2. See *Blossom.*
Snoff, CORN. A short candle-end, put under a fuse to light it.
Snore-hole. The hole in the lower part of *wind-bore* of a mining pump, to admit the water.
Soapstone. Compact talc or steatite; often applied incorrectly to soft unctuous clays or marls.
Softening. Of lead, the removal of antimony and other impurities.
Solder. A metal or alloy used to unite adjacent surfaces of less fusible metals or alloys. *Soft solder* is a compound of tin and lead; *hard solder,* of copper and zinc, or tin, copper, and zinc, or tin and antimony; *gold solder,* of gold, silver and copper; *silver solder,* of silver and copper, or silver and brass; and so on.
Sole. 1. The bottom of a level. 2. The bottom of a reverberatory furnace.
Solid crib-timbering. Shaft-timbering with cribs laid solidly upon one another.
Sollar, CORN. A platform in a shaft, usually constituting a landing between two ladders.
Sough, DERB. See *Adit.*
Sow. 1. See *Salamander.* 2. See *Pig-iron.*
Spate, CORN. To fine for disobedience of orders.
Spall or *Spawl.* To break ore. *Ragging* and *cobbing* are respectively coarser and finer breaking than *spalling,* but the terms are often used interchangeably. Pieces of ore thus broken are called *spalls.*
Spar. A name given by miners to any earthy mineral having a distinct cleavable structure and some lustre; in Cornwall usually quartz.
Spears. See *Pump-rods.*
Speise or *Speiss,* GERM. Impure metallic arsenides (principally of iron), produced in copper and lead smelting. Cobalt and nickel are found concentrated in the speiss obtained from ores containing these metals.
Spel or *Spell.* A change or turn.
Spence-furnace. A long *reverberatory,* for thorough roasting.
Spend. To break ground; to continue working.
Spiegeleisen. Manganiferous white cast-iron.
Spiking-curb, ENG. A *curb* to the inside of which *plank-tubing* is spiked.
Spilling, CORN. A process of driving or sinking through very loose ground.
Spills, CORN. Long thick laths or poles driven ahead horizontally around the door-frames, in running levels in loose ground—a kind of *lagging* put in ahead of the main timbering.
Spire. The tube carrying the train to the charge in a blast-hole. Also called *reed* or *rush,* because these, as well as spires of grass, are used for the purpose.
Spitting. The violent ejection of globules by a body of molten silver, in the act of becoming solidified by cooling.
Splint coal. See *coal.*
Split. 1. To divide a ventilating current. 2. When a *parting* in a coal-seam becomes so thick that the two portions of the seam must be worked separately, each is called a *split.* See *Bench.*
Sponge. Metal in a porous form, usually obtained by reduction without fusion. See *Chenot process.*
Spoon. 1. An instrument made of an ox or buffalo horn, in which earth or *pulp* may be delicately tested by washing to detect gold, amalgam, etc. 2 (or *Spoon-end*). The edge of a coal-basin when the coal-seam *spoons, i. e.,* rises to the surface, after growing thinner as it approaches its termination.
Spout, S. STAFF. See *Air-head.*
Sprag. 1. A *prop.* 2. A short round piece of wood used to block the wheels of a car.
Spreader. A horizontal timber below the *cap* of a set, to stiffen the *legs,* and to support the *brattice* when there are two air-courses in the same gangway.
Spreaders. Pieces of timber stretched across a shaft as a temporary support of the walls.
Sprue. A piece of metal attached to a casting, occupying the *gate* or passage through which the metal was poured.
Spud. A nail, resembling a horseshoe nail, with a hole in the head, driven into mine-timbering, or into a wooden plug inserted in the rock, to mark a surveying-station.
Spur. A branch leaving a vein, but not returning to it.
Spurns, S. STAFF. Small connecting masses of coal, left for safety during the operation of cutting between the *hanging coal* and the main body.
Square sets. A kind of timbering used in large spaces.
Squat, CORN. 1. Tin-ore mixed with spar. 2. See *Bunch of ore.*
Squeeze. The settling, without breaking, of the *roof* over a considerable area of workings.
Squeezer. A machine for reducing the *puddle-ball* to a compact mass, ready for the hammer or rolls.
Squib. A slow-match or safety-fuse, used with a *barrel.*
Squirting. Forcing lead by hydraulic pressure into the form of rods or pipes.
Stack. 1. A chimney. 2. See *Shaft-furnace.*
Stall, S. STAFF. See *Room, Breast* and *Post-and-Stall.*
Stamping. Reducing to the desired fineness in a *stamp-mill.* The grain is usually not so fine as that produced by grinding in *pans.*
Stamp-mill. An apparatus (also the building containing the apparatus) in which rock is crushed by descending pestles (*stamps*), operated by water or steam-power. Amalgamation is usually combined with the crushing when gold or silver is the metal sought, but copper and tin-ores, etc., are stamped to prepare them for *dressing.*
Stamps, S. WALES. The pieces into which the rough bars *shingled* from the finery ball are broken, to be *piled* for subsequent rolling into sheet-iron.
Stamp-work, LAKE SUP. Rock containing disseminated native copper.
Stanchion. See *Leg.*
Standage, ENG. A large *sump,* or more than one, acting as a reservoir.
Stannary. A tin-mine or tin-works.
Station. 1. See *Platt.* 2. Also a similar enlargement of shaft or level to receive a balance-bob (*bob-station*), pump (*pump-station*), or tank (*tank-station*).
Steamboat-coal, PENN. See *Coal.*
Steam-coal. See *Coal.*
Steel. A compound or alloy of iron, principally with carbon, which may be cast, forged, hardened and tempered. Ordinary steel contains from 0.5 to 1.5 per cent. of carbon. More carbon makes cast-iron; less carbon, wrought-iron. But this classification is not now strictly adequate or applicable, either to the scientific or to the commercial use of the term. The so-called *mild* or *low* or *structural*

steels (low in carbon, and hence relatively soft and tough), as compared with *high* or *hard* or *tool* steels, do not always harden or temper. An international committtee appointed by the American Institute of Mining Engineers has recommended the use of the following classification:

1. That all malleable compounds of iron with its ordinary ingredients, which are aggregated from pasty masses, or from piles, or from any forms of iron not in a fluid state, and which will not sensibly harden and temper, and which generally resemble what is called "wrought-iron," shall be called *weld-iron* (GERM. *Schweisseisen;* FR., *fer soude*).

2. That such compounds, when they will from any cause harden and temper, and which resemble what is now called "puddled steel," shall be called *weld-steel* (GERM., *Schweissstahl;* FR., *acier soude*).

3. That all compounds of iron with its ordinary ingredients, which have been cast from a fluid state into malleable masses, and which will not sensibly harden by being quenched in water while at red heat, shall be called *ingot-iron* (GERM., *Flusseisen;* FR., *fer fondu*).

4. That all such compounds, when they will from any cause so harden, shall be called *ingot-steel* (GERM., *Flussstahl;* FR., *acier fondu*).

This proposed classification does not cover ordinary cast or pig iron. It is a classification of the malleable compounds only. The Institute has recommended its use in papers and discussions, except as to the term *weld*, for which a substitute was desired, and meanwhile the continuance of the old term *wrought*, though in a somewhat wider significance, was suggested. The resolution of the Institute concludes as follows: "It being understood that the *ingot-iron* and *ingot-steel* of this classification constitute, taken together, what is now commercially known as *cast-steel*, including the so-called low or soft cast-steels." *Bessemer-steel* is made by decarburizing cast iron in a *converter*. (See *Bessemer process.*) *Blister* or *cement-steel* is made by carburizing wrought iron bars by packing them in charcoal powder and heating without access of air. It is melted in crucibles to *cast-steel*, or hammered (*tilted*) to *shear-steel* (for cutlery, etc.), or rolled to *spring-steel*. *Puddled steel* is made by arresting the *puddling* process before wrought iron has been produced, and thus retaining enough carbon in the bath to constitute steel. *Natural* steel is a similar product, obtained from the refining of cast-iron. *Crucible cast-steel* is steel made by the fusion in crucibles, either of *blister-steel*, or *puddled steel*, or steel scrap, or other ingredients and fluxes which will produce the desired quality. *Cast-steel* in its widest sense, as now employed, comprises all malleable compounds produced by fusion, including therefore the *Bessemer* and *open-hearth* metal. *Open-hearth*, called also *Martin-Siemens steel*, is made in the reverberatory furnace (almost invariably a gas-furnace on the Siemens regenerative system, since an intense tenmperature is required) by the reaction, in the fused bath, of cast-iron with wrought-iron, iron-oxide, or iron ore. At a certain stage of the process a *deoxidizing* or *recarburizing* agent (*spiegeleisen, ferro-manganese*) is added. *Chrome-steel* is a crucible cast-steel in which chromium is a constituent. *Tungsten* or *Wolfram-steel* is a steel containing tungsten. *Phosphorus-steel* is a steel in which the amount of phosphorus exceeds that of carbon. *Damascus-steel* is a laminated mixture of steel and wrought iron. *India-steel* or *Wootz* is manufactured in India direct from the ore.

Stemmer, NEWC. See *Tamping-bar.*

Stemming, NEWC. The tamping put above the charge in a bore-hole.

Stempel or *Stemple*. 1. DERB. One of the cross-bars of wood placed in a mine-shaft to serve as steps. 2. A *stull-piece*. 3. A *cap*, both sides of which are *hitched* instead of being supported upon legs. See *Stull.*

Stenton, NEWC. A passage between two *winning headways*. A *stenton-wall* is the *pillar* of coal between them.

Step-grate. A grate made in steps or stairs, to promote completeness of the combustion of the coal burned upon it.

Step-vein. A vein alternately cutting through the strata of *country-rock*, and running parallel with them.

Stetefeldt furnace. A shaft-furnace for desulphurizing or chloridizing roasting, in which the pulverized charge falls freely down the shaft.

Stirrup. See *Temper-screw.*

Stock-work (GERM., *Stockwerk*). An ore deposit of such a form that it is worked in floors or stories. It may be a solid mass of ore, or a rock-mass so interpenetrated by small veins of ore that the whole must be mined together. *Stockworks* are distinguished from *tabular* or *sheet*-deposits (veins, beds), which have a small thickness in comparison with their extension in the main plane of the deposit (that is, in *strike* and *dip*).

Stone-coal. See *Coal.*

Stone-head, ENG. The solid rock first encountered in sinking a shaft.

Stoop-and-Rooms, SCOT. See *Post-and-Stall.*

Stope, CORN. To evacuate ore in a vein by driving horizontally upon it a series of working, one immediately over the other or *vice versa*. Each horizontal working is called a stope (probably a corruption of *step*), because when a number of them are in progress, each working face being a little in advance of the next above or below, the whole face under a jack assumes the shape of a flight of stairs. When the first stope is begun at the lower corner of the body of ore to be removed, and after it has advanced a convenient distance, the next is commenced above it, and so on, the process is called *over-hand* stoping. When the first stope begins at an upper corner, and the succeeding ones are below it, it is *under-hand* stoping. The term *stoping* is loosely applied to any subterranean extraction of ore except that which is incidentally performed in sinking shafts, driving levels, etc., for the purpose of opening the mine.

Stopping. 1. See *Stoping*. 2. A partition of boards, masonry, or rubbish, to stop the air-current in a mine, or force it to take a special desired direction.

Stove. The oven in which the blast of a furnace is heated.

Stove-coal, PENN. See *Coal.*

Stowbord, NEWC. A place into which rubbish is put.

Stowce. 1. A Windlass. 2. DERB. *Stowces* are wooden landmarks, placed to indicate possession of mining ground.

Stowing. A method of mining in which all the material of the vein is removed and the waste is packed into the space left by the working.

Straightening press. A power-press to straighten iron and steel bars, such as rails, shafting, etc.

Strake, CORN. An inclined *launder* for separating or *tying* ground ore in water.

Stratum. A bed or layer.

Streak. The powder of a mineral, or the mark which it makes when rubbed upon a harder surface.

Stream-tin, CORN. Tin-ore in alluvial deposits, as pebbles.

Stream work, CORN. Work on *stream-tin.*

Streamers, CORN. Searchers for *stream-tin.*

Striated. Marked with parallel grooves or *striæ.*

Strike. The direction of a horizontal line, drawn in the middle plane of a vein or stratum not horizontal.

String, CORN. A small vein.

Stringing-deals, ENG. Thin planks, nailed to the inside of the curbs in a shaft, so as to suspend each curb from those above it.

Strip. To remove from a quarry, or other open working, the overlying earth and disintegrated or barren surface rock.

Studdles, CORN. 1. Props supporting the middle of *stulls*. 2. Distance-pieces between successive frames of timbering.

Stull, CORN. A platform (*stull-covering*), laid on timbers (*stull-pieces*), braced across a working from side to side, to support workmen or to carry ore or waste.

Stulm. See *Adit*. From the GERM. *Stollen.*

Stump, PENN. A small pillar of coal, left at the foot of a *breast* to protect the *gangway.*

Stup. A pulverized mixture of clay and coke or coal. Probably from the GERM. *Gestubbe.*

Sturt. A *tribute*-bargain which turns out profitable for the miner.

Stythe, NEWC. *Choke-damp.*

Sublimation. The volatilization and condensation of a solid substance, without fusion.

Sublimation-theory. The theory that a vein was filled first with metallic vapors.

Sucker-rod. The *pump-rod* of an oil-well.

Sulphur. 1. Iron pyrites. 2. Carburetted or sulphuretted hydrogen.

Sulphurets, PAC. In miner's phrase, the undecomposed metallic ores, usually sulphides. Chiefly applied to auriferous pyrites.

Sump, CORN. (from GERM. *Sumpf.*) The space left below the lowest landing in a shaft to collect the mine-water. The lowest pump draws from it. 2. NEWC. That part of a *judd* of coal which is extracted first.

Sump-fuse. A water-proof fuse.

Swad, NEWC. A thin layer of stone or refuse coal at the bottom of the seam.

Swape. An implement for shaping the edge of a boring bit.

Swalls, Swallows or *Swallow-holes*. Surface holes caused by the subsidence of rocks; or openings into which mine-water disappears.

Swamp. A depression in a nearly horizontal bed, in which water may collect.

Swedish process. See *German process.*

Sweeping table. A stationary *buddle.*

Sweeps. The dust of the workshops of jewellers, goldsmiths, silversmiths, and assayers and refiners of gold and silver.

Sweet-roasting. See *Roasting.*

Synclinal. The axis of a depression of the strata; also the depression itself. Opposed to *anticlinal*, which is the axis of an elevation.

TACKLE, CORN The *windlass*, rope, and *kibble.*

Tacklers, DERB. Small chains put around loaded *corves.*

Tail-house, Tail-mill. The buildings in which *tailings* are treated.

Tailing. See *Blossom.*

Tailings. The lighter and sandy portions of the ore on a buddle or in a sluice. The *headings* are accumulated or discharged at the upper end, the *middlings* in the middle, while the *tailings* escape at the foot. The term *tailings* is used in a general sense for the refuse of reduction-processes other than smelting.

Tail-race. The channel in which *tailings*, suspended in water, are conducted away.

Tamp. To fill (usually with clay-tamping) the bore-hole or other opening through which an explosive charge has been introduced for blasting.

Tamping-bar. CORN.
Tank. A subterranean reservoir into which a pump delivers water for another pump to raise.
Tap-Cinder. The cinder drawn from a *puddling* furnace or *bloomary*.
Tap-hole. The opening through which the molten metal is *tapped* or drawn from a furnace.
Teem, ENG. 1. To dump. 2. To pour steel from a melting-pot.
Temper. 1. To grind and mix plastic materials, such as clay, or the ingredients of mortar. To give the metals (especially steel) the desired degree of hardness and elasticity by a process of heating and cooling, suitably regulated. A metallic compound in which these qualities can thus be produced is said *to temper*, or *to take temper*.
Tempering-bar. See *Furgen.*
Temper-screw. A screw-connection for lengthening the column of boring-rods as boring advances.
Tenant-helve, ENG. See *Frontal-hammer.*
Tepetate, SP. Waste rock and rubbish in a mine.
Tern-plate. A variety of tin-plate coated with an alloy of one-third tin, and two-thirds lead.
Test. See *Cupel.*
Test-ring. An oval iron frame for holding a test or movable cupelling-hearth.
Thermo-aqueous. Produced by, or related to, the action of heated waters.
Thill, NEWC. The floor of a coal mine.
Thirling. See *Thurling.*
Thomas and Gilchrist process. See *Basic lining process.*
Three-high train. A *roll-train* composed of three rolls, the bar, being entered on one side between the bottom and the middle rolls and on the other side between the middle and upper roll. The *passes* in both directions thus take place without reversing the movement of the rolls, as is done in so-called *reversing-rolls.*
Throw. A dislocation or fault of a vein or stratum, which has been *Thrown up* or *down* by the movement.
Throwing, S. STAFF. The operation of breaking out the *spurns*, so as to leave the *hanging coal* unsupported, except by its own cohesion.
Thrust. The breaking down or the slow descent of the roof of a *gangway*. Compare *Creep.*
Thurl, S. STAFF. To cut through from one working into another.
Thurlings. Passages cut from *room* to *room* in *post-and-stall* working.
Thurst. The ruins of the fallen roof, after *pillars* and *stalls* have been removed.
Ticketings, CORN. Meetings for the sale of ores.
Tick-hole. See *Vug.*
Tierras, SP. Fine dirt impregnated with quick-silver ore, which must be made into *adobes* before roasting.
Tiger. See *Nipping-fork.*
Tile-copper. See *Bottoms.*
Tiller. See *Brace-head.*
Tilt-hammer. A hammer for shingling or forging iron, arranged as a lever of the first or third order, and "tilted" or "tripped" by means of a cam or cog-gearing, and allowed to fall upon the billet, bloom, or bar.
Tin-frame, CORN. A *sleeping-table* used in dressing tin-ore *slimes*, and discharged by turning it upon an axis till its surface is nearly vertical, and then dashing water over it, to remove the enriched deposit. A *machine-frame* or *self-acting frame* thus discharges itself automatically at intervals; a *hand-frame* is turned for the purpose by hand.
Tin-ores. Tinstone (*cassiterite*, oxide); *tin-pyrites*, (*stannite*, sulphide of tin, copper, iron and zinc). The latter is not, so far as I am aware now actually treated for tin. Ores containing it are smelted as copper ores, and the tin is lost.
Tin-plate. Sheet-iron coated with tin.
Tin-witts, CORN. The product of the first dressing of tin-ores, containing, besides tinstone, other heavy minerals (wolfram and metallic sulphides), It must be roasted before it can be further concentrated. Its first or partial roasting is called *rag-burning.*
Tipe. To upset or "dump" a *skip.*
Toadstone. A kind of trap-rock.
Ton. For many things, such as coal and iron, the ton in use is the *long* ton of twenty hundredweight at 112 pounds avoirdupois. Allowances ("sandage," etc.), are made in weighing pig-iron and other crude metals, so that the "smelter's ton" is still greater. The Cornish mining ton is twenty-one hundredweight or 2352 pounds avoirdupois. In gold and silver mining, and throughout the Western States, the ton is the *short* ton of 2000 pounds.
Tonite. A nitrated gun-cotton, used in blasting.
Top-wall. See *Hanging-wall.*
Torta, SP. A flat heap of silver ore (*slime* or *pulp*) prepared for the *patio* process.
Tossing or *Tozing,* CORN. 1. Washing ores by violent agitation in water, their subsidence being accelerated by *packing* or striking with a hammer the *keeve* in which the operation is performed. *Chimming* is a similar process on a smaller scale. 2. Refining tin by allowing it, while molten, to fall several feet through the air.
Touchstone. A black, hard stone (basalt or jasper), on which the fineness of an alloy of gold and silver can be tested by comparing its *streak* with that of a piece of alloy (*touch-needle*) of known fineness.
Tough-cake. Refined or commercial copper.
Toughening. Refining, as of copper or gold.
Tough-pitch. See *Tough-cake.*
Towt, NEWC. A piece of old rope.
Train. See *Roll-train.*
Tram, WALES. 1. A four-wheeled truck to carry a *tub*, *corve*, or *hutch*, or to carry coal or ore on a railroad. 2. One of the rails of a *tramroad* or railroad.
Trap. In miners' parlance, any dark, igneous or apparently igneous, volcanic rock.
Trap-door. See *Weather-door.*
Trapiche, SP. A rude grinding machine, composed of two stones, of which the upper is fastened to a long pole.
Trapper. NEWC. A boy who opens and shuts the *trap-door.*
Tribute, CORN. A portion of ore given to the miner for his labor. *Tributors* are miners working under contract, to be paid by a *tribute* of ore or its equivalent price, the basis of the remuneration being the amount of clean ore contained in the crude product.
Trip-hammer. See *Tilt-hammer.*
Trogue. A wooden trough, forming a drain.
Trolly. A small four or two-wheeled truck, without a body. The two-wheeled trolly is used in a *rolling-mill* to wheel the *puddle-balls* to the *squeezer.*
Trombe or *Trompe,* FR. An apparatus for producing an air-blast by means of a falling stream of water, which mechanically carries air down with it, to be subsequently separated and compressed in a reservoir or drum below.
Trommel. A revolving sieve for *sizing* ores.
Trouble, NEWC. A dislocation of the strata.
Trow. A wooden channel for air or water.
Trumpeting, S. STAFF. A small channel cut behind the brick-work of a shaft lined with masonry.
Trunk, CORN. A long narrow box or square tube, usually of wood.
Trunking, CORN. Separating slimes by means of a *trunk.*
Tubbing. A shaft-lining of casks or cylindrical caissons, of iron or wood. See *Plank-tubbing.*
Tubing. Lining a deep bore-hole by driving down iron tubes.
Tubs, NEWC. Boxes for lowering coals. See *Trolly.*
Tuff or *Tufa.* A soft sandstone or calcareous deposit.
Tug, DERB. The iron hook of a hoisting bucket, to which the *tacklers* are attached.
Tunnel. 1. A nearly horizontal underground passage, open at both ends to *day*. 2. PAC. See *Adit.*
Tunnel-head. The top of a *shaft-furnace.*
Turbary. A peat-bog.
Turn. A pit sunk in a *drift.*
Turn-bat. A wooden stick used in turning the tongs which hold a *bloom* under the hammer.
Turning-house. The first working on a vein where it has been intersected by a *cross-cut.*
Tut-work. See *Dead-work.* In general, work paid for by the amount of excavation, not (as in *tribute*) of product.
Tuyere, Tweer, Twyer or *Twere.* A pipe inserted in the wall of a furnace, through which the blast is forced into the furnace. Usually the tuyere enters through an embrasure in the masonry (*tuyere-arch*). A *nozzle* or interior pipe is frequently inserted at the inner end of the *tuyere*. By changing the *nozzle*, the size of the opening for the blast may be thus regulated without changing the *tuyere*. The latter is either an annular hollow casting of iron (*box-tuyere*) or bronze (*bronze-tuyere*), or a coil of iron pipe. In either case, water is continually circulated through it, to protect it and the nozzle from the action of the melting materials in the furnace. *Spray-tuyeres* are open *box-tuyeres*, in which a spray of water, instead of a current, is employed. This is vaporized by the heat, and passes away as steam.
Tuyere-plate. See *Bloomary.*
Tying, CORN. See *Strake.*
Tymp. A hollow iron casting, cooled interiorly by a current of water, and placed to protect the *tymp-arch*, or arch over the *dam* in a blast furnace having a *fore-hearth*. (See *Open front.*)

UNDER-HAND. See *Slope.*
Underlayer, CORN. A vertical shaft sunk to cut a lode.
Underlie or *Underlay,* CORN. The departure of a vein or stratum from the vertical, usually measured in horizontal feet per fathom of inclined depth. Thus a *dip* of 60° is an *underlay* of three feet per fathom. The *underlay* expressed in feet per fathom is six times the natural cosine of the angle of the dip. See *Dip.*
Under-poled copper. Copper not *poled* enough to remove all sub-oxide.
Universal train. A *roll train* having adjustable horizontal and vertical rolls, so as to produce sections of various sizes.
Unwater. To drain or pump water from a mine.
Upcast. 1. A lifting of a coal seam by a dike. 2. The opening through which the ventilating current passes out of a mine. See *Downcast.*
Upraise. See *Rise.*
Ure's process. The treatment of quicksilver ores by heating in iron retorts with admixture of lime.

VALL' ALTA FURNACE. See *Hahner furnace.*
Vamping. The *debris* of a stope, which forms a hard mass under the feet of the miner.
Vanning, CORN. A method of washing ore on a shovel, analogous to *panning.* Concentrating machines are sometimes called *vanners.* See *Percussion-table.*
Vein. See *Lode.* The term *vein* is also sometimes applied to small threads, or subordinate features of a larger deposit.
Vena, SP. A small vein.
Vend, NEWC. The total sales of coal from a colliery.
Verifier. A tool used in deep boring for detaching and bringing to the surface portions of the wall of the bore-hole at any desired depth.
Vermillion. Mercury sulphide.
Vestry, NEWC. Refuse.
Veta, SP. A vein. As compared with *vena, veta* is the main vein.
Viewer. A colliery manager.
Vigorite. See *Explosives.*
Vug, vugg or *vugh.* A cavity in the rock, usually lined with a crystalline incrustation. See *Geode.*

WAD-HOOK. A tool with two spiral steel blades for removing fragments from the bottom of deep bore-holes.
Wagon. A four-wheeled vehicle used in coal mines, usually containing 75 to 100 cubic feet.
Wagon-breast. A *breast* into which wagons can be taken.
Wale, NEWC. To clean coal by picking out the refuse by hand. The boys who do this are called *Walers.*
Wall. 1. The side of a level or drift. 2. The *country-rock* bounding a vein laterally.
Wall-plates, CORN. The two side-pieces of a timber frame in a shaft, paralled to the strike of the lode when the shaft is sunk on the lode. The other two pieces are the *end-pieces.*
Washer. See *Ore-washer.*
Water-jacket. See *Jacket.*
Waste. NEWC. Old workings. The signification seems to include that of both *goaf* and *gob.*
Wastrel. A tract of waste land or any waste material.
Water-barrel or *Water-tank.* A barrel or box with a self-acting valve at the bottom, used for hoisting water in lieu of a pump.
Water-level. 1. The level at which, by natural or artificial drainage, water is removed from a mine or mineral deposit. 2. A drift at the water-level.
Water-packer. A water-tight packing of leather between the pipe and the walls of a bore-hole.
Way-shaft. See *Blind-shaft.*
Weather-door. A door in a level to regulate the ventilating current.
Weathering. Changing under the effect of continued exposure to atmospheric agencies.
Wedging-curb or *Wedging-crib,* ENG. A *curb* used to make a water-tight packing between the *tubbing* in a shaft and the rock-walls, by means of split *deals,* moss and wedges, driven in between the *curb* and the rock.
Weld. To join pieces of metal by pressure, at a temperature below that of complete fusion.
Weld-iron. Wrought-iron. See *Iron* and *Steel.*
Weld-steel. See *Steel.*
Weld. The crucible of a furnace.
Welsh process. See *English process.*
Wetherill furnace. A furnace with perforated iron bottom, under which a blast is introduced, and upon which zinc-ore (red oxide) is reduced.
Wharl or *Wharr,* NEWC. A sledge for hauling corves in low drifts.
Wheal, CORN. A mine.
Whim or *Whimsey.* A machine for hoisting by means of a vertical drum, revolved by horse or steam power.
Whin or *Whinstone,* NEWC. Basaltic rock; any hard, unstratified rock. In Scotland, greenstone.
Whip. The simplest horse-power hoisting machine, consisting of a fixed pulley and a hoisting rope passing over it, to which the animal is directly attached.
White-ash, PENN. See *Coal.*
White-damp. A poisonous gas sometimes (more rarely than fire-damp or choke-damp, etc.), encountered in coal mines. It has been supposed to contain carbonic oxide, but this is doubtful.
White furnace. See *Howell furnace.*
White-lead. Carbonate of lead.
White tin, CORN. *Metallic tin.*
Whits or *Witts,* CORN. See *Tin-witts.*
Whitwell stove. A fire-brick hot-blast stove, on the regenerative system.
Whole-working, NEWC. Working where the ground is still whole, *i. e.,* has not been penetrated as yet with breasts. Opposed to *pillar-work,* or the extraction of pillars left to support previous work.
Wild lead. Zinc-blende.
Wicket. A *breast.* See *Breast,* and *Post-and-stall.*
Wimble. A shell-auger used for boring in soft ground.
Win. To extract ore or coal.
Windbore, NEWC. The pipe at the bottom of a set of pumps.
Winch or *Windlass.* A man-power hoisting machine, consisting of a horizontal drum with crank handles.
Winding. Hoisting with a rope and drum.
Winds. See *Winze.*
Winning. 1. A new opening. 2. The portion of a coal field laid out for working.
Winning headways. NEWC. Headways driven to explore and open out the coal seam.
Winze. An interior shaft, usually connecting two levels.
Wood-tin. Tinstone of light wood-color.
Wootz. See *Steel.*
Work. Ore not yet dressed.
Working. See *Labor.* The Spanish and the English term are synonymous in meaning and alike in application. A *working* may be *shaft, quarry, level, open-cut,* or *stope,* etc.
Working-barrel, CORN. The cylinder in which a pump piston works.
Working home. Working toward the main shaft in extracting ore or coal, as in *longwall retreating.*
Working-out. Working away from the main shaft in extracting ore or coal, as in *longwall advancing.*
Work-lead. See *Base bullion.*

YELLOW-ORE. CORN. Chalcopyrite. See *Copper ores.*
Yokings. See *Stowces.*

ZAWN, CORN. A cavern.
Ziervogel process. The extraction of silver from sulphuret ores or matte by roasting in such a way as to form sulphate of silver, leaching this out with hot water, and precipitating the silver by means of metallic copper.
Zighyr, zigger, or *sicker,* CORN. To percolate, trickle or ooze, as water through a crack. From GERM., *sickern.*
Zinc-dust. Finely-divided zinc, zinc-oxide, and impurities, incidentally produced in the manufacture of *spelter.* It is sometimes used as an inferior paint (*zinc-gray*).
Zinc-gray. See *Zinc-dust.*
Zinc-ores. *Red ore* (*zincite,* oxide); *black-jack* (*zinc-blende, sphalerite,* sulphide); *zinc-spar* (*noble calamine, smithsonite,* carbonate, and *earthy calamine, hydrozincite,* hydrated carbonate); *silicious oxide* (*willemite,* anhydrous, and *calamine,* hydrated silicate).
Zinc-scum. The zinc-silver alloy skimmed from the surface of the bath in the process of desilverization of lead by zinc.
Zinc-white. Oxide of zinc.
Zones. In a shaft-furnace, the different portions (horizontal sections) are called *zones,* and characterized according to the reactions which take place in them, as the *zone of fusion* or *smelting-zone,* the *reduction-zone,* etc.

THE PROPERTIES OF METALS.

THE word Metal appears to be derived from the Greek μετ ἄλλα, *in quest of other things,* whence come μεταλλάω *to search after, to explore,* or in gold-diggers' language *to prospect,* and the corresponding substantive μέταλλον *a mine.* About fifty of the undecomposed or *elementary* substances are classed together under the head of Metals by the chemist, because they manifest certain properties when acted upon by chemical tests, without regard to those external characters which are commonly associated with the idea of a metal. Many of these are unfit to be employed in the metallic state for any of the ordinary uses of metals, because they cannot be exposed to the action of air, even for a short time, without being rusted or corroded, by combining with the oxygen of the air, to such an extent that they entirely lose their metallic characters. Among those which offer sufficient resistance to the action of air, many are excluded from useful application in their metallic state, on account of their rarity, or of the great difficulty which is experienced in extracting them from their ores. The metals which are employed for useful purposes in their pure or metallic state are—

Aluminum	Copper	Magnesium	Platinum
Antimony	Gold	Mercury	Silver
Bismuth	Iron	Nickel	Tin
Cadmium	Lead	Palladium	Zinc

On considering this list, it will be seen that several of the metals named in it are employed to produce some effect dependent upon a peculiar property of the metal, and not upon qualities which belong to it in common with the rest. Thus, mercury or quicksilver is used for amalgamating or dissolving, and also as a suitable liquid for constructing barometers and thermometers; antimony owes its usefulness to its property of hardening lead and tin when melted with them; bismuth and cadmium are employed to render lead and tin capable of being melted at lower temperatures; nickel is used to whiten copper in order to make German silver; and magnesium is valuable for its property of burning easily with production of a brilliant white light. Moreover, gold, platinum, palladium, and silver, being comparatively rare, and aluminum being obtainable by a somewhat costly process, the useful applications of these metals are limited by their high price, so that there remain only tin, lead, copper, iron and zinc to be considered as metals largely employed for useful purposes.

The qualities possessed by these metals, rendering them fit for purposes which could not be fulfilled by non-metallic substances, are lustre, or the power of reflecting light, tenacity, or resistance to any attempt to pull asunder their particles; malleability, or the capability of being hammered or rolled into thin sheets; ductility, or the property of being drawn out into wire; high specific gravity or relative weight; high conductive power for heat and electricity; and fusibility, or the property of becoming liquid when heated.

Metallic Lustre.—The power of reflecting the rays of light is possessed in a much higher degree by metals than by non-metallic substances. Although some examples of the latter class, such as iodine and plumbago, reflect much of the light which falls upon smooth surfaces of them, they have a black appearance, caused by their absorbing a large proportion of the luminous rays, which is quite different from the true metallic lustre. Iron, in the form of steel, is capable of exhibiting this lustre in very great perfection, because the hardness of steel allows its surface to be ground perfectly smooth by the application of fine particles of very hard substances, such as emery and diamond-dust, which rub off minute projections from the surface without producing scratches or indentations. A surface, so polished sends back directly to the eye of the observer almost all the light falling upon it, whilst a rough surface, being made up of a number of small surfaces, scatters the reflected rays in all directions. Tin is naturally a brilliant metal, but is not hard enough to be polished, like steel; if, however, it be dissolved in twice its weight of melted copper, an alloy of great hardness and brilliancy is formed, which is employed for the specula or mirrors of reflecting telescopes. Zinc and lead exhibit the metallic lustre in an inferior degree, and become dull when exposed to air, because the metal at the surface combines with oxygen, forming a thin film of oxide which has no metallic lustre. The natural lustre of silver is very great, and if it be hardened by admixture with a little copper, it becomes susceptible of a very high polish which is not dimmed by the action of the oxygen of air, though it is easily tarnished by sulphur existing in foul air in the form of sulphuretted hydrogen. The splendid combination of lustre and color exhibited by burnished gold is proverbial and is undiminished by the action of the atmosphere. The lustre of palladium and platinum resembles that of silver, and is not affected by oxygen or sulphur in the air. Aluminum has also a permanent lustre, though inferior to that of silver. When dissolved in nine times its weight of melted copper aluminum forms a hard yellow alloy capable of being polished to resemble gold, but becoming slowly tarnished by the action of the oxygen in air.

Tenacity.—The strength with which the metals oppose any attempt to pull asunder their particles is one of their most useful properties, and is determined by ascertaining the exact weight which must be suspended from the ends of wires or rods of equal diameter, in order to break them. The weight required to break a given metallic wire is found to vary according to the manner in which the strain is applied, the resistance of the wire being greater when the whole of the breaking weight is applied at once than when it is added gradually, probably because, in the latter case, the wire becomes stretched and weakened by each additional weight. Steel (iron combined with about $\frac{1}{100}$th part of carbon) is by far the most tenacious of metals, and lead is the least tenacious of those in ordinary use. If the weight required to pull asunder a wire of lead be taken as unity, that required by similar wires of the other metals will be found to approach nearly to the number contained in the following table:—

Relative Tenacity of the Metals.

Lead	1	Silver	12½
Tin	1⅓	Platinum	15
Zinc	2	Copper	18
Palladium	11½	Iron	27½
Gold	12	Steel	42

The tenacity of metals is very seriously affected by variations in their structure, purity and temperature. Thus, rods of metal which have been cast in a mould are generally weaker than rods of equal dimensions made by drawing the metal through the gradually diminishing holes of the wire-drawer's plate. The tenacity of iron rods which have been rolled until they have acquired a fibrous structure, is much higher than that of rods which are crystalline in texture, the metal tending to break asunder where the smooth surfaces of the separate crystals are in contact with each other. The tenacity of metal when hot is, as might be anticipated, less than its tenacity when cold; and if the metal be made red-hot and allowed to cool slowly, it will generally be found to have diminished in tenacity, probably because a high temperature tends to encourage the formation of a crystalline structure. The effect of the presence of impurities upon the tenacity of metals will be more appropriately studied elsewhere, but it may be stated generally that chemical purity is not of necessity accompanied by the highest degree of tenacity. Thus, the small proportion of carbon present in steel is seen in the above table to have greatly increased in tenacity of the iron, and pure zinc has a much lower tenacity than the ordinary zinc of commerce.

Malleability.—The facility with which a mass of metal can be hammered or rolled into a thin sheet without being torn, must depend partly upon its softness, and partly upon its tenacity. If it depended upon softness alone, lead should be the most malleable of ordinary metals; but, although it is easy to hammer a mass of lead into a flat plate, or to squeeze it between rollers, any attempt to reduce it to an extremely thin sheet fails from its want of tenacity, which causes it to be worn into holes by percussion or friction. On the other hand, if malleability were entirely regulated by tenacity, iron would occupy the first place, whereas, on account of its hardness, it is the least malleable of metals in ordinary use; whilst gold, occupying an intermediate position with respect to tenacity, is the most malleable, which appears surprising to those who are only acquainted with gold in its ordininary forms of coin and ornament, in which it is hardened and rendered much less malleable by the presence of copper and silver. During the rolling or lamination of metals their particles are obviously squeezed into unnatural positions; it becomes necessary, therefore, in order to avoid breaking, to enable the particles to resume their former relative situations; this is effected by heating the metallic sheet after every two or three rollings, and allowing it to cool slowly, a process of annealing similar to that by which glass vessels are rendered less brittle. In the following table the ordinary metals are arranged in the order of malleability:

Table of Malleability.

1. Gold.	4. Tin.	7. Zinc.
2. Silver.	5. Platinum.	8. Iron.
3. Copper.	6. Lead.	

Ductility.—The ease with which a metal can be elongated into a wire, by being drawn through the gradually diminishing holes of the wire-drawer's plate, will be greater in proportion to the softness of the metal; but the thinness of the wire to which it can be reduced is regulated by the tenacity of the metal, which enables it to resist, without breaking, the force required to draw it through the holes. and it is found that their tenacity has more influence upon the ductility of metals than upon their malleability, for the particles of a weak metal, like tin, may cohere under the hammer, although they would be easily torn apart by the direct pull necessary in wire-drawing. Gold, silver, and platinum, which occupy an intermediate position with respect to tenacity, are the most ductile of the metals, whilst tin and lead, which are lowest in tenacity, are the least ductile, though their softness gives them a higher place in the order of malleability.

Table of Ductility.

1. Gold.	5. Copper.	8. Zinc.
2. Silver.	6. Palladium.	9. Tin.
3. Platinum.	7. Aluminum.	10. Lead.
4. Iron.		

The metals require annealing during the process of wire-drawing, as in that of lamination, and for a similar reason.

Specific Gravity.—The relative weights of equal bulks of the metals exercise considerable influence upon their useful applications. The relative weight of gold being very high it is well adapted for a circulating medium, a large value being compressed into a portable form. On the other hand, iron would be employed with far less advantage in building if its relative weight did not happen to be low, whilst aluminum, being the lightest of metals in ordinary use, is particularly well adapted for the production of small weights, as fractions of a grain, which shall yet be large enough to handle; such weights being nearly nine times as large when made of aluminum as they are when platinum is employed, as was the case before the introduction of aluminum. The specific gravities, or comparative weights of equal bulks of the metals, are generally expressed by numbers which show that each metal is so many times as heavy as an equal bulk of pure distilled water at the ordinary temperature (60° F.); thus zinc is a little more than seven times as heavy as an equal bulk of water, so that its specific gravity is expressed by 7 and a fraction. The first column of numbers in the following table gives the specific gravities of the metals in round numbers, which can be easily retained in the memory, and are sufficiently exact for ordinary purposes, the more accurate numbers usually employed in scientific works being given in the next column:—

Table of Specific Gravities of the Metals.

Platinum	$21\frac{1}{2}$	21.53	Nickel	$8\frac{4}{5}$	8.82
Gold	$19\frac{1}{3}$	19.34	Iron	$7\frac{4}{5}$	7.84
Mercury	$13\frac{3}{5}$	13.59	Tin	$7\frac{1}{3}$	7.29
Palladium	$11\frac{4}{5}$	11.8	Zinc	$7\frac{1}{7}$	7.14
Lead	$11\frac{1}{3}$	11.36	Antimony	$6\frac{2}{3}$	6.71
Silver	$10\frac{1}{2}$	10.53	Aluminum	$2\frac{2}{3}$	2.67
Bismuth	$9\frac{4}{5}$	9.79	Magnesium	$1\frac{3}{4}$	1.74
Copper	9	8.95			

Conducting Power of Metals for Heat.—The sensation of cold when the hand is placed upon a piece of metal of the ordinary temperature of the air shows us that metals are better conductors of heat than non-metallic bodies, for the particles of metal which are warmed by contact with the hand give up the acquired heat to the neighboring particles, and being thus cooled to nearly their former temperature, are able to abstract a fresh supply of heat from the hand; whereas, when the hand is placed upon wood, or other inferior conductors of heat, the particles in contact with it are warmed by the removal of a trifling amount of heat from the hand, and are not soon cooled again by parting with their heat to the particles adjoining. In consequence of the rapidity with which heat applied to one portion of a mass of metal is communicated to the whole of the particles composing it, metals may be suddenly heated or cooled with much less risk of causing them to crack or fly than is the case with non-metallic substances. When an earthenware pipkin or a glass bottle is placed upon the fire, the outside immediately becomes much hotter than the inside, and being expanded by the heat, tears apart the particles of the inside of the vessel and produces a crack, but in the case of a metallic vessel the heat is rapidly transmitted, and all parts of the vessel are expanded almost simultaneously. The much greater rapidity with which water can be heated in metallic vessels is another useful result of the superior conducting power of the metals. In the following table the metals are arranged in the order of their conducting power, the first being the best conductor:—

Table of Conducting Power for Heat

1. Silver.	5 Zinc.	9. Lead.
2. Gold.	6. Iron.	10. Antimony.
3. Copper.	7. Tin.	11. Bismuth.
4. Aluminum,	8. Platinum.	

Conducting Power of Metals for Electricity.—The conducting power of electricity, of metals, refers to the facility with which an electric disturbance excited in portion of a mass of metal is transmitted to the other particles composing the mass. Thus, a very slight electric disturbance at one end of a copper wire is sufficient to produce movement in a telegraph needle at the other extremity, whilst a much greater amount of disturbance, or, in other words, a more powerful current, is required if an iron wire of the same length and thickness be employed. Only one non-metallic substance—carbon, in some of its varieties—at all approaches to the metals in the power of conducting electricity. Those metals which are the best conductors of heat are also the best conductors of electricity, and in both cases the conducting power is seriously impaired by the presence in the metal even of small quantities of other metals, or of non-metallic bodies, as well as by an increase of temperature in the metal. When heated to the boiling point of water, the metals have only about three-fourths of the conducting power which they exhibit at the freezing point. The following table shows the relative conducting power of the most important metals in a pure state at 32° F., the conducting power of silver, which is higher than that of any other metals, being taken as 1000:—

Table of Conducting Power for Electricity.

Silver = 1000

Copper	999	Nickel	131
Gold	779	Tin	123
Zinc	290	Lead	83
Palladium	184	Antimony	46
Platinum	180		
Iron	168	Bismuth	12

Fusibility.—Although the property of becoming liquid at high temperatures is not confined to the metals, it must be mentioned among the properties which conduce to their utility, for it enables the founder to produce a large number of objects of a given pattern with little expenditure of time and labor, and offers to the worker in metals a ready method of soldering together, in a durable manner, the separate pieces of his work. Tin and lead, being the most fusible of ordinary metals, are the constituents of solder, whilst iron (wrought iron), as the least fusible of the common metals, is used for firebars, melting-pots and similar purposes.

Table of Fusibility.

Tin	melts at	442° F.	Silver	melts at	1800° F.
Cadmium	"	442	Copper	"	1990
Bismuth	"	507	Gold	"	2000
Lead	"	617	Cast Iron		2780
Zinc	"	773	Steel	"	4000
Antimony	"	1150	Wrought Iron	"	above 4000 *

Platinum melts only in the oxy-hydrogen blowpipe flame.

In practical work the temperature is commonly inferred from the appearance of the fire; thus, the red heat of an ordinary domestic fire is roughly valued at 1000° F., so that tin, lead, and zinc can be very easily melted in a crucible or ladle placed in such a fire; but aluminum, silver, copper, and gold, require a bright red (cherry red) or furnace heat to melt them: cast iron requires a very bright red heat, only attainable in a furnace with a very good draft; and for melting steel, a furnace of special construction (wind furnace) is employed. Wrought iron can be fused only at a white heat, producible by a blast of air in a forge, and platinum melts at a greenish white heat in the flame of hydrogen supplied with pure oxygen. The production of a temperature adequate to the fusion of steel and wrought iron in large quantities has been much facilitated by the introduction of Siemens' regenerative furnace, in which the waste heat of the fire, instead of escaping up the chimney into the air, is accumulated into masses of fire-brick, and restored again to the furnace.

Compiled from "Metals, their properties and treatment, by C. L. Bloxam."

TABLES OF REFERENCE FOR THE MINER, ENGINEER, AND MINE-OWNER.

HEREWITH we introduce a number of tables, collated facts, dimensions, gauges, standard measurements, and other tabulated data, that doubtless will often be of service to our reader.

* Estimates of temperature above the fusing point of zinc cannot be regarded as exact, on account of the difficulty of ascertaining them.

CHRONOLOGICAL ERAS AND CYCLES FOR 1882.

The year 1882, *or the* 107*th year of the Independence of the United States of America, corresponds to*

The year 7390-91 of the Byzantine Era;
" 6595 of the Julian Period;
" 5642-43 of the Jewish Era;
" 2658 of the Olympiads, or the second year of the 665th Olympiad, commencing in July, 1881, the era of the Olympiads being placed at 775.5 years before Christ, or near the beginning of July of the 3938th year of the Julian Period;
" 2635 since the foundation of Rome, according to Varro;
" 2194 of the Grecian Era, or the Era of Seleucidæ;
" 1601 of the Era of Diocletian.

The year 1299 of the Mohammedan Era, or the Era of the Hegira, begins on the 7th of February, 1882.

The first day of January of the year 1882 was the 2,408,447th day since the commencement of the Julian Period.

Dominical Letter	A	Lunar Cycle or Golden Number . .	2
Epact	11	Solar Cycle	15

Chronology.

B. C.

4004. Creation of the World (according to Julius Africanus. Sept. 1st, 5508; Samaritan Pentateuch, 4700; Septuagint 5872; Josephus, 4658; Hales, 5411).
2348. Deluge (according to Hales, 3154).
2203. Chinese Monarchy.
2090. First Egyptian Pyramid.
1180. Troy destroyed.
1111. Mariner's Compass discovered.
753. Foundation of Rome.
676. Money coined at Rome.
605. Geometry, Maps, etc., first introduced.
289. First Sun-dial.
219. Hannibal crossed the Alps.
219. Land Surveying first introduced.
155. Time first measured by water.
51. Cæsar invaded Britain.

A. D.

214. Grist Mills introduced.
667. Glass discovered.
991. Arabic Minerals introduced.
1066. Battle of Hastings.
1180. Mariner's Compass introduced in Europe.
1383. Cannon introduced.
1492. America discovered.
1627. Barometer and Thermometer invented.
1752. New Style, introduced into Britain; Sept. 3 reckoned Sept. 14.
1769. James Watt—First design and patent of a steam-engine having a separate vessel of condensation.
1789. French Revolution.

A. D.

1772. Oliver Evans—Designed the non-condensing engine, 1792. Applied for a patent for it 1801. Constructed and operated it.
1790. Water lines first introduced in the models of vessels in the U. S., by Orlando Merrill, of Newburyport, Mass.
1797. John Fitch—Propelled a yawl boat by the application of steam to side wheels, and also to a screw propellor, upon the Collect pond, New York.
1807. Robert Fulton—First passenger Steam-boat.
1827. First Rail Road in the U. S., from Quincy to Neponset, Mass.

UNITED STATES MEASURES AND WEIGHTS.

According to Act of 1866.

Measures of Length.

Denominations and Values.		*Equivalents in use.*
Myriameter	10 000 meters.	6.2137 *miles.*
Kilometer	1 000 meters.	.62137 *mile*, or 3280 *feet* and 10 *ins.*
Hectometer . . .	100 meters.	328 *feet* and 1 *inch.*
Dekameter	10 meters.	393.7 *inches.*
Meter	1 meter.	39.37 *inches.*
Decimeter	$\frac{1}{10}$th of a meter.	3.937 *inches.*
Centimeter	$\frac{1}{100}$th of a meter.	.3937 *inch.*
Millimeter	$\frac{1}{1000}$th of a meter.	.0394 *inch.*

Measures of Surface.

Denominations and Values.		*Equivalents in use.*
Hectare.	10 000 square meters.	2.471 *acres.*
Are.	100 square meters.	119.6 *square yards.*
Centare	1 square meter.	1550 *square inches.*

Measures of Volume.

Denominations and Values.			*Equivalents in use.*	
Names.	No. of Liters.	Cubic Measure.	Dry Measure.	Liquid or Wine Measure.
Kiloliter or Stere	1000	1 cubic meter	1.308 *cubic yards.*	264.17 *gallons.*

Names.	Number of Grams	Weight of Volume of Water at its Maximum Density	Avoirdupois Weight.
Millier or Tonneau.	1 000 000	1 cubic meter.	2204.6 *pounds.*
Quintal.	100 000	1 hectoliter.	220.46 *pounds.*
Myriagram	10 000	10 liters.	22.046 *pounds.*
Kilogram or Kilo .	1 000	1 liter.	2.2046 *pounds.*
Hectogram	100	1 deciliter.	3.5274 *ounces.*
Dekagram	10	10 cubic centimeters.	.3527 *ounce.*
Gram.	1	1 cubic centimeter.	15.432 *grains.*
Decigram.	$\frac{1}{10}$	$\frac{1}{10}$th of a cubic centimeter.	1.5432 *grains.*
Centigram	$\frac{1}{100}$	10 cubic millimeters.	.1543 *grain.*
Milligram	$\frac{1}{1000}$	1 cubic millimeter.	.0154 *grain.*

For Measuring Surfaces the square Deckametre is used under the term of ARE; the Hectare, or 100 ares, is equal to about 2 acres.

The Unit of Capacity is the cubic Decimetre or LITRE, and the series of measures is formed in the same way as in the table of lengths.

The cubic Metre is the unit of measure for solid bodies, and is termed STERE.

The Unit of Weight is the GRAMME, which is the weight of one cubic centimetre of pure water weighed in a vacum at the temperature of 4° Centigrade, or 39°.2 Fahrenheit, which is about its temperature of maximum density.

In practice, the term cubic Centimetre, abbreviated C. C., is used instead of Millilitre, and cubic Metre instead of Kilolitre.

EQUIVALENTS OF OLD AND NEW U. S. MEASURES.

Length.

	Meters.
1 Inch =	.02540005
1 Foot =	.3048006
1 Yard =	.9144018
1 Chain =	20.1168396
1 Furlong =	201.168396
1 Mile =	1609.347168

Surface.

1 Drachm =	3.888024
1 Ounce (Troy) =	31.104192
1 Ounce =	28.350175
1 Pound =	453.6028
1 Ton =	1016070.272

NOTE.—A square Meter is 1549.9969 square inches, but by Act of Congress it is declared to be 1550 square inches; hence the Liter (cubic decimeter)=61.02377-953 cubic inches. In the Act of Congress, a Liter is declared to be 61.022 cubic inches, which is erroneous, as here shown, by the .001+ of an inch.

According to Previous and Existing Laws.

MEASURES OF LENGTH.

The Standard of measure is a brass rod, which at the temperature of 32°, is the standard yard.

Lineal.

		Inches.	*Feet.*	*Yards.*	*Rods.*	*Furl.*
12 inches	= 1 foot.					
3 feet	= 1 yard.	36=	3.			
5.5 yards	= 1 rod.	198=	16.5=	5.5.		
40 rods	= 1 furlong.	7920=	660 =	220 =	40.	
8 furlongs	= 1 mile.	63360=	5280 =	1760 =	320=	8.

The inch is sometimes divided into 3 *barley corns*, or 12 *lines.*

A hair's breadth is the .02083 (48th part of an inch.)

1 yard is . . . . .000568 of a mile.
1 inch is . . . . .0000158 of a mile.

Gunter's Chain.

7.92 inches=1 link.
100 links =1 chain, 4 rods, or 22 yards.
80 chains =1 mile.

Ropes and Cables.

6 feet=1 fathom. | 120 fathoms=1 cable's length.

Geographical and Nautical.

1 degree of a great circle of the earth= 69.77 Statute miles.
1 mile =2046.58 yards.

MEASURE OF TIME.

	″	′	°
60 seconds = 1 minute			
60 minutes= 1 degree.	3600=	60.	
360 degrees = 1 circle.	1296000=	21600=	360

Sidereal day=23 h., 56 m., 4.092 sec., in solar or mean time.
Solar day, mean=24 h., 3 m., 56.555 sec.. in sidereal time.
Sidereal year, or revolution of the earth, 365.25635 solar days.
Solar, Equinoctial, or Calendar year, 365.24224 solar days.
1 day=.002739 of a year. | 1 minute=.000694 of a day.
30°=1 sign.

MEASURES OF SURFACE.

144 square inches =1 square foot.
9 square feet =1 square yard.
100 square feet =1 square (*Architect's Measure*).

Land.

		Yards.	*Rods.*	*Roods.*
30.25 square yards	= 1 square rod.	1210		
40 square rods	= 1 square rood.			
4 square roods / 10 square chains	= 1 acre.	4840 =	160.	
640 acres	= 1 square mile.	3097600 =	102400 =	2560.

208.710326 feet, 60.570109 yards, or 220 by 198 feet square=1 acre.

Paper.

24 sheets=1 quire. | 20 quires=1 ream.

Drawing Paper.

Cap	13 ×16 inches.	Columbia	23× 33.75 inches.
Demy	15.5 ×18.5 "	Atlas	26× 33 "

1 quarto = 8 "	1 eighteenmo =36 "
1 octavo =16 "	1 bundle =2 reams.

Roll of Parchment=60 sheets.

Dimensions of Drawings for Patents.

United States, 8.5×12 inches.

MEASURES OF VOLUME.

The Standard gallon measures 231 cubic inches, and contains 8.3388822 avoirdupois pounds, or 58373 troy grains of distilled water, at the temperature of its maximum density 39°.83, the barometer at 30 inches. The Standard bushel is the *Winchester*, which contains 2150.42 cubic inches, or 77.627413 lbs. avoirdupois of distilled water at its maximum density. Its dimensions are 18.5 inches diameter inside, 19.5 inches outside, and 8 inches deep; and when heaped, the cone must not be less than 6 inches high, equal 2747.715 cubic inches for a true cone.

Liquid.

		Gills. Pints.
4 gills	=1 pint.	8.
2 pints	=1 quart.	32 = 8.
4 quarts	=1 gallon.	

Dry.

		Pints. Quarts. Gallons.
2 pints	=1 quart.	8.
4 quarts	=1 gallon.	16 = 8.
2 gallons	=1 peck.	64 = 32 = 6.
4 pecks	=1 bushel.	

Cubic.

		Inches.
1728 cubic inches	=1 foot.	46656.
27 cubic feet	=1 yard.	

NOTE.—A cubic foot contains 2200 cylindrical inches, 3300 spherical inches, or 6600 conical inches.

Fluid.

		Minims. Drachms. Ounces.
60 minims	=1 drachm.	480.
6 drachms	=1 ounce.	7680 = 128.
16 ounces	=1 pint.	61240 = 1024 = 128.
8 pints	=1 gallon.	

Miscellaneous.

1 cubic foot . . . . 7.4805 gallons.
1 bushel . . . . 9.30918 gallons.
1 chaldron=36 bushels, or . . . . . 57.244 cubic feet.
1 cord of wood . . . . 128 cubic feet.
1 perch of stone . . . . 24.75 cubic feet.

1 quarter =8 bushels.	1 load hay or straw=36 trusses.
1 sack flour=5 bushels.	1 M quills =1200 quills.

MEASURES OF WEIGHT.

The Standard avoirdupois pound is the weight of 27.7015 cubic inches of distilled water weighed in air, at 39°.83, the barometer at 30 inches.

A cubic inch of such water weighs 252.6937 grains.

Avoirdupois.

		Drachms. Ounces. Pounds.
16 drachms	=1 ounce.	256.
16 ounces	=1 pound.	28672 = 1792.
112 pounds	=1 cwt.	573440 = 35840 = 2240.
20 cwt.	=1 ton.	

1 pound=14 oz. 11 dwts. 16 grs. troy, or 7000 grains.
1 ounce=18 dwts 5.5 grains troy, or 437.5 grains.

Troy.

		Grains. Dwt.
24 grains	=1 dwt.	480.
20 dwt.	=1 ounce.	5760 = 240.
12 ounces	=1 pound.	

7000 troy grains = 1 lb. avoirdupois.
437.5 troy grains = 1 oz. "
175 troy pounds =144 lbs. "
175 troy ounces =192 oz. "
1 troy pound = .822857 lb.
1 avoirdupois pound= 1.215278 lbs. troy.

Apothecaries.

		Grains. Scruples. Drachms.
20 grains	=1 scruple	60.
3 scruples	=1 drachm.	480 = 24.
8 drachms	=1 ounce.	5760 = 288 = 96.
12 ounces	=1 pound.	

45 drops =1 tea spoonful or a fluid drachm.
2 table spoonful=1 ounce.
The pound, ounce, and grain are the same as in Troy Weight.

Miscellaneous.

Coal and Wood per cubic feet.

	lbs.		*lbs.*
Anthracite, ordinary	50 to 55	Charcoal, hard-wood	18.5
Bituminous, ordinary . . .	45 to 55	Charcoal, pine-wood	18
Cumberland	53	Pine, Virginia	21
Cannel	50.3	Pine, Southern	25.5
1 ton Welsh coal .	=43 cubic feet.	1 ton Newcastle coal .	=45 cubic feet.

1 ton Scotch Coal . . . =43 cubic feet.

Lead.

1 fodder=8 pigs. Roll sheet lead=6.5 to 7.5 feet in width and from 30 to 35 feet in length.

MEASURES OF VALUE.

10 mills=1 cent.	10 dimes =1 dollar.
10 cents=1 dime.	10 dollars=1 eagle.

Standard of gold and silver 900 parts of pure metal and 100 of alloy in 1000 parts of coin.

Fineness expresses quantity of pure metal in 1000 parts.

Remedy of the Mint is allowance for deviation from exact standard fineness and weight of coins.

Nickel cent (old) contained 88 parts of copper and 12 of nickel.

The bronze cent contains 95 parts of copper and 5 of tin and zinc.

Pure gold, 23.22 grains=$1.00. Hence the value of an ounce is $20 67.183+.

Standard gold, $18 60.465+ per ounce.

GEOGRAPHICAL MEASURES AND DISTANCES.

To Reduce Longitude into Time.

RULE.—Multiply the degrees, minutes, and seconds by 4, and the product is the time.

To Reduce Time into Longitude.

RULE.—Reduce the hours to minutes and seconds, divide by 4, and the quotient is the longitude.

Or, multiply them by 15.

Table of Departures for a Distance run of 1 Mile.

Course.	*Departure.*	*Course.*	*Departure.*	*Course.*	*Departure.*
3.5 points.	.773	4.5 points.	.634	5.5 points.	.471
4. "	.707	5. "	.556	6. "	.383

Thus if a vessel holds a course of 4 points, that is, without leeway, for the distance of 1 mile, she will make .707 of a mile to windward.

Or, a vessel sailing E. N. E. upon a course of six points for 10 miles, will make 38 3 miles (100×383) longitude.

Table showing the Degrees, Minutes, and Seconds of each Point on the Mariner's Compass with the Meridian.

MISCELLANEOUS NOTES.

Natural Power.

Sun.—Power or work performed by Sun's evaporation is estimated at 90 000-000 000 horse-power.

Niagara.—Volume of water discharged over the Falls is estimated at 33 000 000 tons per hour; the fall of Niagara River from Lake Erie at Buffalo to face of Falls 65 feet, to foot of Falls 230, to Lake Ontario 330.

Heat of the Sun.

Sir Isaac Newton	3 138 740°	Soret	10 443 323°
Capt. John Ericsson	4 909 860°	Waterston	16 000 000°

Sundry others ranging from 2520° to 183 600°.

Frigorific Mixture.

Lowest temperature yet produced. Faraday obtained —160° by evaporation of a mixture of solid carbonic acid and sulphuric ether.

Light.

Light.—Sun's rays have a velocity of 185 000 miles per second, equal to 7.5 times around the earth.

Mirage.

A mirage is that condition of the atmosphere when air near to surface of earth becomes so highly heated, as upon a sandy plain, that its density within a defined distance from it increases upward. A ray directed obliquely downwards will be rendered by refraction more and more nearly horizontal, gradually increasing as it advances, until its direction is so great as to produce a total reflection; and the reflected ray then, by successive refractions, is gradually elevated until it meets the eye of an observer.

Looming is inverted mirage, frequently seen over calm water, and is the effect of lower or surface stratum of air being colder than that above it.

Colors for Drawing.

MATERIAL.	COLOR.	MATERIAL.	COLOR.
Brass	Gamboge	Granite	Indian ink, light.
Brick	Carmine.	Lead	Indian ink and Prussian blue.
Cast Iron	Neutral tint.	Steel	Light blue and lake.
Clay	Burned umber.	Water	Cobalt or verdigris
Earth	Burned umber, light.	Woods	Bur'd sienna, deep and light for dark and light wood
Concrete	Sepia with dark spots		
Copper	Lake and burned sienna	Wro't Iron	Prussian blue, light.

Tenacity of Iron Bolts in Wood.

Diameter 1.25 ins. and 12 ins. in length: required for Hemlock 8 tons and for Pine 6 tons to withdraw them.

Retaining Walls of Iron Piles.

Piles.—7 feet from centres, 18 ins. in width, and 2 ins. in thickness, strengthened with 2 *ribs* 8 ins. in depth

Plates.—7 feet in length by 5 feet in width and 1 in. in thickness, with 1 diagonal feather 1 by 6 ins.

Tie-rods 2 ins. in diameter.

Interception of Light by Glass.

Polished plate .25 in. thick, 13 per cent.; rough cast, 30; polished plate, rolled, 4 flutes per inch, 63; and sheet glass, 32 or 22.

Adhesion of Glue.

From 500 to 700 lbs. per sq. inch on wood.

Cost of Dredging

Actual cost if on an extended work, inclusive of delivery of dredging into or on a vessel at side of dredger. (*Trautwine*).

Labor at $1 per day and Repairs of Plant included.

NOTE.—The mean interval has been increased 12 hours 26 minutes (half a mean lunar day) for some of the ports in Delaware River and Chesapeake Bay, so as to give the succession of times from the mouth, hence 12 hours 26 minutes is to be subtracted from the establishments which are greater than that time, in order to give the interval required.

Bench Marks referred to in preceding Table.

† BOSTON.—The top of the wall or quay, at the entrance to the dry-dock in the Charlestown navy-yard, 14.76 feet above mean low-water.

‡ NEW YORK.—The lower edge of a straight line, cut in a stone wall, at the head of the wooden wharf on Governor's Island, 14.56 feet above mean low-water.

§ OLD POINT COMFORT, VA.—A line cut in the wall of the light-house, one foot from the ground, on the southwest side, 11 feet above mean low-water.

‖ CHARLESTON, S C.—The outer and lower edge of embrasure of gun No. 3, at Castle Pinckney, 10.13 feet above mean low-water.

Establishment of the Port for several Places not included in the preceding Table.

Earth Digging.

Number of Cubic Feet of Various Earths in a Ton.

Loose Earth 24	Clay 18.6	Clay with Gravel . . 14 4
Coarse Sand 18.6	Earth with Gravel . 17.8	Common Soil . . . 15.7

The volume of Earth and Sand in bank exceeds that in embankment in the following proportions:

Sand . . . . ½ | Clay . . . . ⅓ | Gravel . . . . $\frac{1}{12}$

and the volume of Rock in embankment quarried in large fragments exceeds that in bank fully one half.

MINING AND BLASTING.

MINING.

In ordinary Soil, $\frac{l^3}{10}$ *= charge of powder in pounds, l representing half the depth of the line of least resistance.*

In Masonry, $l^3 \times C$ *= charge in pounds; C representing a coefficient depending upon the structure.*

In a plane Wall, C=.15, in one with counterforts=2, and under a foundation when it is supported upon two sides=.4 to .6.

BLASTING.

In small blasts 1 lb. of powder will loosen about 4½ tons.

In large blasts 1 lb. of powder will loosen about 2¾ tons.

50 or 60 lbs. of powder, inclosed in a resisting bag, hung or propped up against a grate or barrier, will demolish any ordinary construction.

One man can bore, with a bit 1 inch in diameter, from 50 to 100 ins. per day of 10 hours in granite, or 300 to 400 ins. per day in limestone.

Two strikers and a holder can bore with a bit 2 inches in diameter 10 feet in a day in rock of medium hardness.

Rock Blasting.

The proper charge of powder for a blast is determined by dividing the cube of the line of least resistance in feet by 32. Thus, a line of 4 feet will require $4^3 \div 32 = \frac{64}{32} = 2$ *lbs.*; or, for every ton of rock to be removed there is required ½ lb. of powder.

A hole 1 inch in diameter will contain 5 oz. in each foot of its depth.

Examples.—What is the weight of a bar of iron 5¼ ins. in breadth by ¾ in. in thickness?

In column 7, page 756, find 5.¼; and below it, in column 5.¾; and opposite to that is 13.307, which is 13 lbs. and .307 of a pound.

For parts of a pound and of a foot, operate according to the rule laid down for table, page 756.

Note.—These Weights do not include any allowance for spigot and faucet ends.

CAST IRON.

To Compute the weight of a Cast Iron Bar or Rod.

Find the weight of a wrought iron bar or rod of the same dimensions in the preceding tables or by computation, and from the weight deduct the $\frac{2}{27}$th part; or,

As .1000 : .9257 : : the weight of a wrought bar or rod : to the weight required. Thus, what is the weight of a piece of cast iron 4 × 3.¾ × 12 inches?

In table, page 756, the weight of a piece of wrought iron of these dimensions is 50,692 lbs.

Then 1000 : .9257 : : 50,692 : 46.93 *lbs.*

To Compute the Weight of a piece of Cast or Wrought Iron of any Dimension or Form.

By the rules given in Mensuration of Solids (page 759), ascertain the number of cubic inches in the piece, then multiply by the weight of a cubic inch, and the product will give the weight in pounds.

Weights of Wrought Iron, Steel, Copper and Brass Plates.

SOFT ROLLED.

Thickness determined by American Gauge.

No. of Gauge	Thickness of each number.	*PLATES—per square foot.* Wrought Iron.	Steel.	Copper.	Brass.

SHEET LEAD.

Sheet Lead is designated by the weight of a square foot of it, and it usually ranges from $2\frac{1}{2}$ to 10 lbs. per square foot.

Weight of a Square Foot of Cast and Wrought Iron, Copper, Lead, Brass and Zinc.

From $\frac{1}{16}$ to 1 Inch in Thickness.

Application of the Table.

When the Thickness of the Metal is given in the Divisions of an Inch.

To the internal diameter of the tube or pipe add the thickness of the metal; take the area of a plate in square feet, from the table for a diameter equal to the sum of the diameter and thickness of the tube or pipe, and multiply it by the weight of a square foot of the metal for the given thickness (see tables, page 757), and again by its length in feet.

When the Thickness of the Metal is given in Numbers of a Wire Gauge.

To the internal diameter of the tube or pipe add the thickness of the number from table, page 757; multiply the sum by 3.1416, divide the product by 12, and the quotient will give the area of the plate in square feet. Then proceed as before given.

ROPES, HAWSERS AND CABLES.

Ropes of hemp fibres are laid with three or four strands of twisted fibres, and run up to a circumference of 12 inches.

Hawsers are laid with three strands of rope, or with four rope strands.

Cables are laid with three strands of rope only.

Tarred ropes, hawsers, etc., have 25 *per centum* less strength than white ropes; this is in consequence of the injury the fibres receive from the high temperature of the tar $=290^{\circ}$.

Tarred hemp and Manilla ropes are of about equal strength. Manilla ropes have from 25 to 30 *per centum* less strength than white ropes.

Hawsers and cables, from having a less proportionate number of fibres and from the increased irregularity of the resistance of the fibres, have less strength than ropes, the difference varying from 35 to 45 *per centum*, being greatest with the least circumference.

Ropes of four strands up to 8 inches are fully 16 *per centum* stronger than those having but three strands.

Hawsers and cables of three strands up to 12 inches are fully 10 *per centum* stronger than those having four strands.

The absorption of tar in weight by the several ropes is as follows:

Bolt rope . . . . . 18 *per centum.*	Cables . . . . 21 *per centum.*
Shrouding . . 15 to 18 "	Spun yarn . . 25 to 30 "

White ropes are more durable than tarred.

The greater the degree of twisting given to the fibres of a rope, etc., the less its strength, as the exterior alone resists the greater portion of the strain.

To Compute the Strain that can be borne with safety by new Ropes, Hawsers, and Cables.

Deduced from the experiments of the Russian Government upon the relative strength of different Circumferences of Ropes, Hawsers, etc.

The U. S. Navy test is 4200 lbs. for a White rope of three strands of best Riga hemp, of $1\frac{3}{4}$ inches in circumference (=17000 lbs. per square inch), but in the following table 14000 lbs. is taken as the unit of strain that can be borne with safety.

RULE.—Square the circumference of the rope, hawser, etc., and multiply it by the following units for ordinary ropes, etc.

Table showing the Units for computing the safe strain that may be borne by Ropes, Hawsers, and Cables.

Description.	Ropes.				Hawsers.		Cables.	
	White.		Tarred.		White	Tar'd	White	Tar'd

" " 18 " 26 "	. . .	. . .	. . .	. . .	. . .	. .	560	. .

When it is required to ascertain the weight or strain that can be borne by ropes, etc., in general use. The above Units should be reduced *one-third*, in order to meet the reduction of their strength by chafing and exposure to the weather.

Ex. 2. What is the weight that can be borne by a tarred hawser 10 inches in circumference, in *general use?*

$$10^2\times\left(505-\frac{505}{3}\right)=100\times336.7=33667 \ lbs.$$

To Compute the Circumference of a Rope, Hawser, or Cable for a Given Strain.

RULE.—Divide the strain in pounds by the appropriate units in the above table and the square root of the product will give the circumference of the rope, etc., in inches.

EXAMPLE.—The stress to be borne in safety is 165550 lbs.; what should be the circumference of a tarred cable to withstand it?

$165552\div550=301$, and $\div301=17.35$, say $17\frac{3}{8}$ *ins.*

Ex. 2. What should be the circumference of a Manila cable to withstand a strain, in general use, of 149336 lbs.?

Assuming the circumference to exceed 18 ins., the unit=560.

$$149336\div\left(560-\frac{560}{3}\right)=149336\div373.34=400, \text{ and}\div400=20 \ ins.$$

WIRE ROPE.

Wire rope of the same strength as new *Hemp rope* will run on the same-sized sheaves, but the greater the diameter of the sheaves, the longer it will wear. Short bends should be avoided, and the wear increases with the speed. It is better to increase load rather than speed. The adhesion is the same as that of hemp rope.

Wire rope should not be coiled, or uncoiled like hemp rope, but should be wound upon a reel.

When substituting wire rope for hemp rope, it is well to allow for the former the same weight per foot which experience has approved of for the latter. As a general rule one wire rope will outlast three hemp ropes. To guard against rust, stationary rope should be oiled once a year with linseed-oil, or kept well painted or tarred. Running rope, while in use, requires no protection.

Where great pliability is required, the centre or core of wire rope is made of hemp, and small-sized rope is generally made with hemp centres.

Running rope is made of fine wire, and standing rope of coarse wire.

Wire rope made from charcoal made iron is fully one-fourth stronger than the ordinary rope.

The standing rigging of a vessel when composed of wire rope is one-fourth less in weight than when of hemp.

Results of an Experiment with Galvanized Wire.

A strand of 2-inch wire rope broke with a strain of 13564 lbs., and a piece of a like rope, when galvanized, withstood a strain of 14796 lbs. before breaking.

Proof and Breaking Strain of Chain Cables.

Diameter of Chain.	Proved.	Breaking Strain	Diameter of Chain.	Proved.	Breaking Strain
Ins.	*Lbs.*	*Lbs.*	*Ins.*	*Lbs.*	*Lbs.*

In the above table the determination of the circumference of the rope. etc., is based upon the Breaking Weight or Tensile resistance of the wire being reduced by one-fourth, and the *units* or the ultimate resistance of the rope, etc., are reduced one-third.

In the U. S. Navy the relative dimensions of Hemp Cable and of Wire Rope are as follows:

Circumference in inches.

Hemp	3,	4,	5,	5½,	6,	6¾,	7¼,	8,	9,	10,	10½,	11,	12
Wire	1⅝,	2⅛,	2¾,	3,	3¼,	3⅝,	4,	4⅜,	4⅞,	5½,	5¾,	6,	6½

Note.—The difference between the dimensions of the wire rope here given and in the preceding table, of one-fourth in area, is in consequence of the high estimate of strength given to the hemp rope made in the U. S. Service.

The circumferences given are for Tarred ropes, etc., alone; if, therefore, the circumferences for White and Manila ropes are required, proceed as follows:

To Compute the Circumference of a White or Manila Rope, Hawser, or Cable, compared with one of Tarred Hemp.

Rule.—Multiply the square of the circumference of the given rope by the unit for the circumference, from the table, see below, divide the product by the unit for the circumference of the rope etc., required, and the square root of the product will give the circumference required.

Note.—If the circumference is required for a rope in general use, reduce the units in the table one-third.

Illustration.—Required the circumference for a white rope and a Manila hawser, for general use—equivalent to a tarred rope of three strands, and 9½ inches in circumference.

Units of tarred rope of 9½ ins.= 780—⅓=520.
Units of white rope of about 9½ ins.=1045—⅓=697.
Units of Manila hawser of about 9½ ins.= 760—⅓=507.

Then $9.5^2 \times 520 = 46030$, which $\div 697 = 67.33$, and $\div 67.33 = 8.2$, say 8¼ *ins.* for the white rope.

Again, $9.5^2 \times 520 = 46930$, which $\div 507 = 92.56$, and $\div 92.56 = 9.62$, say 9⅝ *ins.* for the Manila hawser.

To Compute the Weight of Ropes, Hawsers, and Cables.

Rule.—Square the circumference, and multiply it by the appropriate unit in the following table, and the product will give the weight per foot in pounds:

	Ropes.	Hawsers.	Cables.
3-strand Hemp	.032	.031	.031
3-strand tarred Hemp	.042	.041	.041
3-strand Manila	.032	.031	.031
4-strand Hemp	.033	. .	. .
4-strand tarred Hemp	.048	. .	. .
4-strand Manila	.035	.034	.034

The units for Thread Ropes is the same as that for Ropes of like material.

SOLIDS.

Rule.—Divide the specific gravity of the substance by 16, and the quotient will give the weight of a cubic foot of it in pounds.

In the Scour of water-course Beds.

¼ ft. per second will scour fine clay.
½ " " " " sand.
¾ " " " coarse sand.
1 " " " fine gravel.
2 ft. per second will scour round shingle 1 in. diam.
3 ft. " " angular stone, size of an egg.
3 ft. " " conglomerate.

Value of Gold according to fineness.—Pure gold, 1000 fine, is worth \$20.67 per oz.; gold 500 fine, is worth \$10.33; 600 fine, \$12.40; 700 fine, \$14.49; 800 fine, \$16.53; 900 fine, \$18.60. At the mint in San Francisco, the charge for melting, assaying and refining is 14 cents per oz. The charge for coining is ½ per cent. No deposits are received at the mint in less sums than \$100. The value of a ton of pure gold is \$602,799.21. The value of a ton of silver is \$37,704.84. The weight of \$1,000,000 in gold coin is 3,685.8 lbs. avoirdupois. The weight of \$1,000,000 in silver coin is 58,929.9 lbs. avoirdupois. For other facts relating to the weight of the precious metals consult pp. 762.

Phillips gives the following rule for ascertaining the amount of gold in a lump of auriferous quartz:

"The specific gravity of the gold—19,000.

"The specific gravity of the quartz—2,600.

"These numbers are given here merely for convenience in explaining the rule; they do not accurately represent the specific gravities of all quartz and quartz gold. (The quartz gold of California has not, on an average, a specific gravity of more than 18,600.)

"1. Ascertain the specific gravity of the lump. Suppose it to be 8,067.

"2. Deduct the specific gravity of the lump from the specific gravity of the gold; the difference is the ratio of the quartz by volume: 19,000—8,067 = 10,933.

"3. Deduct the specific gravity of the quartz from the specific gravity of the lump; the difference is the ratio of the gold by volume: 8,067—2,600 = 5,467.

"4. Add these ratios together, and proceed by the rule of proportion. The product is the percentage of gold by bulk: 10,933+5,467=16,400. Then as 16,400 is to 5,467, so is 100 to 33,35.

"5. Multiply the percentage of gold by bulk by its specific gravity. The product is the ratio of the gold in the lump by weight: 33,35×19,00=643,65.

"6. Multiply the percentage of quartz by bulk (which must be 66,65 since that of the gold is 33,35) by its specific gravity. The product is the ratio of the quartz in the lump by weight: 66,65×2,60=173,29.

"7. To find the percentage, add these two ratios together, and proceed by the rule of proportion: 633,65+173,29=806,94. Then, as 806,94 is to 633,65, so is 100 to 78,63. Hence, a lump of auriferous quartz, having a specific gravity of 8,067, contains 78,73 per cent. of gold, by weight.

Mr. Black, of San Francisco, estimates that in mining operations the average cost of handling a cubic yard of auriferous gravel with the pan is $20; with the rocker, $5; with the long tom, $1; and with the hydraulic process, 20c.

Stowage of Coals.—The following information will be valuable to many coal dealers and consumers who may be in doubt as to the capacity of their coal bins. A box 4 feet long, 3 ft. 5 in. wide, and 2 ft. 8 ins. deep, has a capacity of 36½ cubic feet, and will contain 2000 lbs. or one ton of Beaver Meadow or Lehigh (American) coal. The spaces occupied by one ton of the undermentioned English coals, economic weight are:—Haswell's Wallsend, 45·25 cubic feet. North Percy, Hartley (Newcastle) 46·93 cubic feet. Balcarras Arley (Lancashire) 44·35 cubic feet. Cannel (Wigan, Lancashire) 46·37 cubic feet. Duffryn (Welsh) 42·09 cubic feet. Pontypool (Welsh) 40·22 cubic feet. Hence, a shed 16 feet high, 20 feet broad, and 30 feet long, will hold over 212 tons of Haswell's Wallsend (Newcastle) coals, about 207 tons of Cannel, and 228 of Duffryn. The *average* space occupied by one ton of Newcastle coal, economic weight, is 44 cubic feet, that of one ton of Lancashire coal, 44½ cubic feet, and that of 1 ton of Welsh coal, 41 cubic feet. Therefore a shed of the above dimensions, would, on the average, hold 217 tons of Newcastle coal, 216 of Lancashire, and 234 of Welsh. From the above data, any intending purchaser can easily calculate the capacity of his coal bins, sheds, &c., and in many cases secure a good bargain by laying in a large stock when coals are cheap.

Explosive force of various substances used for Fire Arms, Artillery, Blasting, &c.

Gun Cotton	590	0.801 "	472
Picric Acid	687	0.780 "	536
Picrate Potash	578	0.585 "	680
Gun Cotton mixed with Chl. Potash	1420	0.484 "	680
Picric Acid " " "	1424	0.408 "	582
Picrate " " "	1422	0.337 "	478
Nitro-Glycerin	4320	0.710 "	939

The above instructive table is by the celebrated M. Berthelot, who further describes nitro-glycerin as "really the ideal of portable force. It burns completely without residue; in fact, gives an excess of oxygen; it develops twice as much heat as powder, three and a half times more gas, and has seven times the explosive force, weight for weight, and, taken volume for volume, it possesses twelve times more energy." From the extreme danger of the work, none but competent chemists should attempt to manufacture it.

Effects of heat on various bodies:

Fine Gold melts	2590°	Heat, cherry red	1500°
" Silver "	1250	" bright "	1860
Copper melts	2548	" red visible by day	1077
Wrought Iron melts	3980	" white	2900
Cast " "	3479	Mercury boils	662
Bright red " in the dark	752	" volatilizes	680
Red hot " in twilight	884	Platinum melts	3080
Glass melts	2377	Zinc melts	740
Common fire	790	Highest natural temperature (Egypt),	117
Brass melts	1900	Greatest natural cold (below zero)	56
Air furnace	3300	" artificial " "	106
Antimony melts	951	Heat of human blood	98
Bismuth "	476	Snow and Salt, equal parts	0
Cadmium	600	Ice melts	32
Steel	2500	Water in *vacuo* boils	98
Lead	504	Furnace under steam boiler	1100
Tin	421		

Shrinkage of Castings.

Iron, small cylind's=1-16th in. per ft	Ditto, in length . . ⅛ in 16 ins.
" Pipes . . . . =⅛ " " ft.	Brass, thin . . . . = ⅙ in 9 "
" Girders, beams, etc. . . . . . . =⅛ in. in 15 ins.	Brass, thick . . . ⅛ in 10 "
" Large cylinders, the contraction of diameter at top . . . . =1-16th per foot.	Zinc . . . . . . =5-16ths in a foot.
Ditto at bottom . . =1-12th per foot.	Lead . . . . . = 5-16ths " "
	Copper . . . . . = 3-16ths " "
	Bismuth . . . . = 5-32nds " "

Green sand iron castings are 6 per cent. stronger than dry, and 30 per cent. stronger than chilled, but when the castings are chilled and annealed, a gain of 115 per cent. is attained over those made in green sand. Chilling the under side of cast iron very materially increases its strength.

WEIGHTS AND MEASURES OF COAL.

In the United States, by the tariff act of 1872, coal is computed at 28 bushels per ton of 2340 pounds, 80 pounds to the bushel. In Pennsylvania 2000 pounds is a ton. In most of the States coal is sold at 2000 pounds to the ton.

In Great Britain a ton is 2240 pounds.
In France 1000 kilogrammes make a ton of 2204.86 pounds.
In Belgium the French ton is the standard.
In Austria 18.14 centuers of 123½ pounds make a ton.
In Spain 14.45 quintals of 155 pounds make a ton.
In Russia 62.22 hords of 36 pounds make a ton.

The following gives the number of cubic feet in a loose ton of coal of the districts named:

BITUMINOUS.	*Cubic feet.*
Cumberland, maximum	42.3
" maximum	41.2
Duffruyn, (Welsh)	42.99

Pictou and Sydney	8,000
Pine Wood	11,800
Pittsburgh Coal	9,520

ALLOYS.—The substances produced by the intimate intermixture of metals are sometimes of the nature of distinct chemical compounds, their formation being accompanied by considerable heat-development and their composition being expressible by definite formulæ. In most cases, however, they partake more of the nature of simple mixtures, or of homogeneous solutions converted into the solid state without the separation of particles, differing from one another in physical and chemical nature, of sufficient magnitude to be discernible by a microscope. Nevertheless the formation of these bodies in almost every instance is fairly included in the term "chemical action," according to the usual definition that "chemical action takes place when the properties of the resultant substances are different from those of the original bodies;" for, save in comparatively few instances, the physical and often the chemical properties of an alloy are different from the arithmetical average of those of its components. Thus, according to Matthiessen, all metals excepting zinc, lead, tin, and cadmium, yield alloys, the physical properties of which are not in the proportions calculable from those of the constituents. The physical properties of specific gravity, specific heat, and expansibility are never greatly different in alloys (no matter what the constituents) from those calculable from the constitution; but the properties of fusibility, crystalline form, conductivity for heat, electricity, and sound, elasticity, tenacity, &c., are invariably considerably different from those calculable from the composition (save only alloys containing no constituents other than zinc, tin, lead, or cadmium). The following tables give a general idea of the average composition of many of the more important alloys in common use for various purposes.

In many instances the precise combination of metals employed for any particular purpose is regarded as a valuable trade secret by the manufacturer, so that the product preferred by one is not necessarily identical with that used by another. Thus, the character of the alloys pewter, Britannia metal, and the like, vary with the manufacturer, and the purpose for which the alloy is intended, &c.; the pewter for tankards (hard pewter) and that employed for covering over public-house bars, &c. (counter metal,) are generally prepared by adding to the tin which forms the basis different amounts of other metals (lead, antimony, bismuth) constituting what is termed "temper." Similarly very different "tempers" are employed to add to tin to form "Britannia metal," "Queen's metal," &c., by different manufacturers; whilst the exact composition of bell-metal is subject to considerable variations according to the size of the bell, &c.

In the practical manufacture of alloys, as a general rule, the materials are melted, (either separately or together), well incorporated, and then cast into ingots or such other form as may be required; some few alloys, however, are prepared in other ways; for example, brass may be obtained by heating copper-plates with a mixture of calamine and small coal, which gives off zinc in the form of vapor; this zinc is absorbed by the copper and retained by it much as a sheet of gold heated over mercury absorbs the mercurial vapor and becomes whitened in consequence. Certain alloys are obtained directly from complex ores, *e.g., spiegeleisen.* The standard alloys used for coinage are prepared by incorporating together the right quantities of the ingredients and casting into bars which are rolled into ribbons of the requisite thickness for the kind of coin required, the degree of thickness being judged by punching out discs or "blanks" and weighing them. When the sheet has been rolled to the requisite extent blanks are punched out by machinery, and are then (after undergoing softening, annealing, and other processes) stamped in the coining press, and passed through a machine which weighs and sorts the coins into those of the just weight (or rather which fall within a slight difference from the true weight, termed the "remedy"), those which are too light and those which are too heavy. These incorrect pieces are melted up again and the metal employed a second time. Great care must be taken in the selection of the copper used for alloying with the gold or silver, and also purity of the precious metal employed is essential, as minute quantities of foreign metals in the coinage-alloy impair its softness, and either prevent it from rolling or taking the impression from the dies, or render it brittle.

The verification of the correctness of the mixture of metals employed (*assaying*) is a most important part of minting operations. In the case of gold coins the process employed depends on the circumstances that whilst neither gold nor silver will oxidize in hot air, other metals, especially in presence of a certain quantity of lead, will do so, so that a separation of precious and common metals may be thus effected with due precautions; also that from an alloy of gold and silver containing not less than two or three parts of silver to one of gold hot nitric acid will dissolve out the silver, leaving behind the whole of the gold (*Quartation*). The metal to be assayed is accurately weighed, pure silver to the extent of two or three times its weight added, and the whole rolled up in a piece of pure sheet lead weighing from six to ten times the amount of gold present (the quantity of lead varying with the amount of foreign alloy). The whole is then heated in a "cupel" (made of bone-ash compressed in a mould) placed in a "muffle," by a furnace. The fused mass oxidises on the surface, the lead, whilst oxidising, causing copper and other base metals present to oxidise too; the fused oxides are absorbed by the porous cupel and finally a button of pure gold and silver is left. This is rolled out into a ribbon, annealed, twisted up into a "cornet" and acted on by hot nitric acid, whereby the silver is dissolved out and the pure gold left. After annealing, the residual gold cornet is weighed, and thus the weight of gold present known. If silver be also present, another portion is cupelled with lead without the addition of pure silver; the difference between the weight of the button thus obtained and the pure gold previously found representing the silver present. Silver alloys may be similarly cupelled with lead; or may be dissolved in nitric acid, and the silver estimated by precipitation with a soluble chloride, the silver chloride thrown down being collected and weighed, or else the bulk of a chloride solution of known strength required to completely precipitate the silver being noted.

Certain of the metals and alloys commonly used for household and other purposes, give rise, by their corrosion, to poisonous substances; and in consequence the contact of articles made of such materials with alimentary products not unfrequently gives rise to illness, and sometimes produces fatal results. Lead, copper, and zinc are the metals most injurious in this respect, especially the first. When most kinds of drinking-water are allowed to stand in leaden pipes or cisterns a certain amount of the noxious metal is taken into solution, or becomes suspended in the water; wherefore, whenever water is drawn from a housepipe for drinking purposes the portion which first runs out should be rejected as being liable to contain lead from the pipe; whilst no water from lead cisterns should ever be used for culinary or potable purposes. Tinned meats, fruits, and the like, are apt to contain lead from the presence of that metal in the impure tin used in making the tinplate canisters, or from that in the soldering junctions. Beer, &c., that has stood in the tubes of a beer-engine all night is apt to contain lead, and cases of lead-poisoning are on record from the continued use of the ale first drawn in the morning. Similarly soda-water, and aërated waters generally, as well as artificially prepared sparkling wines, (more commonly met with than is supposed), are apt to contain lead from the aërating apparatus, whilst pickles, &c., sometimes contain it from the pewter capsule of the bottles in which they are sold. Brass and copper stew-pans occasionally become verdigrised, whilst preserved peas, pickles, and the like, are often purposely treated with copper compounds to improve the color. For the same reason many cooks habitually boil greens for the table with a rusty pennypiece or brass or copper bolt, etc. Acid or saccharine liquids sometimes act on galvanized iron vessels, taking up zinc therefrom. In order to diminish some of these risks, tubes are now manufactured for water supply, beer-engines, and the like, in which the outside portion of the pipe is composed of lead, but the internal lining is of pure block tin, so that liquids passing through such pipes cannot take up lead unless the tin lining be first eaten through, which is unlikely in most cases, from the less tendency to oxidise and rust exhibited by tin. Even tin, however, is not always free from objection on the score of corrosion under certain circumstances, and consequent impregnation of food with deleterious metallic compounds; the author has recently met with instances of this action in the case of preserved fruits, etc., put up in ordinary tinned canisters; an unpleasant metallic taste was noticeable, and on analysis considerable amounts of *tin* were detected in solution in the juice, besides iron from the underlaying metal of the tinplate; in one case, violent colic and diarrhœa lasting for several hours, was produced in the persons partaking of the preserved fruits; this corrosive action on tin has only been noticed as yet in the case of very *acid* fruits, etc., such as apples and rhubarb.

COMPOSITION OF BRONZE FOR MACHINERY.

Below will be found the composition of alloys approved of and used by prominent French mechanics in government and railway work.

FRENCH MARINE.	*Copper.*	*Tin.*	*Zinc.*
Tough bronze for rods, valves, etc.,	88	12	2
Very tough bronze for eccentric straps, etc	90	10	2
Bronze for plummer blocks	86	14	2
Hard bronze	84	16	2
Very hard bronze for steam brass-cocks	82	18	2
Bell bronze	78	22	0
Anti-friction bronze, with 8 parts antimony	4	96	0
FRENCH RAILROADS.			
Car pillows	82	18	2
Locomotive and tender oil boxes	84	16	2
" slide valves	82	18	2
Cocks	88	12	2

The bronze composed of eighty-six copper, fourteen tin, and two zinc, is least porous, and therefore is most suitable when pressure is to be resisted.

—*Compiled from "Metals and their Chief Industrial Applications, by C. R. A. Wright, D. Sc."*

VALUE OF BARS.

Large bullion scales, and troy weights, are not always at hand; yet it is often desirable to know the value of a bar before sending it from the works, and as good counter scales, with avoirdupois weights, are generally accessible, the following facts may be found useful.

The assay value of one avoirdupois pound of pure silver is $18.85; that of one avoirdupois ounce is $1.17. The pound of pure gold is worth $301.44, and the ounce $18.84. Hence it is easy to calculate the value of a bar of which the fineness is known, and which has been weighed on common counter scales to the nearest quarter ounce. For example, a silver bar is .969 fine, and weighs 82 lbs. 3¼ ounces.

Then : $18.85 × .969 = $18.26 × 82 = $1,497.32
and 1.17 × .969 = 1.13 × 3¼ = 3.67

Making the value of the bar $1,500.99

Each 1-1000th of silver in a bar is worth 1.885 cents, and each 1-1000th of gold 30.14 cents per avoirdupois pound; therefore, if in the above example the bar contained also a little gold, say .003, and perfect accuracy is not required, it would be sufficient to add to the value 3 times 30.14 cents for each pound weight, or in all $74.14. Again, a gold bar is .969 fine and weighs 7 lbs. 13½ ounces, or 125½ ounces; then 18.84×.969 =18.26×125½=$2,291.63. Or, the value of a gold bar may be calculated as though it were silver, and the result multiplied by 16.

The commercial or market value is different from the assay value. The discount on silver varies from 10 per cent. to 15 per cent. of the assay value, to which is added ½ of 1 per cent. for mintage, or assayer's fee. Gold bars free from base metal are subject to a discount or a premium, equal to 1.10 of one per cent. for every 10 "points," or thousandths, above or below the quoted par fineness; discount if above, premium if below. The apparent anomaly is due to the fact that, if there is no base metal in the bar, all that is not gold is silver, whence, at par fineness, there is just enough of silver in the bar to pay parting charges, etc., while in a finer bar those charges must be met by a discount on the value of the gold. Conversely, a bar which is below par fineness commands a premium for the extra silver it contains. On account of this arrangement, bars which are more than half gold are stamped with the gold value only, unless they contain much base metal, when both gold and silver value is stamped on them. These facts we take from Aaron's "Leaching of Gold and Silver Ores," for sale by Dewey & Co.

Mixed bars, in which the gold forms a large part of the value, but less than half the weight, are called "dore" bars, and are stamped with the value of both the gold and the silver.

ATMOSPHERIC AIR.

The volume of carbonic acid gas given off daily by human respiration averages 4.08 per cent. of the air respired.

In twenty-four hours a man gives off 10.7 cubic feet of carbonic acid gas, and receives from the atmosphere the same volume of oxygen.

An ordinary sized candle consumes as much oxygen, during combustion, as the respiration of a man.

The volume of pure air required for the respiration of a man in twenty-four hours is 266 cubic feet.

A miner's lamp will not burn in an atmosphere containing 3 per cent. of carbonic acid gas. The miner himself will live for several hours after his lamp becomes extinguished.

One cubic foot of air at the surface of the earth, with the barometer at 30 degrees and the thermometer at 34 degrees, weighs 527.04 grains, and is 829.43 times lighter than water.

The mean weight of a column of air a foot square, at the level of the sea, is 2120.14 pounds, and is equal to the support of 33.95 feet of water.

Thirteen thousand eight hundred and seventeen feet of air weigh a pound avoirdupois.

Air contains 21 parts of oxygen and 79 parts of nitrogen by volume, and in 1000 parts there are 4.9 parts of carbonic acid gas.

The rate of expansion of air and all elastic fluids for all temperatures is uniform. From 32 degrees to 212 degrees they expand from 1000 to 1376, equal to $\frac{1}{478}$ for each degree of their bulk for every degree of heat applied.

CARBONIC ACID GAS.

The difference in constitution and temperament of individuals makes it impossible that any exact rule should be laid down as to the precise quantity of carbonic acid which may be present in the air without injury to respiration, but it may be safely asserted that it is not advisable to breathe for any length of time in air containing more than ($\frac{1}{1000}$) one-tenth of one per cent. of its volume of carbonic acid.

There appears to be no immediate danger, however, until the carbonic acid amounts to one-two-hundredths, or five-tenths of one per cent., when most persons are attacked by languor and headache, attending the action of this gas A larger proportion of carbonic produces insensibility, and air containing one-hundredth of its volume of carbonic causes suffocation.

WATER.

Water contains 88.9 parts of oxygen and 11.1 parts of hydrogen, by weight, and 1 part of oxygen and 2 parts of hydrogen, by measure.

One cubic inch of distilled water at its maximum density of 39.83 degrees, and the barometer at 30 inches weighs 252.6839 grains. A cubic foot weighs 62.37925 pounds avoirdupois. For facility of computation a cubic foot of water is taken at 62½ pounds. The standard gallon of water, contains 231 cubic inches and weighs 8.3388822 pounds avoirdupois. The British imperial gallon measures 277.274 cubic inches and weighs 10 pounds.

35.84 cubic feet of water weigh a ton.

39.13 cubic feet of ice weigh a ton.

34.83 cubic feet of sea water weigh a ton.

COMBUSTION OF COAL.

The constituents of coal are carbon, hydrogen, azote and oxygen.

The volatile products of the combustion of coal are hydrogen and carbon, the union of which relating to combustion in a furnace are carbureted hydrogen and bi-carbureted hydrogen or olefiant gas, which upon combining with atmospheric air becomes carbonic acid or carbonic oxide, steam and uncombined nitrogen.

Carbonic oxide is the result of imperfect combustion, and carbonic acid of perfect combustion. The perfect combustion of carbon evolves heat as 15 to 4.55 compared with the imperfect of it, as when carbonic oxide is produced 1 pound of carbon combines with 2.66 pounds of oxygen, and produces 3.66 pounds of carbonic acid.

Weight of a cubic foot of Coal after it has been mined and broken up.

Anthracite, (Peach Mountain)	53.79 pounds.
Semi-bituminous, (Frostburgh)	53 "
" " (Blossburgh)	53 "
Bituminous, (Newcastle)	50.82 "
" (Pictou)	49.25 "
" (Pittsburgh)	46.81 "
Cannel, (Wigan)	48.03 "

The average weight of a cubic foot of solid coal is 83 pounds. It contains 1728 cubic inches. One cubic yard of solid coal (27 cubic feet) weighs 2240 pounds—1 ton—and contains 46656 cubic inches.

A bushel of loose coal, of 80 pounds, contains 2688 cubic inches. A bushel of 75 pounds contains 2520 cubic inches.

METRICAL ABBREVIATIONS.

It may interest our readers to know that the following abbreviations for metrical units have recently been decreed by the Spanish Government for Spain and its colonies:

Kilometer	km.	Cubic decimeter	dm³.
Meter	m.	Cubic centimeter	cm³.
Decimeter	dm.	Cubic millimeter	mm³
Centimeter	cm.	Hectoliter	hl.
Millimeter	mm	Decaliter	dal.
1-1000 millimeter	m.	Liter	l.
Square kilometer	km².	Deciliter	dl.
Hectare	ha.	Centiliter	cl.
Are	a.	Ton	t.
Square meter	m²	Metrical cwt	q.
Square decimeter	dm².	Kilogram	kg.
Square centimeter	cm².	Gram	g.
Square millimeter	mm².	Decigram	dg.
{Stere	S.	Centigram	cg.
{Cubic meter	m³.	Milligram	mg.

RECKONING QUANTITY OF COAL IN PLACE.

A summary way of reckoning the quantity of available coal in a given area of a seam is to take an acre of coal one inch thick to contain 100 tons; this leaves a sufficient margin for faults and loss in working.

Example: A seam of coal 24 inches thick will yield 2,400 tons per acre. But to ascertain the exact quantity of coal under a given area—presuming the seam to be lying of regular thickness and quality throughout—the first thing necessary is to obtain the specific gravity; then, as this represents the weight of a cubic foot in ounces, it is a simple matter of calculation to obtain the gross weight.

The exact weight of coal seams can be got from the table below:

Specific gravity.	*Weight in the natural bed, per acre, pe inch thick, in tons.*	*Weight of a cubic foot in the broken state. in lbs.*	
		Large coal.	*Small coal.*
1.10	111.411	43.62	37 12
1.15	116.475	44.56	38.81
1.20	121.540	46.50	40.50
1.25	126.604	48.43	42.18
1.30	131.668	50.37	43.87
1.35	136.732	52.31	45.56
1.40	142.796	54.25	47.25
1.45	146.860	56.18	48.93
1.50	151.925	58.12	50.62

If the figures in the second column be multiplied by the number of inches any coal seam is in thickness, the result will be the contents in tons per acre.

The weight of coal in its broken state, that is, as it comes to the surface in tubs or otherwise, will depend on its mechanical structure; it has here been computed to weigh in proportion to the solid coal as 62 is to 100, and the weight of the small as 54 is to 100.

RULES FOR THE PREPARATION OF ALLOYS OF A GIVEN FINENESS.

Manufacturers of silverware may obtain an alloy of silver of any desired fineness in melting fine silver with silver of an inferior quality by observing the following rules:[1]

Obtain the difference between the two higher finenesses and divide by the difference between the two lower; the quotient indicates the number of ounces of the silver to be raised in fineness, which are required to be added to one ounce of fine silver.

Example.—Required to raise a quantity of silver of the fineness of $\frac{867}{1000}$ to $\frac{900}{1000}$ by the mixture with it of fine silver at $\frac{999}{1000}$.

Difference between the two higher finenesses $\frac{99}{1000}$. Difference between two lower finenesses $\frac{33}{1000}$. 99÷33=3. From this it appears that one ounce of fine silver at $\frac{999}{1000}$ will raise the fineness of three ounces of silver at $\frac{867}{1000}$, so that the compound will consist of four ounces at $\frac{900}{1000}$.

MODE OF VALUATION.

According to law, the standard gold of the United States consists in 1000 parts by weight, of 900 of pure gold and 100 of an alloy composed of copper and silver.

[1] This and the following rules are extracted by special permission from the "Bullion dealers' Guide," by George W. Edelman, which contains many valuable tables useful to dealers in the precious metals.

Three hundred and eighty-seven ounces of pure gold are worth $8,000, and 99 ounces of pure silver are worth $128. These relations furnish the following proportions, from which are readily derived the subjoined rules:

For Gold.—As 1000 : $\frac{8000}{387}$, or as 99,000 : 128 : : the given weight multiplied by its particular fineness in thousandths: the value of said weight.

For Silver.—As 1000 : $\frac{128}{99}$, or as 387 : 8 : : the given weight multiplied by its particular fineness in thousandths : the value of said weight.

RULES.

To find the value in the United States money of any number of troy ounces of gold or silver, the weight and fineness being given:

For Gold.—Multiply the given weight by the fineness and by 8, and divide the product by 387.

For Silver.—Multiply the given weight by the fineness and by 128, and divide the product by 99,000.

SHORT METHODS OF CALCULATION.

FOR GOLD.—1. *To Convert Weight into Value.*—Multiply the weight by double the fineness, add to the product $\frac{1}{30}$ thereof, plus $\frac{1}{129}$ of the $\frac{1}{30}$ the answer will be in cents.

Example.—What is the value of 1,258 ounces at 774 thousandths?

	1258 × 1548 =	19473.81
	$\frac{1}{30}$	649.128
	$\frac{1}{129}$	5.032
Answer:		$20,128.00

By this rule the value of one ounce of gold, of any fineness, may be readily determined.

Example.—What is the value of 1 ounce at 658½ thousandths?

	658½ × 2 =	1317.
	$\frac{1}{30}$	43 9
	$\frac{1}{129}$	.34
Answer:		$13.6124

The division by 129 being somewhat difficult, it will be found sufficiently accurate, in most cases, to divide by 130.

2. *To Convert Value into Standard Weight.*—Divide the value in dollars by 20, this quotient by 20, and the second quotient by 2, add the three quotients together; the answer will be in standard ounces.

Example.—What is the weight in standard ounces of $154,686 56?

	20)	154686.56
	20)	7734.328
	2)	386.7164
		193.3582
Answer:		8314.4026 ounces.

FOR SILVER.—1. *To Convert Weight into Dollar Value.*—Add to the weight in standard ounces $\frac{1}{11}$ thereof, plus the $\frac{8}{10}$ of the $\frac{1}{11}$; the answer will be in dollars.

Example.—What is the value of 1268.30 standard ounces?

		1268.30
	$\frac{1}{11}$	115.30
	$\frac{8}{10}$ of $\frac{1}{11}$	92.24
Answer:		1475.84

2. *To Convert Dollar Value into Standard Ounces.*—Subtract from the value $\frac{1}{8}$ thereof, plus $\frac{1}{8}$ of this quotient; the answer will be in standard ounces.

Example.—What is the weight of $1475 84?

		$1475.84
	$\frac{1}{8}$	184.48
	$\frac{1}{8}$	23 06
		207.54
Answer:		1268.30 standard ounces.

MINERS' INCHES FOR VARIOUS HORSE POWERS.

Since the measure of a large quantity of water is most apparent to the mind from a consideration of the size of the opening which is required for its passage at a certain fixed velocity, the miners' inch forms a good standard of measurement. Four miners' inches will permit the passage of sufficient water in one minute to give an effect, with a fall of 100 feet, of one-horse power, at a percentage of 80. The scale has been constructed upon this standard by the "Union Iron Works" of San Francisco. (See next page.)

The diagonal lines in the left-hand section represent heads of water from 4 feet to 500 feet. The column at the bottom shows the number of miners' inches to one-horse power for the various heads. To find how many inches are required for one-horse power at any head, the horizontal line occurring at the intersection of the line on the right with the margin, is followed to the diagonal marked 500 HP. The perpendicular line at this intersection is followed to the column of miners' inches, where the amount is indicated. Thus, with ten feet head, the horizontal line at the intersection with the margin is followed to the line marked 500 HP. Here a vertical line intersects, which, on being followed to the column of miners' inches, indicates 40 inches to one-horse power.

The remaining portion of the scale is simply a scale of multiplication. The diagonals represent horse powers from 10 to 500. The perpendicular lines represent miners' inches to one-horse power, and are numbered from one up to ten. By following the line of inches to the line of the horse power, and then taking the horizontal line to the margin at the right, the number of miners' inches for the horse power are found indicated in the margin. Thus, four inches followed to 300-horse power, and then carried to the margin at the right, indicate 1,200 inches. The result may also be found by one operation. Suppose that there is required the number of miners' inches necessary to 200-horse power at a head of six feet. The horizontal line followed from the intersection of the six-feet line on the left margin, to the line 500 HP., gives the vertical line of 64; this line carried to the line of 200 HP., gives the horizontal line of 1,280; but, since the line of 64 has 10 times the value at the end from which we have worked that it has at the other end, the horizontal line will in this case have a value 10 times as great as the margin indicates. This will make the result 12,800 inches for 200-horse power at six feet head.

—*Mining and Scientific Press*

A MINER'S INCH OF WATER.

There is no legal or other authoritative determination of the quantity of water meant by a miner's inch; neither is there any uniform method of ascertaining it; and even if there were, unless the method employed makes allowances for the influences of latitude, altitude, and temperature, the result could not be exact. The following are some of the various determinations of a miner's inch, which have fallen under our observation. The gallons mentioned are Winchester gallons, and the pounds avoirdupois. In the California State legislature of 1866–'67, a bill was introduced which defined a miner's inch to be $2\frac{1}{3}$ cubic feet, or $7\frac{4}{10}\frac{054}{000}$ gallons, or $145\frac{86}{100}$[1] pounds of water per minute. (Mineral Resources 1868, p. 184.) If 2.3333 cubic feet=7.4054 gallons, then 1 cubic foot=3,17374 gallons: and if 7.4054 gallons=145.86 pounds, then 1 gallon=19.6964 pounds. It also follows that 1 cubic foot=62.51125 pounds. The equivalents of 1 cubic foot assumed in this bill are, therefore, as follows: One cubic foot=3.17374 gallons=62.51125 pounds. These equivalents are wrong. One gallon=231 cubic inches. (Kelley's Cambist. II, 235.) Therefore, 1.728 cubic inches, or 1 cubic foot=7.48052 gallons. One gallon of water weighs 8.3388 pounds; therefore, 7.48052 gallons or 1 cubic foot, weighs 62.37856 pounds. The true equivalents of 1 cubic foot are, therefore, as follows: One cubic foot= 7.48052 gallons=62.37856 pounds. The assumed and the true equivalents are nearly alike with respect to the relation between cubic feet and pounds; but they differ very widely with respect to the relations between gallons and feet and gallons and pounds. In reducing the terms mentioned in this bill to the number of gallons which would be supplied by a miner's inch in twenty-four hours, it becomes necessary to choose between the feet, gallons, and pounds which it erroneously assumes to be equivalents. Taking the feet as the basis of calculation, a miner's inch, according to this bill, would supply 25,134.48 gallons in twenty-four hours.

1 This quantity of water—145.86 pounds per minute, herein erroneously assumed to be equal to 7.4054 gallons per minute—is the determination of a machinist's inch, not a miner's inch.

2. The above bill was referred to a committee on mines, which reported a substitute defining a miner's inch as that quantity of water which would pass through an orifice one inch square, through plank one inch thick with a pressure of seven inches, measured from the centre of the orifice to the surface of the water; provided the water has no other motion than that caused by its flow through such orifice. This determination of the miner's inch is unspecific. Both the original bill and substitute were indefinitely postponed. (Mineral Resources, 1868, p. 184.)

3. At Smartsville, California, a miner's inch is calculated to discharge 2.534.4 cubic feet in twenty-four hours, or 1.76 cubic feet per minute. (Pacific Rural Press, Nov. 17, 1877.) Hence, 2,534.4×7.48052=18,958.53 gallons in twenty-four hours.

At the Parke Canal (Eureka ditch), Placerville, California, a miner's inch is reckoned at 1.39 cubic feet per minute. (*Ibid.*) Hence, 1,329×7·48052×1,140=14,972.68 gallons in twenty-four hours.

5. At the South Yuba Canal, Nevada City, California, a miner's inch is that quantity of water which will pass through a 2-inch hole in a 1½ inch plank with 6 inches pressure. (*Ibid.*) This is unspecific.

6. The miner's inch used at the North Bloomfield, Milton, and La Grange placer mines, California, was practically measured at Columbia, a place whose altitude above the sea was assumed at 2,900 feet. The aperture employed measured 20 by 2 inches, and was made through a 3-inch plank. The last or outer inch of the aperture was chamfered at the bottom, so as to form a sort of lip, out of which the water flowed. The pressure was that of 7 inches of water, measuring from the center of the discharge. The result was, in effect, that 1 inch actually discharged 1.5744 cubic feet per minute, or 2,267.135 cubic feet per day of twenty-four hours, and that this result bore a ratio of 61.6 per cent. to the theoretic discharge of a miner's inch, assumed in the arithmetical formula employed at the mines mentioned. (*Ibid.*) Hence, 2,627.136×7.48052=16,959.36 gallons in twenty-four hours.

7. Mr. Culver, of San Francisco, says that a miner's inch is the quantity of water that will flow through a 1-inch aperture in a 2-inch plank, the water having a 6-inch head. This quantity, he says is 17,032 gallons in twenty-four hours.

8. Mr. James A. Gibson, an attorney of San Bernardino, California, who has made some researches, says, on the subject, that a miner's inch is that quantity of water that will flow through an aperture with a free discharge and constant pressure of 6 inches above the top of the opening. This determination is unspecific. He then goes on to say that an aperture 12½×15¾ will discharge 200 inches of water. This is erroneous, for 12½×15¾=196,875, and not 200. Finally, he says that a miner's inch will discharge 2,250 cubic feet, or 17,000 gallons, or 130,500 pounds of water in twenty-four hours. These equivalents are not precise. For 2,250×7,48052=16,831.17, and not 17,000. And 2,250×62.37856=140,361.76, and not 130,500. And 8.3388×17,000=141,759.6, and not 130,500. And 16,831.17×8.3388=140,351.76, and not 130,500. But the number of gallons flowing in twenty-four hours is specifically stated, and this is the determination which is now being sought.

9. According to "Mineral Resources, 1871, page 447," a miner's inch equals 17,033.46 gallons in twenty-four hours. Neither of these determinations can be regarded as entirely satisfactory. No. 1 is evidently a theoretical calculation; Nos. 3 and 4 are not sufficiently specific; No. 6 is objectionable on account of the aperture employed having been chamfered; Nos. 7 and 8 are not sufficiently specific; No. 9 is believed to be correct for the altitude where it was taken; but this is not positively specified, the determination must be regarded as defective in this respect. Perhaps the most practical, because the nearest even figure is 17,000 gallons in twenty-four hours, and, in the absence of any legal determination, this may be regarded as the correct equivalent of a miner's inch of water.

Miscellaneous.

One pound of anthracite coal in a cupola furnace will melt from 5 to 10 lbs. of cast iron; 8 bushels of bituminous coal in an air furnace will melt 1 ton of cast iron.

Small coal produces about ¾ the effect of large coal of the same description.

Experiments by Messrs. Stevens at Bordentown, N. J., gave the following results:

Under a pressure of 30 *lbs.*, 1 lb. pine wood evaporated 3.5 to 4.75 lbs. water, 1 lb. Lehigh coal, 7.25 to 8.75 lbs.

Bituminous coal is 13 per cent. more effective than coke for equal weights; and in England the effects are alike for equal costs.

Radiation from Fuel.—The proportion which the heat radiated from incandescent fuel bears to the total heat of combustion is,

From Wood. . . . . .29 | From Charcoal and Peat 5

The least consumption of coal yet attained is 1½ lbs. per indicated horse-power. It usually varies in different engines from 2 to 8 lbs.

The bulk of pine wood is about 5⅓ times as great as its equivalent bulk of bituminous coal.

PART IX.

THE ROMANCE OF MINING—MINE ACCIDENTS—MINE SUPERSTITIONS—THE MINING REGIONS—THE PRACTICAL PART OF MINING.

COLORADO and the mining States to many an Eastern man who obtains his impression from nowhere particularly, are not much more than a succession of huge, deserted brickyards. The very name of the State conjures up forsaken mining camps, ragged ravines, and barren mountains, rocks, plains and precipices that go to make up a very uninviting view, and yet if you question him as to the source of his impressions he can give none. But ignorance of the west is very common in the East where much more is known concerning the summits of the Alps, the shady sides of the Pyrenees, the fjiords of Norway than the glorious and surprisingly wonderful scenery of the Western States. Partly for this reason we have inserted in various places in this volume illustrations of Western scenery, of which the frontispiece is an admirable example, and open PART IX of the MINES, MINERS, AND MINING INTERESTS OF THE UNITED STATES, with a number of illustrations of a magnificent region. In this Part we have also brought together something of the more picturesque, less prosaic side of the mining industry, something about the superstitions, the weird ideas, the bravery, the kaleidoscopic life of the mining classes. To this much of a scientific nature has been added, and some papers that have not found a place in this volume until now. A series of articles upon the practical side of mining are included. They were prepared for this volume by Mr. Alfred Balch, of New York. Some of the articles in this Part are rendered more valuable by a free use of the engraver's art, the illustrations aiding materially the force of the text.

THE PHYSICAL GEOLOGY OF THE GRAND CANYON DISTRICT.

THE Grand Canyon District is a part of the Plateau Province, and to this province as a whole we may now devote our attention. As already indicated, it lies between the Park and Basin Provinces, and its topography differs in the extreme from those found on either side of it. It is the land of tables and terraces, of buttes and mesas, of cliffs and canyons. Standing upon any elevated spot where the radius of vision reaches out fifty or a hundred miles, the observer beholds a strange spectacle. The most conspicuous objects are the lofty and brilliantly colored cliffs. They stretch their tortuous courses across the land in all directions, yet not without system; here throwing out a great promontory, there receding in a deep bay, and continuing on and on until they sink below the horizon or swing behind some loftier mass or fade out in the distant haze. Each cliff marks the boundary of a geographical terrace and marks also the termination of some geological series of strata, the edges of which are exposed like courses of masonry in the scrap-walls of the palisades. In the distance may be seen the spectacle of cliff rising above and beyond cliff, like a colossal stairway leading from the torrid plains below to the domain of the clouds above. Very wonderful at times is the sculpture of these majestic walls. There is an architectural style about it which must be seen to be appreciated. The resemblances to architecture are not fanciful or metaphorical, but are real and vivid; so much so that the unaccustomed tourist often feels a vague skepticism whether these are truly the works of the blind forces of nature or of some intelligence akin to the human, but far mightier; and even the experienced explorer is sometimes brought to a sudden halt and filled with amazement by the apparition of forms as definite and eloquent as those of art. Each geological formation exhibits in its cliffs a distinct style of architecture which is not reproduced among the cliffs of other formations, and these several styles differ as much as those which are cultivated by different races of men. The character which appeals most strongly to the eye is the coloring. The gentle tints of an eastern landscape, the pale blue of distant mountains, the green of vernal or summer vegetation, the subdued colors of hillside and meadow, are wholly wanting here, and in their place we behold belts of brilliant red, yellow, and white, which are intensified rather than alleviated by alternating belts of gray. Like the architecture, the colors are characteristic of the geological formations, each series having its own group and range of colors. They culminate in intensity in the Permian and Lower Trias, where dark, brownish red alternate with bands of chocolate-purple, and lavender, so deep, rich, and resplendent that a painter would need to be a bold man to venture to portray them as they are.

The Plateau country is also the land of canyons, in the strictest meaning of the term. Gorges, ravines, canyads are found and are more or less impressive in every high region; and in the vernacular of the West all such features are termed canyons, indiscriminately. But those long, narrow, profound trenches in the rocks, with inaccessible walls, to which the early Spaniards gave the name of *cajon* or *canyon*, are seldom found outside the plateaus. There they are innumerable and the almost universal form of drainage channels. Large areas of the Plateau country are so minutely dissected by them that they are almost inaccessible, and some limited though considerable tracts seem wholly so. Almost everywhere the drainage channels are cut from 500 to 3,000 feet below the general platform of the immediate country. They are abundantly ramified and every branch is a canyon. The explorer upon the mesas above must take heed to his course in such a place, for once caught in the labyrinth of interlacing side gorges, he must possess rare craft and self-control to extricate himself. All these drainage channels lead down to one great trunk channel cleft through the heart of the Plateau Province for eight hundred miles—*the chasm of the Colorado*, and the canyons of its principal fork, the Green River. By far the greater part of these tributaries are dry during most of the year, and carry water only at the melting of the snow and during the brief periods of autumnal and vernal rains. A very few hold small, perennial streams, coming from the highlands around the borders of the province, and swelling to mad torrents in times of spasmodic floods. The region is for the most part a desert of the barrenest kind. At levels below 7,000 feet the heat is intense and the air is dry in the extreme. The vegetation is very scanty, and even the ubiquitous sage (*Artemisia tridentata*) is sparse and stunted. Here and there the cedar

WESTERN SCENERY.—SIDE CANYON.

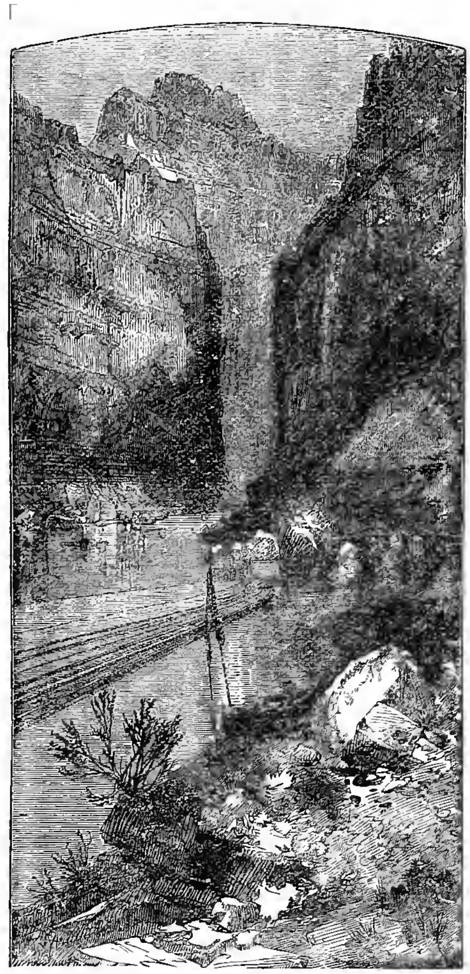
(*Juniperus occidentalis*) is seen, the hardiest of arborescent plants, but it is dwarfed and sickly and seeks the shadiest nooks. At higher levels the vegetation becomes more abundant and varied. Above 8,000 feet the plateaus are forest-clad and the ground is carpeted with rank grass and an exuberant growth of beautiful summer flowers. The summers there are cool and moist; the winters severe and attended with heavy snow-fall.

The Plateau Province is naturally divided into two portions, a northern and a southern. The dividing barrier is the Uinta range. This fine mountain platform is in one respect, an anomaly among the western ranges. It is the only important one which trends east and west. Starting from the eastern flank of the Wasatch, the Uintas project eastward more than 150 miles, and nearly join perpendicularly the Park ranges of Colorado. Of the two portions into which the Plateau Province is thus divided, the southern is much the larger. Both have in common the plateau features; their topographies, climates, and physical features in general, are of similar types, and their geological features and history appear to be closely related. But each has also its peculiarities. The northern portion is an interesting and already celebrated field for the study of the Cretaceous strata and the Tertiary lacustrine beds. The subjects which it presents to the geologist are most notably those which are embraced under the department of stratigraphy—the study of the succession of strata and co-related succession of organic life. Otherwise the region is tame, monotonous, and unattractive. The southern portion, while presenting an abundance of material for stratigraphical study, and in this respect fully rivaling, and perhaps surpassing, the northern portion, also abounds in the grandest and most fascinating themes for the student of physical geology. In respect to scenery, the northern portion is almost trivial, while the southern is the sublimest on the continent. With the former we shall have little to do; it is the latter which claims here our exclusive attention. The southern part of the Plateau Province may be regarded as a vast basin everywhere bounded by highlands, except at the southwest, where it opens wide and passes suddenly into a region having all the characteristics of the Great Basin of Nevada. The northern half of its eastern rim consists of the Park ranges of Colorado. Its northern rim lies upon the slopes of the Uintas. At the point where the Uintas join the Wasatch, the boundary turns sharply to the south, and for 200 miles the High Plateaus of Utah constitute the elevated western margin of the Province. It is from the summits of the High Plateaus that we gain our first comprehensive view of those grand facts which are the principal subjects of this discourse. But let me first ask the reader to endeavor to frame some conception, however crude, of three lines, each 200 miles long, placed in the positions of three sides of a square; the fourth side being, for the moment neglected. Upon the eastern side conceive the Park ranges of Colorado; upon the northern, the Uintas; and upon the western side the southern portion of the Wasatch and the High Plateaus of Utah; and all these highlands having altitudes ranging from 9,000 to 12,000 feet above the sea, while the included area varies from 5,000 to 7,000 feet high. The space thus partially bounded may represent the northern part of the southern Plateau Province. Along the line required for the fourth and south side of the complete square there is no boundary. The topography continues on beyond it to the southward, and also widens out both west and east and overspreads an additional area more than twice as great as that already defined. From the eastern crests of the High Plateaus we may obtain an instructive overlook of the northern portion of the southern Plateau country. The easiest line of approach is from Salt Lake City. Proceeding south from that town along the western base of the Wasatch, we reach the southern end of that fine range about 90 miles from Salt Lake. The last mountain pile is Mount Nebo, and skirting around its southern flank we soon perceive to the southeastward a long and very lofty ridge 20 to 30 miles distant. This is the Wasatch Plateau, the northernmost member of the group of High Plateaus. It has nothing in common with the Wasatch Mountain range, being wholly disconnected from it and standing with a wide interval *en echelon* to the southeastward of it. The Wasatch Plateau presents a long straight, horizontal summit projected against the sky without peaks or domes, resembling somewhat the ridges of Pennsylvania and Virginia, but on a grander scale. We perceive along its entire western front a rapid slope, descending to the bottom of the San Pete Valley at its foot. It is not deeply incised with ravines and amphitheaters, nor notched with profound transverse gorges, as are ordinary mountain ranges, but shows a slightly diversified slope in every part. As we draw nearer we begin to see the attitudes of the strata composing its mass, or, as the geologists say, its "structure." The strata are inclined at the same angle as the slope of its flank. In the valley below, the beds are horizontal; as they approach the base of the plateau they flex upward and ascend the slope; as they reach the summit they flex back to horizontality. If we ascend the plateau and ride eastward a very few miles, there suddenly breaks upon the view a vast and impressive panorama. From an altitude of more than 11,000 feet the eye can sweep a semicircle with a radius of more than 70 miles and reach far out into the heart of the Plateau country. We stand upon strata of Lower Tertiary age, and beneath our feet is a precipice leaping down across the level edges of the beds upon a terrace 1,200 feet below. The cliff on which we stand stretches far northward into the hazy distance, gradually swinging eastward and then southward through a course of more than a hundred miles, and vanishing below the horizon. It describes, as we well know, a rude semicircle, around a center about 40 miles east of our standpoint. At the foot of this cliff is a terrace of greatly varying width, rarely less than 5 miles, consisting of Upper Cretaceous beds nearly but not quite horizontal. They incline upwards towards the east at angles rarely so great as 3°, and are soon cut off by a second cliff plunging down 1,800 feet upon Middle Cretaceous beds. This second cliff describes a semicircle like the first, but smaller and concentric with it. From its foot the strata still rise gently towards the east, through a distance of about 10 miles, and are cut off as before by a third series of cliffs concentric with the first and second. For the fourth and fifth time this process is repeated. In the center of these girdling walls is an elliptical area about 40 miles long and 12 to 20 miles broad, completely surrounded by mural escarpments more than a thousand feet high. This central spot is called the SAN RAFAEL SWELL, and it is full of interest and suggestion to the geologist. From its central point the strata dip away in all directions, the inclinations, however, being always very small.

* * * * * * * * * *

Throughout the great Carboniferous age the entire area of the Plateau Province was submerged beneath the ocean. Deposition of strata went on continuously. The thickness of the strata accumulated in that age appears to have varied greatly, and the deposits were laid down unconformably over the surface of a country which had been ravaged by a great erosion. Such exposures of the Carboniferous as now exist, however, exhibit for the most part a remarkable evenness of stratification. In the interior spaces of the province the beds are either horizontal, or if disturbed, give full evidence that the disturbances took place long after their deposition. The close of this age evidently left a subaqueous surface, which was exceedingly flat, and, except around the borders of the province, quite free, so far as we now know, from any appreciable inequalities. The thickness of the Carboniferous system is from 4,500 to 5,000 feet in the interior of the province, but around its borders, and in the Uinta Mountains, it is sometimes found in far greater volume. Its strata consist of impure limestones, occasionally of enormous thickness in the individual beds, and alternating with fine-grained homogeneous sandstones. Extensive beds of gypsum also occur. After the Carboniferous came the Permian age, in which were laid down from 800 to 1,500 feet of sandy shales. The stratification was wonderfully even and everywhere horizontal. The Permian beds are often ripple-marked and betray many evidences that they accumulated in shallow waters. Among these evidences are the appearance at several horizons of indications that for a time the sea-bottom was laid bare by the recession of the waters, or by the elevation of the platform itself; for we may discern evidences of slight erosion at the contacts of the beds. But the horizontality of the beds appears never to have been notably disturbed. The same state of affairs continued through the Trias. There, too, we find evidence of alternations of emergence and submergence in the shape of slight unconformities by erosion, and in the occurrence of extensive remains of silicified forests. The Triassic series is composed almost wholly of sandstones, the only calcareous matter being thin seams of gypsum. The sandstone beds are very numerous and often shaly. They are usually of no great thickness individually, but there is one very notable member of which we shall see more when we come to view the Vermilion Cliffs.

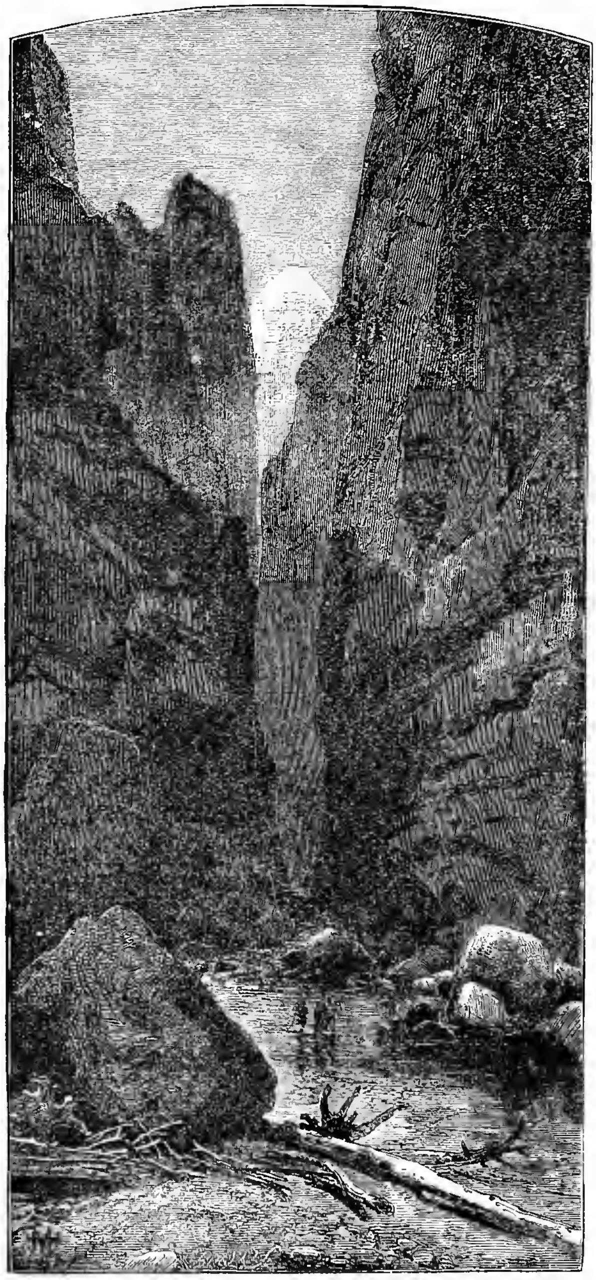
Directly upon the Trias rests the Jurassic. A wonderful bed of sand-stone 800 to 1,200 feet thick, and very white and sugary in color represents the principal part of this series. It is a very notable formation because of its remarkable homogeneity, the persistent way in which it preserves its lithological characters through great distances, and the absence of divisional planes of stratification—the mass being solid from top to bottom. But most striking of all its wonderful cross-bedding, far surpassing in beauty, extent, and systematic character, any similar phenomenon elsewhere with which I am acquainted. The summit of the Jurassic suddenly changes to calcareous and sandy shales, abounding in fossils. This series, as well as the Trias, appears to have been laid down horizontally in shallow waters. Next comes the Cretaceous system—a mass of yellow sandstones with clayey and marly shales, aggregating from 4,000 to 5,000 feet thick. In this series we find abundance of plant remains, many beds of good coal,



WESTERN SCENERY.—MARBLE CANYON.—COLORADO RIVER.

and much carbonaceous shale. The conditions during the Cretaceous appear to have been quite similar to those which prevailed in the Appalachian region during the Carboniferous. Perhaps the conditions which attended and rendered possible the accumulation of coal are not sufficiently well understood to enable us to say confidently just what they were, but there seems to be a general agreement that they have involved a flat, low, moist country lying almost exactly at mean sea-level, and subject to alternate emergence and submergence. No other supposition seems to meet the requirements of the case, or to be capable of explaining how a mass of strata could be so accumulated, consisting of alternations of thin seams of coal and carbonaceous shale with layers of sand-stone containing marine fossils. We have now the following remarkable state of affairs. From the close of the Carboniferous to the close of the Cretaceous there is strong evidence that the surface of deposition was always very near to sea-level, sometimes a few feet above it, but for the most part a little below it. And yet in the interval about 9,000 feet of strata accumulated with remarkable uniformity over the entire province, and always in a horizontal position. From this it necessarily follows that the mass of material thus deposited sank or "subsided" at a rate which, in the long run, was exactly or sensibly equal to the rate of deposition. At the close of the Cretaceous we find evidence that the long calm which had characterized the action of the physical processes was invaded. Some extensive disturbances took place, resulting at some places in the dislocation and flexing of the strata, and the elevation of some portions of the region to considerable altitudes. Erosion at once attacked the uplifted portions, and around the borders of the province we find numerous localities, usually not very extensive, which were greatly devastated. At some of these places the entire local Cretaceous series was denuded, and even a portion of the Jurassic and across the beveled edges of the flexed Cretaceous strata. But even these localities were again submerged, as the presence of the Tertiary fully attests. These disturbances were not general—did not extend to the entire province, but appear to have occurred around, or a little within, its marginal portions. The last period of deposition was marked by the accumulation of the Eocene beds, which form such a striking feature in the stratigraphy of the peripheral parts of the Plateau country. Around the southern flanks of the Uintas their aggregate thickness exceeds 5,000 feet, but southward the upper members disappear, and 80 miles north of the Grand Canyon only about 1,000 to 1,200 feet, representing the lowest portion of the series, make their appearance. It is highly probable that the middle and upper portions of the Eocene were never deposited there. But the lowest beds, most probably, once covered the entire province, while the middle and late Eocene were confined to its more northerly portions. The lowest members were deposited in brackish water, as their fossils amply attest; but in the succeeding beds the fossil forms are entirely those which live in fresh water. From that epoch to the present time there has been no recurrence of marine conditions. We now reach a turning point in the history of this region. That long continuance of marine conditions lasting from the beginning of Carboniferous time to the close of the Cretaceous came gradually to an end. The waters became brackish and then fresh. During the prevalence of the marine condition it seems to be a necessary conclusion that the waters which covered it had abundant access to the ocean. Whether its waters were wide open to the ocean, like the Gulf of Mexico or Hudson's Bay, or whether they formed a broad expanse, with a comparatively narrow outlet, like the Mediterranean, we do not know, and it would be useless to conjecture at present. At all events the communication was sufficiently free to maintain a degree of saltness suitable to the existence of molluscan forms of the ordinary marine types. When the waters became brackish, we infer that the straits became greatly narrowed; when they became quite fresh, we infer that the access of the ocean to the area was wholly cut off, and that the water brought by the rivers and rains merely outflowed, and the region became an inland lake of vast proportions. For the deposition still went on. Through Eocene time from 1,000 to 5,000 feet of lacustrine beds, containing an abundance of fresh-water fossils, were deposited. Among them are also found layers of coal and carbonaceous shales, and sandstones thickly imprinted with the traces of arboreal vegetation. But at length the deposition of lacustrine strata ceased; not, however, at one and the same time in all parts of the province. The evidence indicates that in the southern and southwestern portions it stopped after about one-fourth or one-third of the Eocene horizons had been laid down. In the central portions it appears to have ceased after about one-half to two-thirds of those horizons had been deposited. In the northern portions, in the vicinity of the Uintas, the entire system of Eocene strata is found in immense volume. These facts lead us to infer that the great Eocene lake, soon after its waters became quite fresh, began to shrink its area, and that its bottom became through a slow progression dry land. The southern and southwestern portions were the first to emerge; then the middle portions; the lake gradually retracting its boundary to the northward, until in the latter part of the Eocene it occupied a greatly diminished area in the vicinity of the San Rafael country and the southern base of the Uinta Mountains. At the close of the Eocene this remnant of the lake also disappeared.

We now reach another turning point in the history of the region. Hitherto and for an immense stretch of geological time it had been an area of deposition and of subsidence. It now became an area of elevation and denudation, and these processes have been in operation ever since. In the periods of deposition and subsidence, from the Carboniferous to the Eocene, both inclusive, the thickness of the strata



Western Scenery.—The Parunumcap.—Colorado River.

accumulated varied from 14,000 to 20,000 feet, and the subsidence of the base of the Carboniferous was of nearly equal extent. In the periods of elevation and denudation these vast masses of strata rose bodily up again; the amount of elevation varying according to locality from 6,000 to 18,000 feet. The havoc wrought by erosion has been, as already shown, stupendous; the thickness of strata removed exceeding 10,000 feet in some considerable areas, and averaging probably 5,500 to 6,000 feet over the entire province. The points which it is desirable to notice here concerning the progress of the Tertiary and Quaternary erosion of the province, are few and of the broadest nature. In truth it is necessary to speak very guardedly. For while the most general features of the work have left well-marked traces which can be interpreted, yet when we come to details the vast erosion has swept away so much of its mass that a large portion of the evidence of the details has vanished with the rocks. There is reason to believe that the greater part of the denudation was accomplished in Miocene time. This was a period of slow but continuous uplifting, reaching a great amount in the aggregate, and it was most probably also a period of rapid erosion. The uplifting, however, was unequal in the different parts of the province. The comparatively even floor of the old lake was deformed by broad swells and plateaus rising above the surrounding country. As we shall see hereafter, the action of the denuding agents is much more vigorous and efficient upon the higher than the lower parts of a region; and consequently these upswellings at once became the objects of special attention from the destroying forces and were wasted more rapidly than the lower regions around them. Here were formed centers or short limited axes, from which erosion proceeded radially outwards, and the strata rising gently towards them from all directions were beveled off. Thus were formed those areas of maximum erosion, already spoken of, and of which the San Rafael Swell is the most perfect and simplest type.

The Toroweap and Uinkaret.—The first stage of the journey from Kanab to Pipe Spring is an easy one. It leads southward to a gap cut through the low Permian terrace, and out into the open desert beyond. The road, well travelled and easy, then turns westward, and at length reaches the spring twenty miles from Kanab. Pipe Spring is situated at the foot of the southernmost promontory of the Vermillion Cliffs, and is famous throughout Southern Utah as a watering place. Its flow is copious, and its water is the purest and best throughout that desolate region. Ten years ago the desert spaces outspreading to the southward were covered with abundant grasses, affording rich pasturage to horses and cattle. To-day hardly a blade of grass is to be found within ten miles of the spring, unless upon the crags and mesas of the Vermillion Cliffs, behind it. The horses and cattle have disappeared, and the bones of many of the latter are bleached upon the plains in front of it. The cause of the failure of pasturage is twofold. There is little doubt that during the last ten or twelve years the climate of the surrounding country has grown more arid. The occasional summer showers which kept the grass alive, seldom come now, and through the long summer and autumn droughts the grasses perished even to their roots before they had time to seed. All of them belong to varieties which reproduce from seed, and whose roots live but three or four years. Even if there had been no drought, the feeding of cattle would have impoverished and perhaps wholly destroyed the grass by cropping it clean before the seeds were mature, as has been the case very generally throughout Utah and Nevada. Northeastward, the Vermillion Cliffs extend in endless perspective towards Kanab, and beyond the Paria. Northwestward, with growing magnitude, they extend towards the Virgen, ever forming a mighty background to the picture. To the southward stretches the desert, blank, lifeless, and as expressionless as the sea. For five or six miles south of the Pine Spring promontory there is a gentle descending slope, and thence onward the surface feebly ascends through a distance of thirty miles to the brink of the Grand Canyon. Thus the range of vision is wide, for we overlook a gentle depression of great extent. Though the general impression made is that of a smooth or slightly modulated country, yet we command a far greater expanse than would be possible among the prairies. To the southeastward the Kaibab looms up, seemingly at no great distance, and to the southwestward the flat roof of Mount Trumbull is more than a blue cloud in the horizon. Towards this latter mountain we take a straight course. The first few miles lie across drifting sands bare of all vegetation. The air is like a furnace, but so long as the water holds out the heat is not enervating, and brings no lassitude. Everything is calm and still, except here and there a hot whirling blast which sends up a tall, slender column of dust diffusing itself in the air. At a slow pace the sand hills at length are passed, and we enter upon a hard, firm soil, over which we move more rapidly. Just here, and for three or four miles in either direction, the Permian terrace has been obliterated. It has been bevelled off by erosion and buried beneath the wash brought down from the foot of the Vermilion Cliffs to the northward. But seven miles from Pipe Spring, the Permian terrace springs up out of the earth, scarped by its characteristic cliff. Stretching northwestward, it increases in altitude, becoming at last eight hundred to one thousand feet high. At its summit is seen the Shinarump conglomerate, of a pale brown color, and beneath are the gorgeous hues of the shales. Nothing can surpass the dense, rich, and almost cloying splendor of the red-brown seen in these shales. They suggest the color of old mahogany, but are much more luminous and quite uniform. Under them are belts of chocolate, slate, lavender, pale Indian red, and white. Very wonderful, too, is the evenness of the bedding, which is brought out in great clearness and sharpness by the etching of minute layers of clays, holding selenite. Between the shales and overhanging conglomerate, careful scrutiny enables us to detect an unconformity by erosion without any unconformity of dip. As stated in a preceding chapter, Mr. Wolcott fixed provisionally the separating horizon between the Permian and Trias at this unconformable contact.

Along the route the vegetation is scanty indeed. Several forms of cactus are seen looking very diseased and mangy, and remnants of low desert shrubs browsed to death by cattle. Yet strangely enough there is one plant and one alone that seems to flourish. It is the common sunflower (*Helianthus lenticularis*), found anywhere from Maine to Arizona, and seeming indifferent to the vicissitudes of climate. About 18 miles from Pipe Spring the trail leads gently down into a broad shallow valley known as the Wild Band Pockets. The drainage from the fronts of the Permian cliffs now far to the northward here collects into a gulch, which gradually deepens and becomes a tributary of Kanab Canyon. In every stream-bed may be found many depressions which would hold water even though the sources of supply were cut off. This is as true of wet-weather channels as of perennial streams. After the infrequent showers, and after the surface waters have ceased to run, the beds of the stream will still retain pools of water, provided the bottom of it is of a consistency which will prevent it from filtering away. To these pools the people of the west have given the name of "water-pockets." They are very common in the stream-beds which bear away the wash from the Permian and lower Triassic shales. These shales yield a very fine impervious clay, which forms an excellent "puddling" for water holes and basins. The Wild Band Pockets have received their name from the fact that they are the resort of bands of wild horses that roam over these deserts, far from human haunts, ranging from spring to spring, which they visit by stealth only at night, and never so long as they can find chance water in these and other pockets. Beyond the Wild Band Valley there is a slight ascent to a rocky platform, consisting of the summit beds of the Carboniferous. In the course of 20 miles we have crossed the entire Permian series, which now lies to the north of us. A few stunted cedars, most of which are dead or dying of drought, are scattered over this platform and give us until nightfall some slight shelter from the sun. It is as good a camping place as we are likely to find, and if we are fortunate enough to reach it after a copious shower, the hollows and basins in the flat rocks may contain a scanty supply of clear rain-water. It is a good locality, also from which we may overlook the outspreading desert, which is not without charms, however repulsive in most respects.

To the northward rises the low escarpment of the Permian, forming a color picture which is somewhat indistinct through distance, but weird because of its strange colors and still stranger forms. Beyond and in the far distance rise the towering fronts of the Vermillion Cliffs, ablaze with red light from the sinking sun. To the eastward they stretch into illimitable distance, growing paler but more refined in color until the last visible promontory seems to merge its purple into the azure of the evening sky. Across the whole eastern quarter of the horizon stretches the long level summit of the Kaibab as straight and unbroken as the rim of the ocean. To the southwestward rises the basaltic plateau of Mount Trumbull, now presenting itself with somewhat imposing proportions. Around it a great multitude of basaltic cinder cones toss up their ominous black waves almost as high as Trumbull itself. Their tumultuous profiles and gloomy shades form a strong contrast with the rectilinear outlines and vivid colors of the region roundabout. At dawn we move onward, reaching soon the summit of a hill which descends two or three hundred feet to a broad flat depression called the Wonsits Plain. It is a smooth and very barren expanse, dotted with a few moldering buttes of Upper Carboniferous rocks, now wasting to their foundations. The plain is about seven miles in width, and on the further side rises a low mesa of great extent capped with basalt. It is the Minkaret. Beyond the nearer throng of basaltic cones Mount Trumbull rises with a striking aspect dominating strongly the entire western landscape. The smaller cones are now seen to be very numerous, all of them are apparently perfect in form, as if time had wrought no great ravage among them. The *lapilli* and *peperino* with which they are covered, have become dull red by the oxidation of the iron, and this peculiar color is easily recognized though the cones are far away. Just before reaching the basaltic mesa we must make our choice between two routes to the Toroweap, one direct, and the other very circuitous. No spring is to be found until we reach the further side of Mount Trumbull, but we know of a large water-pocket on this side, which has never been known to dry up. The spring water is sure to be good, but the water in the pocket will depend for its quality upon the length of time which has passed since the last heavy rain. Let us here choose the shorter one, and go to the water-pocket.

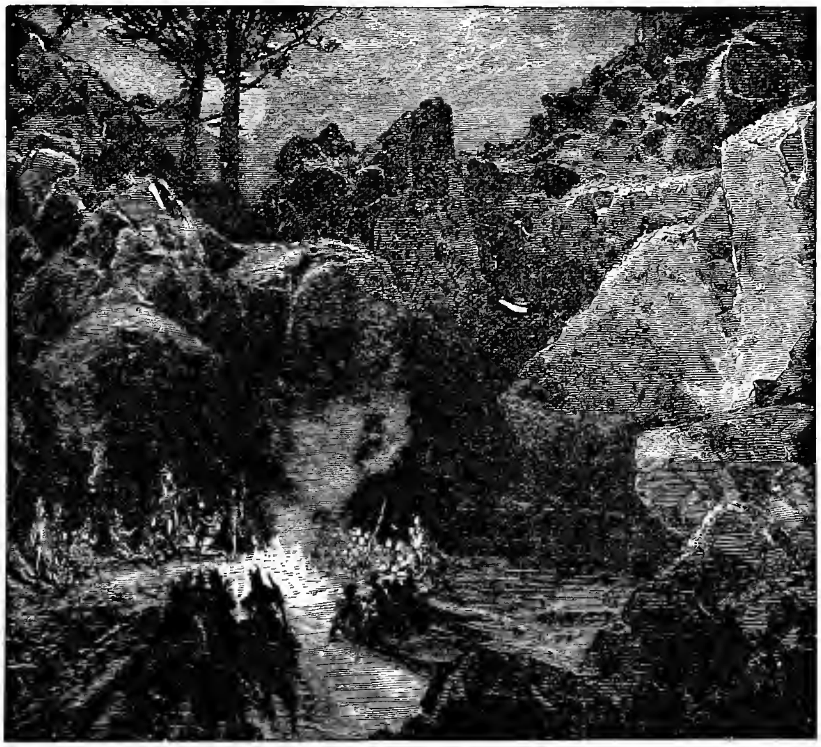
Ascending the mesa which rises abruptly about 200 feet above the Wonsits Plain, we find ourselves at once upon the basalt. The ground is paved with cinders and fragments half buried in soil, the debris of decaying lava sheets. These sheets are rarely of any great thickness, seldom exceeding 30 or 40 feet, and often much less, and none of the individual eruptions of lava seem to have covered any very great expanse. Probably the area covered by the largest would be less than a square mile. They show no perceptible differences in composition or texture, and all are basalts of the most typical variety—very black and ferruginous in the unwithered specimens and speckled with abundant olivine. At the time of eruption they appear to have been in a state of perfect liquidity; spreading out very thin and flowing rapidly and with ease. In none of them has erosion wrought much havoc, though here and there some local destruction has been effected, most conspicuously upon the edges of the principal mesa where the sheets have been undermined and their fragments scattered upon the plain below. The cones, which stand thick around us, are still in good preservation. They are of ordinary composition—mere piles of cinders thrown out of central vents and dropping around it. The fume and froth of the lava surfaces, the spongy inflated blocks, the lapilli and peperino, are not greatly changed, though all of them here show the oxidation of the iron. We wonder what their age may be; what time has elapsed since they vomited fire and steam. But there is no clew—no natural record by which such events can be calendared. Historically they have doubtless stood in perfect repose for very many centuries. Not a trace of activity of any kind is visible, and they are as perfectly quiescent as the dead volcanoes of the Auvergne or of Scotland. Geologically, they are extremely recent; yet even here where historic antiquity merges into geologic recency the one gives us no measure of the other. Following a course which winds among the silent cones and over rough, flat surfaces of lava beds half buried in drifting sands, we at length reach the border of a slight depression, into which we descend. It is hardly noteworthy as a valley just here, and might be confounded with any one of the innumerable shallow-water courses which occur round about; only when we look beyond we see it growing broader and much deeper. It is the head of the Toroweap. Upon its smooth bottom is a soft clayey soil, in which desert shrubs and stunted sage-brush grow in some abundance. Here and there a cedar, dwarfed indeed, but yet alive, displays a welcome green, and upon the valley slopes are a few sprays of grass. The valley bottom descends at a noticeable rate to the southward, and as we put the miles behind us we find the banks on either side rising in height, becoming steeper, and at last displaying rocky ledges. In the course of six or seven miles the left side has become a wall 700 feet high, while the other side, somewhat lower, is much broken and craggy. Huge piles of basalt lie upon the mesa beyond, sheet upon sheet, culminating in a cluster of large cones. At length the course of the valley slightly deflects to the left, and as we clear a shoulder of the eastern wall, which has hitherto masked its continuation, a grand vista breaks upon the sight. The valley stretches away to the southward, ever expanding in width; the walls on either side increase in altitude, and assume profiles of wonderful grace and nobility. Far in the distance they betoken a majesty and grandeur quite unlike anything hitherto seen. With vast proportions are combined simplicity, symmetry, and grace, and an architectural effect as precise and definite as any to be found in the terraces. And yet these walls differ in style from the Trias and Jura as much as the Trias and Jura differ from each other. In the background the vista terminates at a mighty palisade, stretching directly across the axis of vision. Though more than 20 miles distant it reveals to us suggestions of grandeur which awaken feelings of awe. We know instinctively that it is a portion of the wall of the Grand Cañon. The western side of the valley is here broken down into a long slope descending from the cones clustered around the base of Mount Trumbull, and covered with broad flows of basalt. Turning out of the valley we ascend the lava bed, which has a very moderate slope, and about a mile from the valley we find the Witches' Water Pocket. In every desert the watering places are memorable, and this one is no exception. It is a weird spot. Around it are the desolate Phlegræan fields, where jagged masses of black lava still protrude through rusty, decaying cinders. Patches of soil, thin and coarse, sustain groves of cedar and piñon. Beyond and above are groups of cones, looking as if they might at any day break forth in renewed eruption, and over all rises the tabular mass of Mount Trumbull. Upon its summit are seen the yellow pines (*P. ponderosa*), betokening a cooler and a moister clime. The pool itself might well be deemed the abode of witches. A channel half-a-dozen yards deep and twice as wide, has been scoured in the basalt by spasmodic streams, which run during the vernal rains. Such a stream cascading into it has worn out of the solid lava a pool twenty feet long, nearly as wide, and five or six feet deep. Every flood fills it with water, which is good enough when recent, but horrible when old. Here, then, we camp for the night.

Filling the kegs at daylight we descend again into the Toroweap and move southward. Our attention is strongly attracted by the wall upon the eastern side. Steadily it increases its mass and proportions. Soon it becomes evident that its profile is remarkably constant. We did not notice this at first, for we saw in the upper valley only the summit of the palisade; but as the valley cuts deeper in the earth the plan and system begin to unfold. At the summit is a vertical ledge, next beneath a long Mansard slope, then a broad plinth, and last, and greater than all, a long, sweeping curve, descending gracefully to the plain below. Just opposite to us the pediments seem half buried, or rather half risen out of the valley alluvium. But beyond they rise higher and higher until in the far distance the profile is complete. In this escarpment are excavated alcoves with openings a mile wide. As soon as we reach the first one new features appear. The upper ledge suddenly breaks out into a wealth of pinnacles and statues standing in thick ranks. They must be from 100 to 250 feet high, but now the height of the wall is more than a thousand feet, and they do not seem colossal. Indeed, they look like a mere band of intricate fretwork—a line of balustrade on the summit of a noble façade. Between the alcoves the projecting pediments present gable-ends towards the valley plain. Yet whithersoever the curtain wall extends the same profile greets the eyes. The architect has adhered to his design as consistently and persistently as the builders of the Thebaid or of the Acropolis. As we pass alcove after alcove, and pediment after pediment, they grow loftier, wider and deeper, and their decoration becomes more ornate. At length we pass one which is vast indeed. It is recessed back from the main front three-fourths of a mile, and shows three sides of an oblong room with walls 1,800 feet in height. The fourth side is obliterated and the space opens into the broad valley. Wonderfully rich and profuse are the pinnacles and statues along the upper friezes. The fancy is kindled as the eye wanders through the enclosure.

We look across the valley, which is here three miles in width, and behold the other wall, which presents an aspect wholly different, but quite as interesting. The western wall of the Toroweap, is here lower than the eastern, but still is more than a thousand feet high. The geologist soon surmises that along the valley bottom runs a fault which drops the country on the west several hundred feet, and the conjecture soon becomes certainty. Above and beyond the western escarpment is the platform of the Unikaret Plateau. Upon its summit is a throng of large basaltic cones in perfect preservation. Streams of lava larger than any hitherto seen have poured from their vents, flooding many a square mile of mesa land, and in the wide alcoves they have reached the brink of the wall and cascaded over it. Still pouring down the long taluses they have reached the valley bottom below and spread out in wide fields, disappearing underneath the clayey alluvium, which has buried much of their lower portions. The appearance of these old lava cascades, a mile or more wide, a thousand feet high, and black as Erebus, is striking in the extreme. There are five of these basaltic cataracts, each consisting of many individual *coulées*. Between them the bold pediments of brightly-colored Carboniferous strata jut out into the valley.

At length we approach the lower end of the Toroweap. The scenery here becomes colossal. Its magnitude is by no means its most impressive feature, but precision of the forms. The dominant idea ever before the mind is the architecture displayed in the profiles. It is hard to realize that this is the work of the blind forces of nature. We feel like mere insects crawling along the street of a city flanked with immense temples, or as Lemuel Gulliver might have felt in revisiting the capital of Brobdignag, and finding it deserted. At the foot of the valley the western wall is nearly 1,500 feet high, the eastern about 2,000, and the interval separating them is about three miles. Suddenly they turn at right angles to right and left, and become the upper wall of the Grand Canyon of the Colorado. The Toroweap now opens into the main passage way of the great chasm. The view however, is much obstructed.

At the foot of the eastern gable is a medley of rocky ledges of red sandstone, while around the base of the western gable are large masses of basalt reaching more than half-way across the valley. In front rises a crater, which is about 600 feet high, seemingly a mere knoll in the midst of this colossal scenery. Beyond it, and five miles distant, rises the palisade which forms the southern upper wall of the chasm, stretching athwart the line of vision interminably in either direction. Its altitude is apparently the same as that of the palisade above us, and its profile is also identical. Climbing among the rocky ledges which lie at the base of the escarpment, we at length obtain a standpoint which enables us to gain a preliminary view of the mighty avenue. To the eastward it stretches in vanishing perspective forty miles or more. Between symmetric walls 2,000 feet high and five miles apart is a plain, which in comparison with its limiting cliffs might be regarded as smooth, but which in reality is diversified by rocky hummocks and basins, and by hillocks where patches of soil give life to scattered cedars and pinons. Of the inner chasm nothing as yet is to be seen. Moving outward into this platform we find its service to be mostly bare rock, with broad shallow basins etched in them, which hold water after showers. There are thousands of these pools, and when the showers have passed they gleam and glitter in the sun like innumerable mirrors. As we move outward towards the centre of the grand avenue the immensity and beautiful proportions of the walls develop. The vista towards the east lengthens out and vanishes against the blue ramp of the Kaibab, which lies as a cloud upon the horizon. To the west the view is less symmetric and regular, and the eye wanders vaguely among cliffs and buttes of stupendous magnitude, displaying everywhere the profile with which we have become of late familiar. Much of the distance towards the west is obstructed by the crater, but the portions in view bewilder us by the great number of objects presented, and oppress us by their magnitudes. At a distance of about two miles from the base of the northern wall we come suddenly upon the inner chasm. We are not conscious of its proximity until we are within a few yards of it. In less than a minute after we have recognized the crest of the farther wall of this



WESTERN SCENERY.—ELFIN WATER POCKET.—CANYONS OF THE COLORADO.

abyss we crane over its terrible brink and gaze upon the waters of the river full 3,000 feet below.

The scene before us is a type of the Grand Canyon throughout those portions which extend through the Kanab, Uinkaret, and Sheavwits Plateaus. The plan and section here presented are quite simple. They consist of a broad upper chasm from five to six miles in width with walls varying in altitude but little from 2,000 feet. Between these escarpments is a rocky plain, rough indeed, but in the overpowering presence of such walls seeming relatively smooth and uniform. In this floor is cut the inner chasm 3,000 feet deep and from 3,500 to 4,000 feet wide from crest to crest. The strata in which the chasm is excavated are all of Carboniferous age except three or four hundred feet at the bottom of the gorge. The strata beneath the Carboniferous are at present believed to be Lower Silurian, and their contact with the Carboniferous is unconformable, both by dip and by erosion. In the upper part of the palisades which form the wall of the upper chasm we find at the summit two series of limestones. The upper contains an abundance of siliceous matter, one portion of which is intimately disseminated through the mass while another portion is aggregated into myriads of cherty nodules varying from two to ten inches in diameter. The lower one is a purer lime stone with few nodules. The cherty members form a nearly vertical band at the summit of the wall; the purer members form a Mansard slope beneath, covered with talus. The total thickness of the limestones is about 700 to 750 feet, Beneath them come sandstones a little more than 250 feet thick, which form everywhere a vertical plinth or frieze. They are very adamantine in texture, and one of the members, about 160 feet thick, is in every exposure seen to be uniformly cross-bedded. Under the cross-bedded sandstone is a mass of thinly bedded and almost shaly sandstones, having an aggregate thickness very closely approximating to 1,000 feet. They are of an intensely brilliant red color, but are in greatest part, covered with a heavy talus of imperishable cherty nodules, fragments of the cross-bedded sandstones, and spalls of limestone shot down from above. The color of these is pale gray, with occasionally a yellowish or creamy tinge. The brilliant red sandstones form the long curved slope which descends from the plinth of cross-bedded sandstones to the plain below.

The walls of the inner gorge have at the summit about 325 feet of hard sandstone of a brown-red color. Beneath the sandstone are about 1,800 feet of impure limestone in layers of the most massive description. Very few such ponderous beds of limestone are found in any part of the world. The color is deep red with a purplish tone, but the brilliancy of the coloring is notably weakened by weathering. Still lower are red-brown sandstones again having a dark and strong shade and lying in very massive beds. The strata forming the walls of the outer chasm from the summit to the plain below are designated the Aubrey group, and this is again subdivided at the base of the cross-bedded plinth into Upper and Lower Aubrey groups. The two subdivisions are believed to be the equivalents, in age, of the Coal Measures of Pennsylvania and England. The strata disclosed in the inner gorge correspond in age to the Lower Carboniferous of those countries, and are here termed the Red Wall group. Some uncertainty exists regarding the beds which lie at the base of the conformable series deep down in the chasm, but they are regarded at present as being just what they seem and just what they would naturally be inferred to be—a part of the Carboniferous system. Of the strata at the bottom of the canyon, we shall have more to say hereafter. They are regarded at present as being of Lower Silurian or Primordial age.

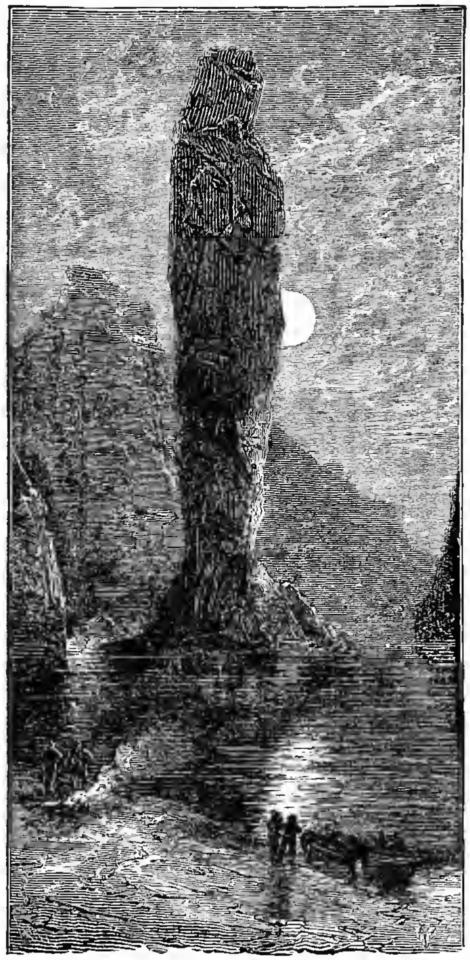
The observer who, unfamiliar with plateau scenery, stands for the first time upon the brink of the inner gorge, is almost sure to view his surroundings with commingled feelings of disappointment and perplexity. The fame of the chasm of the Colorado is great; but so indefinite and meager have been the descriptions of it that the imagination is left to its own devices in framing a mental conception of it. And such subjective pictures are of course wide of the truth. When he first visits it the preconceived notion is at once dissipated and the mind is slow to receive a new one. The creations of his own fancy no doubt are clothed with a vague grandeur and beauty, but not with the grendeur and beauty of nature. When the reality is before him the impression bears some analogy to that produced upon the visitor who for the first time enters St. Peter's Church at Rome. He expected to be profoundly awe-struck by the unexampled dimensions, and to feel exalted by the beauty of its proportions and decoration. He forgets that the human mind itself is of small capacity and receives its impressions slowly, by labored processes of comparison. So, too, at the brink of the chasm, there comes at first a feeling of disappointment; it does not seem so grand as we expected. At length we strive to make comparisons. The river is clearly defined below, but it looks about large enough to turn a village grist-mill: yet we know it is a stream three or four hundred feet wide. Its surface looks as motionless as a lake seen from a distant mountain-top. We know it is a rushing torrent. The ear is strained to hear the roar of its waters, and catches it faintly at intervals as the eddying breezes waft it upwards; but the sound seems exhausted by the distance. We perceive dimly a mottling of light and shadow upon the surface of the stream, and the flecks move with a barely perceptible cloud-like motion. They are the fields of white foam lashed up at the foot of some cataract and sailing swiftly onward.

Perhaps the first notion of the reality is gained when we look across the abyss to the opposite crest-line. It seems as if a strong, nervous arm could hurl a stone against the opposing wall-face; but in a moment we catch a sight of vegetation growing upon the very brink. There are trees in scattered groves which might at first have been mistaken for sage or desert furze. Here at length we have a stadium or standard of comparison which serves for the mind much the same purpose as a man standing at the base of one of the sequoias of the Mariposa grove. And now the real magnitudes begin to unfold themselves, and as the attention is held firmly the mind grows restive under the increasing burden. Every time the eye ranges up or down its face it seems more distant and more vast. At length we recoil, overburdened with the perceptions already attained and yet half-vexed at the inadequacy of our faculties to comprehend more. The magnitude of the chasm, however, is by no means the most impressive element of its character; nor is the inner gorge the most impressive of its constituent parts. The thoughtful mind is far more deeply moved by the splendor and grace of Nature's architecture. Forms so new to the culture of civilized races and so strongly contrasted with those which have been the ideals of thirty generations of white men which cannot indeed be appreciated after the study of a single hour or day. The first conception of them may not be a pleasing one. They may seem merely abnormal, curious, and even grotesque. But he who fancies that Nature has exhausted her wealth of beauty in other lands strangely underestimates her versatility and power. In this far-off desert are forms which surprise us by their unaccustomed character. We find at first no place for them in the range of our conventional notions. But as they become familiar we find them appealing to the æsthetic sense as powerfully as any scenery that ever invited the pencil of Claude or of Turner.

The inner gorge, as we sit upon its brink, is indeed a mighty spectacle; but as we withdraw a little, it fades out of view, and, strangely enough, the sublimity of the scene is not very greatly impaired. It is, after all, a mere detail, and the outer chasm is the all-engrossing feature. On either side its palisades stretch away to the horizon. Their fronts wander in and out, here throwing out a gable, there receding into a chamber, or gaping widely to admit the entrance of a lateral chasm. The profile is ever the same. It has nothing in common with the formless, chaotic crags, which are only big and rough, but is definite, graceful, architectural and systematic. The width of the space inclosed between the upper walls is one of the most essential elements of the grandeur. It varies from five to six miles. If it were narrower the effect would be impaired; nor could it be much wider without diluting and weakening the general effect. This proportion seems quite just. It is a common notion that the distinctive and overruling feature of the great chasm is its narrowness relatively to its depth. No greater mistake could be made. Our highest conceptions of grandeur are most fully realized when we can see the greatest mass. We must have amplitude in all of the three dimensions, distance, breadth and depth, and that spectacle is in point of magnitude the grandest which has the three dimensions so proportioned and combined as to make the most of them. Another common and mistaken idea is that the chasm is pervaded by a deep, solemn gloom. The truth is almost the reverse. In the depths of the inner gorge there is a suggestion of gloom, but even in the narrower portions there is seldom less than sixty degrees of sky from crest to crest, and a hundred and sixty along the track of the river. In the outer chasm the scene is unusually bright. The upper half of the palisades have a pale, ashy or pearl-gray color, which is very lustrous, and this sometimes gives place to a creamy or Naples yellow tint in the frieze of cross-bedded sandstone. The Lower Aubrey sandstones are bright red, but they are in great part masked by the talus shot down from the pale gray limestones above, and peep out in lustrous spots where the curtain of the talus is drawn aside. There is nothing gloomy about such colors. Under a burning sun that is rarely clouded they have a brilliancy seldom seen in any rocks, and only surpassed by the sugary whiteness of the Jurassic sandstone or the brilliant red of the Vermillion Cliffs.

Directly in the southward prolongation of the axis of the Toroweap Valley there stands a basaltic cinder-cone immediately upon the brink of the inner gorge. Its altitude above the surrounding plain is 580 feet. The summit is readily gained, and it is an admirable stand-point from which the entire panorama may be viewed. We named it Vulcan's Throne. To the eastward about forty miles of the main chasm are well in view. The altitude of the cone, though small in comparison with surrounding objects, is sufficient to bring into view about twelve miles of the opening of the inner gorge, while in the foreground its depths are seen. To the westward the scenery is much more broken and diversified. The chasm is seen through the entire stretch in the Uinkaret Plateau and reaching a few miles into the Sheavwitts. But about twenty miles westward it makes a southward turn and disappears. From the north the Toroweap Valley descends from near Mount Trumbull. It is cut down only to the base of the upper cañon wall and opens into the main chasm on the level of the plain above the inner gorge. There is reason to believe that at some prior epoch it was cut a few hundred feet deeper than its present floor, and was subsequently built up by many floods of basalt coming from the cones on the Uinkaret and by considerable quantities of alluvium washed from its cliffs and overlooking mesas. On the south side of the Grand Cañon is a valley quite the counterpart of the Toroweap. It enters the main chasm directly opposite the Toroweap, so that the two form the arms of a transept, the main chasm being regarded as the nave. Vulcan's Throne is situated almost exactly at the intersection of the axes of the nave and transept.

It would be difficult to find anywhere else in the world a spot yielding so much subject-matter for the contemplation of the geologist; certainly there is none situated in the midst of such dramatic and inspiring surroundings. The chasm itself, with its marvelous story of erosion, and the two lateral valleys adding their quotas of information are grand subjects indeed; but other themes are disclosed which are scarcely less surprising and suggestive. The cone stands immediately upon the line of a large fault. And never was a fault and its consequences more clearly displayed. The Toroweap fault is one of six which at wide intervals traverse the Grand Cañon district from north to south with a rude approximation to parallelism. It is the smallest of the six. Twenty miles north of the chasm no trace of it is visible. Its beginning there is small, but as it approaches the chasm it increases in the amount of displacement; and at the crossing of the river the shear or "throw" is between 600 and 700 feet. In the wall-face of the inner gorge it is disclosed as clearly as a draughtsman could delineate it on paper. The masses of horizontal limestones and sandstones, displaying their fretted edges and lines of bedding, advance from the eastward in the face of the wall until they reach the vertical fault plane. Then they "break joints" and drop at once six or seven hundred feet, and continue westward as before, but at a lower level. The whole topography goes with it. Looking beyond to the upper wall of the outer chasm the "jog" where the break occurs is plainly seen. The whole platform of the country is dropped to the westward. The plain between the upper palisades descends by a single step from east to west across the fault by an amount equal to the displacement, and the inner gorge and the whole chasm becomes by so much reduced in depth. Excepting the dislocation itself, the faulting does not appear to have been accompanied by any injury to the strata. Not a trace of shattering, crumbling, or mashing of the beds is discernible. All looks as clean and sharp as if it had been cut with a thin saw and the smooth faces pressed neatly together. But the only attainable view of it is from the distance of a mile. Yet miles here are less than furlongs in other countries, and all details as well as broader features are upon the Brobdignagian scale. What a nearer view might disclose



Western Scenery.—Island Monument in the Glen Canyon.—Colorado River.

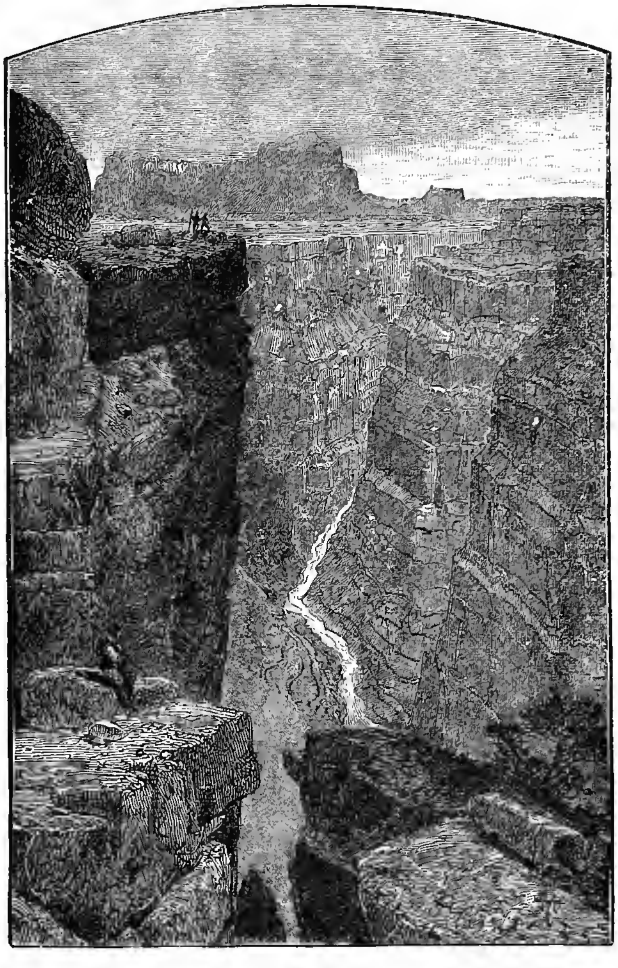
is of course impossible to conjecture. The plane of the fault is about vertical, though there seems to be a slight inclination to the east, which may be apparent only and a result of perspective. After a careful study of the surroundings of the fault, it becomes apparent that it is of recent occurrence in comparison with other events which have been in progress here. The tenor of all evidence bearing upon the subject goes to show that these faults were not suddenly produced by violent convulsions, but gradually developed through long stretches of time, and inch by inch or foot by foot. The Toroweap fault gives no evidence of being exceptional in this respect. Its recency is disclosed by many facts. It is seen that the amount of erosion in the face of the transverse "cliff of displacement" produced by the faulting is very small. This cliff has not receded from the fault plane to any considerable extent. Yet the giant palisades which wall the outer chasm have receded from the median line of the cañon more than two miles since the corrosion of the river laid bare the edges of their strata. It seems very plain that the outer chasm had been formed and attained very nearly its present condition before the fault started. But there is still more conclusive evidence of recency. At the foot of the southern palisade and at the jaws of the lateral valley are several basaltic craters. They look like mere bee-hives under the eves of such an escarpment, though in truth they are four or five hundred feet high. From their vent streams of basalt are seen flowing down into the lateral valley across the fault plane, and clear to the brink of the inner abyss. The fault shears the lava floods as nearly as it does the Red Wall limestone. Many other facts might be cited to the same purport, but this one is so conclusive that nothing further is necessary. We shall find similar evidences of recency when we come to the study of the great Hurricane fault.

Another subject which will awaken the enthusiasm of the geologist who visits this unique spot is the volcanic phenomena. Turning to the northwestward he beholds the heights of the Uinkaret. Upon its broad expanse stand many basaltic craters in perfect preservation. We know of about a hundred and fifty distinct cones in this plateau, included in the space which lies between the Grand Canyon and a limit forty miles north of it. But it is in the vicinity of the chasm that they cluster most thickly together and present the largest proportions. This part of the Uinkaret is thickly covered with basalt, above which rises the tumultuous throng of craters. Very many wide and deep floods of basalt have poured over the edge of the plateau into the lower Toroweap Valley and upon the great esplanade of the canyon, 1,500 to 1,800 feet below, and, spreading out into wide fields, have reached the brink of the inner gorge. Pouring over its brink, the fiery cascades have shot down into the abyss and pursued their way many miles along the bed of the river. At one epoch they had built up the bed of the Colorado about 400 feet, but the river has scoured out its channel again and swept them all away, regaining its old level, and is now cutting the sandstones below. The spectacle of the lava floods descending from the Uinkaret, as seen from Vulcan's Throne, is most imposing. It tells the story so plainly that a child could read and understand it. Compared with many classic volcanic regions the volcanism of the Uinkaret is a small affair. In those classic regions the mind does not come into direct contact with the enormity of the facts by a single glance of the eye. But here, if kind Asmodeus were to lift the basaltic roof of the plateau, we should see no more than we do now. The boldness of the picture is much increased by the pediments of Carboniferous strata projecting from the body of the plateau, showing the brilliant colors of the strata and their sharply-defined architecture, with the dark masses of basalt wrapping around them. Hard by, and almost within hail, is a superb gable projecting between two broad floods of lava, and so beautifully proportioned and richly colored that we cannot help wishing to transport it by magic to some more habitable region. The Toroweap Valley has a significance to the geologist which might not be at once apparent to the tourist. Even the geologist would be slow to discern it unless familiar with cognate facts displayed in the country at large bordering the Grand Cañon. In the effort to interpret its meaning it becomes necessary to take a hasty view of one or two broad facts relating to the lateral drainage of the chasm. Upon the north side, in all the distance between the head of the Marble and the foot of the Grand Canyons, there is but one side canyon, carrying drainage from distant regions. This single exception is Kanab Canyon. In this respect the Colorado is much like the lower courses of the Nile; and the cause is plainly the same. The region is too arid to sustain any living streams or even to keep open the conduits which in former periods might have sustained them. Yet upon the assumption that at some former period the climate was much more humid all analogy compels us to believe that the Colorado once received many tributaries which are now extinct, and upon examination we find good evidence that this was really the case. The Toroweap Valley is the modified channel of an ancient river. On the west side of the Uinkaret is another. A third is seen upon the south side of the Colorado, directly opposite the Toroweap; and a few others may easily be designated. It appears that all these rivers dried up before the inner gorge was excavated. For if they had continued to carry water we may be sure that they would have cut their chasms as deep as the Grand Canyon itself—just as the Little Colorado, Kanab Creek, and Cataract Creek have done. For we have only to look at the great multitude of lateral chasms of the upper courses of the Colorado and of its forks, the Grand and Green, to be deeply impressed with the fact that so long as a tributary river carries, we will not say a living stream, but even occasional floods, its channel will be scoured down to the same level as the trunk river itself. It is apparent, then, that the Toroweap dried up before the cutting of the inner gorge of the Grand Cañon began, and hence we infer that the arid climate which caused it to dry up existed before the beginning of the inner gorge.

By the application of other homologous facts, and by the same method of reasoning, we infer that the outer chasm has also been excavated during the prevalence of an arid climate. The platform of country adjoining the canyon is at present devoid of lateral chasms, yet traces are often found of ancient channels which became dry at about the time the excavation of the outer canyon began, or very soon thereafter. They are cut to comparatively slight depths—from one hundred to three or four hundred feet. That they are not of recent origin is proved by the fact that they often have slopes away from the river, though it is clear that they formerly sloped towards it. In truth, the entire chasm betrays everywhere the continued action of an arid climate through the entire period of its formation. This arid period is limited, approximately, to Pliocence and Quaternary time. The general tenor of the facts is to the effect that the Miocene was a humid period and the Pliocene a dry one throughout the greater part of the West. This is one of the reasons which lead us to the very probable conclusion that the age of the Grand Canyon is not older than the beginning of Pliocene time. We might also draw a similar inference from a consideration of the enormous erosion which took place here before the excavation of the chasm was begun. The denudation of the Mesozoic system was an incomparably greater work, and yet that denudation could not have begun until the last strata (the Lower Eocene) was deposited. If these inferences are well founded, we may assign the greater part of Eocene and the whole of Miocene time for the principal denudation of the Mesozoic, and the Pliocene and Quaternary for the excavation of the entire canyon. The proportion thus suggested between the portions of the work done and the divisions of time required to accomplish them seems very fair and reasonable. But the strongest evidence of all it would be almost impossible to recite here in detail. In general terms, it may be characterized as that internal evidence which appears when a vast array of facts, at first disjointed and without obvious relation, are subsequently grouped aright into a coherent system. Each constituent fact is then seen to admit of one intelligible interpretation and no other; and each subsidiary proposition has an overwhelming justification and an evidence of verity far stronger than any which could be summoned if we endeavored to prove it independently.

Another question which the geologist asks here is, how happens it that the outer chasm is so broad while the inner one is so narrow? The outer chasm is five to six miles wide and 2,000 feet deep; the inner is about 3,500 feet wide and 3,000 feet deep. The disparity is great. We have seen enough to say at once that the widening of the outer chasm was effected by the recession of its cliffs. If the corrosion of the canyon went steadily onward without a halt or respite this disparity demands some explanation. Although we should expect less recession in the cliffs of the inner gorge than in those of the outer, we should not expect it to be so much less if the only variable concerned was length of time. We might explain it by assuming the rocks of the inner gorge to be much more obdurate than those above. This is true in part, but still the difference in this respect is insufficient. A much more satisfactory explanation is found in the supposition that the broad esplanade of the canyon between the upper palisades was an ancient base-level of erosion. We might imagine that when the Colorado had cut its channel down to that level, it had reached the limiting depth of corrosion for the time being. Then for a long period the palisades on either sides wasted and receded from the river. At last another epoch of upheaval set in; the entire platform of the district was lifted several thousand feet; the power of the river to corrode was restored; and with comparative rapidity it sank the inner gorge. This becomes more than a mere guess when we take account of its relation to the general category of facts. Thus the great faults attest the fact that such an upheaval did occur; that it occurred, too, just at the time supposed; and that in amount it was quite equal and probably not more than equal to the amount required. Other evidence might also be produced, but they are too intricate to be discussed here. We leave the Toroweap Valley and the Grand Canyon, regretting that all its wonderful and instructive subjects should receive such brief notice. Retracing our steps up the Toroweap for a distance of about six miles, we at length select one of the great lava streams on the western side. Although quite steep, we may ascend it with the animals and packs without serious difficulty. At the end of an arduous climb upon the rugged slope, we find ourselves upon the platform of the Uinkaret. Around us are the old cinder-cones, most of which are of considerable dimensions. All of them have given vent to floods of basalt, which have spread out thinly over extensive surfaces, but as the number of superposed sheets is considerable in this part of the plateau, the aggregate thickness, though somewhat roughly inferred, must be three or four hundred feet, and occasionally much more. There is not much to add to this description. The lava is apparently all of one kind, but some of it much older than other portions. In truth, it soon becomes apparent that the period of volcanic activity was a long one. A few miles from the point where we attained the summit of the plateau and in a northwest direction from it, we come upon the termination of a lava stream which has the appearance of being extremely recent. It looks as fresh as the emanations from Vesuvius or Ætna which have outflowed within the last fifty years. Its surface is intensely black, and only here and there can we perceive that weathering has even impaired its freshness. Two miles away is seen the cone from which it emanated. The last eruptions from it have almost destroyed it, and melted down a greater part of its mass. Skirting the edge of this lava-sheet, we find at the eastern base of Mount Logan a small spring, named the Oak Spring. It is a central point, from which the southern part of the plateau may be visited. There is another very small spring high up on the southwestern side of Mount Trumbull, and its waters have been brought down by a wooden pipe to the plain below, to supply the wants of a saw-mill. A third and much larger spring is found on the western side of the Uinkaret. These are the only available sources of supply, and each may be used as occasion requires for the examination of different parts of the plateau.

The Kaibab.—It is difficult to say precisely wherein the charm of the sylvan scenery of the Kaibab consists. We, who through successive summers have wandered through its forests and parks, have come to regard it as the most enchanting region it has ever been our privilege to visit. Surely there is no lack of beautiful or grand forest scenery in America, and it is a matter of taste what species of trees are the most pleasing. Probably few people would select the conifers and poplars as the highest types of arboreal beauty. I suspect that the charm consists in influences far more subtle than these outward forms. The delicious climate, neither cold nor hot, neither wet nor excessively dry, but always exhilarating, is a fundamental condition by virtue of which the body and mind are brought into the most susceptible mood. The ease with which we move from place to place, the absence of all anxiety or care for the three great requisities of camp life, fuel, water, and grass, are accessory conditions. The contrast of the desert with its fatigue, its numberless discomforts and privations, is still another. But the scenery is also very beautiful in itself. The trees are large and noble in aspect and stand widely apart, except in the highest parts of the plateau where the spruces predominate. Instead of dense thickets where we are shut in by impenetrable foliage, we can look far beyond and see the tree trunks vanishing away like an infinite colonnade. The ground is unobstructed and inviting. There is a constant succession of parks and glades—dreamy avenues of grass and flowers winding between sylvan walls, or spreading out in broad open meadows. From June until September there is a display of wild flowers which is quite beyond description. The valley sides and platforms above are resplendent with dense masses of scarlet, white, purple, and yellow. It is noteworthy that while the trees exhibit but few species, the humbler plants present a very great number, both of species and genera. In the upper regions of the High Plateaus, Mr. Lester F. Ward collected in a single season more than 600 species of plants, and the Kaibab, though offering a much smaller range of altitude and climate, would doubtless yield as rich a flora in proportion to the diversity of its conditions.



Western Scenery.—A View of the Grand Canyon.

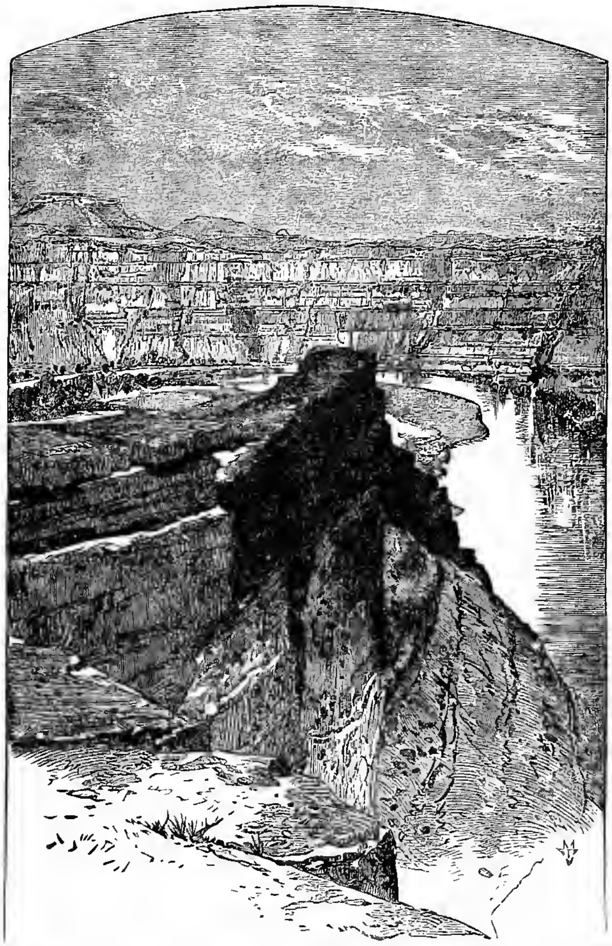
At a distance of about eight miles from its mouth, the ravine we have chosen has become very shallow, with gently sloping sides. At length we leave it and ascend its right bank to the upper platform. The way here is as pleasant as before, for it is beneath the pines standing at intervals varying from 50 to 100 feet, and upon a soil that is smooth, firm, and free from undergrowth. All is open, and we may look far into the depths of the forest on either hand. We now perceive that the surface of the plateau undulates with rolling hills and gently depressed vales. These valleys are the ramifications of the drainage channels. They are innumerable and cover the entire surface of the plateau. The main channels all deepen as they approach the edges of the plateau and often attain considerable depth, becoming at the same time precipitous. The deepest are those which emerge near the elbow of Stewart's Canyon and north of that point. These attain depths exceeding a thousand feet. The ravines which descend towards the eastern flank of the plateau terminate in a different manner. In the interior parts of the plateau these drainage valleys are all shallow, rarely exceeding 300 or 400 feet in depth, and seldom abrupt. After two or three miles upon the summit, the trail descends into another valley, whose course we follow upward for about seven miles. At the distance of about twenty miles from Stewart's Canyon, we find that we have gained about 1,200 feet of altitude, and that the vegetation has changed its aspect somewhat. The pines, though still abundant, are now in minority, and the spruces and aspens greatly predominate. The spruces form dense thickets on either hand, which nothing but the direst necessity would ever induce us to enter. Of this genus there are several species, varying much in habit. The great firs (*Abies grandis*, *A. Engelmanni*) are exceedingly beautiful on account of their sumptuous foliage. But the most common species is a smaller one (*A. subalpina*), with a tall and straight trunk, its branches spreading only five or six feet. These trees cluster so thickly together that a passage through them is extremely difficult and sometimes impossible. But we are not constrained to attempt it, for they seldom grow in the valley bottoms. Again we leave the ravine, and winding about among the hills, passing from glade to glade, we at length find ourselves upon the summit of a long slope, which descends rapidly into a great park, the largest on the Kaibab. It has received the name of

De Motte Park.—Its length is about ten miles, its average width is about two miles. It is a depressed area in the heart of the plateau, and is on every side girt about by more elevated ground rising by strong slopes 300 or 400 feet above its floor. The borders and heights above are densely forest-clad, but not a tree stands within the park itself. Descending into its basin and proceeding southward about two and a half miles, we reach a little spring where we make camp. The distance from the Big Spring to Stewart's Canyon is about twenty-six miles by trail. De Motte Park is eminently adapted to be the base of operations in a campaign of geological investigation upon the southern part of the Kaibab. It is a central locality from which we may radiate in any direction to the bounds of the plateau. Here the great bulk of the supplies may be deposited, and from the supply-camp we may make journeys with light packs for one, two or three days, as it may suit our convenience, and to it we may return to fit out for another short trip. The circumstances which make the park so advantageous in this respect are worth reciting. Notwithstanding the open character of the forest there are two difficulties in the way of travel on the Kaibab. The first has already been mentioned, scarcity of water. We know of about a dozen small springs, some of them conveniently located for the purposes of the explorer, others not. There is, however, another source of water supply which will be described presently. The second difficulty is the danger of getting lost and bewildered in the forest. This may seem to be a singular source of danger for an explorer, who of all men is bound to know his exact whereabouts at every step. But if he were to visit the Kaibab with that easy confidence and without a guide he would probably learn a severe lesson in less than a fortnight. The young Mormon herders who range over this region, and who follow a trail with the keen instincts of Indians, and with more than an Indian's intelligence, dread the mazes of the forest until they come to know them. Even the Indians who live and hunt there during the summer and autumn have sad tales about comrades lost when the snows came early and buried the trails so that they could not be followed. The bewildering character arises from the monotony of the scenery. There are hundreds of hills and gulches, but they all look alike. There are no landmarks except trees, which are worse than none at all. If you enter a ravine for the second time at a point other than that at which you first entered it you would probably fail to recognize it. As with the faces of the Chinese, no conscientious white man would be willing to swear that he had ever seen any particular one before. Yet the riddle of the Kaibab is soon solved, and once read, all danger is over. If the traveler is lost there is an infallible clue. He must go at once to De Motte Park. But how shall he find the way? If he has reason to suppose that he is within a dozen miles of it he has only to enter a main ravine and follow it to its head. This, however, does not apply to the portions of the plateau which lie more than five miles north of the park. The way may be long, but it is easy and sure. A few ravines fade out before reaching the near neighborhood of the park. In that event take the nearest one on the right or left. All of them head upon the summit which looks down into the park. It is necessary, however, to keep to the *main* ravine and avoid its minor tributaries, and there is a criterion by which it may be distinguished. At the confluence of a lateral ravine the grade of the main ravine is always the less of the two.

Although this may seem to be nothing more than a trivial bit of woodcraft, it really illustrates an important fact—the drainage system of a large portion of the Kaibab. The study of this drainage system will shed some light upon the geological history not only of the plateau itself, but of the region adjoining, and of the Grand Canyon. The thought which must be predominant in the mind of one who for the first time enters the Kaibab is of the Grand Canyon. The fame of its grandeur is world-wide, and the desire to see it as it is grows stronger the nearer he approaches to it. This longing must be at least tempered if not wholly satisfied before the mind is in the humor to contemplate anything else. Our first expedition, then, shall be to the brink of the great abyss. As the sun is rising and before his beams have penetrated to the bottom of the park we are on the way. On either hand is the forest, covering the slopes and the heights above, but ending suddenly at the foot of every incline. Before us to the southward stretches the open field with hardly an undulation. Six or seven miles away we can see the sylvan walls approach each other, leaving a narrow gateway between the tall spruces where the surface of the ground for a moment is sharply projected against the sky. The scene is, on the whole, a very attractive one. There is a great wealth of vegetation, somber indeed, and monotonous, but the darkness of the tone is suggestive of depth and richness of color. The only alleviating contrast is between the smooth expanse of the park and the myriads of sharp spikes which terminate the tree tops. The spirit of the scene is a calm, serene, and gentle one, touched with a tinge of solemnity and melancholy. About a mile from camp we came upon an object worthy of attention. It is rather a deep depression in the earth about 200 feet across and very nearly circular. Within it is a large pool of water. Its depth below the valley floor may be about 40 feet, and the depth of the water 5 or 6 feet in the middle. It is a fair specimen of a frequent occurrence upon the Kaibab. I have never seen them elsewhere, and the explanation is difficult. The interest lies in the mystery of their origin. In every day's ride we usually find three or four of them and sometimes more. Some of them contain water, but the majority do not. Some hold water throughout the year, some only in the early summer or until autumn. They vary in size and depth very considerably. Some are as narrow as 20 feet; some are 300 to 400 feet across. The depths vary from a yard or two to a hundred feet. The form is crater-like—always approximately circular. They do not appear to occur under any special set of conditions. They are found as often upon the platforms as in the valleys, and are not uncommon upon the slopes of the ravines. In a few instances traces may be seen of rain gullies or washes leading into them, but not often, and none have ever been noted leading out of them. Whatever running water may enter them sinks within their basins; but it is certain that many of them rarely receive any running water. In the cases of those which do the wonder is that they do not soon fill up with sand and silt, for the water generated by heavy rain storms or by melting snows, when sufficient in volume to run in a stream, is always thick with mud. The scarcity of running water on the Kaibab has been mentioned. Yet the precipitation is comparatively great and the evaporation small. It is apparent that all the water which falls upon its vast expanse, with the exception of a slight percentage evaporated, must sink into the earth, where it is doubtless gathered in subterranean drainage channels which open in the profound depths of the great amphitheaters of the Grand Canyon. In those depths are large creeks of perennial water issuing from the openings of those underground passages. This implies a system of subterranean rivulets, but it is not more wonderful than the endless caverns in the limestones of Kentucky and Indiana, and it is probably not upon so large a scale nor so greatly ramified. It also argues a high degree of permeability both in the upper strata and in the overmantling soil. The water sifts through them as easily as through sand, and rarely gathers into streams even in the most copious showers or most rapid melting of the snow. Whether these "lagoons" and "sink-holes," as we termed them, are the openings of pipes leading down into the subterranean rivers and kept open by a gradual solution of the limestone, it is difficult to say. There are some difficulties in the way of this theory.

Moving rapidly southward, at length we reach the Sylvan Gate at the lower end. Passing through we immediately find ourselves at the head of a second park very similar to De Motte's, but smaller, having a length of nearly three miles. It is named Little De Motte Park, and the Sylvan Gate occupies a divide between the two. It contains a large lagoon holding stagnant water. There is a chain of these parks reaching from the northern end of De Motte's southward, a distance of 25 miles, separated only by necks of forest. Our aspens, the golden shafts of sunlight shot through their foliage, the velvet sward—surely this is the home of the woodland nymphs, and at every turn of the way we can fancy we are about to see them flying at our approach, or peeping at us from the flowery banks.

By half-past ten the spring is reached. Next the Big Spring, in Stewart's Canyon, it is the largest on the summit of the plateau. Here, too, is the only semblance of running water, for the stream flows a little more than half a mile before it sinks. The water is cold and delicious. It has a faint whitish cast like that which would be produced by putting a drop or two of milk into a bucket of pure water. I presume it is caused by a fine precipitate of lime. We called it the "Milk Spring." Pausing here for a hasty lunch, and to fill the kegs (for to-night we may make a "dry" camp), we push on. We climb out of the ravine, and in fact we only came here to obtain water, as it is the



WESTERN SCENERY.—SUMNER'S AMPHITHEATRE.—COLORADO RIVER.

first objective point is a spring situated in one of the large ravines which head in the heights overlooking these two parks. Without some foreknowledge of the way to reach it, or without a guide, it would be impossible to find it, and the same is true of any other spring on the summit, but with this foreknowledge we seek the southwestern border of Little De Motte and enter the timber. During half an hour there is a miserable struggle with fallen trees and thick set branches of spruce and aspen, but at length the heights are gained, and we descend into a shallow ravine where the way is once more open. The winding glade with smooth bottom richly carpeted with long green grass, aglow with myriads of beautiful blossoms is before us, and the tall trees are on either hand. Soon it leads into a larger one, and this into another, until at last the main ravine is reached. Very sweet and touching now are the influences of nature. The balmy air, the dark and somber spruces, the pale green

only place near to the point of destination at which water can be procured. The route now becomes more rugged, leading across ravines and over intervening ridges, crossing the grain of the country, so to speak. But it is not difficult, for the pines have taken place of the spruces, and where the pines predominate the forest is very open. For eight miles from the Milk Spring we continue to cross hills and valleys, then follow a low swale shaded by giant pines with trunks three to four feet in thickness. The banks are a parterre of flowers. On yonder hillside, beneath one of these kingly trees, is a spot which seems to glow with an unwonted wealth of floral beauty. It is scarcely a hundred yards distant; let us pluck a boquet from it. We ride up the slope. The earth suddenly sinks at our feet to illimitable depths. In an instant, in the twinkling of an eye, the awful scene is before us.

—Taken from an article by Clarence E. Dutton, Report of U. S. Geological Survey.

THE ROMANCE OF MINING.

WHAT romance can there be connected with such an occupation as that of mining? Is the doing of the hardest work romantic? Can poetry be associated with deep pits and long underground galleries in which the never ending rows of timbers look like processions of ghosts and the masses of fungus remind you of strange monsters without form, yet of most fantastic shape, as seen in the dim light of the lamps which gleam like stars in the heads of the miners? The answer is yes. Are we not to find romance associated with the occupation of the Dwarfs and the drolls; poetry in the ground sacred to the Pixies? Mining is full of romance, of quaint superstitions, of dazzling tales which would not disgrace eastern imaginations; of poetry which comes down to us from the dead and gone races who centuries ago worked the metals under the frozen hills with their pine tree coronets in the far north; of strange Indian legends which as we hear them told remind us of the time when the dazzling Emperors of the South, the mighty Montezumas, watched the hecatombs of victims slain on the Obsidian altars of the dead war god; of the wonderful stories which were first told in the mines of sunny Spain and carried thence by the stern *conquistodares* to the land they made their own, reappearing to-day in quaint form and quainter language at the campfire of the lusty prospectors. In modern days too mining has shown its romantic side in the changes of fortune which have marked the careers of those who followed it, changes whcih are only paralleled in the oriental tales of *Genii*. Sudden wealth and equally sudden poverty, long years of patient waiting to be followed by affluence, hard and exhausting toil resulting in the finding of a placer or a pocket out of which the gold is taken in such quantities as to turn the brain of the discoverer. Can romance and poetry be denied to a form of work in which heroism of the grandest has been shown again and again? The very strangeness of the life of these human moles which we call miners, has brought about phases of human nature as strange as the life itself; and as the lonely miner toils under-ground by the light of his flickering lamp, his imagination has peopled the dark places in the mine with spirits of potent power; of a kindliness in the nature of some only equalled by the fell cruelty of the others. How often have poets sung and great musicians wedded to deathless music the *Niebelungen Leid?* How often have they told the story of the capture of Lohi, of the Dwarf King Andvari and Marr's first possession of the wonderful treasure when Lohi gave it to Huidman as a ransom for the three from Asgard, how Seigfried captured it and compelled Andvari the dwarf to pound it, how after Seigfried married Brumhild, Haco killed him for the treasure and how Haco hid the glittering hoard, refusing his life in exchange for the secret. The great German epic turns about a treasure of the mines. From the southland come the stories of the Moorish kings of Spain and the wonderful treasures procured and kept for them by the mighty power of the magicians; of the deep and hidden caves founded by *genii* and only to be opened by strange spells, in which the gold and the jewels were placed. Every race upon the earth has had its wonderful legends about mining, some as simple as the fairy tales for children; some as complex as the most involved drama in which human passions have played their parts.

The Madre D'Oro.—There has always been a strange fascination to the minds of men about the sudden acquisition of wealth. About the idea of gold so secured there has always been that mental glitter which has attracted the poet and the romancer. To the men who search for gold, whose lives are devoted to the discovery of the precious metals, there is a double measure of this fascination. The modest and least imaginative of them can picture to himself a ledge which is not solid gold shall at least contain nuggets and veins of the virgin metal bright with its yellow gleam. And so there is no story in the west half as often told as that of the *Madre D'Oro*, the "Mother of gold," the Treasure House destined by nature for her fortunate child. The story comes to us from the Aztecs, they in turn may have heard it from the Toltecs who preceded them. When the Great Empire of the Montezumas fell under the stern assaults of Don Herman Cortez and the army of heroes which he led; and when the last of the Montezumas who placed on his head the imperial plumes, the unfortunate Guatimozin died, the Indians adopted a belief similar in many respects to that which was so common among the English about the return, some day, of the fabled Arthur. Under the grinding tyranny of the *Anquistadores* this belief was the sole hope left among the unfortunates who lived and died under the lash. When Montezuma returned, he would, so the legend ran, lift the race from slavery, drive out the hated Spaniards, rear once more the altars to the war God on top of the *teocallis* and resume his ancient state and power. Until that time came, the Aztecs who were left must endure as best as they might the evil days which had fallen upon them. And so they lived and died, nursing the vain hope that some day better times would come when the long delayed vengeance would be fully satisfied. But they realized that when Montezuma returned he would need in order to resume his power, stores of gold, and so they told to each other with bated breath the story of the wonderful valley, where, under the guardianship of the faithful tribe, descended from the remnant of the priests who united with their devotion to their terrible Deity almost as sincere a worship for the House of Montezuma, the treasures destined by the Gods to furnish forth the rehabilitated glories of the kingdom lying waiting for the coming. Although, as is Indian nature, the Aztecs were to the last degree reticent, such a story as this was too wonderful not to be told again. Perhaps more Aztec maidens whispered the legend she had heard from the grandsires of her race to the ears of her Spanish lover. Perhaps some poor slave tortured to death let fall the story to delay for a time the intolerable torment. It matters not how the tale came to be told. In time the Mexicans heard it and in retelling gave it possibly, still further wonderment as it passed through brains colored by the vivid imagination of the Spanish nature. And so it came to us, as wonderful a story as was ever told to men; one rivaling the wildest legends of the East. Somewhere in Southeastern Arizona or in Northern Mexico, so runs the tale to-day, there is a small valley. It is always described as being about five miles long and two wide, and walled in by towering mountains. It was formed originally by water, being simply the widening out of a Canyon, through which at the lower end is the only entrance to it. Its sides are airy, are from three to five —thin sand—feet high, and they go down there from the top. While they have been fashioned into strange shapes during the long ages that have passed since the water began its work, they are always said to be so precipitous as to prevent anyone climbing down. The upper part of the Canyon, that above the valley, is simply impassible for men owing to a tremendous precipice, over which the ancient river once ran and down which the stream now falls in an exquisitely beautiful water fall. The Canyon below the valley, however, may be passed through the entrance cave. When the river was cutting it, it encountered a deposit of hard stone, under which it slowly worked its way through a softer bed and gradually hollowed this out, until, in time, it cut a long tunnel, like a cavern. Through this is the entrance to the valley. But not only is the exact location of the valley not known but the entrance to the cave is carefully hidden by the efforts of men. The Indians, who guard the treasure for the coming of Montezuma, live near the entrance, and they have carefully concealed all the approaches to it, and are, if it be necessary, prepared to give up their lives in its defence. It is said that even among them the entrance to the cavern is only known to the three most aged men, and is never communicated except when, on the death of one, it is necessary to give the knowledge into the keeping of another. When this occurs, the tribe know, for the first time, that the man who has gone was one of the guardians of the secret. The communication of the knowledge to another is done after many ceremonies and in a way which absolutely prevents all knowledge on the part of the tribe as to who is chosen. The women and children and such of the men who are not old enough to belong to the medicine lodge, or what is apparently —supposing this story, as told, to be true—a kind of order of priesthood in the medicine lodge, prepare enough food to maintain them for ten days. They start in the direction of the setting sun and travel five days. On the morning of the sixth they turn and travel back. The day after they leave, each of the members of this order of priesthood, taking with him enough food to last seven days, leaves the *rancheria* or village, and goes alone to some designated spot within half-a-day's trip. Here he stays for the seven days, at the end of which time he comes back. Among these men, who are always old, there are two, known only to each other, who possess the secret. They set forth like the others, but they alone have the right to leave the places to which they go on the morning of the third day. Together they journey to one of the spots where the priests have gone, and greeting the man they find there by some form of words, said to be a remnant of the old Aztec language, bid him rise and follow them. They take him to the long cavern and through it to the valley, they show him the ledge which they have guarded in the past and which he must guard in the future, they reveal to him the knowledge which they have of Montezuma, they tell him of the signs which will point to the coming again of the Imperial race. Slowly and carefully they show him the method by which the place is found. They exact from him oaths of the most solemn sort that as he has received the secret so alone he will impart it, unless the fulness of time should come and Montezuma return. They give him the signs by which Montezuma will be known; the form of words which Montezuma will use when he asks the faithful guardians of the secret for his own. They indulge in a sacrificial banquet, in which it is said, the flesh of the man who has just died forms the sacrament, on which the living swear that as he kept the secret entrusted to him, so they will keep it until the end. Returning to the *rancheria*, and effacing with infinite pains the marks of their feet after they leave the cavern, each of the three goes to his appointed place to return with all the others on the seventh day. No one knows who has been selected to carry on the trust, except the three to whom it is confided. On the tenth day the young men, women and children return to find the members of the priesthood quietly awaiting them. They know that during their absence some one of the old men who sit there so calmly and quietly, has seen the valley and the ledge but they know no more.

The valley is as I have said, described as being about five miles long and two wide. Surrounded on all sides by towering and precipitous cliffs, grim in their stern and rugged shapes, the valley itself is a paradise. Watered by the stream which flows through it, its soil is covered with flowers and beautiful trees, through the branches of which flit the bright-hued birds of the South land. Brilliant insects dart here and there through the delicious air; the only reptiles seen are the gold snakes with their glittering greenish-yellow scales. Perfectly harmless, they but serve to give added beauty to the scene. Stretching across the valley from one side to the other lies the great ledge, like a golden zone; its masses of virgin metal gleaming and glistening in the sunlight. It is said to be five feet, ten feet, fifty feet, a hundred feet wide. The gold lies in it in great veins and nuggets, embedded in clear quartz, the sharp angles of which glitter in the sunlight like gigantic diamonds.

Across the ledge the stream flows, and forms a little waterfall, below which the nuggets of gold can be seen in the water and out. Growing beside the ledge, just by the fall, is an exquisite tree at the base of which lies a great gold snake, ever watching with unmoving eyes the treasures of Montezuma. It is the war-god in person who guards the place. Gold in the ledge, gold in the scales of the snakes, gold in the stream, gold in the colors of the insects, and birds, gold across the valley, gold down the valley; gold, gold, gold, gold, is the refrain of the golden story. The fearful precipices which surround the place, the strange ceremonies and horrid banquets which have served to keep the secret safe, the tribe of Aztecs, living only to preserve for their mysterious ruler this treasure-house of nature, have all aided in giving to the story its strange interest. Small wonder is it that the pulse should quicken and the eye grow bright, as you hear the tale from the lips of men who more than half believe it. The lonely desert surrounding you, with the tall *cacti* looking like ghosts in the half-moonlight; the long-drawn melancholy of the cayote's howl, the prospector's fire of greasewood, the men with their rough clothing and quaint language, all vanish as you listen, and in imagination you are transported to the wonderful valley, in which is the "*Madre D' Oro*, the "Mother of Gold." Nor are they content to tell the story as an Indian legend. They cite instances of white men who have seen the place, who have descended into the valley in some way and returned with all the gold they could carry. The location of the spot is always in a dangerous Indian country; I have been told twice that it was in the Chicahua Mountains. It is always said to have been found purely by accident, by men who were either hunting or prospecting for ledges; about the only two occupations which will make unscientific men climb high mountains. It can only be seen from the upper end and after the morning mists in the valley have cleared away. Then as one stands on the rugged peaks and looks down he sees the great ledge spanning the valley below him, the virgin metal glittering in the sunlight, and he knows that he has before him the place of which he has heard so much and dreamed so often.

Is there any truth in the story? I cannot tell. The Indians believe it implicitly, as anyone who contrives to get on sufficiently intimate terms with them to be trusted can, if he takes enough trouble, find out. The Mexicans are far more communicative than the Indians, and will tell the tale on the slighest provocation, appealing to all saints in the calendar to convince you of its truth. Many of the old projectors believe it absolutely and a number of them have gone upon the search themselves or have known men who had done so. The treasures of the western half of this continent are not more than suspected as yet, and it may be that there will be discovered in time ledges of far greater value, especially in free gold, than any yet found. Who can tell what will be developed in the future. In the mean time the story is one worth preserving, if for nothing else, for the wealth of barbaric magnificence which it contains.

The dangers of mining are great under the most scientific methods known; judge what they must have been in the days when men carried out the ore in leather buckets on their backs by ascending steep ladders. Wherever there is danger superstition steps in to account for it, and it is small wonder that the acts of the demons and evil spirits with which the imaginations of the miners has peopled the mines should have about them a horror all their own. One of the most common "bogies" or devils supposed to haunt the mines is the "step devil," "Sauch," or "the Ladder Dwarf," for he is called by all these names. He is described as a hunch-backed dwarf with a short body, large head and enormously long and powerful arms. In fact a gorilla is as good a comparison as could be made of this particular spirit. His favorite trick is climbing the ladders by means of which the miners leave the mine, by raising himself with his long arms and as he passes the rungs, kicking them out one by one. He is supposed to always do this just before an accident of some kind in the mine. This superstition may be found in the far south as well as in the north. In Mexican mines in the old days, the descent and ascent of the shaft was made by the aid of tree trunks, having notches cut in them, in which the piens or laborers rested the great toe as they stepped from one to the other. "Sauch" in the southern legends became a demon having on each great toe an enormous nail or claw by the aid of which he would gouge out these places where the feet of the ascending miners rested. In both these stories it will be noticed that the demon is described as being possessed of a kind of refined cruelty, for he leaves the ladders or the tree trunks after having destroyed their usefulness, to tantalize the unfortunate men who are imprisoned in the mine. A superstition which is common, is that about the "gold snake." This species of serpent is perfectly harmless, and is rather handsome, being green in color with a sort of golden hue or irridescence in the scales. It is believed that wherever a gold snake makes his lair there is a ledge containing the precious metal, and there are many Mexicans who will locate a claim at once if they find a gold snake. I saw an instance of this in Arizona where a gold snake was found and a claim located. Not only was this done but a fine mustang was actually given for a share in it by a Mexican who was as credulous as the original locator. My own curiosity was sufficiently excited to make me prospect in the most careful manner for a ledge in the place and its vicinity, in order to find out if there were any truth in the theory, but I must say that I could not find one. There may, of course, be this much at the bottom of this widely-spread belief, the gold snake is found in a country where ledges of precious metals are also found, and it is no very extraordinary step for the imagination of the credulous to take, that of believing that the gold snake indicates the gold. The name of the reptile too, may have something to do with the theory. One of the most common beliefs of miners is that before an accident happens, the rats, of which there are generally large numbers in the workings, will leave the mine. This belief is so universal that I should hesitate before pronouncing it to be absurd, as certainly one is tempted to do on first hearing of it. I have had miners give me many instances in which they said it had occurred, and I had then no reason to doubt the truthfulness of what they said nor have I now. As will probably occur to the reader, this belief is one which is directly akin to that of sailors about rats leaving "a sinking ship." A similar story is told about the cockroaches which swarm the mines. They are said to crawl out of the shaft before accidents take place and to be particularly anxious to leave before an earthquake. Animals often seem to have some mysterious instinct by the aid of which they can reason or feel that something is going to take place, when as yet the signs are not perceptible to man. I know for a fact that in the desert horses will find water when there is nothing to guide a man in the search. Of course they may do this by the power of smell just as dogs follow "scent," and it would be ridiculous to suppose that they smell an earthquake. Still, before one of these convulsions of nature, animals are exceedingly uneasy, and it may be that they have some instinct or perception which we have not. I have certainly seen enough of this to make me slow in disbelieving the miners' stories about the rats in a mine.

The Divining Rod.—One of the most common and most curious superstitions among miners is the belief in the Divining rod. If any class are distinguished above their fellows by this, it is that which comes from Cornwall. The broad statement about the Divining rod may be said to be as follows: You take a forked twig of witch hazel, mountain ash, mountain cherry or alder and place one of the forked ends in each hand. The twig must be shaped like the letter Y. The end placed in one of the hands is laid across the palm which is turned up, the fingers are shut down over it and the thumb bent over the ends of the fingers. The hands are then held in front of the body, the elbows being bent at a right angle. Between the hands holding the forked ends of the twig, the single end rises straight up so that the twig looks like a Y upside down, thus ⅄. Now the theory is that when a person walks over a ledge or deposit of any mineral, or over a spring of water, this upper stem of the twig will of its own volition turn down in spite of all that the person holding it can do to restrain it. This may be said to be the divining rod in its simplest form, and its use depends upon the existence of some mysterious force or attraction exerted upon it by the neighborhood of the metal, or the water. The Cornish miner who almost always uses the witch hazel twig does not hesitate to tell you that persons having the "gift," as some mysterious power inherent in certain individuals which permit of this equally mysterious force being exerted on the rod, is called, are able to find deposits of ore by its aid without the slightest difficulty. And what is more, he firmly and honestly believes what he says. There is a class of men however, who with the acquisition of some knowledge have acquired a certain amount of distrust in the simple rod, or perhaps I should say, in the proposition that a body of metal can by any occult power affect a twig. It may be too that they feel a certain degree of shame in confessing their belief in such a bald superstition as is that of the rod, in its simplest form. These men, then, having a desire to give some excuse for the faith that is in them have invented the rod complex. The virtues of the rod complex are supposed to rest upon what they call the affinity of metals. This is a belief that every metal may be said to have some one other among the metals for which it has a strong affinity or liking which it will manifest whenever and wherever you give it an opportunity. It is of course easy to see that this idea is based upon a misconception of the laws of chemical affinity. Having this idea they make rods which are suitable for, or which it is supposed will work in particular metals. I knew a very clever man who had been bitten by this theory and he told me how he had constructed his rod. Knowing that gold has a strong chemical affinity for tellurium, he procured a bar of the latter metal and lashed it between the ends of two pieces of whalebone. Taking the other ends of the whalebones, one in each hand and holding them in the manner described, he walked over a ledge in which he knew there was gold. Sure enough the rod turned down, without, he said, and I did not disbelieve him, any conscious effort on his part. He made a number of similar experiments which resulted in the same way. In some of these he did not know until afterwards that there was any gold present. I prepared two specimens of gravel, one with and one without gold and he tried the rod upon each. The rod bent in the former and failed to move in the latter, and my friend was triumphant as might naturally have been expected. He accounted for the movement of the rod by saying that he supposed there was some inhuman form of electricity akin to that which attracts iron to a magnet. I suggested to him that if this was the case and if gold was attracted by or would attract tellurium, it was perfectly evident that it would do so under any and all circumstances. To this he agreed. I then suggested the following experiment. We placed the bar of tellurium in one pan of an assayer's scales, accurately balancing it with common sand. Placing the scales in a large bell receiver we exhausted the air as far as possible and introduced two ounces of fine gold under the pan having in it the tellurium bar. It is perhaps scarcely necessary to say the index of the scales did not move. Somewhat chagrined by the result my friend suggested that it might be that the human body supplied a form of electricity necessary to the experiment. I then took a common wooden rolling pin and bored eight holes in it in which I inserted pegs six inches long. Weighing out seven portions of sand, each of which balanced the tellurium bar, we bound these to the ends of seven of the pegs, binding the tellurium bar to the end of the eighth. The apparatus looked something like a wheel from which the felloe and tire have been removed; and by holding the handles the whole thing could be spun around with the greatest ease. But, and in this lay the value of the test, by no possible means could the person holding the handles cause the pegs to move. Placing the tellurium peg on top, as the stem of the Y shaped rod had been, we, or rather he, tried it on rock containing gold, or pure gold, gold in alloy and finally upon three ledges on which the rod had worked perfectly. Upon none of these did the machine turn. We then substituted for the tellurium some mercury with the same result. Being then as anxious to prove the rod theory a failure as he had formerly been to convince me it was a success, my friend went to several "rod makers" in the place and procured from them their rods which had been used many times and always with success. Removing the mysterious charms which were supposed to attract or to be attracted by the gold, he placed them in turn upon the apparatus, but the thing would not turn. There was in the neighborhood a man whose rods were celebrated as being always reliable and who was himself believed to have the "gift" to an extraordinary degree. By telling him that the rolling pin was a German rod which I had brought from Heidelberg, we persuaded him to use it over a ledge in which we all three knew there was gold, but even in his hands the rolling pin refused to move. In this case the eighth peg had on it a charm taken from a rod manufactured and often used by the man himself; who by the by pronounced the German rod to be useless, and taking one of his own showed us how it would turn down whenever he crossed the ledge—which in fact, it did. We then took the original whalebone rod a small bag of sand having been fastened to the tip, and gave it to the man with the "gift." Of course he supposed that the bag contained one of the charms. In his hands the rod so prepared turned down every time he crossed the ledge, although feebly. He told me that the charm in the bag was not a good one, but that if he had the rod made by him and lent to us he could make it work. This rod was the one from which we had taken the charm, then attached to the rolling pin. When this had been done however, a bag of sand had been substituted for it. Giving him the rod, we found that it worked perfectly, whirling around in his hands the moment he placed his foot upon the ledge. The result of these experiments was satisfactory as far as they went.

There was one more however, which I was anxious to try and the next day we invited the man with the "gift" to come over to my friend's place. In the meantime we took the charm from the rolling pin and replaced it upon his rod. When he came I broached the theory that the cause of the rods working was the weight on the tip, and that the charms had nothing to do with it. This the man with the "gift" strongly combated. I suggested that we should try it, and, he agreeing, I removed the charm from his rod and substituted a bag of sand of the same weight. The rod was then in precisely the same condition as it had been the day before when, it had worked perfectly, the difference in the experiment being that he was then aware of the change, whereas, the day before he had been ignorant of it. We adjourned to the same ledge, and the rod in his hands refused to work. Now it must be remembered that in none of these experiments was there any conscious fraud on the part of the operator—except indeed, on my part, when I told the man with the "gift" that the rolling pin was a rod from Heidelberg. If I ever was convinced of anything, I was that the man was sincere in his belief in the virtues of the rods as prepared by him. A single experiment on his part convinced me of this. He and I were together hunting specimens from a placer-claim, and he was exceedingly anxious that I should find gold in the dirt. I had tried some five or six specimens without success, and he went down the stream to find a spot from which we could take dirt that would show color. In hunting for a place, he used the rod. Now his one desire then was, that I should find gold, and, he believed that the rod would show him where to tell me to take a specimen.

It is a fact that the divining rod will turn down when the person who carries it crosses a spot where he believes there is a ledge. I have seen this, not only in the case of the rod complex, but when the simple witch-hazel rods have been used by the Cornish miners. Nor have I had any reason to doubt the perfect honesty of those using them. They believed that the rods worked of themselves, and were perfectly unconscious of doing anything to make them turn. The reason why they turn, or at least my own theory upon the subject, I may illustrate by citing an experiment which I tried. Weighting a rod with two pounds of lead, I got the gentleman who constructed the rod, with the tellurium bar attached, to hold it in the prescribed manner. In performing the experiment, I told him to rest his elbows upon a table. This I did because, under such circumstances, he would be able to resist the strain upon the muscles for the longest time. I also told him to hold the rod tight. At the end of three and a half minutes his hands began to tremble, and at the end of five the rod turned slowly down. He said that his hands were so tired he was unable to hold it up any longer. I tried the same experiment myself and found that he had accurately described the feeling in the hands. It was, to use a slang expression, as if they had "lost their grip." I found, too, that there was a feeling of soreness along the inner side of the forearm, and that the nerves at the wrists were quite painful. Now all those who had used the rods, believing in them, had spoken of a tingling sensation in the arms after the trials, and this they ascribed to the currents of electricity which they believed to be excited by the experiments. In the experiment just cited the weight of the rod was enormously increased, for as a rule the charms weigh about an ounce and a half—the average of nineteen charms weighed by me was 4,665 centigrams—and the effect, therefore, upon the muscles of those making the experiment was proportionately increased. The fact that we knew the experiment to be one which was simply a test; that is, the fact that we did not believe there was any power besides that of gravity acting upon the rod, caused us to resist the action longer and to strain the muscles more. But the experiment proved to me that with a light rod and a desire to yield to any attraction at once, the natural feeling of fatigue might be easily mistaken for such attraction, especially when combined with a full belief in the power exerted upon the rod by the deposits. All believers in the rods tell you that they must be held in the hands with the palms turned up and the thumb side of the hand outward. I am not enough of an anatomist to know whether this produces any unusual strain upon the muscles, but I found that by taking the heavily weighted rod in the reverse way; that is, with the backs of the hands up and the thumbs towards each other, both my co-experimenter and I could keep the stem upright for a much greater length of time; and I, therefore, concluded that the prescribed position for the hands during the trials is one which causes the muscles to be exceedingly sensitive to fatigue. I merely give this as a theory of my own, adopted as the result of the experiments cited and not as a fact. About the causes of the movement of the rod in cases where the experimenters are honest, I have not, however, the slightest doubt; and speaking of the honesty of those using the rods, I must mention one fact, I found that it was impossible to mistake the movement of the rod by any voluntary action of the muscles. The rods, as held by those using them, will often twist in the hands; the whalebone becoming bent or the twig twisted to that extent that the bark is sometimes broken. This cannot be imitated voluntarily, and the fact of this twisting is appealed to by those who use the rods to show two things; first, that they are holding them tightly, and second, that there is some external force being exerted upon them. It would, certainly, seem that the force of gravity as exerted upon the stem of a small shaped twig, would not be sufficient to cause it to twist in this way; at least, I took one the same size and shape as that which had turned on a gold ledge, and nailed it to two sticks within six inches of the ground, and it did not move, then I transposed the sticks to a pile of exceedingly rich gold-ore and the rod remained upright as before. I do not know if it be possible, anatomically speaking, for the muscles of the hand and fingers to twist the rod in the hand, but this is apparently what is done. It is certain that in one of the experiments, that in which the man "with the gift" had the rod prepared with the bag of sand in his hands, he supposing that the charm was still on the rod, the whalebone bent in the manner described. There is another explanation of this twisting which is possibly the correct one. In the forked ends of the twig or the pieces of whalebone, there is a considerable amount of spring, and it may be that this is unconsciously taken advantage of to cause the stem to turn. I have devoted a considerable amount of space to this discussion of the divining rod for the simple reason that it is not only one of the most widely spread beliefs among miners, but because I have found instances where money has been spent as a result of its use. Men have bought charms on ledges solely upon the mystic information conveyed by twigs or the rods complex, and as I cannot help feeling that this is a great piece of folly on their part, I am anxious, if possible, to aid in stopping it. I have, therefore, given my own experiments at length, not that they possess any great amount of intrinsic value, but because they served to convince me that there was nothing in the theory and nothing to be derived from the use of the rods; and I hope that my readers before giving their support to the practice, before, if I may be permitted the expression, allowing themselves to be "rod-bitten," will test for themselves in some such way as I have tested. To me, the theory that chemical affinity can be correlative with anything like magnetic attraction, is one which I have never seen supported by any test that would stand examination.

The Whims of Fortune.—Mining owes a great share of the romance which attaches itself to it to the sudden changes of fortune which it brings about. This is particuarly true of mining for gold and silver. The prospectors, or that class of men who spend their lives looking for deposits of the precious metals, are poor to-day and rich to-morrow. The history of the West is full of these sudden changes, and in nothing is this better shown than in the fact that there is a common phrase or form of words used to describe such a change. They say, "So and so has made a strike." As it takes many instances of a certain defined alteration in a man's life to introduce into the language a phrase expressive of such alteration, we may reason not unfairly from the phrase to that which has caused it. As we find that "making a strike" is one of the most common group of words used, we may conclude that the doing so has been a common thing. And as a matter of fact this is true. Were the histories of the men who have risen to the possession of great wealth upon the Pacific Coast written, it would be found that many of them if not the majority have acquired their money as a result of "making strikes" in mining. From the case of the pocket prospector whose credit has declined to that point that he is unable to obtain a side of bacon, a bag of flour and a bag of beans, and who, finding a pocket, takes from one to twenty thousand dollars in a day or two, and spends it gloriously in a spree which lasts anywhere from one month to twelve, to that of the man who buys stock in a mine which is supposed to be worthless and wakes up some morning to find that he is worth millions as the result of his purchase, all "make a strike." The Bonanza Firm are instances of this, perhaps as good as could be selected. Years ago Messrs. Flood and O'Brien were the proprietors of a saloon on Washington street, in San Francisco; Mr. Fair was a miner, and Mr. Mackay a timber-man in the Mexican mine. They made money in the Hale and Norcross, and put that money where it would do the most good, in developing the Consolidated Virginia and California. After driving the drift 1200 feet they "made a strike"—they struck the Big Bonanza, and fortune was the result. It is this chance of making large amounts of money very suddenly which gives its fascination to mining, to prospecting and to investments in mines.

I remember the story of a friend of mine who went to New Mexico. A Fellow of the Royal Chemical Society, he had drifted into journalism in San Francisco, and his ability and talents had raised him to a high place in his adopted profession. He was engaged to go to a town in New Mexico and there edit a paper to be started by a man who believed that there was money in the venture. Two weeks after their arrival in the place the owner of the paper died and his companion, finding that the paper project was at an end, was obliged to cast about for something to do. Having a little money, enough to purchase an outfit, he joined himself to two others, and started on a prospecting expedition. Striking into a new district, they found ledges and located five claims. Clubbing their funds together, they sent the ex-journalist to San Francisco, where he soon succeeded in selling the property for $21,0000; his share, of course, being $7,000. Not a bad stake for a man who two months before had found himself all but penniless in a frontier town. And mining history in the west is full of such instances.

Here is another case I remember, which has about it all the elements of romance. A young engineer, by the name of Jackson—all the names given are fictitious—who had had some experience in mining, fell in love with the daughter of a prominent merchant in San Francisco named Smith. Young Jackson found that Miss Helen Smith returned his affection with, so to speak, legal interest, and he applied to Smith, *père*, for permission to marry his daughter, Smith, *père*, being of the truculent order of sires, and knowing that Jackson had nothing but his profession as an engineer to depend on, rejected the suit with much contumely for the suitor. A consultation between the lovers revealed the fact that Miss Helen said enough for him to wait, and after many vows, Jackson left to seek his fortune. Two years passed but he was not heard from, and during which time there were many applications made by unexceptionable men for Miss Helen's hand, and a very pretty hand it was, too. She rejected each and all, preferring to wait as she had promised, and being fully convinced that in time her lover would return. At the end of the two years, or, to be exact, at the end of two years and three months, Jackson came back. He told his story to sympathizing ears, how he had gone prospecting and had worked without success until his money was exhausted; how he had then labored as a miner until he saved enough to buy provisions for another trip; how he had gone on that trip and failed again; how he had once more gone to work and got another "grub stake" saved up; how he had joined a party and traveled into Idaho; how they had found a ledge of rich ore and opened it; how the ledge widened as it went down, and proved to be exceedingly valuable, and how he was in San Francisco as a representative of the party for the purpose of interesting capital in the mine. What girl could listen unmoved to such a story, especially when told by the lips of her lover, to whom she had been true during the weary months, and who she found was true to her; certainly not Miss Helen. As Jackson's prospects were as yet somewhat misty, they agreed that they would wait a little longer before trying to obtain the consent of Smith, *père*. It was not long, however. Jackson's specimens were sufficiently good to induce men with money to look into the matter, the mine was found upon examination to be all that was claimed for it, and $80,000 was paid for sixty per cent. of the claim. The capitalists who had bought in were sufficiently well pleased with the young fellow who had brought the mine to their notice, to think he would make a good superintendent, and they offered him the place with $20,000, ten per cent. of the stock in the mine, and the position of superintendent. Jackson once more went to Smith, *père*. The old man had found out by this time, that if his daughter did not marry the man of her choice she would not marry anyone, and I suppose that he was pleased with the way in which his would-be son-in-law had shown what there was in him. Besides, it must be conceded that the prospects of the young couple were infinitely better than they had been before. And so the consent was given, and the wedding took place, all parties appearing to forget the unpleasant interview of two and a half years back. What story of the olden days when knights went forth in full armor to win for their ladies fair castle and broad possessions is more romantic than this of young Jackson? What Knight battled more strongly with axe and lance than did Jackson with pick and drill? And what "fair ladye" was more true to her absent knight during the long, weary days, than was the charming girl, whose personality I have hidden under the somewhat unpoetical name of Smith? This story, as I have told it, is literally and exactly true, and is not, as might be possibly imagined, an extract from an unpublished novel.

In speaking of the romance of mining, an article would be incomplete were that strange institution or custom of "partnerships" in the west unmentioned. "Pards," as they are ordinarily called, are men, who from mutual liking when thrown together, form the closest kind of friendships. In a mode of life which is full of strange vicissitudes, men get to know each other as they never can under other circumstances, and it may well be said that their affection for each other passes that of brothers. A man not only backs up his "pard" on every and all occasions, but any other line of conduct on his part would excite no small degree of surprise among his acquaintances. Instances of heroism which seem almost sublime, have been common enough, and some of them have been wedded to verse which will live as a record of what a man can do for his friend. The remark, "He was my pard," is a key to the origin of many a deed which kindles the eye and makes the blood run faster of those who hear the story told. Self-sacrifice of a kind which is sublime, and love almost surpassing that of a mother for her child, have glorified and ennobled "pardnership;" though the word be uncouth, it describes a very beautiful thing. I cannot close my brief allusion to it better than by quoting the poem which commemorates what one "pard" did for his friend.

IN THE TUNNEL.

Here in this tunnel
He was my pardner,
That same Tom Flynn,
  Working together
  In wind and weather,
Day out and in.

Didn't know Flynn?
  Well, That is queer;
Why, it's a sin
To think of Tom Flynn,—
  Tom with his cheer,
  Tom without fear—
Stranger, look 'yar!

Thar in the drift,
Back to the wall
He held the timbers
  Ready to fall;
  Then, in the darkness,
I heard him call:

"Run for your life, Jake!
Run for your wife's sake!
Don't wait for me."
  And that was all.

Heard in the din,
Heard of Tom Flynn,—
Flynn of Virgin'.

—*Alfred Balch.*

DOWN IN A UTAH MINE.

"BEEN *down a mine!* What on earth did you do that for?" said the elder Sheridan to the younger.

"Oh, just to say that I *had* done it," was the reply.

"To *say* that you had done it! Good gracious! Couldn't you have *said* that *without going down a mine?*"

No, Mr. Sheridan, you could not; at least not in these latter days. Too many people do it now for the impostor to remain undiscovered. Take my own case, for instance. I have often read descriptions of mine descents and thought I knew how it happened and how ore was got out. But no one ever told me that you had to go paddling about in water half the time, or that mines were excavated *upwards.* Now, then, if I had tried to pretend that I had been down a mine I should have been promptly found out, by my ignorance of the two first facts that strike one. Again, it is very simple work imagining the descent of a "shaft" in a "cage." But unfortunately a "cage" is only a platform to stand on without either sides or top, and not, therefore, such a cage as one would buy to keep a bird in, or as would keep a bird in if one *did* buy it. Nor without actually experiencing it could anybody guess that the first sensation of whizzing down a pipe, say 800 feet, is that of seeming to lose all your specific gravity, and that the next (after you had partially collected your faculties) is that you are stationary yourself, but that the timbers that line the shaft are all flying upwards past you like sparks up a chimney. Mines, of course, differ from one another just as the men who go down them do, but as far as I am concerned all "mines" are puddly places, and the sensations of descent are ridiculous—for I have only been down one in my life. The mine to which I refer, then, is the "Ontario," in Utah, which may be said, in the preposterous vernacular of the West, to be a "terrible fine" mine, or, in other words, a —— "big thing," that is to say a "daisy." As for daisies, anything that greatly takes the fancy or evokes especial admiration is called a daisy. Thus I heard a very much respected Mormon Bishop, who is also a director of a railway, described by an enthusiastic admirer as "*a daisy!*"

Finding myself in Park "City" one evening—it is a mining camp dependent chiefly upon the Ontario—I took a walk up the street with a friend. Every other house appeared to be a saloon, with a doctor's residence sandwiched in between —a significantly convenient arrangment perhaps in the days when there was no "Protective Committee" in Park City, but—so I am told—without much practical benefit to the public in these quiet days, when law-abiding citizens do their own hanging, without troubling the county sheriff, who lives somewhere on the other side of a distance. The result of this is that bad characters do not stay long enough in Park City now to get up free fights and make work for the doctors. The Protective Committee invites them to "get" as soon as they arrive, and, to do them credit, they "get."

However, as I was saying, I took a walk with a friend along the street and presently became aware above me, high upon the hillside, of a great collection of buildings, with countless windows (I mean that I did not try to count them) lit up and looking exactly like some night scene in a melodrama. These were the mills of the Ontario, which work night and day and seven days to the week, a perpetual flame like that of the Zoroastrians and as carefully kept alive by stalwart stokers as ever was Vestal altar-fire by the girl-priestesses of Rome. It was a picturesque sight, with the huge hills loomin up black behind and their few pine-trees showing out dimly against the darkening sky. Next morning I went up to the mine—and down it. Having costumed myself in garments that made getting dirty a perfect luxury, I was taken to the "shaft." Now, I had expected to see an unfathomably black hole in the ground with a rope dangling down it, but instead of that I found myself in a spacious boarded shed, with a huge wheel standing at one end and a couple of iron uprights with a crossbar standing up from the floor at the other. Round the wheel was coiled an enormous length of a six-inch steel-wire band, and the disengaged end of the band, after passing over a beam, was fastened to the crossbar above mentioned. On the bridge of the wheel stood an engineer, the Rhadamanthus, arbiter of fates, who is perpetually unwinding victims down from stage to stage of the Inferno and winding up the redeemed from limbo to limbo. Having propitiated him by an affectation of intelligence as to the machinery he controlled, we took our places under the crossbar, between the stanchions, and suddenly the floor—as innocent-looking and upright-minded a bit of boarded floor as you could wish to stand on—gave way beneath us, and down we shot *apud inferos,* like the devils in "Der Freischütz." We had our lamps in our hand and they gave just light enough for me to see the dripping wooden walls of the shaft flashing past, and then I felt myself becoming lighter and lighter—a mere butterfly—imponderable. But it doesn't take many seconds to fall down 800 feet, and long before I had expected it I found we were "at the bottom."

Our explorations then began; and very queer it all was, with the perpetual gushing of springs from the rock and the bubble and splash of the waters as they ran along on either side the narrow tunnels, the meeting at corners with little cars being pushed along by men who looked, as they bent low to their work, like those load-rolling beetles that naturalists tell us of; the machinery for pumping, so massive that it seemed much more likely that it was found where it stood, the vestiges of a long-past subterranean civilization, than that it had been brought down there by the men of these degenerate days; the sudden endings of the tunnels that the miners were driving along the vein, with a man at each ending, his back bent to fit into the curve which he had made in the rock, and reminding one of the frogs that science tells us are found at times fitted into holes in the middle of stones; the climbing up hen-roost ladders from tunnel to tunnel, from one darkness into another; the waiting at different spots till "that charge had been blasted," and the dull, deadened roar of the explosion had died away; the watching the solitary miners at their work pecking and thumping at the discolored strips of dark rock that looked to the uninitiated only like water-stained, mildewy accidents in the general structure, but which in reality was silver, and yielding, it might be, $1,600 to the ton. "This is all very rich ore," said my guide, kicking a heap that I was standing on. I got off it at once, reverentially. But reverence for the Mother of the Dollar gradually dies out, for everything about you, above you, beneath you, is silver or silverish—dreadful rubbish to look at, it is true, but the spirit of the great metal in it all none the less; that fairy Argentine who builds palaces for men and gives them if they choose, all the pleasures of the world and the leisure wherein to enjoy them. And there they stood, these latter-day Cyclops, working away like the gnomes of the Hartz Mountains or the entombed artificers of the Bear Kings of Dardistan, with their lanterns glowing at the end of the tunnels like Kanthi gem which Shesh, the fabled snake-god, has provided for his gloomy empire of mines under the Nagas hills. Unless crystals glittered on every side as if they were jewels, and the water dripping down the sides glistened as if it was silver, but the pretty hypocrisy was of no avail. For though the ore itself was dingy and ugly and uninviting, the ruthless pick pursued it deeper and deeper into its retreat, and only struck the harder the darker and uglier it got. It reminded me, watching the miner at his work, of the fairy story where the prince in disguise has to kill the lady of his love in order to release her from the enchantments which have transformed her, and how the wicked witch makes her take shape after shape to escape the resolute blows of the desperate lover. But at last his work is accomplished and the ugly thing stands before him in all the radiant beauty of her true nature. And it is a long process and a costly one before the lumps of heavy dirt which the miner pecks out of the inside of the hill are transformed into those hundredweight blocks of silver bullion which the train from Park City carries every morning of the year into Salt Lake City. From first to last it is pretty much as follows. Remember I am not writing for those who live inside mines; very much on the contrary. I am writing for those who have never been down a mine in their lives, but who may care to read an unscientific description of "mining," and the Ontario mine in particular.

In 1872 a couple of men made a hole in the ground, and finding silver ore in it offered the hole for sale at thirty thousand dollars. A clever man, R. C. Chambers by name, happened to come along, and liking the look of the hole, joined a friend in the purchase of it. The original diggers thus pocketed thirty thousand dollars for a few days' work, and no doubt thought they had done a good thing. But alas! That hole in the ground which they were so glad to get rid of ten years ago now yields *every day* a larger sum in dollars than they sold it for! The new owners of the hole, which they christened "The Ontario Mine," were soon at work, but instead of following them through the different stages of development, it is enough to describe what that hole looks like and produces to-day.

A shaft, then, has been sunk plumb down into the mountain for 900 feet, and from this shaft, at every 100 feet as you go down, you find a horizontal tunnel running off through the mountain. If you stop in your descent at any one of these tunnels and walk along it—water rushing along over your feet and the vaulted rock dripping overhead—you will find that a line of rails has been laid down along it and that the sides and roofs are strongly supported by timbers of great thickness. These timbers are necessary to prevent, in the first place, the rock above from crushing down through the roof of the tunnel, and in the next, from squeezing in its sides, for the rock every now and then swells and the sides of the tunnels bulge in. The rails are, of course, for the cars which the miners fill with ore and which are then pushed along to the "stage;" the miner signals by a bell which communicates with the engineer at the big wheel in the shed I have already spoken of, and there being a regular code of signals, the engineer knows at once where the loaded car is waiting, and how far therefore he is to let the cage down. Up goes the car with its load into the day-light, and then its troubles begin. But meanwhile let us stay a few minutes more in the mine. Walking along any one of the main horizontal tunnels, we come at intervals to a ladder, and going up one of them we find that a stope, or smaller gallery, is being run parallel with the tunnel in which we are walking, and of course, as it follows the same direction of the ore, immediately over that tunnel, so that the roof of the tunnel is the floor of the stope. The stopes are just wide enough for a man to work in easily and are as high as he can reach easily with his pickaxe, about seven feet. If you walk along one of these stopes you come to another ladder and find it leads to another stope above, and going up this you find just the same again, until you become aware that the whole mountain above you is pierced throughout the length of the ore vein by a series of seven-foot galleries lying exactly parallel one above the other, and separated only by a sufficient thickness of pine timber to make a solid floor for each. But at every hundred feet, as I have said, there comes a main tunnel, down to which all the produce of the minor galleries above it is shot down by "shoots," loaded into cars and pushed along to the shaft. But silver ore is not the only thing that the company gets out of its mine, for unfortunately the mountain in which the Ontario is located is full of springs, and the miner's pick is perpetually, therefore, letting the water break into the tunnels, and in such volume too that I am informed it costs as much to rid the works of the water as to get out the silver! Streams gurgle along all the tunnels, and here and there ponderous bulkheads have been put up to keep the water and the loosened rock from falling in. Pumps of tremendous power are at work at several levels, throwing the water up towards the surface—one of these at the 800-foot level throwing 1,500 gallons a minute up the 500-foot level.

Following a car-load of ore we find it, having reached the surface, being loaded into wagons in which it is carried down the hill to the mills, weighed, and then shot down into a gigantic bin—in which, by the way, the company always keep a reserve of ore sufficient to keep the mills in full work for two years. From this hour life becomes a burden to the ore, for it is hustled about from machine to machine without the least regard to its feelings. No sooner is it out of the wagon than a brutal crusher begins smashing it up into small fragments, the result of this meanness being that the ore is able to tumble through a screen into cars that are waiting for it down below. These rush up-stairs with it again and pour it into hoppers, which, being in the conspiracy too, begin at once to spill it into gigantic drying cylinders that are perpetually revolving over a terrific furnace fire, and the ore, now dust, comes streaming out as dry as dry can be, is caught in cars and wheeled off to batteries where forty stampers, stamping like one, pound and smash it as if they took a positive delight in it. There is an *intelligent*, deliberate determination about this fearful stamping which makes one feel almost afraid of the machinery. Some pieces, however, actually manage to escape sufficient mashing up and slip away with the rest down into a "screw conveyer," but the poor wretches are soon found out, for the fiendish screw conveyer empties itself on to a screen, through which all the pulverized ore goes shivering down, but the guilty lumps still remaining are carried back by another ruthless machine to those detestable stamps again. They cannot dodge them. For these machines are all in the plot together. Or rather, they are the honest workmen of good masters, and they are determined that the work shall be thoroughly done, and that not a single lump of ore shall be allowed to skulk. So without any one to look after them these cylinders and stampers, hoppers and dryers, elevators and screens go on with their work all day, all night, relentless in their duty and pitiless to the ore. Let a lump dodge them as it may it gets no good by it, for the one hands it over to the other, just as constables hand over a thief they have caught, and it goes its rounds till the end eventually overtakes it, and it falls through the screen in a fine dust. For its sins it is now called "pulp," and starts off on a second tour of suffering—for these Inquisitors of iron and steel, these blind, brutal Cyclops-machines, have only just begun, as it were, their fun with their victim. Its tortures are now to be of a more searching and refined description. As it falls through the screen another screw-conveyer catches sight of it and hurries it along a revolving tube into which salt is being perpetually fed from a bin overhead—this salt allow me to say for the benefit of those as ignorant as myself, is "necessary as a chloridizer"—and thus mixed up with the stranger, falls into the power of a hydraulic elevator, which carries it up forty feet to the top of a roasting furnace and deliberately spills the mixture into it. Looking into the solid flame I appreciated for the first time in my life the courage of Shadrach, Meshach and Abednego. They were young men of great nerve. There is no doubt of that whatever in my mind.

The mixture which fell in at the top bluish-gray comes out at the bottom yellowish-brown—I only wonder at its coming out at all—and is raked into heaps that have a wicked, lurid color and give out such fierce short flames of brilliant tints and fierce short blasts of a poisonous gas that I could not help thinkiog of the place where bad men go to, and wondering if Satan could not get a hint or two for improving damnation by a visit to the Ontario roasting-furnace. The men who stir these heaps use rakes with prodigious handles and wear wet sponges over their mouths and noses, and as I watched them I remembered Dante's devils who keep on prodding up the damned and raking them about over the flames. But the ore submits without any howling or gnashing of teeth, and is dragged off dumb and soused into great churns, kept at a boiling heat, in which quicksilver is already lying waiting, and the ore and the quicksilver are then churned up together by revolving wheels inside the pans till the contents look like huge caldrons of bubbling chocolate. After some hours they are drained off into settlers and cold water is let in upon the mess, and lo! silver as bright as the quicksilver with which it is mixed comes dropping out through the spout at the bottom into the canvas bags. Much of the quicksilver drips through the canvas back into the pans, and the residue silver, mixed with quicksilver, makes a cold, heavy, white paste called an "amalgam," which is carried off into jars to the retorts. Into these it is thrown, and while lying there the quicksilver goes on dripping away from the silver and after a time the fires are lighted and the retort sealed up. The intense heat that is obtained volatalizes the quicksilver, but this mercurial vapor is caught as it is escaping at the top of the retort, again condensed into its solid form and again used to mix with fresh silver ore. Its old companion, the silver, goes on melting inside the retort all the time, till at last when the fires are allowed to cool down it is found in irregular lumps of a pink-looking substance. These lumps are then taken to the crucibles and passing from them, molten and refined, fall into moulds, each holding about a hundred weight of bullion. And all this bother and fuss, reader, to obtain these eight or ten blocks of metal! True, but then that metal *is silver*, and with one single day's produce from the Ontario Mine in the bank to his credit a man might live like a gentleman in London all the days of his life, like a nobleman in Paris or like a prince in Vienna!

—*N. Y. World.*

SOCIAL LIFE IN THE MINES AND THE SURROUNDING INFLUENCES.

JUSTIN, who wrote during the third century of our era, obtaining his materials from a still earlier historian, informs us that the Lydians were habituated to indolence, gaming, and licentiousness. The Lydians were the inhabitants of the earliest gold-mining country of whose industry we have any account, and although Justin's opinion does not wholly warrant the conclusion that they derived the character he has given them from the influenee of the mines, what we know of the population of other great mining countries leads us to believe that this was the fact. Notwithstanding the immense lapse of time since the earlier Argonautic expeditions, and the scantiness of any literature relating to them, it is not difficult to discern a common character in the populations of all the ancient mining countries of importance, Lydia, Greece, Italy, and Spain. Nor can the glamour which heroic history has thrown over their actions conceal from us the fact that this character belonged also to the Spanish and Portuguese gold-seekers in America.

Nevertheless, until we come to California and Australia, the social influences of the mines cannot be traced with that certainty which would warrant any practical use of the inferences they afford. Here the view is a clear one. Here for the first time in history the mines were worked by free men. Here there was neither slavery, nor serfdom, nor peonage. The character of the miners did not come from the conditions of their service, as it might have done in all previous cases. In this case it can only be attributed to the nature of the industry; and hence from the light obtained in this nearest view of the influence of mining we are enabled to go back some thousands of years in history, and determine the social influences of the mines in the most remote times.

Years have rolled over the graves that stud the gold-fields of California and Australia; the histories, even the names of the dead are forgotten, and the circumstances of disease, destitution and violence through which they passed from life have fallen into oblivion. The best, often the only accounts of these scenes are contained in the newspapers of the day; but as these are not accessible to the general reader, it has been deemed more desirable, though it greatly restricts the range of observation, to cite only such particulars as lie within general reach. In conformity with this plan the following details relating to early mining on the Pacific coast have been taken from volumes usually to be found in public libraries.

Gold was discovered in California, January 19th, 1848. Although the discoverers, Marshall and Sutter, tried to conceal their good fortune (it eventually ruined both of them) the news leaked out; and in the course of a few months the diggings around their now historic mill were occupied by at least 4,000 men of whom a moiety were Indians, some partly domesticated, and the others wild. As to the white miners, it will be profitable to consider their characters more in detail; first, because it is a necessary and common one to all first-comers in placer mines; second, because, although it becomes effaced in time, it nevertheless lasts long enough to impress itself upon the earlier institutions of placer-mining countries when they come to be settled. Placer mines when first discovered, and while the gold is easily found, commonly afford a profitable refuge to a class of men who cannot thrive elsewhere, to adventurers, outcast, fugitives from justice, bullies, and felons. In their train follows a class of law and ordinance-breakers of the softer sex. However rapidly new additions to the community may improve its character, the influence of the first arrivals is bound to be felt for a long time. They are the older and the richer. The laws already established were framed in accordance with their habits, the customs already in vogue were moulded by their necessities, and their social peculiarities are perpetuated for generations. In other communities vice is lost in a mass of healthy surroundings; in the early days of a placer-mining country there is so little sound environment that vice is paramount, and gives law and custom to the future community. It is evident that placers rich enough to invite miners are to be found in old or well-settled countries. The soil of these countries has been completely turned over by the plough, and if there was ever gold enough in it to be worth searching for, it has long since been extracted. Gold placers are therefore only found in new and unexplored countries, beyond the pale of civilization, beyond the domain of the agricultural pioneer, beyond even the outposts of the trader. Such countries are destitute of the means of subsistence to bodies of men in permanent settlements. There is no other protection for property and life than such as may arise out of the forbearance and justice of the assembled adventurers. There is no assistance to be obtained in case of sickness or accident; there are no women; there are no children. To such a country, until it becomes better settled, few prudent persons would seriously think of emigrating. It follows as a necessary consequence that, at the outset, placer mines are occupied chiefly by the reckless and the desperate, few others being willing to encounter their dangers, inclemencies, and deprivations. This, as we shall find from the evidences open to us, often that of the men themselves, was the character of the Argonauts of California. It was likewise that of the first settlers in the gold-fields of Australia. The first-comers at Sutter's mill were from the surrounding country, from Southern California, and from the Sandwich Islands. "The miners were by no means exclusively Americans. They consisted of every kindred and class. There were already some Indians, Mexicans from Sonora, Kanakas from the Sandwich Islands, settlers from Oregon, mixed with the usual dash of Spanish, British, German, and French adventurers, that had for a long time existed in California. Later months were to bring other Mexicans, Chinese, Peruvians, and Chilians, and all these before the great impending immigration of Americans and Europeans."

So much for the origin of the Californian Argonauts; as to their moral character we have it here painted by companions and lookers on. "Among the people engaged in the mines there are many runaway sailors, deserters from the army, trappers, and mountaineers, who are naturally idle, dissipated, and dissolute; in short, taken in the aggregate, the miners are the worst kind of labouring population.

"The miners who survive and return home may carry gold with them, but their morals and manners will have been ruined. The risk is too great for the reward." . . . "I can think of but few men whom I would advise to come to California." "The mines had no sooner been discovered than crime commenced to increase." "Thefts, robberies, murder, and other outrages of the most desperate and criminal nature were taking place (in San Francisco) and there were no proper officials to take cognizance of them and bring the offenders to justice. Every man was intent on merely making money, and provided an outrage did not in a direct manner personally or pecuniarily affect himself, he was content to shut his eyes to the ultimate consequences."

"Ever since the first great immigration many of the inhabitants carried some weapon of defense secretly about them. During the disturbed times in the early part of 1851, when nobody was safe from the assaults of desperadoes, even in the public street or in his own dwelling, the practice of wearing deadly weapons became still more common.

"These were often used, though not so much against the robber and assassin as upon the old friend and acquaintance, or the stranger, when drink and scandal, time and circumstance had converted them into supposed enemies.

"The number of duels and especially of sudden personal affrays was fearfully great. The general population of San Francisco, with shame it must be confessed, in those days as is still (1855) the case, to a considerable extent drank largely of intoxicating liquors. Some scenes of a most savage and atrocious description, ending occasionally in death, took place between parties who were reputed to be of the first class of citizens. Among the lower American orders, and in all classes of foreigners, down to the vilest Greasers, the same violent spirit of personal revenge and deadly outrage was common.

"On the slightest occasion, at a look or touch, an oath, a single word of offense, the bowie-knife leaped from its sheath, and the loaded revolver from the breast-pocket or secret case, and death or severe wounds quickly closed the scene. The spectators often shared in the same wild feelings and did not always seek to interfere. The law was powerless to prevent such conflicts. Men thought as little of their blood and lives as of their money; and to gratify high swelling passions would madly waste them all alike."

Of course there were exceptions to this general character, and these exceptions increased in number every year; but that these descriptions of society during the first few years of the placer settlements of California were truthful cannot be doubted. The better class of Californians, both native and settlers, stayed at home, stood by their fields and flocks, and thereby reaped surer and greater gains in the end.[1]

According to Mr. Newmarch the character of the first gold settlements in Australia was much superior to those of California. "In Victoria," says Mr. Newmarch, "as in New South Wales, there were, long prior to the events of 1850, all the rudiments of an orderly and growing state. There was a powerful central authority, equal laws, perfect individual liberty, a population including wholesome proportions of the sexes, solid and respectable banking institutions, regular and frequent communicatioos with the mother country, and a fair command of the species of capital necessary for the development of a new region."

This is strange language to hold in respect of a land which was settled only sixty years before by 650 men and 200 women belonging to a class of infamous criminals, whose former Governor was a despot armed with absolute power over the lives of the convicts, where famine was frequent, murder committed at any time for a few days' rations, and rum was money.

If true, it can only be so in respect of the towns, and merely goes to show that in the course of sixty years assisted by a continual leavening of better colonists, even a convict settlement can be turned to some good account. That it is a correct description of the placer mining population of Australia is denied. When the gold diggings were discovered they were occupied by 9,000 ticket-of-leave men. "The records of crime show that the terrible outrages against life and property which were committed daily, both in town and country, were almost exclusively the work of convicts." And it may be added that there is not a sinister lineament upon the social features of early California which is not traced in darker lines upon those of Australia.

Society near the Gold Mines.—The following extracts will serve to illustrate the condition of society in the vicinity of newly discovered mines, the character of miners, the hardships and risks of mining, the cost of living near the mines, and the wear and tear of life.

"Kanakas, or Sandwich Islanders, the worst of laborers, are now employed constantly about town in storing and landing merchandise, at *four shillings an hour* each; and the most indifferent laborers are hired by the week together at six or eight dollars a day. Mechanics obtain, when employed by the day, £1 12s. or £2 per day, and by the month about £1 4s. . . . . Washing £1 12s. per dozen. . . Waiters at the hotel £240 to £300 per year; head waiter, £340. . . . For some time last summer (August and July) the officers at Monterey were entirely without servants, and the Governor (Col. Mason) actually took his turn in cooking for the mess. . . . Whole cargoes of goods are sold at an average of 150 per cent. clear profit, and ready pay in gold dust. . . . In a few months real estate that cost me less than £160, I suppose I could now sell for £1,600 or perhaps £2,000. . . . Something should be done here at once for the establishment of peace and good order in the country. All law, both civil and military, is at an end. Among the mines, and indeed most parts of the country out of the villages, no authority but that of the strongest exists, and outrages of the most disgraceful nature are constantly occurring and the offenders go unpunished."

Notwithstanding hardships and deprivations, many of the miners were unsuccessful even so early as 1849. San José was crowded with these men recruiting their purses by highway robbery, and seeking to drown remorse in drinking and gambling.

In 1849 and 1850 "the canopy of heaven was the only tent spread over the slumbering heads of thousands. Some sheltered by canvas, had sheetless, nay blanketless beds, some no beds at all."

At San José, in 1850, flour, £10 a barrel; boots, £6 8s. a pair; eggs, 2s. each; onions, 1s. to 2s. each.

At San José, 1850: "Crimes were numerous. It was not safe to travel at night without being armed. The country was so sparsely settled that it was difficult to catch criminals. Every few days some one was murdered in the valley."

San Francisco, August, 1849: "Many who went to the mines returned unsuccessful, and report that the exertion of getting gold is too great."

San Francisco, 1849: "Potatoes, 1s. 6d. a pound."

Sacramento, October 13, 1849: "A meeting is called today for the relief of those on their way overland; they are said to be dying by hundreds from thirst and hunger upon the great desert."

"Hundreds were coming in daily from over the mountains—sick, destitute, and almost starved. They met here with harpies to prey upon them, and they were often compelled to sell their teams for food enough to last them down to Sacramento city."

"Quinine was in great demand at 4s. a grain. For a shave at a barber's, 4s."

"You have heard of the Battle of Life—it is a reality here; the fallen are trampled into the mud and left to the tender mercies of the earth and sky. No longer ago than last night, I saw a man lying on the wet ground, unknown, unconscious, uncared for, and dying. To-day, some one with more humanity than the rest, will have a hole dug for him; some one else will furnish an old blanket; he will be rolled up and buried, and his friends at home, who may be as anxious about him as mine are about me, will never know his fate. Money, money, is the all-absorbing object."

"There is no government, no law. Whatever depravity there is in a man's heart now shows itself without fear and without restraint."

"A young man died in the street to-day. No one knew him. In his pocket was an ounce of gold, a note-book, and a Bible, the latter of the smallest size, with gilt edges and tucks. In one place was a beautiful card, on which was written in a lady's hand, 'Remember your friend and——.' In another was a card, worked with worsted and mounted with silk ribbon, and the legend 'A sister's prayers go with you.' Disappointment, drinking, gambling, and destitution was the story."

"A pine-board building, 'no better than a barn,' 55 by 35 feet and 1½ stories high, the interior partitioned with muslin, cost £3,000; it rented for £300 a month, or £3,600 a year. Wages of a cook, £50 a month."

"Butter, 6s. per pound; fare from Sacramento to San Francisco, £8."

Sacramento, January, 1850: "The people at home can have no conception of the amount of suffering in the vicinity of this city. Hundreds are encamped in tents through the rains and storms, scantily supplied with food and covering. *Many were driven from the mines for want of food,* and are

[1] When gold was discovered in 1848, one Louis Peralta, an old Spanish soldier and adventurer, upwards of one hundred years of age, said to his sons, who had attained the age of threescore: "You had better not go after it, but let the Americans go; you can go to your ranch and raise grain, and that will be your best gold-field, because we all must eat while we live." Hall's "Hist. of San José," ed. San Francisco, p. 191, Bancroft, 1871. (San José was then the capital of the State.)

begging for employment, asking only subsistence. Yesterday there were 25 deaths. The sickness does not arise from the severity of the climate, which is no colder (now) than November at home, but from a complication of causes. The intermittents of the autumn are aggravated by overwork, scanty and bad food, disappointment, and homesickness. Men in the ravings of delirium call upon friends who are far off, and, dying, mutter the names of their loved ones; men wasting away with chronic disease lose their manhood and weep often, like children, to see their mothers once more." During the river flood of 1850, Dr. Stillman wrote that some men who had been taken into the hospital were "dying on the floor; others, dead, are sewed up in blankets and sunk in the water in a room on the first floor."

"Gold washing is very hard work." . . . "I have been to the mines, was sick, made nothing, and returned."

May 5, 1850: "My friend, Hiram Bingham, goes home by the next steamer. He was a member of our company. He has been leading the nomadic life of a miner, and has picked up about $2,000, which he will carry home. That seems small compensation for all the dangers and hardships passed through and the time spent; yet it is better than the average."

Speaking of an intelligent miner who, after years of blighted hopes and unrequited toil, was preparing to return home to his family, and died before he could do so, Dr. Stillman says: "I went to see his corpse, and, as I gazed upon him alone, I thought it was the saddest case I had ever known. No one of that fond family was here—no hand of affection to put back the locks that fell over that broad forehead."

It is stated that so late as 1850, members of the legislature were paid in State scrip. January, 1851: "Crime continues to be rife in San José and vicinity. Scarcely a day passes without bringing something new to light."

1852: The history of the first few years of this decade is blotted with crime throughout the State; and San José has not been fortunate enough to be excepted from the catalogue of criminal localities. Murder, highway robbery, and stealing were the *avocations* followed by no small number. The law permitted punishment by death, in the discretion of a jury, upon conviction of *grand larceny*.

January 30, 1852: Theodore Basquez was executed for stealing a horse.

November 18, 1852: Ramon Romero was executed for grand larceny. A license for gambling cost £100 a month for each table.

Miners, poor and broken in health, were continually entering the city for relief and medical attendance.

"No city on this continent has equalled San Francisco in the prevalence of gambling, intemperance, licentiousness, and kindred evils. A decided improvement in public morals is said to have been made during the last year; but whoever, even now, takes a stroll through its streets, by night or by day, will be convinced that the unenviable reputation it has acquired is well deserved."

"Among the miners, except for the protection of life and property, the code of morals is generally a dead letter."

According to the Federal Census of California for 1850 the number of females to males at the ages of 20 to 40 is represented by the frightful proportion of 4 to 100. "Here then was a population composed almost wholly of male adults at those ages—20 to 40—when the energies and passions are most active, and almost wholly unrestrained by any of the duties claimed by infancy and old age, or by the respect due to the presence of women."

"Success in mining for gold in California is subject to many contingencies, and mining, as a business, should be classed with very hazardous pursuits. A good prospect does not insure a good mine. Gold may be found there to a large amount, but it may also happen that after the miner, relying on the evidence given by his prospect, has toiled for months, and expended a large sum of money in making the necessary preparations to work his mine, he is doomed at last to irremediable disappointment, and perhaps is made penniless."

"At Grass Valley and Nevada, the country around which has thus far been regarded, as the most fruitful in gold, and where quartz-mining especially has been prosecuted more extensively than in any other section of California, several quartz mills are now useless, the mines having failed for a long time to yield a paying supply of gold. One of these mills at Nevada cost £2,000, and several others £600 to £1,000. All these quartz mines opened richly, and for many months were very productive; but at length the supply decreased, until the product did not pay the expense of mining. . . . The same may be said of other parts of the gold region. Scarcely a district can be mentioned, where mines have been opened to any considerable extent, in which miners have not been ruined by the erection of expensive mills, canals, flumes, or other fixtures for mining, in leads and places which promised well at first, but which too soon, disappointed their expectations."

Diet and Privation among Miners.—Without assenting to all of the inductions presented by Mr. Buckle in his "History of Civilization," that one may be safely accepted which asserts that the nature of the occupations in which a community may be engaged, and the diet and other physical circumstances to which it is exposed, have much to do with the character of the institutions whose establishment may follow. Of this rule we shall find that mining communities offer a peculiar and further exemplification. The labor of the Californian placers was intense and unremitting. The glare of gold was constantly in the men's eyes, blinding them to the frightful bodily and mental risks they ran, and to the many forms of death that lurked behind them. They worked all day and often at night, exposed at times to the scorching rays of a mid-day sun, and at others to the destructive chills of damp nights. Stimulants and medicines, purchased at extravagant prices, were employed to ward off disease and death; while shelter, repose, and moderate labor, the only true palliatives for the ills that beset them, were shunned, because they interfered with gold-getting. "The day was intensely hot, yet about 200 men were at work in the full glare of the sun, washing for gold—some with tin-pans, some with close woven Indian baskets, but the greater part had a rude machine known as the cradle." . . . . "Recently there has been a reaction, which brings many back from the mines and an active immigration is flowing from abroad. Sickness has broken out among the miners, and many have returned prostrated with fevers while others have come back to avoid being so . . Flour and pork vary in the mines from £8 to £40 per barrel . . . . I saw a box of Seidlitz-powders, worth 2*s.* in San Francisco, sold in the mines for £4 16*s.* grain gold; and was credibly informed that brandy had been sold at £9 12*s.* per bottle . . . I was in the mines about the 1st of July. At that time the weather was insufferably hot. I think it by far the most oppressive climate I was ever in. It is much more uncomfortable than the climate of Brazil at the warmest season of the year, and everything was literally parched-up, after a drought which had been continued for near three months, and which had five months to run to the rainy season. The sea breezes which extend up the valley of the Sacramento never pass the Sierra Nevada, and seldom penetrate even the lateral valleys and ravines of those mountains; and there was not a breath of air moving among the mines. The sun was blazing down with more than tropical fervor, while his rays were reflected in ten thousand directions from the sides of the hills until the atmosphere glowed and glimmered like the air in a furnace. I then foresaw (what has since happened) that there would be much sickness among the miners. These people had deserted their reglar occupation, and a complete change of life and unnatural climate could not fail to act unfavorably upon their hea.th. Their diet was bad, their labors were severe, and they were exposed completely without shelter, in the daytime to a burning sun, and at night to the chilly atmosphere of the mountains. Many of them worked with their feet in the water and inflamed their blood in a feverish state by a free use of ardent spirits. The natural consequences followed. Many are now sick with bilious and intermittent fevers, dysenteries, camp-fevers, &c." "All live in tents, in bush arbors, or in the open air."

"During the year commencing July 1st, 1848, there will be £1,100,000 removed from the mines . . . . It is sufficiently obvious that the country will be prematurely filled by a restless, excitable, adventurous, and reckless population, and that extended agricultural or mechanical improvements are at an end for some years to come. Gambling and all sorts of thoughtless profusion begin to prevail. The present excitement will attract vast numbers of the idle, vicious and dissolute. Refugees from justice from the United States as well as other countries will flock to California among the better disposed population, and will find shelter among the almost inaccessible fastnesses of the mountains where such mines of wealth are now opened. These regions are of vast extent and are remote from the regular settlements, and from the operations of the laws. In the solitary recesses of the Sierra Nevada are little clusters of men, with nothing but the trees for their covering, and no protection but their own vigilance and strength. Many of these people are known to possess very large amounts of gold (sometimes as much as £4,000) wrapped in their blankets, where there is no eye to see and no agent to pursue the guilty. Is it strange when the temptation is so great, that the robber and assassin should be abroad among the mountains? Many robberies and some murders are known already to have occurred; but little attention is excited by these events where all are in the eager pursuit of wealth. No one can conjecture the extent of these outrages; for living witnesses are not at hand, and dead men tell no tales. . . . . "Besides living like wild animals, they slept on the bare damp ground exposed to the dews of heaven and the violence of man, a sickly nervous sleep that brought little rest. Some reposed in arbors composed of tree branches; a few in canvas tents. The sold their gold at 16*s.* an ounce, and brought bread and potatoes at from 1*s.* to 4*s.* per pound and meat at double these prices. Besides these articles, few others were to be had at any rate. They lived in fear of each other, buried their gold in secret holes, and robbed and assassinated one another right and left. Most of them succumbed to violence or fever; a few got away with sums which as a rule almost without exception, they soon lost in gambling or debauchery; not one of them acquired a permanent fortune."

"In May, 1849, 20,000 men broke camp on the Missouri river to march to the land of gold." "We had provisions for a year; as there was then no stock in the mines." "In the midst of our rejoicings (upon reaching the new placers) we ran out of provisions and had to live for days on grass and acorns, picked from the holes in trees where they had been placed by woodpeckers." "It was customary to sell the gold (dust) at 16*s.* per ounce, which was intrinsically worth over £3 4*s.*" "California gold averaged 89·58 per cent. pure." "No man would give another a hand's turn for less than £1; while a day's constant labor of the commonest kind, if it could have been procured at all, would cost from £4 to £6 at least."

"In San Francisco in 1849, 4*s.* was paid for a pill, and the same sum for an egg; £20 for a pair of boots, and twice that sum for a decent suit of clothes; a single rough brick cost fivepence, and a plank some twenty feet long was cheap at £2. At one period of that wondrous year, common iron tacks of the smallest size sold for their weight in gold; and for a long period were in request at from £1 to £2 an ounce. . . . In June, 1849, prices were: eggs, 4*s.*, 8*s.*, and even 12*s.* each; sugar, tea, and coffee each 16*s.* per pound; laudanum, 4*s.* per drop, £8 per dose; pills, £2 per dose; spirits, £2 to £8 per quart; wines, £2 to £8 per bottle . . . As for beef, little of it was to be had, and then only jerked, at correspondingly high prices."

Similar details are narrated of Australia during the first few years that followed the discovery of the placer mines in that country.

"In the spring of 1854 there was discovered in Australia one of the richest placers or gold beds, even of that auriferous country. The spot was a deep ravine formed by the Buckland river, enclosed by steep mountain sides, which excluded every breath of wind. It was autumn in Australia, though spring here (in England). The air in the ravine was stagnant, and the scorching sun made it intensely hot during the day; while at night the temperature fell to a piercing cold, so that the sojourners in the ravine were alternately in an oven and an ice-house. Moreover, as the gold beds lay in the channel of the river, the miners worked up to their waists in water.

"To this gold field of surpassing richness hundreds of adventurers flocked in feverish haste; but disease, like the fabled dragons and griffins of old, kept horrid sentry over the buried treasures. A peculiar fever of the typhoid character was the natural denizen of the spot; besides which the gold-seekers suffered severely from eye-blight, owing to the concentrated blaze of the sunshine reflected from the steep sides of the ravine; and they were at all times grievously tormented by clouds of flies. Bad diet and want of vegetables aggravated the diseases natural to the place and to the kind of work. In the strangely interesting accounts which then reached us, we read of onions selling at six shillings a pound; and cabbages, which we buy here for a penny, were so precious that they were cut up and sold by weight, from half-a-crown to four shillings the pound being readily paid for them. Physic, or what passed for it, rose in price in a still more startling manner; Holloway's pills selling at a shilling each or a guinea per box. It was a valley of death! . . . . Constitutions that had borne the hardships of other fields broke down here, wrote an eye-witness of the scene, and hundreds have perished, dying unattended and unknown. The little levels between the stream and the base of the mountain-wall, for ten miles along the valley, are so thickly studded with graves, *that the river appears to run through a churchyard.*

"One new-comer, wiser than the rest, having counted eleven corpses carried past his tent during the dinner hour of his first working day, and thinking that even gold may be purchased too dearly, left the place instantly. Many abandoned it after a somewhat longer trial; but the greater number, fascinated by the unusual richness of the gold-beds, remained, in defiance of disease, and took their chance, with what result the numerous graves of the valley testify to this day."

The low price of gold dust in coin, so peculiar a feature of early California experience, is noticeable in that of Australia. An ounce troy of fine gold was and is still coined by the British Government into 1019·45 pence, or 84·9541 shillings, which is the mint price in London. In 1851 the Australian miners were obliged to sell their dust at probably not over one-half its value. In 1852 they sold it at prices varying from 58 to 68 shillings per ounce; in 1853 from 70 to 76 shillings, and in the three following years from 75 to 77 shillings. These low prices of gold dust were due to the scarcity of coins, particularly the minor ones. The writer has now in his possession some rude lumps of silver stamped with crosses, which passed in the early days of California for 25 cents each, their value in bullion not exceeding 10 cents. He has also been credibly informed by more than one of the original "pioneers," that at one time gold dust was exchanged by the miners for silver dollars, weight for weight. The insecurity of property at the mines is another noticeable feature of early Californian life.

"The miner having obtained the gold, is next chiefly concerned for its safety. He is far up in the mountains and forests, surrounded by roving robbers and thievish lurking Indians, and in his frail shanty, constructed of boards or cloth, has no stone vaults or iron safe in which to secure his treasure. It is too heavy to be carried about his person; and if he secretes it in some hollow tree or peculiar rock, or secret cave or crevice, the hiding-place may be discovered by the marauders, who may chance to discover his visits to the spot. Under these circumstances he resorts to various expedients to secure his gold. Perhaps he digs a small pit under the stones on which he builds his fire, or under the bunk on which he sleeps."

"When these things (the high prices of labor, food, medicines, etc.,) and the risks of sickness, the discomforts of living, and the unusual and severe kind of labor, are all balanced against the average gains, it may appear that after all the miners (were they ever so fortunate) were only enough paid."

"The expenses, the time spent in traveling and prospecting, and lack of all the luxuries and many of the comforts of life, made many of us think it was cheaper to get gold in any other way than by digging for it in the placers. We abandoned the mines. Our bright dreams of becoming millionaires by washing the sands of the Sierra Nevada were all dissipated."

"September, 1849. A short experience of the mines had satisfied most of the citizens of San Francisco that, in vulgar parlance, all was not gold that glittered.

"With a few the dream had been realized; and although in the aggregate vast sums of gold have been obtained, yet a large proportion of the miners have learned the, to them, sad lesson, that man, in any country, to be truly happy, must earn his living by the sweat of his brow. Through much exposure and suffering, wearied and heart-broken, the poor miner has not unfrequently turned from the scene of his brilliant hopes to spend his last hours among his early friends—a sadder but a wiser man."

"One . . . employed nearly one hundred and fifty Indians to dig gold for him: at one time he had nearly £400,000 buried in the ground. But like all other miners, he lost it all."

—Compiled from "The History of the Precious Metals," by Alexander Delmar.

THE WRECK WROUGHT BY MINING.

"MOIL not too much underground, for the hope of mines is very uncertain," said one of the wisest of men, in whose time mining meant chiefly for gold and silver. Few, perhaps, who have read this opinion are aware how shrewd a one it is, and even men who have been the witnesses and subjects of the uncertainty of mining, have shut their eyes to the plain evidence before them, and retained faith in a metaphysical doctrine which has no foundation in fact. One writer, originally a Californian miner, advances as a reason for his faith in the generally accepted theory of value, the inconceivability of the continuance of mining were it not profitable.

The same may be said of the purchase of lottery tickets. This occupation has been systematically pursued ever since the Lotto was established at Florence in 1530. In England lotteries were brought from Holland in the XIth Elizabeth. According to Raynal two American companies were favored with the first lottery that ever was drawn in her dominions. Lotteries as a regular source of government revenue were established in England about 1620, and for nearly two centuries contributed to swell the revenues of the crown. They can be traced back to the mode of distributing, and the practice of purchasing the ancient Roman *congiari*, and may even have had an earlier and more distinct origin. From 1816 to 1828 the French government derived from lotteries an annual income of 14,000,000 francs. At the present day, in spite of prohibition, and penal laws, and of increased intelligence and morality, lottery tickets are sold in every large city in the United States. The "business" is as permanent and well-established as any other. A person of the shallowest intelligence may easily become convinced of the fact that on the average the purchaser must lose, and the seller gain, in a lottery: and yet this institution continues. In the city of New York nearly all, if not quite all, of the adult negro population (who number many thousands), besides a very large number of whites of the lower orders, are systematic lottery gamblers, purchasing their tickets every day, and generally both morning and afternoon; there being four lotteries daily in certain of the Western and Southern States, whose drawings are sent to the metropolis by telegraph. Such of the better classes as purchase lottery tickets—and many of these are stockbrokers and jobbers who are capable of calculating the chances of the game with great exactness—deal in the tickets of the Havana lottery, whose drawings are sent by the Cuba cable and published in the New York newspapers. Some of the "Exchange" offices in Wall Street are engaged in selling lottery tickets, the display of coins in the window being merely a blind. The sale of cigars and other articles are used as blinds in the commercial portions of the city. In the dwelling portions a shop or booth with the word "Exchange" in the window, or merely a shabby curtain, or a screen inside the door, denotes the lottery office. There are stated to be upwards of a thousand such places in New York. They are scarcely less numerous as proportioned to population in other American cities. In New Orleans the tickets are openly displayed (or were a few years ago when the writer visited that city) in the cigar and other shop windows. The sums of money invested from time to time in this manner, where it may be assuredly known beforehand that the whole number of purchasers, or the average purchaser *must* lose, probably amounts to more than the entire product of the gold and silver-mines of the United States. Yet "the business has been maintained" in this country, not like the gold production, during a brief twenty-five years, but during two hundred years, for we hear of its being denounced in Boston so early as 1699.

If it be asked why a practice so evidently unprofitable as lottery gambling is continued in the face both of prudence and interdiction, the answer is that although evidently unprofitable it is not generally speaking obviously so. The mass of those who gamble are incapable of justly estimating the chances of the game, or are destitute of that force of character which is necessary to enable them to eschew so hazardous a pursuit. It is the same with free mining for the precious metals. Apart from the free pioneer, apart from the hired miner who mechanically works with pick and shovel for a day's pay, and would work as steadily in a coal mine or on a farm, and apart from those stipendiaries connected with mines, such as superintendents, officials, &c., these classes together comprising but a small portion of those who have contributed to stock the world with gold and silver, the miners, that is to say the mine hunter, the mine promoter, and the mining speculator, is essentially a gambler.[1] If husbandmen invariably obtained three bad harvests before one good one, they might nevertheless sow the fourth time, because one good harvest might cover even this great deficiency. But it certainly would not cover any more; and an invariable succession of four bad harvests before one good one would put an end to agriculture. Not so with mining for the precious metals. Were ninety-nine-hundredths instead of four-fifths (which is the fact) of all mining adventures unprofitable, still would there be found a class of men willing to hazard the hundredth one in the hope that that one *might* prove profitable.

The uncertainty and uncertain profits of free mining extend the calculation of its cost over long periods of time, and many countries; until it eludes the grasp of the mass of men. This cost is not obvious; it has never been demonstrated by evidence. It is, at the most, suspected by a few persons who have enjoyed unusual opportunities for observation and reflection upon the subject.

Another reason why men continue to pursue gold and silver mining is closely allied to the one above given. That one was its unproved character of unprofitableness: the present one is its uncertainty, and occasional vast profits which liken it to a lottery. One may have reason to doubt that in the long run gold and silver mining is unprofitable, but he has none to doubt that it is risky. And just as there are multitudes of persons who, knowing beforehand the unprofitableness of systematically purchasing lottery tickets, nevertheless continue to do so all their lives, so are there multitudes with even more excuse for their rashness, who are always ready to follow the fascinating pursuit of gold and silver mining.

The secret of this fascination is in the gambling nature of the industry. Every step in mining, from discovery to production, is attended with risks of the most violent character, which are wholly impossible to foresee. One has only to examine the fluctuations in the prices of mining stocks in the San Francisco or Sydney markets to be convinced of this fact. These prices are not quoted, as were

[1] J. R. MacCulloch, in the "Encylopædia Britannica," article "Money:"

"Frequently indeed, the production of the precious metals partakes very largely of the nature of a gambling speculation. . . . Ulloa says that in Peru an individual who embarked in a mining speculation used to be considered as a *ruined man*, or as having adventured *in a lottery*, in which, though there are many great prizes, the blanks had a decided preponderance; and, according to Humboldt, the same thing was experienced in Mexico, the search after mines, and the working of them, being there looked upon as a sort of *gambling adventure*, in which many are ruined, while only a few obtain great wealth."

The facts quoted by MacCulloch will be found in Adam Smith's "Wealth of Nations," book i. chap. xi. part ii. In view of the vast influence which Dr. Smith's Work has exercised upon the welfare of mankind, it is to be profoundly regretted that in this important respect the suggestions contained in the materials before him were turned to such poor account as is to be found in his doctrine of value.

those of railway stocks in New York during the war, in a credit money whose mass was more than once suddenly augmented, but in gold coin, the fluctuations in the value of which at the present time are not nearly so great. The general rule of experience that miners, mine discoverers and mine explorers, rarely or never retain the wealth which exceptional good fortune sometimes bestows upon them, is not without its significance in this connection. These men were successful because they were gamblers, and the habit of gambling, which once acquired is difficult to throw off, is the cause of their so commonly losing what they have gained.

It might be urged still further that although the class of individuals engaged in mining for the precious metals may commonly fail to perceive its unprofitable nature; that although perceiving it they may still be led to pursue the industry on account of its promises of vast wealth to the successful; yet that the rest of society can hardly be supposed to share their imperfect observation or judgment. Conceding that precise data are wanting, and that the historical evidence as yet not segregated from the mass of other events was tediously diffuse and difficult to sift, yet a truth so important must, despite these obstacles, have floated in some shape or another to the surface, and made some mark upon the legislation, the government, or at least the philosophy of the times. We shall have reason in another part of this work to fully verify this suspicion. It is no new discovery that mining for the precious metals is both pecuniarily and in other respects an unprofitable industry. The ancients seem to have been very well aware of it, and at many periods and in many countries its pursuit has been entirely forbidden. As to the absence of any modern recognition of gold and silver mining, we Europeans of this brilliant and eventful century are too apt to forget our very recent emergence from the ignorance, the violence, and the servile condition of the mediæval ages. It is scarcely a century since the occurrence of the American and French revolutions, and, speaking as Europeans, not a century since the enfranchisement of our industrial classes from serfdom. We have scarcely yet become accustomed to the word Liberty, or to know its deep significance; yet here we find ourselves wondering why we have not already penetrated the inmost arcana of a polity to which only the light of a long-continued civilization had led the ancient world. Although neither the unprofitableness nor the gambling character and the immoral tendency of gold and silver mining have as yet found specific recognition in modern legislation, there is not wanting a significance in the absence of popular regret with which many of the European and American States have parted (perhaps forever) with their stocks of the precious metals.

In many of these countries systems of money composed of government numeraries have supplanted the use of gold and silver coins, although in none of them have the latter as yet been prohibited. These coins therefore remain legal tender, generally, as before, and thus offer that same immediate market for the sale of these metals, which has always formed the principal incentive to their reckless production. Any commercial conclusions concerning the cost of the precious metals which are derivable from the course of recent national legislation on the subject are therefore premature. We can gain no light even from the aggregate wisdom of society, until the experience which must furnish its basis has become more matured.

Between ancient and modern legislation there intervenes not the legislation, but rather the government of mediæval countries. As it is from these countries and this period that much of our stock of the precious metals is derived, it remains for us to inquire why society, during the entire period from the subversion of European liberty by the Roman conquerors to its general restoration after the French Revolution, failed to discern the unprofitable character, and to avoid the unprofitable pursuit, of mining. The answer to this question comes in a word. Society was not free, and whether it perceived the unprofitableness of mining or not, it was powerless to avoid its pursuit. The condition of all Europe and America except that of the ruling classes, was one of servility. Under the military power and the form of feudal obligations men were forced into the mines until they perished in them. Political economy had nothing to do with this period; commercial calculations were impossible and futile. It was an era of force, in which on the one side were ranged a few nobles clad in armor, girt with steel swords, and protected by castles, ramparts, and ditches; and on the other a multitude of unarmed and half-naked peasants, incapable of resistance.

Mining as a Promoter of Crime.—Only those who have lived in gold and silver mining countries can fully understand the powerful influence which this hazardous industry exercises upon the moral welfare of the surrounding community. The almost universal passion for gambling which it excites and encourages; the extraordinary freaks of fortune which it gives rise to, where sometimes, and in the course of a few months, the most indigent and illiterate of the community are lifted into opulence and power, while the well-to-do and intelligent are reduced to unexpected poverty and obscurity; the licentiousness of the *nouveau riche*, and the grief and despair of the unlucky and disappointed—all these are social features peculiar to mining countries, whose broad and deep marks to be appreciated must be seen with the observer's own eyes. A continuous residence of more than two years in California has satisfied the writer that, at least in San Francisco, which contains one-third of the entire population of the State, there are few persons of an adult age who are not at some time or other directly interested in the mines; and this is probably also largely the case throughout the State generally, and also throughout Nevada and the remaining portions of the North Pacific slope. The miners themselves, who, now that the placers are exhausted, are, for the most part, workingmen upon daily wages, are probably the least interested of any class in the vicissitudes of the mines. But down to the very boot-blacks and servant-girls there are few others of whom the same can be said. When a new ore discovery is made, or is expected to be made—and this occurs not unfrequently—every kind of productive labor is abandoned for the superior attraction of the Stock Exchange and the broker's office. At these centres of activity can be seen any day thousands of men and women, the latter chiefly of the poorer classes, tradeswomen and domestic servants, waiting for that turn of the wheel of fortune which shall bring them opulence and ease. Little hoards are withdrawn from savings banks and other receptacles, and eagerly exchanged for shares in looked-for bonanzas, and when the prices of the latter advance so as to place them beyond the reach of the purchaser with limited means, the shares of other properties, often so obviously worthless as to be openly and generally alluded to as "wild-cats," are purchased with the same eagerness, and paid for in coin wrung from the sweat of labor and subservience.

Upon the passion thus roused and the credulity which it fosters, there are not wanting classes to prey and thrive. False or exaggerated reports of ore discoveries, delusive tricks and plants in and about the mines, stock deals and jobs concocted to deceive investors, wash-sales and bull-and bear movements on the stock-market, the employment of stool-pigeons, point-givers, and cappers—in short all the devices known to the jockey and the blackleg are brought into active play. The common result is loss and despair to the deluded investor and fortune to the conspirator; and yet the few prizes snatched from the fire are so fascinating, that no degree of general loss appears to be sufficient to deter new aspirants for fortune. There is scarcely a class of the community which does not play some part in this drama. The conservative merchant or banker who lends money upon this or that mining stock, or withdraws the often designedly accorded credit; the influential leader of fashion who confidentially imparts the exclusive intelligence concerning some mine to his or her circle of dearest friends, which, in most cases is certain ruin to them; the fiduciary who borrows from his trust-fund merely for a few days, until he can realize the enormous profit promised by an impending rise in stocks and pay back the dishonestly abstracted money; the clerk who is tempted to seek fortune through the humbler medium of his master's till; the poor shop-girl whose virtue falls an easy prey to the powerful allurements of wealth and who is then employed as the medium for trapping other victims—all these and many other classes are lost in the dangerous and demoralizing pursuit of sudden wealth from the mines.

At the present writing there are four exchanges in San

Francisco, all of them devoted exclusively to mining stocks. So small a quantity as five shares of stock is commonly dealt in, and cases are known where a single share, nay one-half of a share was bought and sold. The prices of the stocks have ranged from several hundred dollars down to two cents a share, so that the smallest speculator can be accommodated. So universal has stock gambling become in California, that mining stocks take the place of the weather in other countries, and have become the commonest theme of conversation, alike in the politest circles and the obscurest retreats. Indeed, one can learn after a brief residence on the coast, and merely by observing the faces and demeanor of those who throng the neighborhood of the exchanges, whether the "market" is up or down. That in a community thus engaged and constituted—and the same may be said of the mine-owning towns of Mexico and Australia—insanity and crime should prevail to an unusual extent is only what would naturally be expected. The intellect is not proof against the sudden changes of fortune induced by the hazard of gold and silver mines, and the sudden and tremendous fluctuations in their value; nor are the passions subject to the same control that distinguish them in communities occupied in safer and more sober pursuits. The evidences of these aberrations of mind, this violence of emotion which distinguishes mining countries, are to be found in every direction. It will suffice for the purposes of this work if two of the principal ones are selected for illustration. These are insanity and suicides.

In arranging the evidence of insanity it is primarily necessary to distinguish between this mental derangement and idiocy, the former being "the product of society and of moral and intellectual causes," and the latter "a state depending on soil and material influences." Next, an allowance must be made for the number of insane in private families or at large, and not confined in the asylums. According to the voluminous, though far from critical report of Dr. Wilkins to the Governor of California, France is the only country whose statistics, as quoted, distinguish the insane and idiotic severally, in asylums and at home. The year selected for illustration, 1861, happens to be that one when the official figures were, for the first time, substantially correct. Of this we are assured by the "Statistique de la France" [par Maurice Block, Paris, 1875, volume i, p. 308], the same work on a previous page giving the number of insane under treatment in France at various recent periods as follows:—

Year.	*In Asylum.*	*At Home.*	*Together.*	*Population of France.*	*Insane to Population, 1 in*
1851	21 353	24,433	45,786	35,783,170	781
1856	25,485	34,004	59,499	36,139,364	607
1861	30,239	53,160	83,399	36,717,254	440

The increase of insanity apparently shown here is due for the most part to the increased completeness of the returns, evidenced by the augumenting proportion of insane treated at home. This, at the latest date, was 175 to 100 in asylums. The statistics of insanity in the United States are obtained for the Federal census from the reports of the asylums. They are somewhat defective as to numbers in private asylums, and do not make any allowance for the numbers treated at home. With an estimate of the latter based on the proportions exhibited in France, the statistics of the United States are as follows:

Year.	*Whites in Asylums.*	*Estimated at Home.*	*Together.*	*White Population.*	*Insane to Population, 1 in*
1850	14,257	24,950	39,207	19,553,068	498
1860	23,593	41,288	64,881	27,461,813	423
1870	35,610	62,318	97,928	33,589,377	343

The estimates in the second, third, and fourth columns for 1860 include free colored persons who are not distinguished from the whites in the census compendium of that year. The proportion of free coloured is little more than 1½ per cent. All of the above numbers include California. The black, formerly the slave population of the United States, is omitted, because, while idiocy is quite common with this race, insanity is rare, and their incorporation into the table would render it misleading. Here, again, the numbers and proportions exhibit increase since 1850, and show that in the United States generally, insanity is half again as prevalent at the present time as it was twenty or more years ago. Let us now see how their case stands in California, considered by itself. In that State there are no private asylums. The official returns of insane at Stockton and Napa include a few idiots—according to the Federal census of 1870, only 14 per cent. of the whole number—and to that extent the comparison which will presently be made is vitiated, certainly for one year, and probably, to more or less than this extent, for all years:

At close of official year.	*In asylums at Stockton and Napa.*	*Estimated at home. Proportion as in France.*	*Together.*	*Population of State.*	*Insane to population, 1 in*
1850	22	38	60	165,000	2.750
1860	417	730	1,147	379,994	331
1866	693	1.213	1.906	476,409	250
1867	769	1.346	2,115	600,039	236
1868	853	1.493	2,346	618,000	221
1869	920	1.610	2,530	638,000	213
1870	1.047	1.832	2,879	660,247	195
1871	1,090	1.908	2,998	682,400	194
1872	1,123	1,966	3,088	605,700	196
1873	1,156	2.023	3,179	630,000	198
1874	1,224	2.142	3,366	655,200	195
1875	1,302	2.279	3,581	681,400	190
1876	1,422	2.489	3,911	708,700	181
1877	1,590	2.783	4,373	737,000	168

The numbers include white and other races; but as the latter form only a small portion (ten per cent., mainly Chinese) of the whole population of the State, it has not been deemed worth while to exhibit their statistics of insanity separately. The proportion of Chinese insane is less than five per cent. of the whole number. The uncertain factor in this table is the proportion of insane not in the two asylums at Stockton and Napa. The proportion estimated is derived from the statistics of France, where wealth being less equally distributed, and the police more scrutinizing, it is to be presumed that this proportion, great as it is, is less than in California. As these statistics do not show the number of new persons afflicted each year, but only show the whole number remaining afflicted at the close thereof, and as the populations of France, the United States and California respectively, are of different ages, there is other room for errors when the table is used for the purpose of international comparisons. But these uncertainties and discrepancies are not important in the present connection. Unmodified by these considerations, it appears that among the white race in France insanity is the condition of 1 in 440 of the population; in the United States, generally, 1 in 343; in California, by itself, 1 in 168. In other words, insanity appears to be twice as rife in California as in the United States, and more than twice and a-half as rife as in France. The number of new commitments for insanity each year since 1866 may serve, in some measure, to indicate the causes of this extraordinary and sorrowful exhibit:

Fiscal year ended June 30.	*Commitments to Stockton and Napa Asylums.*	*Population of the State.*	*Annual commitments to population, 1 in*
1866	279	476,409	1,707
1867	313	500 039	1,597
1868	387	518,000	1,328
1869	482	538,000	1,116
1870	562	560.247	997
1871	523	582,400	1,112
1872	506	605,700	1,197
1873	401	630,000	1,177
1874	524	655,200	1,250
1875	615	681,400	1,108
1876	735	708,700	964
1877	652	737,000	1,130

From 1848 to 1865, inclusive, a period of eighteen years, the whole number of commitments to the State Asylums for the insane was 3,169, or an average of 176 per annum, while from 1866 to 1877, inclusive, a period of twelve years, the commitments have been 5,979, or an average of 498 per annum. The former may be regarded as the area of the placers, when few besides those who worked in or about the mines were subject to their vicissitudes, and when death soon closed the career of the unfortunate adventurer, and shielded him from the milder visitation of insanity. The latter is the area of the vein-mines, of mining incorporations, and of gambling made easy by mining shares and stock markets. It is not difficult to infer that these causes have had much to do with the great increase of insanity shown by the statistics adduced; an inference that becomes greatly strengthened upon turning to the statistics of suicide in San Francisco. These statistics, it must be remarked, are very defective. Until lately, no attempt had been made at the coroner's office to construct tables of suicides comparing one year with another; and nothing beyond the most indifferent effort was made to ascertain their causes. Much improvement in these respects has lately taken place, but still many suicides are not reported. These consists mainly of persons who drowned themselves in the bay, and whose bodies are not recovered and brought under the notice of the coroner; and of Chinese, the deaths of whom in San Francisco from whatever causes, are reported as due to "unknown" causes.[1] Another class of omissions is of persons belonging to the city who may have committed suicide beyond its corporate limits. In such cases the coroner of the city has no supervision and makes no mention of them. Some of these, not all, are included in the reports of the health officer. From the records of these two officials, and, when they disagree, choosing the higher number as the more nearly correct, we have the following comparative results:

Reported Numbers of Suicides in San Francisco.

Year.[2]	*Suicides.*	*Year.*[1]	*Suicides.*	*Year.*[1]	*Suicides.*
1860	31	1867	29	1873	38
1861	30[2]	1868	22	1874	61
1862	13[3]	1869	39	1875	64
1863	18	1870	47	1876	70
1864	20	1871	51	1877	76
1865	17	1872	37	1878	103
1866	24				

Any comparison of these numbers with the reputed population of the city in any other years but those in which a census was taken, is considered hazardous on account of the tendency to exaggerate the number of inhabitants, which is common to the growing cities of the United States, and appears in all the publications relating to them except the census itself. The only years of the series above shown in which a census was taken in San Francisco were 1860 and 1870, when the population was respectively 56,802 and 149,-473. The least objectionable means of determining the relation of the number of suicides in San Francisco to that in other cities is to compare both of them with the whole number of deaths in each place. Without burdening this work with details which would probably weary the reader, it is deemed sufficient to say that, determined in this way, suicides are more than twice as common in San Francisco as in New York, and more than three times as common as in Philadelphia. It is the present writer's belief, that as compared with population—could the latter be satisfactorily determined as to San Francisco—the result would appear still more unfavorable. It is also to be remembered that this result is only given with reference to the numbers of the reported, not the true numbers of suicides in San Francisco. Giving due weight to this consideration, it will probably be not far from correct to regard the proportion of suicides in San Francisco either to all deaths or to population as fully three times as great as in New York where suicide is a much more common occurence than elsewhere in the United States.

All inquiry into the probable causes of such an extraordinary preponderance of suicides is bound to be beset with obstacles. When the predisposing, nay, even the immediate, causes of self-destruction defy, as we know they commonly do, the scrutiny of a legal inquest, there would seem to be little hope of determining them from that more general sort of evidence which is to be found in other ways; and but for a personal knowledge of the habits of life common to several mining countries, the present writer would hesitate to indicate them. In his report for the fiscal year ended June 30, 1878, the coroner of San Francisco reports thirty-five cases as caused by pecuniary, and seven by unknown motives. Three of the former he directly traced to stock gambling. Intemperance, insanity, and unsound mind cover twenty-one more cases. All of these cases and many other attributed to various causes, may have been, and probably were due to gambling in the mines, or the absence from home and friends which forms another condition peculiar to mining countries. This probability is greatly strengthened by the causes of the suicides, covering a portion of the same period. which were reported by the daily press. During the calendar year ended December 31, 1877, the following suicides with their supposed causes were reported in the "San Francisco Chronicle."

Among the conditions that influence suicide there are none, except mine gambling and the separation from home and familiar faces, which is peculiar to mining communities, and especially those of recent growth, in which San Francisco does not enjoy advantages which should exempt it from this crime. The city is exceptionally healthy, it is purified by sea winds that blow every day; its foundations are laid in clean dry sand, it is hilly, it has a good drainage, and is washed by a vast bay on the one side and the ocean on the other. The climate is dry, temperate, and steady. Food of every description is plentiful and cheap; all the other necessaries of life are to be obtained upon the same terms as in other cities throughout the United States; while labour is usually in demand and commands a higher price than elsewhere. Hence, in looking for the cause of this great and peculiar mortality, the inquirer is led at once to the subject of the mines. Before the civil war the number of suicides committed annually in San Francisco was about thirty. During the war—and this period also agrees with the opening and developement of the great Comstock mines—when great profits, rising prices, and abundance of employment for the industrial classes preserved them from those temptations to self-destruction which find their origin in pecuniary difficulties, the annual average fell to seventeen. When the war closed and the Comstock mines came to be incorporated into stock companies, suicides resumed their former frequency, and during the four years ending with 1869 the annual average became again, as before, thirty. The ensuing four years witnessed the opening of the great Crown Point and Belcher Bonanza, and the first series of gigantic stock speculations and jobberies which distinguish the annals of the coast. During this period the average annual number of suicides rose to forty-three. In 1874, while the Crown Point and Belcher Bonanza was still yielding at the rate of £3,600,000 a year, the Big Bonanza was struck in the consolidated Virginia and California mines, and this added some £1,000,000 to the year's product of the precious metals, and proportionately increased the pre-existing mining excitement and the practice of jobbery. From this time forward until 1877 the Big Bonanza continued to increase its product, to augment the predominant mania of the coast, and to afford additional support to the resources and devices of jobbers. In the last-named year the fact was unexpectedly disclosed that this great ore body had passed its point of highest production. Then followed a tremendous collapse in all gold and silver mining shares, numerous bankruptcies, a fall in real estate, rents, commodities, and wages, popular tumults, and numerous misdemeanors and crimes; among the latter an unusual number of suicides. Taking together the five years ended June 30, 1878, the number of suicides reported to have been committed in San Francisco reached the unprece-

[1] Report of the coroner for 1878, p. 5. The Chinese in San Francisco number about one-tenth of the population and although they nearly all consist of adult males in the prime of life, while the whites consist of both sexes and all ages, the whole number of Chinese deaths is in about the same proportion.

[2] Ended June 30. [2] Estimated.

[3] Estimated from returns of nine months. The returns for the year 1867, 1868, 1872, 1874, 1875, 1876 and 1877 are from the Health Board returns, the others from the Coroner's. The latter's summary report for 1878 gives, on p. 124, the following number for each year commencing with 1863, viz., 17, 20, 16, 20, 28, 20, 43, 44, 44, 45, 37, 59, 60, 56, 75 and 103. Total reported in sixteen years, 687. Chinamen are not included in any of these numbers except where, very rarely, a Chinaman is specifically reported to have died from self-destruction. Inquests are not held upon the bodies of Chinamen dying from unknown causes.

dented annual average of seventy-five. It is difficult to believe that these occurrences were not connected. This conviction is strengthened, not only by the statistics of commitments for insanity hereinbefore given, but also by the statistics of death by violence, of crime, immorality, and disorder of every sort; by the accounts of the savings banks, by the returns of bankruptcies, and by the prevalence of indigence and suffering among those classes of the community who did not profit by these speculations, or succumb to the blow which they inflicted on the losers.

CURIOSITIES OF METALS.

MR. J. VAN CLEVE PHILLIPS recently sent the following curious communication to the *London Mining Journal*:

In reading Fourier's Philosophy in a new book by Van Buren Denslow, called "Modern Thinkers," and having read Erasmus Darwin's "Love of the Plants" (Dublin, 1795: grandfather of the present Darwin), I find my idea of sex in mineral veins fortified. My study of the Mississippi lead field was from 1844 to 1853, and of the Missouri lead fields from 1855 to 1880:—1. The lead fields are basins of limestone, these being from 100 yards to 5 miles wide, and vein system duplicated in each basin. 2. All the discoveries of ores in the upper Mississippi and Missouri lead fields may be located geographically in the basin where they occur, and stratigraphically in the rock and family of veins to which they belong. The lead ores mined in these fields have yielded to date $150,000,000 worth of lead, all of which has been taken from the small basins or along the edges of the larger ones, and is from the edge of the vein system, and will not include over 1-20th per cent. of the ores contained in the basins, as shown in my unpublished geographical surveys of the upper and lower Mississippi lead fields. It will be seen from this that the existence of lead and zinc is now known which will supply the people of the center of the continent with these metals when it shall have a population of 300 to the square mile, as England has to-day.

My first attention to the physical outline of crystallization of lead ore was in 1848, while superintending a lead furnace in Wisconsin. The teams were bringing in ores from 20 different lead discoveries, having north and south veins, east and west veins, and stratified veins from the rock and clay. The east and west veins had regular cubes, the north and south veins had the edges of the cubes truncated, and the horizontal veins had the solid angles of the tubes cut off or truncated. The ores from the clay were amorphous, and this form of crystallization was duplicated in each lead basin. This went to establish the fact that the lead producing and crystalline action had been directly connected with the vein system in all parts of the lead basin; that the same force which had been exerted to fill the vein system in one basin of limestone had duplicated that system in the adjacent basins, and the physical outline of the ore was an index of its geographical and stratigraphical position in the basin. Afterwards I was led to the conclusion that the north and south veins were the positive or male veins, and the east and west the negative or female veins. The north and south veins were few in number, the east and west veins many, and the north and south veins always pointed towards the basins of the east and west veins. This law is noticed in the animal and vegetable kingdoms, in the sheep and goat families, and in the cherry and apple trees, the males being in the minority. In applying this law to iron ores we suppose the magnetic ores are the positive or male ores, other varieties the negative or female ores. In the silver fields the Comstock, being a north and south vein, would be a positive or male vein, and the east and west veins of New Mexico and old Mexico the negative or female veins.

The great vein known as the San Pietro, in the town of Hidalgo del Parral, is an east and west vein; also the largest and richest mine worked at the old Spanish mining town of Inde in the State of Durango, Mexico, and known as the Del Aqua (water mine), is an east and west vein. I am not sufficiently acquainted with the courses of the veins in the mountain States to apply this law of sex to the vein system of the numerous silver and gold-bearing fields, yet I have identified it in the vein system of the upper and lower lead fields of the basin of the Mississippi, and feel assured that it can be applied to all the families of veins which, as a rule, are aggregated around a central knob or Boofa, which forms the water-shed of individual families of veins, and which families as aggregated form the great stellar silver belt from Montana south through New and Old Mexico, and that by close observation the explorer and miner may profit by its application.

This *Communique* drew forth the following confirmatory letter from Mr. James Williams, who wrote as follows:

"The subject is not by any means a new one, as it is an idea that has occupied my attention for the last thirty years, and I am fully satisfied, and have been for many years past, that we cannot apply the word sex to mineral veins, as on close inspection I have found that the north and south vein (and which Mr. J. Van Cleve Phillips, New York, would term a male, and non-productive) by a secondary influence has become the bearing or productive vein.

A short account of my investigation of mineral veins and what led to it may not be out of place. Standing on an old mine burrow and elevated, on looking southeast and northwest, I was somewhat surprised at beholding a number of mines in that direction, as our Cornish mines, with but few exceptions, are east and west, and the above was a few degrees south of east and north of west. Where I stood I could take in a distance of from four to five miles, and the number of mines (about six), and on visiting the mines separately, I found that each had been made productive on the east and west vein, except the last. All the former veins had been made productive by the caunter running in the direction named above, and non-productive until forming a junction with the east and west vein, but the last to the south of east was in the direction of and with the Nine-o'clock vein, and up to this point might be called the male or non-bearing vein. But at this point it changed its character, and became the female or bearing vein, in consequence of being disturbed by an elvan course as a secondary element, and was very productive for a short distance, and was called Wheal Chance in South Crenver, where thousands of pounds were recklessly wasted looking over a second Wheal Chance, but not finding a secondary element or elvan course, their money was spent in vain. The next we shall hear of this caunter carrying its head, and pursuing its course, so to speak, east and by south, will be in Polcrebo mine, to the east and south of South Crenver, now commenced to be worked by Mr. Battye, Secretary, Great Winchester street, London, which I have considered for years to be a valuable piece of ground, second to none. As I prefer giving a reason for the faith that is in me, please permit me to do so in this instance, as it is of the utmost importance. This caunter or Nine-o'clock vein, after being traced a few miles through highly mineralized ground, with varied but beneficial results, we now have in Polcrebo mine; to the west and north it will intersect a northeast and west vein, then three veins east and west, parallel to each other, and underlying to form a junction in depth, and which is about the center of the sett. It passes on, and in the south part of the sett it will again form a junction with three other east and west parallel lodes, about thirty feet apart at surface, and coming together in depth. One of those (the south one) was made productive by a cross course as a secondary element. When this vein was first discovered close to the cross-course, and only twenty-eight fathoms from surface, it was in September, 1872, worth more than £84 per ton. The best work made, 7 cwts. 13 qrs. of tin to 20 cwts. of the vein (tin book now before me—amount £209 10s. 6d.); yet this sett was condemned by all the old-fashioned miners. It is quite time a new state of things should take place, so that we could with a greater amount of certainty find our mineral deposits. I have used every effort to form an Inductive Scientific Mineralogical Institution, visited London in 1879, was three times to the Marlborough House to endeavor to see the Prince of Wales and Duke of Cornwall, being extensively interested in mining property in the county, and, as I then stated, I now again affirm that the Prince of Wales' income may be increased 50 per cent.; also all the mineral land proprietors in proportion.

It is only three years since I made the attempt to see and interest the Prince of Wales with my theory. However, I am not out of heart or discouraged, as I read that Mr. Samuel Morse, the inventor of the electric telegraph, presented himself at the White House Congress in America in 1837, where he was laughed at and jeered by those who should have assisted him, and did assist him after wasting six years of precious and valuable time. I suppose I must not hope to be more fortunate than was Mr. Morse with his valuable invention.

Color Relations of Metals.—In a paper on the color relations of copper, nickel, cobalt, iron, manganese and chromium, lately read before the Chemical Society, Mr. T. Bayley records some remarkable relations between solutions of these metals.

"It appears that iron, cobalt and copper form a natural color group, for, if solutions of their sulphates are mixed together in the proportions of 20 parts of copper, 7 of iron and 6 of cobalt, the resulting liquid is free from color, but is gray and partially opaque. It follows from this that a mixture of any two of these elements is complementary to the third if the above proportions are maintained. Thus a solution of cobalt (pink) is complementary to a mixture of iron and copper (bluish green); a solution of iron (yellow) to a mixture of copper and cobalt (violet), and a solution of copper (blue) to a mixture of iron and cobalt (red) red. But, as Mr. Bayley shows, a solution of copper is exactly complementary to the red reflection from copper, and a polished plate of this metal viewed through a solution of copper salt of a certain thickness is silver white. As a further consequence, it follows that a mixture of iron (7 parts) and cobalt (6 parts) is identical in color with a plate of copper. The resemblance is so striking that a silver platinum vessel covered to the proper depth with such a solution is indistinguishable from copper.

There is a curious fact regarding nickel also worthy of attention. This metal forms solutions which can be exactly simulated by a mixture of iron and copper solutions; but this mixture contains more iron than that which is complementary to cobalt. Nickel solutions are almost complementary to cobalt solutions, but they transmit an excess of yellow light. Now, the atomic weight of nickel is very nearly the mean of the atomic weight of iron and copper, but it is a little lower—that is, nearer to iron. There is thus a perfect analogy between the atomic weights and the color properties in this case. This analogy is even more general, for Mr. Bayley states that in the case of iron, cobalt and copper, the mean wave length of the light absorbed is proportional to the atomic weight. The specific chromatic power increases with the affinity of the metal for oxygen. Chromium forms three kinds of salts—pink salts, identical in color with the cobalt salts; blue salts, identical in color with copper salts; and green salts, complementary to the red salts. Manganese, in like manner, forms more than one kind of salt. The red salts of manganese are identical in color with the cobalt salts and with the red chromium salts. The salts of chromium and manganese, according to the author, are with difficulty attainable in a state of purity. He thinks these properties of the metals lead up to some very interesting considerations."—*Chemical Review.*

Of the Forms of Minerals.—The researches of Graham and others have shown that inorganic matter may exist in two perfectly distinct conditions, known respectively as crystalloid and colloid. The same portion of matter may be at one time crystalloid and another colloid, the difference being one of condition not of composition. Thus rock-crystal consists of crystalloid silica, but if a fragment be powdered, fused with carbonate of soda, dissolved in water, and precipitated by hydrochloric acid, the precipitated silica will now be in the colloid state. When in solution, crystalloids differ from colloids in some very important particulars, and on passing into the solid form the differences are still more evident.

Colloid minerals are few in number. They are totally devoid of cleavage or distinct internal structure, but they usually break with a very perfect conchoidal fracture. They occasionally, but not often, occur in what are called imitative forms, but are usually amorphous or without definite external forms. As examples of true colloid minerals, we may mention opal and obsidian.

Crystalloid minerals are very numerous, they include, indeed, the great majority of mineral species. They may be either crystallized, crystalline, or crypto-crystalline.

Crystallized minerals are those which occur in definite geometrical forms. Ordinary rock-crystal is a perfect example of crystallized mineral.

Crystalline minerals are such as have the peculiar internal structure observed in those which are crystallized. They consist, indeed, of a multitude of crystals confusedly crowded together, so that the external geometrical form is lost or disguised. The cavities or "vughs" of such aggregates, however, often display distinct crystals. The kind of quartz known as cross-course spar affords a good example of a crystallized mineral.

Crypto-crystalline minerals are those in which the crystalline structure is so minute that it is not ordinarily observable, but it may be detected in suitably prepared specimens when examined under the microscope. Chalcedony and agate are good examples of crypto-crystalline minerals.

Many crystalline and crypto-crystalline, and some amorphous minerals, occur in what are known as imitative forms. The chief of these are the following:

Globular. This form is often seen in wavellite, prehnite, and other minerals. On breaking a globular mineral, it is almost always seen to be composed of a multitude of indistinct crystals radiating from the center, and sometimes the outside of the sphere is roughened by the projecting points of these crystals. Occasionally the true crystal form of these terminations may be observed, but usually they are indistinct.

Reniform (kidney-shaped). This form is not unfrequently met with in nodules of iron pyrites, or other minerals which occur imbedded in clay or mud. Some kinds of red and brown hematite are called kidney iron from their occurrence in this form.

Botryoidal (grape-like). This form is often seen in that kind of chalcopyrites known as blistered copper ore.

Mammillary. This form is often seen in malachite and blistered copper ore.

Corralloidal. This structure is observable in chalcedony and argonite, especially in specimens from Styria. It sometimes occurs in connection with earthy deposits of iron ore, when it is called flos-ferri, or the flower of iron.

Cone in cone. This structure is often met with in iron ores from the coal measures. It consists of a series of fibrous concentric conical masses, the points of the cones meeting together, or sometimes interlaced.

Stalactitic (icicle shaped). Chalcedony, calcite, and barytes often occur in this form. Sometimes the stalactites are hollow, sometimes solid; but in stalactites of calcite and barytes, a cross-section almost always reveals a structure consisting of fibres radiating from the center, and the same thing is visible in properly prepared slices of chalcedony, when examined under the microscope.

It is probable that most, if not all, of the above-described imitative forms are the result of deposition from solution, at any rate this is known to be the case in some instances. Thus, stalactites of calcite, or carbonate of lime, may be seen in process of formation in caverns in most limestone districts, and they are very frequently formed under bridges or tunnels which have been built with lime mortar. The process of formation is as follows: Rain water containing carbonic acid in solution in filtering through limestone, mortar, or other material containing carbonate of lime dissolves a part of it. On becoming again exposed to the air drop by drop, part of the carbonic acid is given off, part of the water evaporates, and part of the carbonate of lime is deposited. A stalactite once formed, the water naturally descends to its lower end before falling off, and it is there that the greatest amount of carbonate of lime will be deposited, and in this direction its growth will be most rapid, although a small quantity of solid matter will continue to be deposited on the sides of the stalactite, so producing the concentric structure shown in the vertical section of a stalactite, or in the cross-section. The radial structure appears to be of later origin; it is really due to an incipient crystallization set up within the mass. The water dropping from the stalactite will still contain some carbonate of lime in solution. This will be deposited on the ground beneath, when the conditions are favorable, forming what is known as stalagmite. A cross-section of stalagmite, however, will differ from that of a stalactite, owing to the tendency which the drops of water have to spread themselves out. If the supply of water be abundant, a sheet of stalagmite will be formed if only a little falls, a pillar of stalagmite will gradually rise towards the stalactite above; but in all cases the separate layers will be of about equal thickness throughout. The crystalline structure sometimes observable in the imitative forms already described, is probably the result of a secondary action of the crystallizing forces, following the actual formation of the solid mineral. There are, however, other imitative forms which are merely irregular crystals or crystalline aggregates, and in the formation of which the crystallizing forces appear to have been concerned from the first. These are the so-called capillary and wiry forms observable in native silver, the mossy and leafy forms seen in native copper, the dendritic markings of oxide of manganese, the reticulate groupings characteristic of mountain leather, and the stellate groups of crystals often met with in stilbite and other minerals.—*Mining and Scientific Press.*

ACCIDENTS IN THE COMSTOCK MINES AND THEIR RELATION TO DEEP MINING.

EARLY in the month of August, 1877, a miner in Gold Hill, Nevada, made the unlucky remark that, according to his observation, that month was usually quite free from accidents in the mines. Never was presage wider from the truth. When the month closed twelve mishaps had occurred, killing six and wounding nine persons, and for the rest of that year the Comstock mining communities were kept in a ferment by the frequent occurrence of appalling disasters. There was a real tidal wave of calamity sweeping over the mines, which was never known before on the Comstock. This paper deals with the accidents that occurred between July, 1877, and May, 1879. The number in this period of twenty-two months is 101, killing immediately 53 persons and wounding 70 others. This list is incomplete in every way. All accidents which did not injure persons are omitted, and there were several which were of a threatening kind but fortunately did no damage to human beings. Probably others have been overlooked which did not belong to the category included in the lists. Finally, no effort has been made to ascertain how many of the wounded died of their wounds, and the number of fatal casualties includes only those who died so soon after their injury that their death became a part of the current records of the accident. Many of these accidents belong to the usual classes of mishaps in mines and will receive no extended discussion. Others are worth examination from their connection with labor in hot mines, deep mining, and other causes intimately dependent on the local conditions of the Comstock. They may all be classified under eight general heads: 1. Falls of rock, timber, etc.; 2. Tramming; 3. Effects of heat; 4. Falls of men; 5. Explosions; 6. Hoisting apparatus; 7. Overwinding; 8. Miscellaneous. The distribution among these groups in each year is shown in following summary:

	1877. 6 mos.	1878.	1879. 4 mos.
(1.) Casualties due to falls of rock, ice, timber, etc.			
Number of occurrences	8	7	8
Casualties, fatal	2	4	3
Casualties, not fatal	7	4	5
Proportion fatal, 36 per cent.			
(2.) Casualties in tramming.			
Number of occurrences	4	3	
Casualties, fatal	1	0	
Casualties, not fatal	4	3	
Proportion fatal, 12½ per cent.			
(3.) Casualties due to heat.			
Scalding:			
Number of occurrences	1	2	
Casualties, fatal	1	1	
Casualties, not fatal		1	
Proportion fatal, 33 per cent.			
Overheating:			
Number of occurrences	1	8	
Casualties, fatal	1	7	
Casualties, not fatal		3	
Proportion fatal, 73 per cent.			
(4.) Casualties due to falls of men.			
Number of occurrences	7	7	2
Casualties, fatal	2	6	
Casualties, not fatal	5	1	
Proportion fatal, 62½ per cent.			
(5.) Casualties due to explosions.			
Number of occurrences	5	6	3
Casualties, fatal	3	2	5
Casualties, not fatal	5	6	
Proportion fatal, 71 per cent.			
(6.) Casualties in hoisting,			
Number of occurrences	4	6	1
Casualties, fatal	2	3	1
Casualties, not fatal	2	6	
Proportion fatal, 43 per cent.			
(7.) Casualties by overwinding.			
Number of occurrences	1	2	
Casualties, fatal	1	2	
Casualties, not fatal	1	1	
Proportion fatal, 60 per cent.			
(8.) Casualties due to miscellaneous causes			
Number of occurrences	7	8	
Casualties, fatal	1	3	
Casualties, not fatal	10	6	
Proportion fatal, 20 per cent.			
Total occurrences	38	49	14
Total fatal casualties	14	28	11
Total casualties, not fatal	34	31	5
Grand total for 22 months:			
Occurrences	101		
Total casualties	53		
Casualties, not fatal	70		
Proportion fatal, 43 per cent.			

This list is not offered as a summary of accidents in the Comstock mines, but merely as an index to the causes which operate there to endanger life. Many of these are common to all mining operations, but others are quite peculiar and deserve discussion, for it is supposed that they are likely to increase in force with the deepening of the mines.

(3.) In the third class, or those casualties which are due to the high temperature of the mines and the rock in which they are opened, we have some of the most singular occurrences known in mining. The injuries by scalding were occasioned entirely by falling into the hot mine waters. Their temperature varies with the locality, but the maximum is 156° F., and usually it is considerably below this. This temperature seems to be sufficient to produce serious effects. One miner, who had slipped into the Julia water, sinking nearly to his knees, got out so quickly that the water did not have time to enter his shoes, and yet his legs were scalded so severely that the skin came off. The same mine was flooded early in 1880 with water which was reported to have a temperature of 158° F., and a miner who in a fit of absent-mindedness stepped into it, immersing himself to the chin, was fatally injured. The water is hot and gaseous, and the unfortunate man who falls in it sinks deeply and probably finds it difficult to regain the surface.

But it is in the effects of work in hot air upon the human frame that the most remarkable casulties are witnessed, and this class is purposely put first among those which are to be discussed, because it seems probable that a considerable proportion of all kinds of accidents in these mines are directly due to the heat. The proportion of fatal casulties is larger in this class than in any other, being seventy-three per cent., and from the peculiar mental effects of the heat it is obvious that it may be and probably is the initiating cause of many mishaps which would, under other circumstances, be ascribed to culpable blundering. On the 1900 level of the Gould and Curry mine a drift was run to the southward from the shaft, following the line of the black dike and lying quite near it. As a rule the drifts at this depth have not been above 108° or 110°, and many have been less hot, but this drift has several times been reported to show a temperature of 123°, 126° and 128° F. Thomas Brown, a miner working in this place fainted, and when taken to the surface and revived was found to have completely lost his memory. He could not tell his name or where he lived, and had to be dressed and taken home by his friends. The paper which records the occurrence says: "This sudden loss of memory from overheating is quite common in the mines, but the effect soon disappears and the men are themselves again. This fact furnishes an explanation of how men who are considered experienced miners walk off into fatal winzes and chutes, seemingly with deliberate intention."

A frequent accident in these mines is fainting in the shaft while the cage is rising to the surface. The faintness is always felt immediately upon reaching the cooler air a hundred or a hundred and fifty feet from the surface, where there is usually a side draft through some adit. This casulty is so common that a man who has been working in a hot drift is not allowed to go up alone. Long habitude to the heat is no safeguard against this danger, and serious accidents have occurred in this way. The faintness is commonly preceded by nausea, but insensibility follows quite suddenly. Among the minor casualties is included one which is said to have happened to Mr. Sutro. Being in the Sutro tunnel before it made connection with the savage mine, and in an air temperature of 110° F., he went to the air pipe to cool off, and staid there so long that the miners told him to get away from the pipe and let them have air. He did not move, and the account says they tried to stir him up with the handles of their shovels, but he had lost all volition and could not budge. Finally he was put on a car and taken out. These are the minor effects of the heat. Its graver results are well shown in the following cases of insanity and death: The first of these, is described by the Virginia *Evening Chronicle* as follows: "At half past nine o'clock Monday morning, March 11th, 1878, a man died at the Caledonia mine in Gold Hill, under peculiar circumstances. The man had been idle for six months, and was working his first shift in that time, he having gone down this morning at seven o'clock. He was put to work as carman on the 1400 level. At the hour stated he rushed into the station at the 1400 level and told the station-tender that the wheels of his car were smashed all to pieces. The station-tender walked back with him to the car, when it was fonnd all right. The station-tender thereupon saw that something was wrong with the man, and took him to the cooling-off place. There he soon began talking wildly and behaving boisterously, and giving other indications of mental aberration. It was therefore thought best to bring him to the surface. He was firmly lashed to the cage and hoisted up, but on reaching the surface he fainted away and died in a few minutes." The heat on the 1400 level of the Caledonia is not very great, being about 90° F., and this man's sudden decease may have been due to other causes.

Of the other fatal casualties one was from cramps, which the account attributes to the heat, but which may have been the result of drinking ice-water, and another was from a cold taken while cooling off after being partially overcome by the heat. It is to the drinking of ice-water and the comfort of a strong draft that the men resort for recovery from the exhaustion caused by the heat, and though these methods, so contrary to the ordinary rules of hygiene, are put in use several thousand times a day, and usually with impunity, these two instances are proof that they may be dangerous. The miners consider the draft of cool air safer than drinking copiously of ice-water.

The next case illustrates the violent effects which excessive heat may have upon a person not accustomed to it: "On Friday, October 11, 1878, John McCauley went to work for the first time in the Imperial mine. He was cautioned against overexerting himself in the extreme heat of the lower levels. He replied that he thought he was strong enough to stand anything, and paid no attention to the advice. At half-past two in the afternoon he was brought to the surface in an unconscious state and died the next morning at half-past ten o'clock." Two other cases very similar to this have occurred in the Imperial within a few years. This mine is excavated in one of the hot spots of the Comstock. The hot drift on the 1900 level of the Gould and Curry is the scene of the most serious of these casualties due to heat. Five men were sent there in June, 1878, to load a donkey pump on a car. This work was so exhausting that when the pump caught on a plank they were not able to move it. They seem to have been in a state of mental confusion, but felt that they could not remain longer. Starting up a winze which connects with the 1700 level one man fell on the way, and the others were afraid to stop to help him, but pressed on, reaching the 1700 in half an hour from the time they left it. They were very confused and nearly speechless, and hardly realized what had occurred. Three men went down to the rescue, and found the fallen man still alive. Clearing the pump they got into the car and signalled to hoist, but on the way up the winze the man they had gone to rescue reeled and fell off. The car was stopped at once, but he was jammed between it and the brattice so fast that the others left him and went for help. They all gave out, two half way up, and the other just as he reached the 1700 level, where a friendly hand pulled him up. A new rescue party went down and found two men dead, and the third died soon after. The shift boss reports that "the accident was due solely to the heat, as the air is good enough and pure enough, barring the heat." The winze was not an abandoned one, but in daily use. A heavy volume of steam is reported to rise through it from the 1900 level, the temperature of which, at the time of this accident, is given at 128° F. It may be from the detailed account, that the death of the man is possibly attributable to the fact that when the miner fell off the car the latter was stopped in a place that was hotter than the rest of the winze. It is to be regretted that no adequate studies have been made upon the precise physiological phenomena presented by death under these circumstances. The legal requirements are satisfied when it is proved that the casualty was due to "heat," but if the theory of heat production in these rocks is correct, and currents of hot gas rich in carbonic acid are pouring through narrow belts of shattered rock, the death of men who are stopped in one of these belts may have a more complex cause.

(4.) The most appalling accident which can occur in mining work, the falling of men down a deep shaft, repeats itself in the Comstock mines with a frequency unknown elsewhere. Sixteen occurrences of this kind took place in twenty-two months, and ten of the casualties were fatal. There were seven falls in the shaft, six in winzes and one in a chute, and three in the floors. One of these deaths was traceable to the effects of foul air, the lights having gone out and the party being on the cage in retreat from the drift. These dreadful accidents being more common on the Comstock than in any other mines, it is important to ascertain whether this frequency is attributable to the heat. In some cases we may answer in the affirmative. When a timberman repairing the upcast shaft of an unusually hot mine falls to the bottom we may fairly conclude that the tendency of blood to the head which the lifting of a heavy weight occasions may have been increased to momentary stupefaction by the heat, steam, and gases of the shaft. But though my own impression before examining this subject was that the heat was largely accountable for these mishaps, one is forced by study of the casualties in this record to admit that this is not the most frequent cause of them. If the Comstock miner is more liable than his fellows to this form of accident it is because he is more often called to work in the shafts after they have been completed. The Comstock shafts are all sunk in the hanging wall, and the vast excavations which have been made in most of the mines make the settling of this wall inevitable. But besides that the Comstock rocks are forever moving, swelling, and forcing the shafts out of line. No shaft there is in perfectly good condition. Some stand remarkably well, and keep in working order for years, while others require frequent repairs; but from the day they are completed their deterioration is steady, until a general overhauling is necessary. They are timbered in a manner which allows remarkable variation from their original alignment without loss of local support to the ground, and this timber is rapidly and conveniently readjusted when pushed too far out of line. The work of repair is necessarily dangerous and more hazardous in a hot steaming upcast shaft than in a cool one, and it is to the frequency with which the Comstock miner is called upon to perform this work that the number of falls in the shaft is to be attributed. It is also undeniable that the unfavorable heat conditions may contribute essentially to the result, but of the two causes I consider that frequent opportunity is the greater. But the falling of timbermen is not the only mode in which this accident occurs. Another is the product of pure forgetfulness. A man working near the shaft will sometimes step off upon vacancy and meet his death. The movement is made quietly, not in the heat of action but after the completion of some task, and above ground such actions are attributed to "absent-mindedness." This state of inactive perception is exceptionally frequent among Comstock miners, and it stands in such strong contrast to the habits of forethoughtfulness to which they train themselves that we must attribute it to the effect of physical exertion in hot air.

Another class of falls in the shaft are partly due to the high professional spirit and sense of individual responsibility which makes the Western miner one of the most trustworthy of his class. This mode of occurrence, which is unexpectedly frequent, is the pushing of a car into a shaft where there is no cage. This is sometimes due to pure absentmindedness, and sometimes to an interruption of the routine work by a cage going up empty, with a message, with tools, or with a passenger. It is said to be a fact that when a carman has pushed his car to the open shaft and has suddenly awakened to the dreadful situation, he never fails to sacrifice his own life in efforts, however hopeless, to stop it. Whenever a car thunders down the shaft there is always a man with it, and whenever the circumstances have come under observation it has been evident that the loss of a life was not due to stupefaction, but to a dogged determination to stake everything on the hope of preventing a possible calamity to men below. The spirit is well illustrated by the act of a man who fell down a shaft at Bodie, and used his last breath in calling out "Look out below!" Though this casualty appears so frightful to these who witness it, it is probably as painless as other modes of certain instantaneous death. It is said that the unfortunate men always lose their shoes in their fall, and also that they invariably reach the bottom sooner than the car, if one falls with the man.

(5). The history of blast accidents in the Comstock mines enforces the truth that the nitroglycerine explosives do not enjoy the immunity from ignition by friction which has been asserted for them so confidently. We have to admit that a box of cartridges can be thrown off a house with safety, for that has been frequently done, but inclosed in a drill-hole they have been fired repeatedly by friction, jarring, or a blow. Out of fourteen accidents five occurred from the explosion of unsuspected cartridges by one of these causes. Two cases of wounding are peculiar from the fact that the exploding cartridges had been in the rock a long time. Each of them lay, not in the header, but in the floor of a drift or chamber, and the accident occurred when orders were given to level up the floor. The explosions were in different mines, and one of the miners was using a pick, the other a gad. Neither was killed. Two men were wounded by the explosion of a cartridge which they were drilling out for repriming. Three accidents occurred from the explosion of old cartridges left in the header, the presence of which was not suspected, and which were fired, not by direct impact of the tool, but by the jar or the crowding in of the rock upon the cartridge, owing to the starting of a new drill hole near by. Two of these were caused by machine drills, and one by hand drilling. It is supposed that in some cases at least the exploding cartridge was not a complete one but merely a fragment—the upper portion having done its work. This seems probable, for instance, in the cases of the two men who were injured while leveling off the floor, for it is hardly conceivable that a full cartridge could blow up the floor beneath a man's feet and leave him alive. One of the explosions took place under peculiar circumstances which exhibit very well the sensitiveness of nitro-glycerine to the conditions in which it is placed. A hole having missed fire the next shift opened and recharged it. After lighting the fuse the men waited the usual time, and one of them then went to the face and found the cartridge was "boiling," making what the miners call a "stinker." It was concluded to drown the hole out, and a man took up water from the wet floor in his shovel and threw it on the boiling cartridge. While stooping for another shovelful the half-burnt charge exploded. The superintendent, Mr. Forman, who was present, attributes the explosion to the confinement of gas by the water, and the suggestion is a sensible one.

(6.) Hoisting on the Comstock has peculiar dangers from the movement of ground in the shafts already spoken of. It is often impossible to keep the guides in anything approaching a straight line. The shove is not only considerable, but it is frequently confined to short reaches in the shaft, and this displacement of line is the cause of frequent dangers and sometimes of serious casualties. The cage sways from side to side with motion sufficient to make it absolutely necessary to hold firmly to a rod placed in the top for that purpose. Among the casualties of 1877 was one caused by the violent surging of the cage in the Consolidated Virginia shaft, by which a miner was thrown off his balance, one foot going over the side. He escaped with a sprained ankle. Sticking of the cage during its descent, and its subsequent fall with a jerk, is one of the most frequent causes of these accidents, and the cage sometimes also gives a sudden bound when rising.

(7.) Though overwinding is neither the most frequent source of casualties nor the most fatal in its results, it has aroused more attention than any other. In twenty-two months, cages containing men were twice "run into the sheaves," as the local expression is, and there are on record notes of four others, where no men were hoisted, but one of which proved injurious to persons. Two of the fatal cases occurred at the same mine within five and a half months, and the other, which was caused by overwinding a heavy bailing-tank, followed soon after. These, and the running of several empty or ore-laden cages into the sheaves, made a great excitement, and the Society of Engineers tried to prove that the men at the engines were overworked. They formerly worked twelve hours at many shafts, and on solicitation were reduced to eight hours at some. The pay for twelve hours' work was usually \$6, and for eight hours \$4.50 or \$5. One result of the excitement occasioned by these dreadful casualties was the introduction of several safety devices. Nothing new was presented, there being detaching devices which depended on safety-catches for supporting the cage when connection with the cable was severed, others with special chairs to detain the cage, and one with a rope wound on a false reel to support the cable and carry it quietly to the hoisting drum or reel. In addition the usual appliances for throttling the exhaust from the cylinders of the hoisting engine, shutting off steam gradually and putting on the brake, have been re-invented. The gallows frames at most of the old shafts are thirty-five feet high, and with a "double-decker" cage that takes up twelve or fourteen feet of this space, it is evident the engineer has but a small margin for safety. The new shafts have frames forty-five feet high. The tendency on the Comstock is to employ unbalanced reels and with these, mere bleeding of the steam pipe should be sufficient to prevent serious injury. With balanced reels it would be absolutely necessary to put on the brake also.

(8.) One of the accidents classed among the miscellaneous causes is worthy of attention. Several years ago an electric signaling apparatus was introduced into the Savage mine, but abandoned on account of the uncertainty of its signals, which would sometimes sound without human aid. In 1877 a new apparatus was put in with improvements which it was thought would prevent this disadvantage, but after working well for some time it failed one morning, and caused a fatal casualty by ringing only three bells when ten were intended. Whether the signal-man was at fault is doubtful, but it is a fact that the apparatus had worked badly that morning, and before the accident a man had been stationed to signal with the bell-rope in case the battery did not work. There is little confidence in the electric mode of signaling. A small wire hand-rope is used, and on the whole is safe and convenient. In looking over this list of casualties it is evident that the accidents which possess most interest are those which have near or remote connection with the heat of the mines, for the latter are sinking with great rapidity, and becoming hotter each year. It is difficult to deny that the greater depth increases the chances of accident in mines which, in addition to the ordinary liabilities of mining work, have the insidious and ever-present effects of hot air, water, and rock upon the physical and mental condition of the men. Out of 101 accidents twelve were directly caused by the heat or hot water. Undoubtedly the falls of men down a shaft have been caused sometimes by sudden exhaustion, due to the heat and steam in upcast shafts, but on looking over the accounts of the accidents of this kind which are included in the above list none of them show a connection with this cause. The casualties positively traceable to the heat are therefore twelve per cent. of the whole. Probably the heat increases the bad effects of powder fumes and natural gases, and by making repairs to the shafts more frequently necessary it adds indirectly to the occasions when disasters may occur. Some allowance should be made for a less active mental condition, a dulling of the faculties, and a certain recklessness to which the heat sometimes goads the men. On the other hand the heat makes them more cautious except when under momentary impulses, and there are no American miners more careful of themselves than in these mines. On the whole the good and bad effects of the heat seem to nearly balance each other, and an allowance of five per cent. for the casualties indirectly caused by the high heat would be fairly sufficient. The specific cases I presented do not warrant even that allowance. The accidents recorded here relate to a time when the number of miners at work in the district was from three thousand to thirty-five hundred, including top men and underground men. Most of them worked eight hours, but some of those on top had twelve-hour shifts, and probably there was a constant force of nine hundred or one thousand men below. It is not possible to make a comparison between these casualties and the amount of ore raised, as the practice is in statistics of coal mines, for the reason that only two out of about forty mines were producing much ore throughout the period covered by the list. The comparison can be made for those two, the Consolidated Virginia and California, and is as follows for the year 1878:

		Proportion to tons ore.
Number of accidents.	10,	1 to 25,771
Fatal casualties,	5,	1 to 51,542
Casualties not fatal,	8,	1 to 32,214
Tons of ore extracted, 257,718.		

Of the casualties included in the list for twenty-two months there were in these two mines twenty-five accidents, twelve fatal, and eighteen not fatal casualties, or twenty-five, twenty-two and a half, and twenty-six per cent. of the whole.

From all these facts it may be concluded that increasing heat will not debar the Comstock mines from continuing to the greatest depths which are considered practicable in the existing adjustment of mining appliances to the market value of mining products. It is true that an air temperature of 108° F. is common at the 2000 feet level, while 110° and 112° are not infrequently observed, and that a drift which showed a temperature of 123°, 126° and 128° F., according to different reports, has proved to be the most deadly on the lode. It is also true that the temperature of the rock is increasing, and with it that of the air, and at some depth, for the calculation of which there are absolutely no data, the temperature of this drift may be expected to prevail throughout the lode unless the present conditions change. But this being an *air* temperature it is always possible to mitigate it by artificial means. It is already observable that drifts 1800 feet below the surface may show a much higher heat than others 400 feet below them. High temperature is largely a matter of locality and temporary conditions, and by various expedients it may be confined to its localities, or combated in other ways. Deep mining, by extending the line of work through the moving hanging wall, and compelling increased repairs to shafts, will perhaps tend to heighten the already great frequency of falls of men. In addition to heat, the peculiar mode of timbering in square setts, the almost exclusive use of nitro-glycerine powders, the necessity of frequent repairs to shaft timbers, the incessant movement of the rocks through which the shafts are sunk, making accidents in hoisting more than ordinarily frequent, and the necessity of transporting large quantities of rock through narrow gangways entirely by human labor, are the conditions in which mining on the Comstock may be said to suffer rather more than the usual liability to danger. Two of these causes, both connected with the movement of the ground, may be expected to increase with depth. Together with the heat they comprise forty per cent. of the whole number of accidents, and we may therefore sum up our conclusions by saying that the conditions of deep mining will increase forty per cent. of the causes which lead to casualties and will leave sixty per cent. unaffected. What the amount of this increase will be cannot be foretold, and indeed, cannot be estimated until an ore body has been found and worked at great depth. The year 1879, which was preeminently one of deep sinking on the Comstock, has been remarkably free from casualties.

The above is taken from a paper by Professor John G. Church, M. E., published in the Transactions of the American Institute of Mining Engineers. To it we append the following from the *Mining and Scientific Press:*

On Wednesday, the 31st May, 1882, the main pump column in the Alta mine on the Comstock was broken. Men were at work making the necessary repairs, when, at 11 o'clock, the bulkhead recently placed in the main east drift on the 2150 level gave way. This bulkhead was constructed of plank and timbers, and was placed in a part of the drift where the rock was hard and perfectly solid. It would seem that it at first gave way at one end, as the first rush of water was not very alarming, though it was thought best for all to get off the level. Three or four men who were near the shaft went up, and Richard Bennett, the shift boss, at once started out into the main west drift to notify the men at work at that point of the danger. About the time he started on his errand it would seem that the whole bulkhead went down, and there was a tremendous rush of water. This drift is 1400 feet long, and the last seen of Bennett was when he started in on his errand of mercy. At the face of the drift six miners were at work, whose names are as follows: P. Denney, Malachi Curran, T. McDonald, John Black, John Mulligan and Morris Conners. This drift was run with a raise of about one foot in each hundred, therefore, at the face it would be 14 feet higher than the floor of the station at the shaft. This circumstance gave some hope of being able to save the seven men who were imprisoned. Every possible effort was made to keep the pump going at best speed, but there were over 2,500 feet of drifts in the level to be emptied. It was found that the men were tapping on the compressed air pipe as a signal of their existence. A boat for navigating the drift was made, but it was too high. Another boat made of canvas and used for gunning purposes was lowered into the mine. All the time the bailing tanks and pumps were kept at work all day Thursday and Friday. During this time the excitement was, of course, intense. Two men, George Gornest and Anthony Smith tried to penetrate the drift, but had to return. At 4 o'clock on Friday morning the water was so far lowered that it was thought the boats could venture in. William Bennett, a nephew of Richard Bennett, the shift boss, and Denis Callahan took the canvas hunting boat belonging to Fred. Ritter, the gunsmith, and the flat wooden boat constructed at the mine, and ventured into the drift. They had placed in the boats ice, water and some refreshments, and hoped to be able to force their way into the end of the drift. They pulled out into the drift and that was the last seen of them alive. It appears that they started off without the knowledge of Superintendent Boyle or John Husking the foreman, who had not intended that the venture should be made at that time. It would seem that the two men were very anxious to reach their friends, and supposed the air was no worse at any point ahead than near the mouth of the drift. Both these men died. We condense from the Virginia *Enterprise* an account of the incidents: "In the afternoon, about 3 o'clock, when the water in the mouth of the drift had been reduced to about three feet, John Van Dusen entered the drift. He had on him an apparatus invented and constructed by Andrew Peasley, of this city. This armor consisted of a mask for the face from which there was a rubber breathing tube passing into a tin box strapped on the man's back, which box was filled with fragments of ice and perforated with holes to allow of air passing in through the pounded ice. Wearing this armor, Van Dusen struck boldly into the drift. He was gone about half an hour, when those at the station heard a call for help. Men went in the diretion of the cry, and, when out about 100 feet from the shaft, found Van Dusen in an exhausted and fainting condition. As soon as Van Dusen was able to converse he said that he had found the seven men originally imprisoned in the drift alive and all right. He said they were in the cooling-off house, about 100 feet from the face of the drift. With picks or bars they had broken the pipe carrying compressed air and had then so bent it as to carry the end into the cooling-house. In this house, when they were first imprisoned, they had nearly a barrel of ice water. When this was exhausted they poured into the barrel hot water from the drift. Then they twisted the end of the compressed air pipe down into the water in the barrel, and allowed it to exhaust there. This rendered the water quite cool and drinkable. They had a light in the cooling-house, but nothing to eat. The great heat rendered them weak and feverish. Mr. Van Dusen told the men he would inform their friends that they were all right, and assured them that they and a host of brave men were outside doing all that could be done by human beings for their rescue. As his ice was fast melting away, Mr. Van Dusen could not remain long with the men, besides he was anxious to get out and give notice of their being alive and of their situation. It was owing to the consumption of the ice in the box at his back that Mr. Van Dusen came near losing his life. There being but a few lumps rolling about, much hot and foul air entered his armor, whereas had there been the proper quantity all the air entering the mask must first have been cooled and purified by coming in contact with the fragments among which it passed.

That evening, about seven o'clock, six men entered the drift and, at the risk of their lives, pushed their way through to the cooling-house. They carried with them some milk punch and some ice. They found the men about as described; indeed, the six men were in a worse state when they reached the cooling station than were those they found in it. However, they recovered on reaching the fresh air sent in by the compressor. The men in the cooling station tried to persuade the new arrivals to remain and take their chances with them instead of venturing back. This, however, they dared not do, as it would have left their friends on the outside in doubt as to their fate, and would have caused great uneasiness. Though the six men had seen the bodies of Bennett and Callahan, while on their way in, they thought it best to say nothing about their having lost their lives. Work was then pushed on with great vigor on the air pipe, and at length a current from the blower was sent through its whole length. This gradually forced out the belt of foul air. The men about the mine became so exhausted by about nine o'clock last night, that they sent up from the mine to superintendent McKenzie, of the Sierra Nevada, to send down a fresh force from his mine. Meantime the air had so far improved that the imprisoned men could be visited. By the advice of the physicians they were given stimulants and refreshments, and kept in the cooling house to get some strength before an attempt was made to bring them out. The men told the visitors that they had at no time been much alarmed for their ultimate safety. They said that before the accident happened they had frequently talked about what they would do in case of the bulkhead giving way, and had concluded it would be best to remain in the upper end of the drift and wait for the water to be pumped out. When the men were all safely out of the drift, the Alta whistle began a prolonged scream, and this was taken up all along the lode. It was kept up for about five minutes, just as in case of fire in the early days, and for a time the whole country was made to howl. The only drawback to the general joy was the sad fate of the two brave men, William Bennett and Denis Callahan. It is saddest of all, to find how unnecessary was the noble attempt and the willing sacrifice they made. It is said that the scenes that occurred at the shaft when the men were brought up and restored to their wives, children, relatives and friends were such as no pen could describe. Among all the spectators present there was the wildest excitement. In this city, when the whistles sounded the signal that the men were at last saved, after their imprisonment of some seventy hours, people rushed out into the streets and shook hands right and left, and were so full of joy that they could hardly speak.

DEEP WORKINGS.

A ROYAL Parliamentary Commission of Great Britain recently made extended inquiry as to the possible depth at which coal can be worked, and the evidence thus collected bearing upon this important subject, is in substance as follows: The possible depth from which coal can be worked, does not appear to be limited to any consideration of a mechanical nature. The cost of the steam power required for hoisting coal from an unusual depth, will not be sufficiently large to be regarded as an obstacle to deep working, and the expense per yard of sinking does not greatly increase with increase of depth. The introduction of steel wire ropes, tapering downwards, renders it practicable to draw coal from extreme depth without overstraining the rope by its own weight, and it is also quite practicable to draw in successive stages by engines placed in the shaft. As regards pumping, it seems to be an established fact, so far at least as experience has yet gone, that water is seldom if ever met with in large quantities at great depths in British coal fields. As a rule, deep mines appear to be not more liable to inflammable gas than shallow mines, so that no impediment to deep working is to be apprehended in regard to increased liability to explosion.

The increase of temperature which accompanies increase of depth is the only cause which it is necessary to consider as limiting the depth at which it may be practicable to work coal. In this country the temperature of the earth is constant at a depth of about fifty feet, and at that depth the temperature is 50° Fahr. The rate of increase of the temperature of the strata in the coal districts of England is, in general, about 1° Fahr. for every sixty feet of depth. In some instances the increase is very irregular, being probably affected by local conditions, such as percolation of warm or cold water, and varying conductive power of the rocks penetrated. These cases, however, are exceptional, and throw no doubt upon the general conclusion that the rate of increase amounts, as a rule, to about 1° Fahr. to every sixty feet. As the present inquiry applies only to English coal-fields, it is immaterial to inquire whether the same rule holds good for other places. It may, however, be observed in passing, that whenever Artesian wells have been sunk in this or other countries, the rate of increase is in close harmony with that observed in English coal mines; but, on the other hand, by observations made in Belgian coal mines, the rate of increase appears to be less than in English colliers, though it is quite possible that this apparent difference may have arisen from the thermometer having been applied in a manner which would not correctly indicate the temperature of the strata. In the metalliferous mines of Cornwall, the deviations from the scale of 1° Fahr. for every sixty feet are very great, but it is probable that the disturbing causes of variable conduction and percolation of heated water exists to a much greater extent in the geological formations containing metalliferous veins than in the sedimentary rocks embracing the coal measures. The deepest colliery in England is at Rosebridge near Wigan, where the shaft has already attained a depth of two thousand three hundred and seventy six feet, and is still being sunk to a greater depth. The temperatures of the rock, as observed in this shaft, are in general agreement with the ordinary rate of increase to a depth of one thousand eight hundred feet. After that the increase becomes considerably more rapid, but it would be rash to conclude from this single example that the increase would in all cases be accelerated when that depth was exceeded. At the lowest point of this shaft the temperature of the earth, as indicated by a thermometer placed in a bore hole a yard in depth, is 92° Fahr.

According to the evidence of Mr. Elliott, and his assistant, Mr. Wilmer, the temperature of the strata in horizontal coal workings accords with the rise and fall of the surface above; but there is reason to believe that this rule will only apply to gradual variations of surface, and not to abrupt prominences in the nature of peaks, since in the Mont Cenis tunnel the temperature of the rock is very much less than would be due to the depth measured from the top of the mountain. It may, however, be assumed, that under the ordinary configuration of the surface in British coal-fields the increase of temperature will have reference to the depth from the surface of the ground, and not from the level of the sea. High temperature of the strata operates as an impediment to deep working by heating the air circulating through the passages of the mine. When cool air enters a heated mine, it absorbs heat from the surfaces of the passages through which it flows, and the rate of this absorption somewhat exceeds the ratio of the difference between the temperature of the air and that of the surrounding surface with which it is in contact. By the absorption which thus takes place the air is heated, and this heating process is most rapid at first when the difference of temperature is greatest, and gradually diminishes as the length of the passage is extended, never ceasing until complete assimilation of temperature is effected. The progress towards assimilation of temperature is much more rapid when the air comes in contact with the working face of the coal, which from being newly exposed is more highly heated than the surfaces of the permanent air courses. The rapidity, however, with which the air takes up heat from the working face depends, in a great degree, upon the system of working. In the cellular system, called "Pillar and Stall," the air seems to acquire almost immediately the full temperature of the coal, but under the "Long Wall" system there are instances of the air retaining a considerable inferiority of temperature after sweeping past the working face. The great outlay of capital involved in sinking pits to coal lying at extreme depths would render it necessary to work a large area of coal from each sinking, and this would involve air courses of great length. It thus becomes necessary to consider the question of ventilation under the double aspect of great depth from the surface, and great length of air passages.

At present, the ventilation of coal mines is almost always effected by means of a furnace applied at the foot of an upcast shaft, in which an ascending current is produced by rarefaction, as in an ordinary chimney. Ventilating fans and other mechanical contrivances propelled by steam engines have of late been partially introduced, and are found to be advantageous in reducing the consumption of fuel necessary to circulate a given volume of air. This superiority, however, will diminish as the depth of mines is increased, because the deeper the mine the more powerful is the suction in the upcast shaft. But whatever method be used for producing the current, it would require an extravagant increase of power to accelerate the velocity of the air in any considerable degree, because the resistance of the air increases in ratio somewhat exceeding that of the cube of the velocity. Thus if the volume of air were doubled by doubling the velocity of the current, more than eight times the present power would be needed. The longer air courses incident to deep mining also involve an extension of frictional surface, and this would further add to the difficulty of increasing the ventilation by acceleration of current. In short, the only way in which the volume of air would be very materially increased would be by enlarging the sectional area of the shafts and air courses.

The more general introduction of coal-cutting machines, worked by compressed air conveyed into the mine by pipes, would have some effect in lowering temperature, and would at the same time supersede the labor of hewing, which, from its arduous nature, is that form of labor against which high temperature chiefly militates. Mr. Lindsay Wood states in his evidence that the air discharged from the pneumatic coal-cutting machine is reduced by expansion in the act of escaping to a temperature of 7° Fahr. below freezing, and that the air from one machine is sufficient to lower the temperature of the whole body of air flowing past a working face by 1° Fahr. He thinks that as many as seven of these machines might be employed at one working face; but it does not follow that the collective action of these seven machines would reduce the temperature sevenfold, because the principle of accelerated absorption by reduction of temperature again intervenes, and would in a great measure defeat the cooling action of the machines. Moreover, if jointly with the use of these machines, reduction of temperature were to be attempted by increasing the volume of air in circulation, the diluting effect of the cold air from the machines would be reduced in proportion as the volume of circulating air was increased. It remains to be considered whether it be practicable to reduce the temperature of the air by surrounding the air courses with an intercepting air space, or with a layer of non-conducting material. Upon this point it may be observed that the air courses in a mine are already naturally encased in a partially cooled envelope of imperfectly conducting material. The coal itself is a very imperfect conductor, and every suggestion for jacketing the air courses, either with a surrounding air space or with solid material, must be regarded as an expedient for giving further effect to a retarding action already in operation. It is doubtful whether any increase of retardation could by these means be effected at all commensurate with the cost and difficulty attending their adoption. The evidence of Mr. Elliott, and of most of the other witnesses, is adverse to the feasibility of thus stemming back the heat, and it appears that no such method has yet been put in practice. The question of the maximum temperature of air which is compatible with the healthful exercise of human labor is one of the most difficult questions which the committee have had to investigate. Evidence has been given of extraordinary temperatures endured in the stoke holes of steamers, and in the places where glass blowers work. In some of these cases labor has been carried on without serious detriment to health where the thermometer has indicated 180° Fahr. In these instances, however, the thermometer is chiefly acted upon by radiant heat, and therefore does not truly indicate the actual temperature of the air. In an experiment made at Elswick by Sir W. Armstrong, it was found that a thermometer suspended in a stoke hole at a distance of four feet from the front plates of the boilers indicated a temperature of 105° Fahr., while another thermometer, at a distance of only three inches from the former, but carefully screened from the radiant heat, stood at 78° It is important, also, to observe that the men who work in stoke holes and glass houses have ready access to the external air, and avail themselves of numerous intervals in their labor to cool themselves. One of the medical witnesses, who had spent a great part of his life in tropical climates, states that he had experienced a temperature of one hundred and twenty-five degrees Fahrenheit in the shade, and that this great heat was rendered quite endurable by the dryness of the atmosphere; on the other hand, he had felt a damp atmosphere almost intolerable at the comparatively low temperature of eighty-six degrees. The committee had information of mining work being executed in a Cornish mine, where the air was heated by a hot spring to a temperature which was said to amount to one hundred and seventeen degrees, and was also by the same cause saturated with moisture. They therefore, deputed Doctor John Burdon Sanderson to visit this mine, and investigate the facts of the case. He found the highest temperature to exist at the extremity of an excavation, forming a sort of cul de sac, where a stream of water entered at a temperature of a hundred and fourteen and one-half degrees. At the distance of one yard from the end of this cul de sac, the thermometer indicated a temperature of a hundred and three degrees, but at a distance of only ten feet there was access to air, where the thermometer stood at eighty-one degrees. According to other evidence the temperature of the air occasionally reached one hundred and twenty-three degrees. The miners remained in the workings six hours out of the twenty-four. Four men were employed at a time, of whom two were always at rest in the cool air, and the other two were *not* always at work; the time occupied in resting being considerably more than that occupied in working. Thus the total duration of each man's work was less than three hours in the twenty-four. No miner remained more than fifteen minutes in the heat at one time. Doctor Sanderson described the condition of each miner on retreating into the cool air to be one of complete exhaustion, but by allowing cool water to pour over his body the distress and exhaustion quickly passed off: and he concluded that the occupation in question was not necessarily inconsistent with the enjoyment of vigorous health; but he found that there were many men who, after trying to work, were compelled to desist on account of the distress and exhaustion which were produced. In Doctor Sanderson's opinion, the immunity from injury to health, which most men employed in these hot workings appear to enjoy, is attributable to the shortness of the period during which they are exposed to the high temperature, and to the readiness with which they can escape to a well ventilated cooling place the moment they are incapacitated for further exertion by disorder of the circulation and increase of the temperature of the body.

Doctor Sanderson also states it to be his decided opinion that labor is not practicable in moist air of a temperature equal to that of the blood, namely ninety-eight degrees, excepting for very short intervals; and this conclusion is in harmony with the other medical evidence. The evidence having shown that the question of the maximum temperature under which work could be carried on in a coal mine hinges in a great measure on the hygrometric condition of the air, the Committee proceeded to inquire what was the state of the air in regard to moisture in coal mines. The observations which they collected on this point show that the air at the working faces of the coal was always humid, and often saturated with moisture. In general, however, the deepest collieries appear to be the dryest, although there does not appear to be any ratio between depth and dryness. The depth at which the temperature of the earth would amount to blood heat, or ninety-eight degrees, is about three thousand feet. Under the long-wall system of working, a difference of about seven degrees appears to exist between the temperature of the air and that of the strata at the working faces; and this difference represents a further depth of four hundred and twenty feet; so that the depth at which the temperature of the air would, under present conditions, become equal to the heat of the blood, would be about three thousand four hundred and twenty feet. Beyond this point the considerations affecting increase of depth and temperature become so speculative, that the Committee felt it necessary to leave the question in uncertainty: but, looking to possible expedients which the future may elicit for reducing the temperature, they considered it might fairly be assumed that a depth of at least four thousand feet might be reached.

The Temperature of the Soil.—The temperature of the ground surface is almost entirely dependent on the heat of the sun, and is therefore always greater in the daytime than at night. Considering all the circumstances which affect the temperature of the ground, there must be included the kind of exposure of the surface, the nature of the soil, the permeability of the ground by rain and the presence of underground springs, the sun's declination, the elevation above the sea, and the amount of cloud and sunshine. The temperature of the soil is observed at the Royal Botanic Gardens, London, three times daily, at depths of 3 inches, 6 inches, 12 inches, 24 inches and 48 inches. The underground thermometers used are considered better than any previously made. A series of observations made with unfailing regularity, extending over six years, have been discussed by G. J. Symons, F.R.S., with some interesting results. The mean temperature of the air at 4 feet above soil, and that of the surface of the lake, which covers more than an acre of ground have also been deduced for the same period. The lowest mean monthly temperature under the various relations to the surface of the earth are:

	At 9 a m.	*At 3 p.m.*	*At 9 p.m.*
	Deg.	*Deg.*	*Deg.*
Air at 4 feet	38.9	42.1	40 0
Surface of lake	39 7	40.7	40.2
3 in. below grass	37.3	39.1	37.9
6 in. below grass	38.1	39.0	38.8
12 in. below grass	38.1	38.3	38.3
24 in. below grass	39.5	39.4	39.4
48 in. below grass	41.6	41.6	41.6

For the highest mean monthly temperatures we have the following results:

	At 9 a.m.	*At 3 p.m.*	*At 9 p.m.*
	Deg.	*Deg.*	*Deg.*
Air at 4 feet above the soil	64.8	71.3	62.0
Surface of lake	66.3	70.1	68.4
3 in. below grass	64.9	75.0	67.2
6 in. below grass	63.4	70.4	68.3
12 in. below grass	63.6	64.8	65.9
24 in. below grass	62.1	62.0	61.9
48 in. below grass	60.5	60.5	60.5

These maxima temperatures occur in July, except those at 2 ft. and 4 ft. which fall in August. At this the hottest portion of the year the temperature of the air is on the whole slightly below that of the water, but it has a greater diurnal range. The temperature of the soil is greater than that of the air only at the surface; it decreases with the depth, and at 2 feet the diurnal range ceases. The results of the earth temperature observations made at the Royal Observatory during the years 1847 and 1873 are given in the "Greenwich Meteorological Reductions." Referred to noon as the time observation the lowest mean monthly temperature of the series are for the

Air	38.4°	in January.
At 1 inch below soil	40.9°	in January.
At 38.4 inches below soil	41.7°	in February.
At 76.8 inches below soil	44.8°	in March.
At 153.6 inches below soil	46.4°	in April.
At 307.2 inches below soil	48.9°	in June.

Similarly the highest mean monthly temperatures are:

In air	62.5°	in July.
At 1 inch below soil	65.4°	in July.
At 38.4 inches below soil	62.5°	in August.
At 76.8 inches below soil	59.6°	in August.
At 153.6 inches below soil	55.8°	in September.
At 307.2 inches below soil	52.2°	in November.

It thus appears that whereas the coldest temperature of the air is in January, the wave of cold (if it may be so called) travels slowly downward and does not reach 25 feet until June, and that whereas the hottest temperature of the air is in July, the wave of heat travels slowly downward, and does not reach 25 feet until November. At that depth the temperature decreases until June, then increases until November, whereas the thermometer bulb, covered by only 1 inch of soil, reaches its lowest and highest limits about the same time as the thermometer in air, shaded, and 4 feet above the ground. The retardation of cooling and of heating is greater the deeper the soil, though the yearly range decreases as the depth increases, down to the stratum of invariable temperature. The non-periodic fluctuations of cold and of heat which affect the air are not felt beneath the surface of the ground. Recent advices bring information concerning the temperature of the mines in the Ashton District, England. In Ashton Moss Colliery the temperature was observed at the depth of 930 yards, and was found to be 85.3°, the thermometer being inserted in a hole 2 inches in diameter and 3½ feet deep, drilled for the purpose in hard blue shale. A slow action thermometer was inserted after ten or fifteen minutes, and was allowed to remain for six hours. Assuming 49° as the surface temperature, it will be observed that we have here an increase of 36.3° for 2790 feet which is at the rate of 1° in 76.9 feet. In reference to an apprehension which was expressed that the heat of drilling did not have sufficient time to escape, it is stated that on several occasions further observations were made in the same hole, and similar results were obtained. Experiments were also conducted at Bredbury Colliery, Cheshire County, at a depth of 1020 feet, and the temperature observed was 62°. Assuming (as above) 49° as the surface temperature, we have here an increase of 13° in 1020 feet, which is at the rate of 1° in 78.5 feet. The distance from Ashton Moss Colliery is three or four miles, and the two shafts are sunk through the same coal measures, one being near the outcrop. Making no assumption as to the surface temperature, but comparing the two observations with each other, we have an increase of 23.3° in 1770 feet, which is at the rate of 1° in 76.0 feet. The consistency of these results is eminently satisfactory. Experiments at Nook Pit, belonging to the Broadoak Colliery Company, at a depth of 1050 feet, gave a temperature of 62½° F., showing an increase of 13½°, or 1° for 79 feet. The great quantity of water which is found in some parts of the rock overlying the coal measures is, perhaps, an important factor in the rate of temperatures, which, as shown by the observations, is remarkably slow.

The Physical Limits of Deep Mining.—The *Iron Age* condenses from his English exchauges the following on this subject:

"Much thought and time has been spent on the subject of the probable duration of coal fields, and various papers relating particularly to the coal fields of Great Britain have been read before the British Association. The great point, as a matter of course, is the depth at which the mines can be safely worked, this depth having been limited by the Royal Commission of 1876 to 4000 feet. It is admitted on all hands that the crust of the earth increases in temperature as we descend from the surface, and with respect to the heated walls of the rock in mines and the ventilating current the Commission remarks that when cool air enters a heated mine it absorbs heat from the surface of the passages through which it flows, and the rate of this absorption somewhat exceeds the ratio of the difference between the temperature of the air and that of the surrounding surface with which it is in contact. It is evident, therefore, that when this absorption takes place the air is heated, the process being most rapid at first, when the difference of temperature is greatest, and gradually diminishes as the length of the passage is extended, never ending until complete assimilation of the temperature is effected. But the progress toward assimilation is most when the air comes in contact with the working face, which, from being newly exposed, is more highly heated than the surface of the permanent air courses. In coal mines the rapidity with which the air takes up the heat depends in a great degree on the system of working. In the "pillar and stall" system the air appears to acquire almost immediately the full temperature of the coal, but under the long wall system there are instances of the air retaining a considerable inferiority of temperature after sweeping past the working face. Under the long-wall system of working a difference of 7 degrees appears to exist between the temperature of the air and that of the working face, which represents a greater depth which could be sunk.

But we are told that there is an element which has not been taken into consideration which raises the temperature in deep mines, that is the increased density of the air, the effect of which is greatest when the air is stagnant, but when there is a rapid circulation of the air current it will be only small. The observations made some years since in Cornwall, as well as at the Dukinfield and Rose Bridge collieries, differing as they do considerably, have been looked upon as sufficiently reliable, but different results appear to have been obtained during the present year. In Cornwall, Mr. Fox arrived at the conclusion that the increase of temperature progresses in a diminishing ratio, so that if such were correct it would go to prove, as we approach the source of heat, the heat itself decreased. At the Tresavean Mine the mean temperature at a depth of 1740 feet was 87·9 degrees. The series of observations made at Dukinfield gives an increase of 1 degree for every 80 feet, which is a less rapid increase than that shown as the result of the observations made at other places. At the Rose Bridge Colliery, Wigan, the deepest now in actual work, but not the deepest shaft, although 815 yards deep, there was an increase of 1 degree for every 54·3 feet. The difference has been accounted for, at least to some extent, as owing to the difference in the strata of the two places. At Rose Bridge, the beds are nearly horizontal, and at Dukinfield they are inclined at an angle varying from 30 to 35 degrees, rising and cropping out to the eastward, and strata, such as alternating sandstones, shales, clays, &c., with different conducting powers, offer more resistance to the transmission of heat in a direction across than parallel to their planes of bedding, so that every sudden change of material is equal to an increase of resistance, but deep-seated horizontal strata, like that at Rose Bridge, offer a succession of resisting surfaces to the upward passage of internal heat.

Some of the more recent observations, however, are worthy of every consideration, such as those brought forward at York by Professor Everitt. The observations had been made at three places—at the East Manchester coal field, the Talargoch Lead Mines, Flintshire, North Wales, and at the Radstock Collieries, in the neighborhood of Bath. The Manchester observations were made in three pits of great depth, and the results were as follows: Depth 2790 feet, temperature 85.3 degrees; depth 1020, temperature 62 degrees; depth 1050 temperature, 62½ degrees. Taking the surface temperature to be 49 degrees, the increases were 36.3 degrees in 2790 feet, or 1 degree in 76.9 feet; 13 degrees in 1020 feet, or 1 degree in 75.8 feet; and 13½ degrees in 1050 feet, or 1 degree in 79 feet. In Flintshire, with a surface temperature of 48 degrees, an increase of 14 degrees was shown at 660 feet, or 1 degree in 47 feet; while the three pit observations made in the neighborhood of Bath, brought out the following results: At the depth of 560 feet an increase of 11.7 feet, or 1 degree in 48 feet; 810 feet 13 degrees, or 1¼ degrees in 62 feet; and 1000 feet 13 degrees or 1 degree in 77 feet. From the figures given it will be seen that the observations made at different places vary a great deal, and the cause of this opens out a wide field for the consideration of those who have studied the probable limit to which mining operations can be carried on, and the depth to which it will be safe to sink shafts.

Deep Coal Mining in Wales.—Regarding the great depths from which coal is now won in South Wales, some interesting particulars on the subject of deep mining, in connection with the Harris Navigation pits, situated near Quaker's Yard, Glamorganshire, the deepest in the district, have recently appeared, in a report by Messrs. Thomas Forster Brown and George Frederick Adams, members of the Institution of Civil Engineers, who are professionally connected with the operations.

"The depth of the lowest seam at present sunk to was 760 yards; the pits were each 17 feet in diameter inside the walling. In addition to the depth, a special feature was the thickness of hard and heavily-watered rock penetrated. Guide-ropes, upon the following principle, were used in sinking, and the value of this system was shown in the saving of over two minutes in steadying the bowk at the bottom of the pit; at depths of 475 and 530 yards, the total time occupied in clearance at the latter depth being three minutes and twenty-six seconds. The method of dealing with the various feeders of water during sinking was described: One of the pits was drained by a hole bored by the diamond machine, which was put down, at a depth of 175 yards from the surface, for a farther depth of 860 feet. Where the strata were conformable, and cut up by faults which intersected all the measures, considerable objection existed to metal tubbing, even for comparatively shallow depths; for the water could rarely be prevented from forcing its way through fissures into the underlying strata. Moreover, provision had to be made for the probable working of the Brithdir seam, a very watery measure, lying at a depth of 250 yards. On account of these and other circumstances, it was ultimately decided to provide for the permanent pumping of all the feeders, and a powerful 100-inch Cornish pumping-engine was erected. The parallel motion for the main pump-rods was obtained by a gudgeon, attached to the top rods, carrying two slide-blocks, which worked in cast-iron guides 13 feet long and 27 inches wide. This gudgeon was attached to the beam by two hammered iron radius-rods, 43 feet long 10 inches wide, and tapering from three inches thick at the top and bottom to 1½ inches at the middle. The space between the rods was filled with pitch-pine 12 inches thick at the top and bottom and 18 inches wide in the middle. Five lifts, three of which were 26 inches in diameter, and the others 22 inches and 21½ inches, were worked by the Cornish engine. The total feeders amounted to 440 gallons, of which 298 were pumped from a depth of 467 yards. The rods were double, of pitch-pine, 16 inches square. To economize space in the pit, the lifts were fixed in one perpendicular line; to effect this, the rods directly above the plunger and the rods below were connected by side-rods and distance-pieces; the horizontal connecting pipe of the H-piece being cast semi-circular, to allow the rods to pass down in a straight line. The total weight of rods, etc., amounted to 181½ tons, that of the water being 133 tons; 35 tons of the difference were counterbalanced by a balance-beam in the pit, leaving 13½ tons to overcome friction.

"A large diamond boring-machine was used for a portion of the sinking. The apparatus weighed ten tons, and consisted of four beams or transoms fixed to a center piece. On the transoms were placed the drills—ten in number—which could be moved to any part of, or inclined to any angle parallel with, the face of the transoms, and each drill could be started or stopped singly. In making the first trials, from thirty to forty short holes at varying angles, and from three feet to five feet in depth, were bored, the operation requiring from twelve to fourteen hours. Nearly one half of this time was occupied in jacking the machine for the various positions required to bore the sumping-holes, bench-holes to sump, and finally the cropping-holes. Long holes from 15 to 20 feet in depth were subsequently tried, and blasted in sections; but having to be bored vertically, so as not to pass out of the line of the shaft, they had not always the most effectual lifting power. Better progress was made with single drills; but the cost of diamonds became too great for the frequent holes and changes, and the contracting company completed its contract by means of a percussive drill, designed by Colonel Beaumont. 'Ingersoll' drills were afterward used. These had a diameter of 3¼ inches, and a stroke of 4½ inches, and gave excellent results, the only difficulty experienced being in the wear and tear of the tappets, which, when they broke, generally caused damage in the cylinder.

"In hard and wet rock, dynamite was found to be a much more effective explosive than gunpowder, requiring about half the number of holes, and saving tamping. In shale, without water, powder was more effective, dynamite being more rapid in its action. In sinking through three yards of dry Pennant rock, the cost of powder and dynamite was, respectively, £12 1s. 3d., £10 1s. 8d.

"Under the circumstances which attended the sinking in hard and wet rocks, three yards were considered good progress by hand, and four and a half yards by machine, per week; but the authors were of the opinion that this rate ought to be improved upon with further experience. They had also arrived at the conclusion that the cost of sinking by machine was less than by hand labor. The average rate of sinking, including walling, but exclusive of stoppages, was 3.77 yards per week, there being nearly an equal percentage of hard rock and shale. The actual sinking occupied about one-half of the total time, and walling 12 per cent. The south pit which was the deeper of the two, was begun in February, 1873, and finished in February, 1879."

Messrs. Brown and Adams, in referring to the question of ventilation, allude to a furnace as being probably the most effective means at great depths; but on leaving this question for future consideration, they had meantime erected a Schiele fan fourteen feet three inches in diameter, and capable of producing a current of about 250,000 cubic feet per minute. This had been done after a series of experiments in various districts. They further urge objections to the positive type ventilators, namely, that in the event of obstructions occurring in the air-ways, undue pressure might be applied to separation-doors, air-crossings, etc., besides which they caused a vibratory motion, were costly to erect, and the working parts were in some cases liable to get out of repair. Of the closed fans, which it was stated gave slightly better results than open fans, the Guibal and Schiele were the best. The winding engine in course of construction is designed to raise 2000 tons of coal in ten hours of constant drawing; the weight, exclusive of the rope, being 10½ tons, and the velocity of the ascending cage from 40 to 45 feet per second. The scroll-drum, with a smaller diameter of 18 feet, rising by fourteen coils to 32 feet, was considered the best method of counterbalancing the rope. The cylinders were 4 feet 6 inches in diameter, with seven-foot stroke; they were inverted and placed on cast-iron supports, the drum being fixed below on masonry pillars. The valves were double beat; and for the steam valves, Barclay's simple trip expansion gear was used. The rope was a parallel flat rope of the best selected steel, and consisted of 114 No. 11 gauge wires. The calculated breaking strain was 104 tons, and the factor of safety was nine. The pit-frame is described as constructed entirely of wrought-iron; arrangements being also introduced for loading and unloading a single-decked cage by gravitation of tubs. The empty trains were hoisted about six feet, and made to run down an inclined way to the cage, being stopped and relieved by a system of catches, the cage being so arranged that on landing on the slips the bottom was inclined. In the above deep mining, at the Harris Navigation pits, the deepest in the district, the shaft-pillar is described as having an area of 400 yards square.

THE VENTILATION AND LIGHTING OF UNDERGROUND WORKINGS.

NATURE of Air.—No miner can be too much impressed with a sense of the great importance of good ventilation. The air we breathe consists mainly of two gases called by chemists "oxygen" and "nitrogen." These are mingled together in the proportion of about one part oxygen to four parts nitrogen. It is the oxygen which is really necessary for the support of life, while the office of the nitrogen is to dilute it and to increase its volume. The air being taken into the lungs in the act of breathing, the oxygen combines with some spent carbon from the blood, and is thereby converted into "carbonic acid," or, as it is sometimes called, "carbonic anhydride." Carbonic acid is injurious when breathed, even if it is mixed with a large volume of pure air, and it should therefore be removed as fast as it is formed. When men work in the open air the carbonic acid formed is speedily dispersed, and as the supply of pure air is abundant no ill effect follows. But it is otherwise in rooms, and especially in mines; here the air soon becomes quite unfit for use if it be not constantly renewed, hence the necessity for ventilation. The impurities imparted to the air by breathing are much increased in mines by the constant use of candles or lamps, rendered necessary by the absence of daylight, and by the explosion of powder or other agents used for blasting. In some iron mines carbonic acid is given off in large quantities by the ore as it is broken, and in many metal mines, where iron pyrites is abundant, the air is speedily deprived of its oxygen and rendered unfit for use, and incapable of sustaining life by the oxidation of the pyrites which is continually going on. In coal mines inflammable gases called "fire-damp" are often given off in great abundance, but such gases are very seldom met with in metal mining, except in coal districts. The miner has always a good test at hand for the fitness of the air he is breathing. If his candle burns brightly and well the air is fit to breathe, but if he has great difficulty in keeping it alight when the air is still, or if the flame becomes larger and of a pale blue color, and flickers greatly or goes out, the air which does not properly support combustion will not support life, and some artificial means of ventilation becomes necessary, or the miner's health will give way. This test is much more reliable than the common mode of judging by the rapidity of the current at any given point, as it may be applied in the working "ends" or "faces" themselves where the air is often stagnant, notwithstanding that there is a good current in some of the drifts.

Ventilation may be either natural or artificial. In coal mines it is almost always artificial, in metal mines it is in a majority of instances natural. Sometimes, however, the naturally produced current of air is improved and guided by air stoppings, doors, or other means as may be found necessary, and in some few instances an entirely artificial mode has to be adopted, especially while sinking shafts or driving long levels. Unless the shaft be very deep, a simple division of thin wood or painted canvas, dividing the shaft from top to bottom into two, will often be found sufficient. The men working in the shaft on one side of the parting will raise the temperature somewhat, when it will be converted into an upcast, while the cool air will descend on the other side or downcast to supply its place.

Air Sollars.—A natural current may often be produced in a long level by means of an "air sollar." To form an air sollar the floor of the level carrying the tram road is laid about 6 inches above the actual bottom of the level, and is supported by cross-sleepers resting upon blocks of wood or stones, or the floor in the centre of the level may be excavated somewhat deeper than the sides. Planks are laid over the sleepers just mentioned to form a kind of deck, and the whole is rendered air-tight by plastering with mud. This will divide the tunnel into two very unequal portions. Through the lower division or air sollar, a current of cool and therefore heavy air will pass into the end, and this will be farther cooled if there be water issuing from the lode at any points. The air heated by the breathing of the men, the heat of the candles, etc., will pass out through the level itself, and so a constant current will be kept up. The "level" should be kept as truly level or "dead" as possible for several reasons, two of which may be mentioned here: 1st, if there be water flowing out through the level, and the fall be considerable, the rapidity of the current of water will, to some extent check the ingoing current of air; 2nd, if the level rise rapidly, the floor of the end will soon be at a higher actual level than the "back" of the entrance, when the heated air will actually have to *descend* in order to make its escape, although the natural tendency of heated air is always to *ascend*.

Should it be necessary to to do more than divide the shaft, or air-sollar the levels, the mode known as pipe and cap head, which is similar to that which is so commonly used on board ship, may be resorted to. This is effected as follows: A pipe of thin metal or 1, wood is made of about 1 square foot area or less, to which is fitted a revolving cap-head *a*, fig. 1. The lower end of the pipe is carried down to the bottom of the shaft, and the open mouth *b* is turned towards the wind. A current of fresh air is thus forced down to the bottom of the shaft where the men are at work, and thus displaces the foul air, forcing it up the shaft. In Cornwall, for temporary purposes, the writer has seen a zinc rain-water pipe so arranged with a miner's jacket extending by wires at the top for a "cap-head" or "sail." A similar arrangement may be adopted for ventilating a level, the pipe being carried into the end, but sharp angles in the pipe should be avoided as much as possible. It is plain, however, that this mode of ventilation can only be adopted when the wind is blowing, but in time of calm, underground ventilation is most of all wanted. To meet this difficulty a small fan may be placed in the upper end of the pipe, worked by hand, a water-wheel, or a steam engine, and arranged either to force pure air into the workings, or still better, to draw the impure air out, leaving the pure air to find its way down the shaft. In many cases a jet of high pressure steam from a boiler may be discharged into the upper end of this pipe, when an outward current will be at once set up.

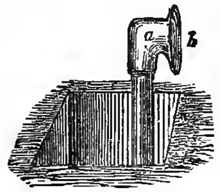

FIG. 1.

In many cases a jet of high pressure steam from a boiler may be discharged into the upper end of the pipe, when an outward current will be at once set up.

The Water Trompe.—Where there is a supply of water at surface, and an adit level to carry away the waste, the water "trunk," or "trompe," may be used for ventilation with much advantage. If there be no adit, and the spent water would have to be pumped up again after its use, it may be better to apply the power directly to produce a current of air by means of a fan or air pump, unless there be a surplus of pumping power. Figs. 2, 3 show two forms of the water trompe. In fig. 2 the water from the launder *a* falls upon the series of iron bars *b*, and down the pipe *c* into the cistern *d*. The stream of water being broken by the bars, a quantity of air is entangled and carried down with it, and this escapes at the trunk or exit pipe *e*. The water overflows the cistern *d* and is pumped up again, or passes away by an adit level. In fig. 2, the water enters the hopper by

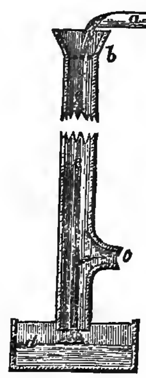

FIG. 2.

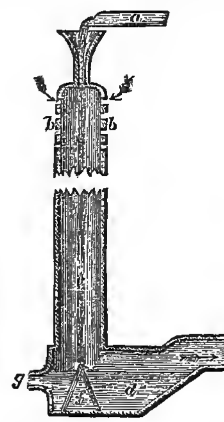

FIG. 3.

the launder *a*, passes down the pipe *c*, and falls upon the dash-block *f*, placed in the cistern *d*, the overflow of which is at *g*. Air is drawn into the pipe *c* through the holes *b*, and makes its exit as before at *e*. By lengthening the exit pipe so as to reach into the "end" of a level, these modes may be made available for ventilating very long drifts. In all cases the exit pipe should be large, as it is quantity rather than a rapid current which is wanted, and sharp angles should be avoided as much as possible, since the air current receives a serious check at every sudden change of direction.

Natural Ventilation.—In working lodes to a moderate depth, the difference of level of the "braces" of the different shafts, due to the irregularities of the surface, is often sufficient to determine the direction of the current of air, and to produce a good natural ventilation, although it is sometimes necessary to use air partings or stop doors to aid this. Thus, if in a mine, situated as in fig. 4, there be two shafts,

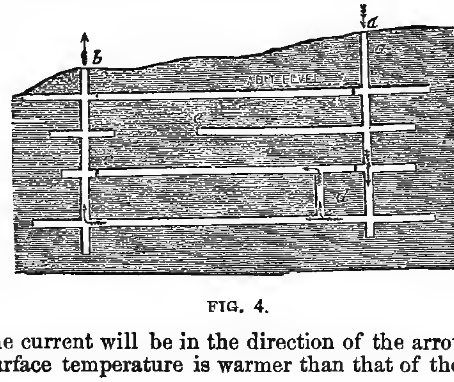

FIG. 4.

a b, the current will be in the direction of the arrows when the surface temperature is warmer than that of the bottom of the mine, and it will be reversed when the surface temperature is lower. Whenever the surface temperature is the same as that of the bottom of the mine, the ventilation will be likely to suffer; but this state of things will not last many hours at any one time, since the temperature of the bottom of the mine will be constant, that of the surface rapidly variable. It may be necessary to place regulating doors at *b b* and *c c*, *b b* being shut when *c c* are opened, and *vice versâ*. At *d* the current will be divided as shown. The level at *e* will be very badly ventilated unless a current of air can be sent along it by means of an air-sollar, or in some similar manner. Sometimes a chimney is built over one shaft to increase the natural inequality of level, and to assist in the determination of the current. This should be of large area, as if small, a sufficient quantity of air will not pass. In very deep mines the difference to be obtained by means of a high chimney is very slight as compared with the whole depth of the shaft, but the naturally high bottom temperature of such mines greatly assists their ventilation by means of natural currents.

Heat of Deep Mines.—The rate of increase of temperature in deep mines varies much in different localities. In some places it has been found as much as 1° F. for each 45 feet in depth, in others little more than half this rate. After about the first 10 fathoms the variations of surface temperature have no effect on that of the mine below, which, in the absence of chemical changes or of hot springs, is always almost exactly the same. One exception, however, must be noted. In deep workings, when they are first opened, the temperature is often much higher than in the same situations after several months' working. Thus, at the Clifford Amalgamated Copper Mines, in Gwennap, the air in the 220 fathom level was 100° F. in 1863; but in July, 1864, it had sunk to 83°. In the 230 fathom level then just opened the temperature at the same date, July, 1864, was 104° F. At the Duckinfield Colliery, in Durham, the temperature was found to increase from a depth of 20 feet down to 358½ fathoms, at an average rate of 1° F. for each 88 feet in depth. At the Rose Bridge Colliery, near Wigan, from a depth of 80½ fathoms to 403 fathoms, the average increase was at the rate of 1° in each 67 feet. This latter is one of the deepest mines yet worked. Perhaps the greatest depth yet attained is at *Viviers Reunis*, near Gilly, in Belgium, where the shaft itself reaches a depth of 3411 feet, or nearly 570 fathoms, and the bottom of a *trial-staple* was found by Mr. W. W. Smyth, in 1871, to be 3489 feet, or 581⅚ fathoms.

Furnaces, air pumps, or powerful steam jets are seldom required in the ventilation of metal mines, unless they are situated in coal districts, or worked in connection with coal mines. The construction and mode of working will be fully described in the elementary treatise on "Coal Mining," forming part of this theory.

Lighting of Workings.—In the metal mines of Cornwall, South Wales, and the north of England, the usual mode of lighting the mines while at work underground is by means of tallow candles. Each man carries a tallow candle in his hand while walking along the levels, using a lump of clay as a convenient holder. The same lump of clay serves to fix the candle to his hat, while he is ascending or descending the shaft, and to attach it to a rock in a convenient position when the place of work is at length reached. The candles used in Cornwall have large wicks, so that a sudden current of air may not too readily extinguish them; and there are from twelve to sixteen to the pound. In the north of England the candles used go from twenty to thirty to the pound; and formerly much thinner candles than these were used, but such very small candles are now seldom seen.

Lamps.—In some of the mines of the north of England, South Wales, and Scotland, and in Saxony and other parts of Germany, small metal lamps are used, in which colza, rape, or other oil is burnt. These lamps are made with a small hook or attachment to the miner's hat, and a spike which may be placed in a joint of the rock when the place of work is reached. The light given by such lamps is not equal to that of good candles, and this is probably the reason why they have not found favor in Cornwall; but the cost does not exceed from ¾d. to 1d. per shift or core of eight hours, which is about one-half the cost of candles. Within the last few years lamps for burning paraffin and petroleum oils underground have been devised. The author has not seen any of them; but they are well spoken of, as they give a good light at little cost. Hitherto, however, they have not been made to burn without much more smell than either oil lamps or candles.

Coal gas was first utilized in Cornwall, by Murdoch, in or about 1792, when he lit up his workshops at Redruth with gas. He had previously been in the habit of carrying a bladder full under his arm, which supplied a lighted jet in his night journey across the moors of Cornwall, to the great alarm of the country folk. Two miles at least have been lighted with gas at different periods in Cornwall, but at present no gas is used for this purpose in the county. At Tresavean Mine, early in the present century, gas was used for lighting the shafts and some of the principal workings. The latest instance, however, was at Balleswidden, about the year 1866, when gas was carried down the shaft and into the levels and pitches where the men were at work, as far as the 120 fathom level. Where four men were at work one gas jet was found to give sufficient light for all, with less smoke and unpleasant smell than candles. The cost was officially reported to be only one-third that of candles; but for some reason or other the apparatus was ultimately removed. Coal gas is extensively used for lighting mines of all kinds in the north of England. Sometimes it is made at the surface, stored in a gasometer, and sent down by means of a fan blower, steam jet, turbine, or a water trompe. A current having a force equal to a pressure of ten or twelve inches of water is found sufficient to carry the gas down to a depth of 150 to 200 fathoms, and to maintain sufficient pressure at the burners. In mines where furnaces are used for ventilation the retorts are sometimes placed over the furnace, and the gas is purified and stored underground. In the United States a kind of gas is produced for mining and other purposes by forcing common air through benzoline. This gas is slightly heavier than air, so that no difficulty is experienced in conveying it underground, as is sometimes the case with coal gas. The first cost of the apparatus is much less than that necessary for the production of coal gas, the complete arrangement for 100 lights only costing from £60 to £100. The forcing apparatus is a kind of clockwork, which is wound up each morning by one man in less than an hour, and the light is said to be quite equal to coal gas, or even superior to it. The cost for each light is about ½d. per hour. This would be too costly a light to supply to each pair of men; but not too costly for lighting of shafts and main roads, or levels, or other fixed positions, where a constant light is needed. This mode of gas lighting is now to be seen in the International Exhibition at South Kensington (July 1874). It seems to be admirably adapted for mining purposes.

—*From "Principles of Metal Mining."*

MINING VENTILATION.

UNDER this heading we gather a few of the more recent notes upon this subject, more as a synopsis of progress than an attempt to cover the subject of Mechanical Ventilation of Mines.

At the closing meeting of the session in connection with the Manchester Geological Society, held at Wigan, on June 30th, the whole of the programme was devoted to subjects specially interesting to mining engineers, of whom there was a large number present. Amongst other subjects was a paper by Mr. Charles Cookson on the relative efficiency and useful effect of centrifugal fans for mine ventilation. The great majority of mining engineers, he said, had become convinced on the ground of safety and efficiency, that mechanical was greatly superior to furnace ventilation, and the point now chiefly at issue was the relative superiority of the various systems of mechanical ventilators. These might be divided into two classes; the first consisting of the Waddle, the Guibal, and the Schiele, which were centrifugal ventilators; and the second consisting of those machines which were known as varying capacity ventilators. The latter class, however, in his opinion, were not at all suited for the enormous volumes of air which were required at the present day for the ventilation of coal mines, and very few comparatively were at work in this country, whilst on the Continent, where all types of mechanical ventilators had been more fully tried than here, the centrifugal fan was being put up practically to the exclusion of all others. It was therefore only necessary to consider the relative merits of this class of ventilators. In the absence of any fair means of comparison obtainable with present experiment as to the useful effects and results, he had turned his attention to one or two other points, which, in his opinion, were quite as important as the question of the percentage of steam utilized. The work of a fan was primarily, to produce a ventilating current in the mine, and they could calculate what ventilating pressure could be produced by a fan running at any speed. Since the quantity of air in a mine depended upon the ventilating pressure or water-gauge that a fan could produce, the question as to which type of fan was able to produce the greatest water-gauge was one of great importance, as it might be said that the fan which at a certain speed could produce the greatest water-gauge was the most efficient ventilator. As a basis on which to test this class of ventilator, they might consider that in all centrifugal fans the air traveled the fan at the speed at which the tips of the fan were traveling. In open running fans the work which was stored up in the air when traveling was nearly all lost, and if they could utilize any of this stored up work by lessening the velocity of the air before discharging it into the atmosphere, they would increase the useful effect of the fan. If all this stored up work could be utilized, and the fan caused no friction to the air in passing through it, they would arrive at what a perfect fan could produce. In order to get a fair average of results, he had worked out the percentage of efficiency in this respect of some six Guibals, three Waddles and five Schieles, of whose working he had particulars, and averaging the results he had found that they gave the following comparison:—

Guibals	64.5	of efficiency with regard to water-gauge produced.
Waddles	44.78	
Schiele	34.45	

Taking this as a fair basis for calculation, they could find out approximately what each of the three types of fan would do at the same or different speeds, and taking 9,000 feet per minute of periphery speed as being about the limit of safe working speed of fans of such dimensions as would pass large volumes of air, they found that at this same speed they would give the following results:—

	Water-gauge.	*Air per minute.*
Guibals,	6.61 inches.	200,000 cubic feet.
Waddles,	4.59 inches.	166,780 cubic feet.
Schiele,	3.53 inches.	146,160 cubic feet.

This showed that if the fans were all working under similar conditions and at the same speed of periphery, the Waddle would give 16.6 per cent., and the Schiele 26.9 per cent. less air than the Guibal, or putting it in another form, they found that to produce the same amount of air the Waddle would have to run at 20 per cent. and the Schiele at 36.6 per cent. greater speed than the Guibal, so that whatever the result as to the useful effect calculations, they might say that as a matter of efficiency with regard to the speed of the fan the Guibal was the most efficient. In the course of a disscussion on the paper, Mr. Wm. Bryham, a well-known mining engineer in the Wigan district, said that although he was prepared to admit that the time was coming when mechanical ventilation would be more applied than it had been before, he scarcely thought that the time had yet come when it could be said that under some conditions it was altogether superior to furnace ventilation. Mr. Cookson replied that no doubt at certain depths furnace ventilation was found to be more econonical than mechanical ventilation, but another point to be considered was the question of safety.

—*Iron.*

On March 22d, 1882, the second of a series of lectures which have been specially arranged for the purpose of affording information to the men employed at the pits in the district on mining matters, was delivered at Dukinfield, England, the lecturer being Mr. C. M. Percy, of the Wigan Mining School, who selected as his subject, "How we Ventilate our Mines by Machinery." Mr. Percy, in the course of his lecture, said there was a great deal that a mechanical engineer might do and ought to do at collieries. Winding was now made expeditious enough, but was the reverse of economical. Pumping would in the future be carried on with appliances, perhaps not cheaper in themselves, but less expensive in working. Hauling was even yet in a somewhat crude state of development, and afforded great scope in the way of improvements, which might be carried into effect by energetic engineers and enterprising colliery proprietors. Coal-getting was carried on, under existing arrangements, in what might almost be termed a barbarous fashion; the danger with explosives was very great, and the work with the very handy but, at the same time, obsolete tool, the pick, was frightful. For every ton of round coal got, in many districts, nearly a ton of slack was made, and this state of things certainly would not and could not continue. And when the coal was brought to bank, not much improvement ás a rule was to be found. The coals were hauled from the tips into the shoots, and in a rough and ready manner found their way into the wagon, insufficiently screened and insufficiently freed from dirt; while in the wagon the round coal was trampled into slack to the loss of the proprietor and the annoyance of the customers. In ventilation, the mechanical engineer had, during the last thirty years, done a great deal, and, on the whole, had done it well; and it was with reference to this that he wished speeially to speak. Fortunately for his hearers, he had no strikingly novel ideas of his own in this matter. He had no bias of his own against the furnace or the mechanical system of ventilation, nor had he any special leaning to one particular fan as compared with another. He believed, however, that in mining operations what could be done by machinery was better so done than in any other way; but he did not believe that any one system of mechanical ventilation possessed all the merits; he believed that in nearly all the systems there were some special good points, while in general the advantages were pretty nearly equal. He should try and discuss them candidly and steer clear of anything like unfair criticism. So far as simply producing a current was concerned, nothing could surpass the excellence of the furnace, and especially for deep mines, because the efficiency of the furnace increased with the depth. But with the furnace there was the danger of setting something on fire in the vicinity or in the shaft, and there were the inconveniences and the injurious influence upon winding ropes, conductors, etc., by having the products of combustion from the furnace passing out at the upcast shaft. No doubt, except for shallow pits, the mechanical system of ventilation was more expensive, but with really good appliances worked with condensing engines, mechanical ventilation, even for deep mines, would come very nearly to the furnace. Mechanical ventilation might either act to compress the air or to exhaust it, and in several respects forcing in air was more effective than sucking it out. But the inconvenience of efficiently closing in the top of a downcast for forcing arrangements has led to the almost universal adoption of exhausting appliances placed at the top of the upcast shaft. Mechanical ventilation might be divided into three classes: first pumps, with clacks such as Strewe's; secondly, revolving wheels sweeping out a fixed quantity of air every revolution, such as Leviselle's, Cooke's, and, perhaps, there might be included Root's; and thirdly, fans working on the centrifugal principle, including the Nasmyth, Brunton, Biram, Ramwell, Guibal, Waddle, and Schiele. Mr. Percy then proceeded to describe the principle of these various ventilators and the engines for driving them, and made special reference to the three last-named fans as those most generally used. The Guibal and the Waddle were made any size up to 50 feet diameter, and worked slowly, the engine being converted directly. The Schiele was a small fan, rarely exceeding 15 or 16 feet diameter, and worked quickly, power being communicated from a large pulley on the engine-shaft by means of a strap to a small pulley on the fan-shaft. All these fans had in practice given excellent results. Mr. Percy expressed no strong preference for either large or small fans, but said his opinion was, that the blades should be inclined backward and curved backward, and that the fan should either discharge freely all around the circumference, or have a complete spiral casing opening out into an enlarging chimney. Reference was then made to several methods by which the upcast or fan-shaft could be used for winding, to allow convenience for loading and unloading the cages without allowing a rush of air into the fan-drift. The lecturer next dealt with the manner of ascertaining the actual power of the fan-engine and of the fan itself, so as to decide accurately the percentage of useful effect obtained. The whole of the matters discussed, including the fans, the percentage of leakage at the surface, and the useful effect, were illustrated by diagrams; and in conclusion, Mr. Percy observed that no doubt among those whom he was addressing there would be some anxious to obtain knowledge which would enable them to raise themselves in the social scale, and that was a laudable ambition. But they could not all rise to distinction and prominence, and what he wished to impress upon them was to get as much knowledge in connection with their occupation as they could. If, then, increasing knowledge led to advancement, well and good; but even if not, their better knowledge would be to them all the same, their labor would be sweeter, and their lives pleasanter, from knowing something of appliances which made mining safer and more efficient.

Mechanical Ventilation and Drainage in Indiana Mines.—Mr. Thomas Wilson, Jr., Mine Inspector of Indiana, has printed the following in his second annual report, recently issued: By mechanical ventilation, I mean the use of machinery to compel the movement of a column of air through the workings of a coal mine. This is done by various means. The present mode with the majority of opertors is the common furnace. A furnace does very well if it is rightly constructed. I would advocate the fan for cheapness and durability. The Champion exhaust-fan is the best. It requires less power to suck or draw a current of air than it does to push or force it. The difficulty of pushing or forcing a current of air through long and rough passages is a great drawback, and both theory and practice are against it. Whether the ordinary blowing-fan or blowing-cylinder is used, the difficulty is the same. But when the same power is reversed and the fan or cylinder is made to draw or suck the air instead of pushing or forcing it, the effect is reversed and the natural or atmospheric pressure becomes an active agent instead of a repelling force. Instead of increasing the density and consequent friction of the air, it decreases them and proportionately decreases the amount of power required to produce a given current. For these reasons, the improved exhaust-fan is the most perfect, safe and economical, and far superior to the furnace method. There is a number of common blowing-fans in use in the State, some of which are doing good service, one at Mr. S. W. Phelps' No. 3 mine on Coal Creek, Fountain County; one at the Buckeye shaft, in Clay County; and another at Watson's South shaft, in Clay County. These were doing excellent service. There was a perfect hurricane of air passing through their mines the whole time. These fans can be erected at a very reasonable cost. It will not exceed $250, including pipes to convey steam from the boiler unless the fan is situated an unreasonable distance from the boiler. After one of these fans is put in operation, the cost to run and keep it in repair is comparatively nothing. But this is not the case with the furnace. It costs nearly as much to erect a furnace in the first place, and then there must be added the cost of keeping it up afterward. In the first place, it will require one ton of coal per day, and it will take a man constantly to attend to it, at a cost of at least $1.25 per day, to produce say 20,000 cubic feet of air per minute, and some of our mines require a great deal more than this to comply with the law. This will amount to quite an expense at the end of the year. Besides, where furnaces are used, the hoisting shaft is always the downcast for the air; and where shafts drip water, there is always a great deal of trouble and annoyance with shafts freezing up in cold weather. It is also very disagreeable for the cager. But this is not the case with fans; the hoisting shafts are always the upcast, and it is always warm and pleasant in the winter season. Besides, the frost air is always distributed among the mines before it becomes charged with foul gases of the mine. I am opposed to furnaces on account of the expense of keeping them in operation. As much air can be produced with a furnace as with a fan, if the furnace is made large enough. The best ventilated mine in the State of Indiana is the Sulphur Spring mine, near Washington, Indiana. There are 29,250 cubic feet of air per minute circulating through the entire mine. They were working a force of 155 men and boys. The air was sufficient for 292 persons, allowing 100 cubic feet of air per minute for every person employed. This current of air was produced with a furnace of 34 cubic feet of heating space. It will cost to build a furnace of this size $130 in the first place, and it requires one ton of coal per day, and the constant attendance of a man to keep up this current of air. This mine is opened on the double-entry system. Every air-course and entry in this mine has a sectional area of 42 cubic feet of space for the passage of air. This is the most extensive mine in the State. The air-current in this mine from where it first enters the mine at the downcast shaft traverses the main entries and air-courses, and runs a distance of four and three-quarter miles to where it enters the furnace and upcast shaft. Among the different modes of ventilation, the difference in cost is greatly in favor of the fans. There have been about fourteen fans erected during the year for ventilating purposes, and I hope to see during the present year all the furnaces done away with for ventilation purposes.

At the present writing, February 20th, 1882, the larger portion of the Sulphur Spring mine is entirely submerged, the water standing in some places to a depth of eight feet. This has been caused by the heavy rains that have been falling for the last eight or ten days. There are at present about 200 persons lying idle on account of it. There is more water handled at this mine than at any four other mines in the State. The water is hoisted here with large boxes. There is one six-inch discharge-pump, but at the present time it is entirely submerged. The capacity for handling water here is 840 gallons per minute. At this rate, it is supposed that it will take about two weeks to drain the mine and put it in a working order. The territory in this mine comprises about 200 acres, and the seam of coal lies so close to the surface that when a pillar is taken out the upper strata is so rotten that it falls through to the surface, and all the water that falls on this ground goes into the mine, and has to be either pumped or drawn out in boxes. This is a great drawback in working the surface veins unless they are worked with drift openings. Coal can be produced cheaper from a vein that lies from two to three hundred feet below the surface than it can from a vein that is between forty and sixty feet. Of course, the first cost is greater with a deep shaft than it is with a shallow one, but you are never troubled with surface water. This is a very important item in operating a mine. I could point out instances where the expense of handling the water and cutting drains in the mine is more than the cost of getting out the coal.

Measuring the Air of Mines.—From the Seventh Report of Andrew Roy, Inspector of Mines in Ohio, we glean the following on this subject: The instruments used for measuring the currents of air in mines in this State are generally anemometers, or air-meters. Beram's 4-inch anemometer, reading to 100 feet, is the favorite. There are some 6-inch instruments of this manufacture, and one or two 12-inch ones in use. The large ones are most costly and more cumbersome to carry around than those of the 4-inch size. Castello's 2-inch air-meter is also used, but Beram's is preferred. The manner of measuring the air is very simple, as the anemometer self-registers the speed of the current. A point is selected in the air-course where the whole column passes, and the instrument is held in the current. The vanes are so constructed that they revolve by the current of air impinging upon them, the speed of the current being indicated by the index-hand or pointer of the dial-plate, which reads to single feet; one revolution of the pointer recording one hundred feet. The anemometer is usually held in the current just one minute, and the speed with which the air travels is noted. The sectional area of the air-way is then ascertained, which multiplied by the number of feet at which the wind is flowing, gives the amount of cubic feet of air. An allowance has to be made for the friction of the anemometer, which is equivalent to 17 feet for 50 feet per minute, and 8 feet for 200 cubic feet per minute. When the speed of the current, as indicated by the anemometer, exceeds 200 feet per minute, the friction, owing to the construction of the instrument, is very little, being only 3 feet for 300, 2 feet for 400 and nothing for 500.

The speed of the current in a good-sized air-course, in the best ventilated mines in the State seldom exceeds 500 feet; in the worst mines there is sometimes so little current moving, that the vanes of the anemometer refuse to revolve, even on the main air-courses. Three hundred feet per minute, which is nearly equal to five miles per hour, is a sufficiently vigorous current for any coal mine in this State. Moving through an air-course of thirty-six feet of sectional area, this rate of speed would produce 11,700 cubic feet per minute, an amount capable of supplying 117 workmen, if properly distributed, with an abundance of fresh and wholesome air. Nearly all the reports sent to this office since the mining law required the bosses to measure the air of mines, give different results at the intake and outlet. For example one boss reports 10,700 cubic feet as entering the mine, and 11,525 as being discharged. Sometimes the results show a larger current at the intake than at the upcast. The facts show that these measurements were honestly, though mistakingly taken, the cause of the varying results being due to the want of care or opportunity in selecting the places of measurement. To measure the current accurately, a straight passage in the entry should be selected, for on a curve the current is stronger on one side than the other, as in seen in a current of water moving along the bend of a river. In selecting a wide place in the air-gallery, also just beyond a narrow point, to make a measurement, the result will show a larger current than really exists, because the air forms a *cul de sac* at the pillar sides, just as water does on being discharged from a pipe of lesser diameter into one of greater diameter. Another reason why a larger current is sometimes shown at the upcast than at the intake, is due to the measurement at the upcast being taken near the mouth of the ventilating furnace where the air has become expanded by heat. In this latter case there is, in reality, a larger volume discharged than enters the mine. The galleries of mines are generally ragged, wider at the top than at the bottom, and in the low veins, where the roof is shot down, the height is irregular, so that accurate measurements cannot be taken; but accurate measurements are not required, the point being to possess a current at least equal in volume to the requirements of law. There are two other methods which are sometimes used in measuring the air of mines. One is by flashing a small quantity of powder in the air-way, and noting with a watch the speed at which the smoke travels along the gallery. The other method is by carrying a lighted lamp or candle in the moving current of air, and maintaining the light in an exactly upright position, noting the time required to pass from one place to another. Both methods are on the same principle. The experiments can only be made along an even part of the air-gallery. A distance of from 100 to 200 feet is generally selected. The cubic area of the chosen part of the air-way is ascertained in feet, which, multiplied by sixty, the number of seconds in a minute, and divided by the number of seconds of time required by the flashed gunpowder, or person traversing the measured distance, gives the amount of cubic feet of air per minute.

Compressed Air in Mines.—Mr. M. G. Johnson, of the Kingswood Collieries, Bristol, writes thus under this topic: Among the collieries visited by Mr. Cossham were included Ryhope and Shireoaks, and at each of these collieries compressed air is being used with excellent results. The same may be said of all the places I visited in South Wales —in one colliery no less than 40 horses have been dispensed with through the application of this power. Great credit is due to Sir George Elliot for the persistant efforts he has made and the money he has spent in order to bring as near perfection as possible the methods for obtaining this power. In the Powell's Duffryn Collieries, in South Wales, the proprietors are so convinced of the benefits to be derived from its use that they are dispensing altogether with animal power, and substituting air engines for their underground haulage; and the testimony of these collieries (Mr. Wakinson, manager, and Mr. Snape, engineer) was to the effect that after ten years' experience in the use of compressed air they are fully convinced that there is no power equal to it for winning coal back to the shaft where steam cannot be conveniently employed and where the coal lies to the dip. At New Tredegar Collieries, belonging to the same firm, this motor is, I am told, extensively employed. They have no coal works but what lie below 1,500 yards to the dip, and from that distance down to 2,000 yards, the lowest point reached at that time (two years ago), they were hauling 800 tons per day.

When the Mont Cenis Tunnel had to be driven, the engineers, Messrs. Sommellier and Grattoni, at once recognized this power, and availed themselves of it, and but for this I have no doubt the completion of that grand engineering feat would have been retarded for at least five years. It not only served as the power for driving their rock drills, but it cleared away the smoke after blasting almost immediately, and enabled the men to resume work at the face of the heading without any unneessary loss of time, and to get the debris at once cleared away. Every miner knows that the hanging of the smoke in the ordinary method very often keeps him away from the place of his work quite one-fifth of his time, so that this power not only permits much more work to be done, but admits of its being done in a healthy atmosphere instead of in a vitiated one. At Mont Cenis Tunnel, too, they got this power very cheaply at merely the cost of the machinery, a mountain stream running down near the mouth of the tunnel was utilized, and supplied the power for compressing the air. Mr. Derilley has published an elaborate and most valuable report on the work done at this tunnel, and much information is given therein respecting their method of compressing the air. Mr. Taylor, of Ryhope Colliery, in a paper read before the North of England Institute of Engineers some few years ago, enumerates some of the advantages resulting from the use of this power:—1. It is obviously of great importance to have a large power which can be applied to any purpose, and at any moment, to any part of the mine. 2. Possessing this power is a mere question of detail to use means for working the coal and bringing it to the point from which it is to be led by the air engine, thus dispensing in a great measure with manual labor, both as regards hewing and putting the coals. 3. Compressed air at 40 lbs. pressure has been successfully tried at Ryhope for airing a stone drift, and he sums up the results as follows: 1. Economy as regards its application to any part of the mine. 2. Additional safety to mine, inasmuch as there is more direct commuication with the control over all parts. 3. Having a power so easy of application to any part of the mine, its use for all purposes where labor is concerned must necessarily follow.

M. Trasenter, Professor of Mining at the University of Liege, considers that great advantages must ensue from the use of this power for driving engines at high speed in the galleries or working places underground, through the freedom from heating and condensation, slight friction in the pipes, and the ventilation in the works; but while enumerating its advantages we must not fail to look fairly in the face of what are considered to be the drawbacks to its general adoption. Mr. Trasenter says compressed air necessitates costly works, and if used without expansion leads to a great loss of power owing to the necessity for conducting the air at the required pressure. In calculating the ratio of the energy expended in compressing the air to the useful work theoretically given out, Mr. Trasenter has laid down a simple and interesting formula. The work given out soon reaches a limit which cannot be exceeded, whatever may be the pressure of the air or the energy expended. The maximium of work given out (increasing the compression indefinitely, and without taking into consideration the elevation of temperature due to this compression) cannot exceed the energy given out by the volume of air caused by the piston of the blowing cylinder working with an effective pressure of one atmosphere, and he demonstrates the law, and goes on to say that the power which a cubic meter of air, compressed to a million atmospheres, is capable of yielding, without taking the rise of temperature into consideration, can never become double that which the same quantity of air, compressed to two atmospheres is capable of yielding. Air compressed to four atmospheres will give out a power proportional to $1-\frac{1}{4}$, or $\frac{3}{4}$, whereas to obtain a power equal to 1 a compression infinitely great is necessary. He gives a formula which expresses the ratio of the work done to the power expended. This power is not a new discovery; Hero, of Alexandria, was in some measure acquainted with it, as well as with the knowledge of steam as a motive power. Hero's tutor, Clestibuis, is said to have discovered that air was compressible, and the pupil is credited with having written a book on pneumatics, showing that when air was compressed it decreased in volume, and expanded itself again when the pressure was removed. Experiments proving its "ponderability" were made in the 17th century by Galileo and Torricelli; about the same time, too, Guericke invented the air pump. Its chemical properties, however, did not engage much attention until another century had elapsed, when Black, Priestly, Lavoisier, and others took up the subject, and great discoveries resulted from their labors. Papin, about the beginning of last century, had an idea of working an engine with air, generated by a water-wheel and compressing pump at a distance, but it was not brought into practice; and just 100 years before the Mont Cenis Tunnel was commenced one Isaac Wilkinson obtained a patent for a machine for compressing air very similar to the one employed at those works. It is generally known that when air or other elastic fluid is compressed, there is generated an amount of heat which is the exact equivalent of the force employed in the compression. It may not be out of place here to give an extract from Professor Tyndall's valuable work, "Heat a Mode of Motion." He says:

"Whenever friction is overcome (by compression or otherwise) heat is produced, and the heat produced is the exact measure of the force expended in overcoming the friction. The heat is simply the primitive force in another form, and if we wish to avoid this conversion we must abolish the friction. We put oil upon the surface of a bone, we grease a saw, and are careful to lubricate the axles of our railway carriages. What is the real meaning of these acts? Let us obtain general notions first, and aim at strict accuracy afterward. It is the object of a railway engine driver to urge his train from one place to another; he wishes to employ the force of his steam; it is not his object or interest to allow any portion of that force to be converted into another form of force which would not promote the attainment of his object; he does not want his axles heated, and hence he avoids as much as possible expending his power in heating them—in fact, he obtained his power from heat, and it is not his object to reconvert by friction the force thus obtained into its primitive form. For every degree of temperature generated in his axles a definite amount would be withdrawn from the urging force of his engine. There is no absolute loss. Could we gather up all the heat generated by the friction, and could we apply it mechanically, we should by it be able to impart to the train the precise amount of speed which it had lost by the friction. Thus every one of those railway porters whom you see moving about with his can of yellow grease, and opening the little boxes which surround the carriage axles, is without knowing it, illustrating a principle which forms the solder of nature; he is unconsciously affirming both the convertibility and indestructibility of force. All the force of our locomotives is derived from heat. When a station is approached—say at the rate of thirty miles an hour—a break is applied and smoke and sparks issue from the wheels on which it presses. The train is brought to rest. How? Simply by converting the entire moving force which it possessed at the moment the brake was applied into heat."

The heat in actual practice is to a very considerable extent lost by radiation from the receiver and pipes in use; and, further, when this compressed air has fallen to the temperature it possessed prior to its being compressed, it has lost in cooling an exact equivalent to the power expended in compressing it. Where, then, is the power to perform work? This remains in the stored-up air in the reservoir, where it is held under considerable pressure, and when allowed to expand in the working-cylinder its temperature then falls below that of the atmosphere, and thus develops the work demanded from it. In accomplishing this, however, there is a loss of about thirty to forty per cent. in consequence of the temperature of expansion not being depressed in an equal proportion to the increase obtained during its compression; and hence, when the air has done its work in the cylinder, and issues forth from the exhaust passage, it is exceedingly cold, being about 28½ degrees Fahrenheit, or 3½ degrees below freezing point. This intense cold formed for a considerable time very serious objections to its practical use as an engine motor, through the formation of ice at the exhaust. Various methods have been resorted to to remedy this defect, but this is effectually accomplished by casting the cylinder so as to have the exhaust openings connected with the exhaust port vertically, and open across the cylinder, so as to discharge the air downward as well as upward, and admit of a bar being passed through, if necessary, to chip off the ice. It would appear from the foregoing that the higher the air was pressed the greater would be the loss in the economic result; but in this there is a great difference of opinion, one party going in for slow speed and low pressures, not above three atmospheres, and another for high speed and high pressures. It is a very common expression and true, that circumstances alter cases, and so, in my opinion, it is in this, the "battle of pressures."

I do not wish to be dogmatic in this matter. Douglas Jerrold once said that dogmatism was grown-up puppyism; and I know, too, there is a proverb which says that a certain class of people, the opposite to wise, rush in where angels fear to tread. Where the work, however, to be accomplished is of a temporary nature, such as tunneling, deep well sinking, or boring, high speeds and high pressures may be adopted with advantage, as they admit of smaller machines being used to do the desired amount of work; but where the power is required for the running of a colliery to extend over 20, 30 or 40 years, and the air to be carried to long distances for hauling, pumping, rock drilling, and coal cutting purposes, then I say put down a good compressing plant, with moderate speed, ordinary pressure of (say) three atmospheres, and plenty of margin. This is my view of the matter, and must be taken for what it is worth. An athlete, in running a hundred yards race, starts away at a very different speed to what the one does who is in for a mile race; it is the old fable of the hare and the tortoise.

Looking at the matter in this light, the Kingswood Coal and Iron Company ordered a pair of air compressers from Messrs. J. Fowler & Co., of Leeds, of the following dimensions: The steam cylinder is 36 in. in diameter, the air cylinders being 40 in. diameter, with a 5-foot stroke. The air cylinders are immediately behind the steam cylinder, and fixed to the same bed plate; the piston is continuous, but so arranged that no part of the rod that works in the steam cylinder shall enter the air cylinders or even the stuffing box. The air cylinders are cast with square ends and flanges to attach flat plates vertically at the sides, thus forming a tank or receptacle for a complete jacketing of cold water, the object of the cold water being to keep the temperature of the air as low as possible during compression, the top left open to allow of evaporation and radiation. The supply of cold water is kept up by a pipe at the under side, getting its supply from a reservoir at a higher level than the tops of the cylinders, and the heated water is passed off at an overflow pipe at the top, the inlet and outlet being regulated by taps. The air is forced into a receiver, which is nothing more than an ordinary egg-end boiler, 25 ft. long and 5 ft. in diameter, fitted with stop valve and safety valves, the latter weighted to 45 lbs. per square inch. Steam is supplied at 40 lbs. per square inch, and the pressure of air stands at 45 lbs. per square inch; the steam is cut off at ¾ in. of the stroke; the fly wheel is 21 ft. diameter, and weighs about 24 tons. From the receiver toward the shaft an old boiler tube, 28 ft. long, 2 ft. 10 in. diameter, is utilized, and from this cast iron pipes 8 in. diameter are carried down the shaft for 225 yards; at this depth, and in an opening in the side of the shaft, a pumping engine is fixed and driven by the compressed air. This engine consists of a pair of air cylinders, 10 in. diameter and 2 ft. stroke, which drives a pair of rams 6 in. diameter, geared 5 to 1, with air pressure of 40 lbs., and delivers 160 gallons of water per minute 700 ft. high. The out and out dimensions of this pump are 15 ft. long, 7 ft. 6 in. wide, and 6 ft. 3 in. high. These compressors and pump, made by Messrs. Fowler & Co., of Leeds, have given the most unqualified satisfaction. The air pressure at this point, more than 250 yards from compressors, stands at 2 lbs. higher than it does in the receiver at surface, and my experience is that the pressure increases 1 lb. for every 100 yards of depth. We have tested this by changing gauges; the same has also been observed by Mr. Snape, engineer, and Sir George Elliot, who has had more than 11 years' experience with compressing machinery. I do not intend here to account for this, but merely state the fact. We have 7 in. pipes continued for the remaining 270 yards down to the bottom of the shaft, and for the present have a dead flange screwed on the end of the pipes, but we have already two pairs of hauling engines in order, and hope to have them at work in a few months—one pair for level haulage, the other for dip haulage. I anticipate, therefore, when we come to put the pressure gauge on at the pit bottom, that the pressure there will register about 5 lbs. higher than at the surface receiver.

ELECTRICITY IN MINING WORK.

AT the February (1882) meeting of the American Institute of Mining Engineers held at Washington, Mr. N. S. Keith of New York read a paper on "Electrical Apparatus and Processes for the Mining and Metallurgical Engineer," from which we take the following:

No oue of the live subjects of the day to which the attention of the mining engineer and metallurgist should be turned is of greater practical interest to him than electricity, in its applications to various mechanical, chemical and metallurgical operations. The object of this paper is to call the attention of my fellow-members and associates of the Institute to the various new, as well as comparatively old, developments in the science and art of electricity, which seem to furnish or promise to furnish, results of advantage. Too many of the comparatively old applications have been neglected by the mining engineer, which, if he had given them a place among his appliances, would have assisted him greatly. The telegraph may be noticed as one. Its use is, however, confined to a person having skill in the manipulations of the key, the reading of the alphabet and familiarity with the sounder. One of the simpler forms—the call bell —without necessity of special education, has a range of application far greater as to distance and convenience than the old wire pull, or the hoarse voice of the windlass man or the bucket dumper. A few Laclanche cells two or more electric bells and a mile or more of wire, judiciously placed, will put the superintendent, at his office, in communication with the foreman of his mills and mines, so that, by the aid of a code of signals, great advantages may be gained without necessitating knowledge of the Morse alphabet, nor the mechanical voice of the sounder. The recent telephone furnishes a means of communication between the often widely separated places of duty which will save many a step, and much loss of time and wear of horse and body. It can be used by any one who can speak. I would speak of appliances in the art of electricity which enable the engineer to accomplish more in an easy manner than he otherwise can do. The preceding remarks are introductory to a description of new applications of electricity, which the miner and metallurgist will find, before long, so essential to his profession that their theory and practice will be taught at the school the same as metallurgy, mineralogy and chemistry now are. That which we may call this *new* electricity is due to the practical development of the theory of the conservation of energy, and the consequent production of mechanism for the generation of currents of electricity of any desired quantity and intensity. So new is this electricity in fact, that even the recent graduate of the mining schools knows little or nothing of its modes of production or of its applications, actually, in practical operation or projection.

I will speak of the new applications which are consequent upon the extensive production of machinery for the generation of electricity. First comes that which appeals so sensibly to the eye—light. It has been fully determined that there is no light, except daylight, as cheap as that produced by the voltaic arc; none so pure in color, none so bright. Many are in use in our rolling-mills, machine shops, hydraulic mines, surface works and other places. The miner needs the electric light in his shaft-house, his stamp-mill and his furnace. If he has no engine at the shaft-house, the one at his stamp-mill or furnace can be used to run an electric generator which will send the electricity through the wire conductors, so that not only his shaft-houses can be illuminated, but also his mill or furnace, and even the road between, much cheaper than he can produce one-tenth of the light by the use of candles or kerosene, with much greater safety. It is doubtful, however, if the voltaic arc light will be of any great practical utility in narrow veins of mines, because the light produced is too great in quantity—and therefore too costly—more than is needed, by far in narrow space; nor in headings or stopes, as it requires in such places too frequent moving. The work at the new railroad tunnel through Bergen Hill, at Weehawken, is lighted by eleven arc lights placed upon the circuit from one electric machine. This circuit is two and a half miles long. The conductors are of well-insulated copper-wire, carried along the ground upon poles down and up the several shafts and into the various headings, all with great success and economy, especially as the men can do more and better work in the good light. In lighting the banks at hydraulic mines, in iron ore pits, in open cuts of railroad work; in fact, in all large spaces in which night-work is carried on, this light has no equal.

Take, now, some of the applications of electricity which can be used by the miner and metallurgist, if he has at his main engine or water-wheel a suitable generator of electricity. He may be sinking a shaft at the top of a mountain, where it would be impracticable to place or operate a steam-engine. But if he places there an electric motor, and connects it with his generator by conducting wires, he will have power at his command at the shaft which, by the mere turning of a switch-handle, will work his whin or windlass, and hoist his ore or rock, or work his pump. I have an instance at hand where electricity is now used in mining, in the Loire Valley, in France, for the transmission of power, at the works of the Compagnie de la Ferroniere. One Gramme machine is employed as a generator of electricity, and another as a motor attached to a drum which stands at the head of an inclined plane 110 m. long, with a grade of 4 cm. per m. The generator is 1200 m. from the motor. The load raised is about 800 kg. (1760 lbs.) and the ascent is made in one and a half minutes. The work goes on with great regularity. The starting and stopping can be done as gently as desired. By means of a galvanometer in the circuit one can tell at any moment what is being done at the incline, whether the work is being stopped, whether the wagons are coming up filled or not, etc. The work is about two-thirds horse power. By means of this current he can ignite his blasts. He can work his electric drills, which are said to be economical in comparison with the steam drill. He can stop or start the drill at will, and have all the advantages of mechanical movements, without the constant personal attention of an engineer at the shaft. He can light all his works from a central station at the mill or other place where he has available power. He can have wires branched to his laboratory, where the electric current will aid him in his analysis and tests. There he can melt his gold, silver and samples. He can heat, boil, cupel, roast, and perform all the operations of the laboratory which require heat, power or the determination of chemical affinity. Think of melting metals by the fall of water! The suggestion of it even not so many years ago, would have secured our excommunication. The iron and steel manufacturer can find the imperceptible flaws in his bars, and determine the amount of carbon in his steel by this agent.

It would take too long, and far exceed the proposed limits of this paper, for me to enter into the particular modes and apparatus for carrying on the various operations which I have enumerated, but I will briefly describe a few practical operations which can be carried out on a large scale. For quite a number of years in the neighborhood of Swansea, in Wales, a method of refining copper and separating such gold, silver and other metals which the impure copper may contain, has been in practical operation on a large scale. Plates of "black copper" are made the anode in an electrolytic bath, consisting of a solution of sulphate of copper. Other thin plates of pure copper are made the cathode in the bath. By the electrolytic action of the current, produced by an electro-generator, copper alone is dissolved from the black copper and it is deposited in a pure state upon the cathode. The impurities of the black copper sink to the bottom of the vat, and are removed from time to time and treated for their contents of gold and silver. The cathodes, as soon as they have reached the desired weight, are removed, and the copper thereon is melted and cast into pigs for the market. This process has been found more economical than any other for accomplishing the same result. An analogous process is the one invented by me for the refining and desilverizing of base bullion. The bullion, in plates, is placed in a solution of acetate of soda and sulphate of lead, and is so connected with the source of electricity as to be an anode, while plates of other metal are cathode. Lead is dissolved and deposited electrolytically, and the deposit is practically pure.

I have invented an improvement on this process, which consists in taking the skimmings of zinc, lead and silver which come from the kettles in the process of desilverization by means of zinc, and putting them in bags as an anode, dissolving both the lead and zinc electrolytically, and depositing them together as an alloy, or mixture, upon the cathode plates. The contents of gold, silver, &c., are retained in the bags, and are smelted for their aggregation. The combination of pure lead and zinc is removed from the cathode and added to the next or some other succeeding lot of base bullion put into the kettles for desilverization, and in that manner the process continues. In place of treating the whole mass of bullion by electrolysis, I get in the first place, by the zinc desilverization, say 80 per cent. of the base bullion as market lead, and, say 22 per cent. of a rich lead and zinc which goes to electrolytic treatment. By adding then the pure lead and zinc to the succeeding lot of bullion I effect the desilverization, and remove from it as market lead an amount approximately the quantity of lead which is in the bullion placed in the kettle.

The process which has within a year or two been reintroduced by Siemens for melting steel by electricity, can be applied to melting the metals and materials. The apparatus for this operation is comparatively simple. Take a black-lead crucible of suitable size and put it in another suitably larger, and in the space between the walls of the two pack some good non-conducting material, like asbestos. Introduce through a hole in the bottom of this combination a carbon rod, like one used in the electric arc light, and lute around it well with a paste of clay and graphite, so that it forms a conductor to the interior of the inner crucible. Next provide a cover with a hole in the center, of a size to freely admit another carbon rod. Now place above the crucible the mechanism of an electric lamp, so that the carbon carried by its movable rod can enter the crucible through the hole in the cover. Place in the crucible an amount of steel or other metal; put on the cover and pass through the hole in it the carbon rod, and connect it with the movable carbon carrier of the lamp; connect the body of the lamp with the positive pole of the current generator, and then connect the carbon which passes through the bottom of the crucible with the negative pole. Immediately the upper carbon will be automatically withdrawn slightly from contact with the metal in the crucible and form a voltaic arc at that place, with its accompaniment of heat. Fusion goes on rapidly, so that some pounds of steel can be fused in twenty minutes. The lamp mechanism serves to keep the carbon rod at its proper separation from the metal. Siemens says that there is no other equally economical mode of fusing small amounts of steel, because there is none which so concentrates the heat upon the material which it is desirable to fuse. In fact, the fusion takes place before the outer crucible is raised any considerable degree in temperature.

The latest development in electricity is in the so-called storage of it. By the term, "storage of electricity," I desire not to be understood literally, no more than I would be so understood in speaking of the store of heat in coal. It is merely a convenient term, which simply avoids giving, as it were, a chapter in physics, and may be readily understood as such. The first storage of electricity, other than in its so-called static condition, was effected by Planté in his well known secondary battery. In his case, as in all arrangements for storage, energy is absorbed in the decomposition of water by electricity, which is again given up as a current of electricity when the proper circuit is furnished; or, better said, when the proper association of materials is made. The value of this arrangement of Planté, and the scope of application of its modifications, has not been recognized until recently. There is nothing to be gained by expending zinc and acid for the production of electricity to effect chemical decomposition, for the sake of the subsequent reverse action as electric current, for the battery can be used directly whenever such current is desired. But the recent mechanical means of generating electricity has so cheapened its production that it is now sometimes desirable to store up the electricity produced, as it were, in some portable form, so that it may be utilized in the place otherwise practically inaccessible for its direct production and use. Therefore some physicists have been directing their attention to the means of storing the electrical energy, with a view to its use at other times and places when and where the use of either batteries or mechanical generators of electricity would be impracticable or too costly. The line of development which has received the greatest attention is the one of which Planté's secondary battery is the type. Faure's arrangement is the most prominent. The capacity of both depends upon the porosity of the surfaces of two lead plates, one in connection with the positive and the other with the negative pole of a source of electricity. Planté's cell acquired its limited capacity by result of repeated oxidations and reductions, effected electrolytically, of the surfaces of the lead while in a bath of acidulated water. Faure increased this capacity by applying a coating of oxide of lead directly to the lead plates so that the increase on a given surface, in comparison with Planté's, is in the proportion of 2000 to 75. The operation of charging and discharging these cells is as follows: A source of electricity, having an electro-motive force somewhat in excess of two volts, is connected, as before stated, with two lead plates in a bath of water acidulated by sulphuric acid, and the current is allowed to flow in them for a time limited by the current and capacity. The result is that the coating on one plate is peroxidized, and the other has its coating of oxide reduced to metallic lead. If the source of electricity be disconnected, and the wires which are attached to the lead plates be kept separate, the charge will be only very slowly discharged. But if the wires be connected, either directly or through any conducting substance, an electric current will flow in the reverse direction to that which was passed through the arrangement from the source of electricity, until the original condition of oxide on both plates is resumed. The action of the current through the plates is first to decompose the water of the solution in which the plates are immersed; the oxygen goes to the positive plate and is absorbed in peroxidation, while the hydrogen goes to the negative plate, and acts there as a reducing agent, making metallic lead from the oxide. The reverse action takes place when the wires are connected. So it will be seen that the original electric current determined a chemical affinity, which, when circumstances allow, reasserts itself with the development of a current of electricity. Following this theory, I have invented a storage battery, which, as in the case of the one just named, is based on an old apparatus, well known, and up to the present time of very little practical utility. The details I am not now prepared to give, pending applications for patents in this and foreign countries, but will say that its capacity for storage of electricity exceeds ten times that of Faure of equal size and weight. Sir William Thompson found 1,000,000 foot-pounds of electrical energy stored in a box weighing, with its contents, 180 pounds, made by Faure in Paris, which he set free by use in Scotland. The decomposition of only one pound of water by electricity absorbs about 5,300,000 pounds of energy, which can be drawn at will from the storage battery through an electric motor. This equals 2⅔ horse-power for an hour. The waste of power in the process of storing is not yet well determined; but the economic results seem promising. If it be so proved, the applications of "bottled electricity" will be many.

Transmission of Power by Electricity in Mining.—The first instance on record of the application of electricity for the transmission of power is reported from France. M. Mathet has submitted the details to the Société de l'Industrie Minerale. The St. Claude shaft at Blanzy was sunk to the depth of 500 meters (1640 feet), for the purpose of searching for a faulted portion of the coal seams, and a heading was run from it across the strata. When this heading had reached a length of 400 meters (1,312 feet), the ventilation became so poor that the temperature at the face rose to 95° F., and the miners could work only for a few hours. After some ineffectual attempts to improve the ventilation by simple means, it was decided to put in a fan 2.63 feet in diameter, and run it by power transmitted by electricity. An 8 to 10 horse-power portable engine was put up above ground, and, with a Gramme dynamo-electric machine, was run at a speed of 1,200 revolutions per minute. The electric current thus generated was conducted by a cable consisting of seven 0.044-inch copper wires, to a second Gramme machine coupled directly with the fan, and placed in the heading near the shaft. Running at 700 to 800, it required 2½ horse-power, the useful effect being at least 50 per cent. The temperature at the face was only lowered 5 degrees, but the men could work in eight-hour shifts. The return current was conducted from the underground machine by an iron wire cable. The cost of the whole plant is stated to have been only one-third of what a machine for delivering compressed air to the heading would have required.

Lighting Mines by Electricity.—In Europe they are doing a good deal more experimenting in the matter of developing the possibilities of the electric light than we are in this country, yet we are by no means idle here. It may interest our inventors as well as the mining community to know that a prize of $2,500 has been offered to the person who produces the best system of lighting mines by electricity. This offer comes from Mr. Ellis Lever, of Manchester, a gentleman who has shown a great and practical desire to improve the position of the working miners of Great Britain, and give them the greatest possible amount of safety whilst following their employment. Such an offer cannot fail to find a good many competitors at the present time, when so much attention is being devoted to electricity for almost every purpose in which coal and gas have hitherto been the principal agents.

Aside from this premium, of course it is well understood that a great reward awaits the inventor of a miner's electric lamp, because so very many would be used. The London *Mining Journal* relates that already lamps have been tested in some mines where a good deal of gas is given off, and that with a fair amount of success for what may be termed first attempts. In such an application of electricity it is necessary that the light should be entirely cut off from all communication with the air surrounding the lamp, and for this purpose the Swan system has been found effective, for by it a number of the lamps can be placed singly in a circuit. The light from an electric lamp in a mine has been found to be equal to from 12 to 15 candles. The lights proceed from the incandescence of a fine fibre of carbon, the combustion of which is prevented by its being inclosed in an exhausted glass bulb. The lamps were inclosed in lanterns which enabled the fragile glass bulbs to be carried about without liability to accident. At one place where the lamp alluded to was tried it was particularly admired by the workmen for its brilliancy in whatever position it was placed, and requiring scarcely any attention whatever. The electricity was supplied by the current of an ordinary Gramme machine, driven by a portable engine placed near the top of the upcast shaft; but there is an easier method, no doubt, for it can be stored up and taken down in a mine and the lamp replenished as required. Seeing that the lamps at present in use not only give a very dim and dismal light, but have been credited with well nigh having been the cause of many of the fatal explosions which have taken place at different times, there is every likelihood that they will be replaced by those lighted by electricity, and that before long, and for this purpose the inducement held out by Mr. Ellis Lever cannot fail to be taken advantage of by those specialists who are now engaged in electrical investigation.

The Application of Electricity to the Prevention of Fire-Damp Explosions.—M. Léon Somzée, a Belgian engineer, has published a treatise on the prevention of fire-damp explosions which deserves careful attention. He says in substance: It is advisable to organize in every mine a special service charged with supervising and keeping a check upon the ventilation, and directing it, if occasion should require. It is indispensable that those set over this service should be constantly, instantaneously, and correctly informed as to the composition of the air in the mine at different points to be determined by practice, especially when lights are used and blasting is carried on, whatever be the variations of pressure and temperature. It is necessary that precise indications be obtained of even very minute quantities of dangerous gases; for it has been observed in England that a proportion of one and even one-twentieth per cent. is sufficient to render explosive the mixture of air and gas where there is coal-dust in suspension. In such a case we would go further and advance the opinion that a trace even of fire-damp is sufficient to bring about an explosion, having, as gas engineer, seen explosions occur in air containing dust of great fineness—explosions which were erroneously attributed to the presence of lighting-gas alone. It is desirable that every working place be put into communication with a central point of observation, either underground or on the surface, and be connected with the mechanism of the ventilator; that an alarm, in communication with the fire-damp, give notice of its presence through the engine-man or manager, by means of a mechanical action set up by the gas itself; and that the miners be also supplied with a warning appliance which shall force them to take precautions, or better still take the precautions independently of their will; to particularize that the presence of fire-damp in the mine in a state of danger be signaled by bells, not only to the miner, but throughout the colliery and on the surface, in the offices, and to the men tending both the ventilator and the winding-engines. Lastly, that measures be taken to regulate the ventilation instantaneously, and also to direct its effect wherever required, through a special ventilating gauge, receiving their orders from far or near by means of electro-motors.

Short of suppressing the cause which produces fire-damp, one of the most efficacious means for warding off mine accidents consists in preventing the mixture of air and gas from attaining the proportion which renders it explosive. In order to do this, it is necessary to be warned of the presence or slow invasion of this dangerous gas in the atmosphere of the mine; that is to say, to have precise indications of slight quantities of fire damp in the air. Various attempts have been made in this direction, but without success, on account either of the imperfect nature of the appliances or of their not being used properly. The best indication of fire-damp at present known is the safety-lamp; but unfortunately, when the state of the flame makes known the presence of this gas, its proportion is already so high in the air that the moment is not far distant when it may become explosive, owing to the presence of coal-dust. This fact alone would imply the necessity of seeking a practical indicator which shall permit of detecting slight traces of fire-damp in the air of the mine; and sensitiveness in revealing the presence of this gas ought to be the first condition in such an appliance. This is the problem which M. Somzée set himself to solve; and his studies ultimately resulted in two classes of instruments, one indicating and the other giving warning of minute quantities of fire-damp, or of carbonic acid. The first permits of ascertaining the precise quantity, even to the slightest trace, of deleterious or explosive gases entering into the composition of the air, and independently of the variations of the barometer and thermometer. It is based upon the principle of the difference of power possessed by gases of absorbing radiant heat, and is set up at any point in the mine, even in the most remote corners. As the safety-lamp is now generally used in collieries, M. Somzée has utilized it for furnishing the calls and indications necessary for keeping a check upon the ventilation. The modification consists only in the addition of a metal ring or band, expanding by heat and capable of closing an electric circuit for causing bells to ring; while there is nothing to destroy the elements of safety. In the portable miners' lamps, a small bell is contained in the case; but the fixed lamps are placed in electrical communication with bells in the office of the ventilation officer. The essential advantage of these warning lamps is, that they reveal fire-damp before the flame of the safety-lamp—even the Davy—makes known the ingress of this gas into the air. The elongation of the flame of the lamp, caused by the presence of fire-damp, is one of the principal properties the effects of which are turned to account in the construction of the apparatus. It affords certain variations of temperature at a given point in the lamp, where the increased heat, due to the gas, sets up a mechanical action which is practically utilized.

Another warning instrument of great sensitiveness, and working automatically whatever be the pressure and temperature of the atmosphere, is based upon the mechanical power of an osmotic current to give an alarm by bells placed in an electric circuit. It may be placed at different points of the advanced workings, and gives warnings to the ventilation officer of ten per cent. of injurious or dangerous gas at the place of observation, carried along by the air-current. In view of the future use of the electric light in collieries, M. Somzée also proposes, as warning instruments, and as means of preventing the mixture of air and gas from attaining dangerous proportions, electro-chemical appliances, based upon the reactions between different substances under the influence of the electric light, for giving calls from all the stations of observation. These lamps would not be for the general use of the miners, but would rather be stationary, or used only by inspectors and foremen. A last class of warning instruments consists in transforming the safety-lamp into a "singing-lamp" by the excitation of a sonorous tube placed over the flame. One tube only may be used; or two or more may give out different notes and come into operation one after the other, as the danger increases. One or the other of these instruments would be placed in well-determined and suitable positions in the workings, each station bearing a letter or number, while in a special office on the surface would be electric bells, with indicators, bearing corresponding letters or numbers, and surmounting a general plan of the colliery, showing the stations, with their letters or numbers, and also all the air-doors for directing the ventilation. Each warning appliance would be in electrical communication with its bells, and the air-doors would be furnished with contacts and connected by wires with the ventilation office, so that the employé might know that his instructions had been followed, and that all was in order for insuring a proper distribution of air. With such an arrangement, a glance at the indicator and at the plan would be sufficient to obtain cognizance of any danger, of its imminence, and the direction from which it threatens. At the same time, the bells in the safety-lamps would warn the miners to put out their lights and retire to a place of safety; or the lamps might be made to extinguish themselves before the critical moment arrives, and before extension takes place in the ordinary safety-lamp.

ACCIDENTS IN MINES.

THOUGH mining is always considered a hazardous work, the general public, and only too often also those engaged in it, have very erroneous ideas concerning the causes of the greatest mortality, and the many circumstances which affect the safety of miners. Accurate statistics, of course, furnish the best guide for an inquiry on the nature of accidents in mines, and furnish some indications as to the character of the measures to be taken to avoid their frequent occurrence. Still, they often furnish only a general result, without allowing precise assignment of the effect of many contributing causes. It is natural to suppose that accidents of one class will be more numerous and more fatal in periods of stagnation of the business; while others will rapidly increase when the state of the markets urges proprietors and managers to strain the capacity of their plant and their force to reap the benefits of round profits. High prices for timber may cause undue economy in protecting miners against falls, or lead to recklessness in robbing the supports in abandoned workings. When a mine is busy, little defects in hoisting arrangements or track will be ignored, and repairs will be left for the dull season. These are causes which often affect the mortality of large districts, and which statistics fail to reveal. Still, with such reservations, accident statistics furnish valuable hints, and certainly are instrumental in dispelling wrong impressions. They are valuable to mine proprietors and managers, both as placing the risks of their business in their true light before the public and as furnishing them a guide as to what dangers they must avoid. Unfortunately, such statistics are collected with care in a few countries only, the returns made by the Prussian government officials being the most elaborate, closely followed by those gathered by the English mine inspectors. In our own country, we possess no data relating to our metalliferous mines, the only figures approaching a high standard of value being those reported annually by the coal-mine inspectors of Pennsylvania.

As the most complete, we may present the statistics of accidents in Prussian mines first They are particularly valuable as showing how different is the proportion of fatal accidents in coal, lignite, and metalliferous mines. We have omitted the list of miscellaneous mines, including salt, slate, limestone, etc.

Fatal Accidents in Prussian Mines.

Year.	Coal.			Lignite.		
	Total number of men.	*Total ac-ciden al deaths.*	*Accidents per 1000 men.*	*Total number of men.*	*Total accidental deaths.*	*Deaths per 1000 men.*
1880	156,125	503	3.222	19,767	42	2.125
1879	149,552	444	2.668	18,627	40	2.147

Year.	Metalliferous.			All Mines.		
	Totol number of miners.	*Total ac-cidental deaths.*	*Deaths per 1000 men.*	*Total number of miners.*	*Total ac-cidental deaths.*	*Deaths per 1000 men.*
1880	67,174	97	1.444	250,294	650	2.597
1879	69,166	82	1,363	235,617	575	2.440
1878	59,848	92	1.537	232,064	542	2.336
1877	59,758	76	1.339	231,117	534	2.310
1876	53,657	61	1.696	240,865	600	2.491
1875	52,773	79	1.499	239,722	587	2.449
1874	55,468	60	1.082	243.155	591	2.431
1873	62,266	68	1.574	247,594	620	2.504
1872	63,493	110	1.732	227,520	564	2.479
1871	58,766	81	1.378	213,156	562	2.632
1870	55,044	79	1.435	133,532	469	2.555

These tables clearly illustrate the greater danger to life of working in coal mines, the average mortality per 1000 men employed, for the period of 1867 to 1880, having been 2·939, against 2·475 in lignite mines, and 1·430 in metalliferous mines. It is the custom to compute also the number of tons of mineral raised per accidental death; the average having been for a period of ten years in Prussia, 77,156 tons for coal, 197,810 tons for lignite, and 44,219 tons for ore. These figures, however, have no value for purposes of comparison, because the quantity raised per miner varies within very wide limits, according to the nature of the deposits, their location, etc. From the detailed statement of the causes of accident given by the Prussian officials, we compile the following table. The figures for the year 1880 show how the various classes of miners were affected. Where the number of accidents is small, of course one single catastrophe may alter the figures very materially. The averages for ten years of all the disasters are added, and they furnish a much better basis for deductions of a general nature. The figures are accidents per 1000 men employed.

Nature of Accidents in Prussian Mines.

Nature of Accident.	1880.			*Average of 1871 to 1880.*
	Coal.	*Lignite.*	*Metallif-erous.*	
Blasting	0.083	...	0.178	0.123
Falls of rock	1.204	0.162	0.566	0 957
On underground inclined planes	0.345	1.052	0.089	0.241
Ascending and descending	0.077	...	0.030	0.114
By falling in shafts	0.135	0.253	0.164	0.208
Miscellaneous in shafts	0.083	0.200	0.045	0.140
Transporting rock in tunnels and galleries	0.090	...	0.045	0.168
Fire-damp explosions	0.576	...	...	0.186
Bad ventilation	0.231	...	0.030	0.076
By machinery	0.077	0.051	0.060	0.068
Water	...	0.253	...	0.030
Above ground	0.256	0.101	0.104	0.174
Not above numerated	0.065	0.051	0.134	0.080
Total	3.222	2.125	1.444	2.465

This table strikingly shows that in all classes of mines, collieries not excluded, falls of rock are the most disastrous source of accident, and that in coal mines they far outnumber the explosions, which are popularly looked upon as such a terror to the miner, while in fact they inflict much greater loss, comparatively speaking, upon the operators. This class of accidents is, of course, more than any other, subject to sudden variations, as the following figures of the deaths in Prussia per 1,000 employés will show:

1880	0.359	1875	0.117
1879	0.221	1874	0.144
1878	0.194	1873	0.166
1877	0.095	1872	0 149
1876	0.112	1871	0.282

An interesting set of figures is given as bearing on the comparative danger of ascending and descending into mines by shafts, by ladder, man-engine, or cage. They cover an average of ten years:

	Ladders.	*Man-engine.*	*Cage.*
Men mining	739,424	71,910	640,710
Number killed	75	41	74
Number killed per 1000	0.101	0.570	0.115

This proves that hoisting the men out of the mines is nearly as safe as the use of ladders, while man-engines are the most dangerous. This, of course, refers to well equipped hoisting-works, carefully watched, which, so far as safety is concerned, compare as favorably with many of the buckets hanging from a rope in our Western camps as a flight of marble stairs to a Mexican notched stick of timber. With that thoroughness which is characteristic of the work of German officials, the mine inspectors of Prussia gather annually a series of statistics which we believe are unique, and the importance of which is not less than the data gathered on accidents terminating fatally. The following figures give the number of accidents in Prussia in 1880 resulting in injury involving a suspension of work of one month or more:

Injuries in Prussian Mines in 1881.

Nature of Accident.	*Per 1000 men employed.*			*Total Average.*
	Coal.	*Lignite.*	*Metalliferous.*	
Blasting	1.839	...	0.521	0.671
Fall of rock	5.637	1.265	1.786	4.111
In underground inclined planes	0.711	0.051	0.119	0.479
Ascending and descending	0.160	0.051	0.149	0.144
Falling in shafts	0.077	0.152	0.830	0.084
Other accidents in shafts	0.198	0.202	0.223	0.200
Transporting rock in tunnels and galleries	0.211	0.708	0.486	0.486
Fire damp explosions	0.717	0.050	0.445	0 445
By machinery	0 243	0.405	0.228	0.228
Above ground	1.057	0.556	0.907	0.907
Not above specified	1.165	0.506	0.927	0.927
Total	12.932	3.946	4.615	9.701

Here, too, the overwhelming preponderance of accidents by falls of rock is fully illustrated, and it may be of interest to note that of the 1029 men thus injured, 108 were totally incapacitated for work, while 921 were able to return after a suspension ranging from one to six months. Taking all the accidents together, 2428 men, out of 250,294 employed, were injured so gravely that they could not go to work in less than a month, and of this number, 211 were made invalids for life.

The statistics collected by the mine inspectors of Great Britain since the year 1851 are somewhat different in form, and some data are added which fully confirm conclusions which it would be natural to draw from the occurrence of certain classes of accidents. The British mine inspectors are careful to enumerate both the number of accidents and of deaths. As might be expected, these figures show that, while the number of fire-damp explosions is small, they usually cause many deaths, while the other accidents show a much lower mortality. Beyond this fact, the figures relating to the number of accidents, and not to the number of deaths, show little that is not better studied from the tables giving the latter.

Comparison of Fatal Accidents and Deaths in English Coal Mines.

Accidents and Deaths.		*Fire-damp.*	*Roof falling.*	*Shaft.*	*Miscellaneous Underground.*	*Miscellaneous Surface.*	*Total.*
Average for ten years ending 1860.	Accidents.	82.0	361.1	183.7	100.3	46.8	773.9
	Deaths	244.1	376.7	211.9	118.6	50.5	1,001.8
Average for ten years ending 1870.	Accidents.	56.5	403.1	133.3	156.1	73.8	822.8
	Deaths	226.7	416.3	150.5	191.6	77.5	1,062.6
Average for ten years ending 1880.	Accidents.	42.4	436.7	120.8	175.5	87.2	862.6
	Deaths	268.6	450.8	135.5	190.2	89.8	1,134.9

The British mine inspectors calculate the ratio of persons employed to each death, a method which does not so strikingly show the variations, because it must be remembered that greater safety is indicated by higher figures, while the ratio of deaths per 1000 persons employed indicates at a glance an improvement or a decline. The following are the figures for the mines classed under the coal mine act, including some fire-clay, ironstone, and shale mines:

Accidents in English Coal Mines.

Ratio of persons employed to each death.

Year.	*Fire damp Explosions*	*Fall of roof*	*Shaft.*	*Miscellaneous under ground.*	*Miscellaneous surface.*	*Total.*
1851–1860	1,008	653	1,161	2,074	4,872	245
1861–1870	1,408	766	2,121	1,666	4,119	300
1871	1.378	852	3,015	2,107	5,151	345
1872	2,914	916	2,697	1,926	5,360	394
1873	5,122	1,043	2,995	2,317	5,955	479
1874	3.245	1,304	3,498	2,517	4 943	510
1875	1,860	1,167	3,115	2,360	5,467	430
1876	5,416	1,145	3,988	3,453	4,635	551
1877	1,433	1,103	3,832	2,643	5,014	409
1878	811	1,013	4,282	2,952	5,527	336
1879	2,591	1,110	3,973	2,772	6,715	490
1880	971	1,049	5,329	2,724	5,510	368
1881	4,271	1,101	4,504	2,607	5,630	519
Ratio of deaths per 1000 persons employed.						
1851–1860	0.992	1.441	0.861	0.482	0.205	4.072
1861–1870	0.710	1.304	0.471	0.660	0.211	3 328
1871–1880	0.557	0.933	0.281	0.394	0.109	2.353

The upper table well illustrates the fluctuations which accidents in mines, and notably those due to fire-damp explosions, are subject to. The lower sets of figures will probably best show at a glance what the result of thirty years of steady improvement in methods of mining, in machinery, in appliances, and in administration, have done in British coal mines, in the face of the fact that underground workings have grown enormously in extent, that shafts are deeper, less numerous, and are, therefore, the scene of wonderful activity. The averages of long periods only can efface fluctuations, which are only too natural, and present the general result so clearly proved in these figures.

The accident statistics for the mines classed under the British Metalliferous Mines Regulation Act unfortunately do not cover so long a period, having been gathered with accuracy only since 1874. Still, as the main cause of great fluctuations, fire-damp explosions, are absent, the briefer period may be accepted as showing the course of events fairly:

Deaths caused by Accident.

Year.	*Falls of ground.*	*In shafts.*	*Miscellaneous underground.*	*On surface.*	*Total.*	*Persons employed.*		*Rate of deaths per 1000 men employed.*
						Per fatal accident.	*Per life lost.*	
1874	40	34	15	14	103	599	547	1.827
1875	32	35	33	19	119	528	488	2.049
1876	25	16	23	6	70	871	821	1 217
1877	41	21	24	11	97	659	501	1.690
1878	27	19	23	8	77	695	668	1.496
1879	24	16	16	8	64	771	735	1.3[illegible]0
1880	31	21	19	13	84	645	630	1.589
1881	36	22	32	9	99	646	555	1.802
Average	32	23	23.1	11	89.1	661	611	1.636

In Great Britain, too, the danger to life is less in metalliferous mines than in coal mines, and in both, falls of ground are the most prolific source of accidents. On the whole, the elaborate statistics quoted are encouraging, especially when it is considered that many circumstances influence progress adversely. A good deal of the improvement is probably due also to the higher grade of intelligence among the miners, although it is probably in the direction of greater care on their part that the chances of further improvement must principally rest.

—*Engineering and Mining Journal.*

FIRES IN MINES; THEIR CAUSES AND THE MEANS OF EXTINGUISHING THEM.

FIRES in mines are so serious in their consequences and of such frequent occurrence, that their causes and the means of extinguishing them are certainly questions of the greatest interest to a large part of the engineering profession. We have already in this country many mines which have been burning for years, and though our hard anthracite is so difficult to ignite that for a quarter of a century after it was first discovered it was not known how to burn it except with the aid of an artificial blast, yet most of the fires which have occurred underground have been in anthracite mines, and in the coal itself. The injury which these fires have caused to properties in various parts of the anthracite regions, and the cost of extinguishing them, would amount to many millions of dollars, and they have also occasioned the loss of many valuable lives. It is not surprising, therefore, that the subject has already attracted much attention, and the exercise of great ingenuity; and the present communication is made less with the expectation of announcing anything new, than with the object of putting upon record the present state of our knowledge upon this subject, or, in other words, of indicating how defective are the present means of combating underground conflagrations.

Causes of Mine Fires.—Even upon the surface, fire is a terrible foe to contend with, and there is probably no other which inspires such thorough and well-founded alarm. With what feelings, then, must we look upon this destructive element, when its field is in the narrow galleries of a mine where the poisonous products of combustion, spreading in every direction, protect, in the most effectual manner, the fire itself from the attacks of extinguishers, while, if the face of attack be ventilated so as to enable them to approach the seat of the fire, the air current simply increases the extent and violence of the conflagration. Fires underground originate in as various ways as those on the surface, and it is scarcely necessary to say that, except in the rare cases where they are the result of design, they are invariably classed as "accidents," and most generally as "unavoidable accidents." In reality, by an intelligent understanding of their causes and with due precautions, they can almost always be prevented. Ignorance and carelessness are their chief causes, and they are generally "unavoidable accidents" only in so far as ignorance is an accident, or carelessness unavoidable. Moreover, what, according to the light we possess to-day, may be styled an "accident," will, it is to be hoped, be rendered avoidable as the increase of our knowledge gives us a better insight into causes now hidden. I will mention some of the more common immediate causes of mine fires, and then speak of the means adopted to prevent fires, and those employed to extinguish them when they have occurred.

It is now happily a rare thing that a mine is ignited through malice or design. The most ignorant and vicious of those who work about them understand too well the enormous injury that is occasioned, to all who live in the district, by a mine fire to indulge in it as a measure of revenge for real or imaginary personal injury. It is not the owner of the mine who is the only, or in most cases, the principal loser. The efforts made to extinguish it are very frequently, we may say generally, accompanied by the loss of the lives of some of those engaged in the work; and during its continuance, which, in many cases, extends through many years, the regular work of the mine is suspended, and the workmen with those dependent, directly or indirectly, on their labor for the means of living are the chief sufferers. Still, rare cases do occur where a vicious individual is so blinded by what he considers injustice or oppression as to overlook the injury he brings upon innocent parties, and to seek revenge in this manner. In the so-called "good old days," before the rights of our neighbor were as well defined or as much respected as they are to-day, fires from this cause were not unfrequent; but as the mines were usually small, the extent of the injury done was limited. An example of one of these ancient fires, and, we believe, the only one, in Belgium, which continues burning from the olden time to the present day, is that in the vein known as the *Grande Masse de Falizolle.* This bed, Ponson tells us, was worked in a piratical way, above water-level, in a hill near Falizolle, between Namur and Charleroi, by the inhabitants of the neighboring country. The quarrels that even in those early days sometimes existed between neighbors were not forgotten when they went below ground, so when the drifts in which they worked happened to meet it was made the occasion for a regular battle, and those that heaven helped with a favorable wind were not slow in taking advantage of the blessing to smoke out their neighbors by burning pieces of old leather on a fire built in some *safe* place in the galleries. On one occasion, about the year 1822, while indulging in this harmless, but effective, method of disposing of their enemies, the coal in the mine became ignited, and has since continued to burn, excluding both sides of the fight from the benefits of free coal. Many attempts have been made to extinguish this fire, but owing to the position of the bed, near the surface and above water-level, it has been found impossible to control it.

In this country, in the anthracite regions particularly, many fires whose origin is unknown, have been attributed to design. In the majority of cases the cause was probably carelessness, though in some rare instances the malice of men on strike, who have had, or thought they had, some grievance, has doubtless been the origin. Among the mines that have been on fire for a great many years may be mentioned the Summit Hill Mine, near Mauch Chunk, the Greenwood Company's Mine, near Tamaqua, and some others in Schuylkill, Carbon, and neighboring counties of Pennsylvania. Some of these fires have now been burning upwards of twenty years. The causes of most of these are shrouded in mystery, but they are probably due to carelessness or spontaneous combustion. Carelessness is by far the most frequent cause of mine fires. A workman will leave his candle, or lamp, attached to a piece of timber in such a manner as to finally ignite it, as was the case in the great fire in the Yellow Jacket Mine of the Comstock Lode, in 1875. A fire basket will sometimes be hung so near the coal or timber as to set it on fire. Smoking in the stables underground has occasionally been the cause of conflagrations by the fire from a pipe falling among the straw and litter. It was from a lamp igniting a bundle of straw in the shaft that the West Pittston disaster occurred, by which 20 persons lost their lives. In a word, carelessness acts through about the same channels below ground that it follows above, though the field for its operation is more restricted in the mines and its effects are more disastrous. If a miner, going into a portion of the mine in which fire-damp has accumulated, with a safety lamp in his hand and *an open light on his hat,* as has been done on many occasions that are well authenticated, the resulting explosion and fire can scarcely be considered as accidental, any more than can the equally well-authenticated case of a man blowing himself up by firing the open keg of powder, from which he was filling a cartridge, by the burning oil dropping into it from the open lamp on his hat. Incredible as these cases of carelessness may seem, they are by no means isolated occurrences, but we have heard, from the very best authority, of several instances of each.

Ignorance is a scarcely less frequent cause of fires in mines than carelessness; indeed, it is difficult to say just where the one ceases and the other begins. It is frequently not altogether carelessness that causes the fire when a miner hangs his lamp so near the coal that it finally ignites it; he may not know that the heat of the lamp, not in itself sufficient to ignite the coal, may liberate and ignite the highly inflammable gases, and thus communicate the fire to the solid coal. Nor is it always carelessness that causes a fire by throwing away among the "gob" the oil-saturated cloth, or the cotton "waste" that has dropped from the oil-box of a mine wagon. He who threw it away among the fine coal may have been ignorant of the fact that the heating which comes from the decomposition of iron pyrites, and from the slow combustion of carbon in a comminuted state, though it may be insufficient to ignite coal alone, may be quite sufficient to ignite the oil-saturated "waste," already heated by the oxidation of the oil. There are few of the mine superintendents, not to mention the miners, who have any knowledge of the very important influence which coal-dust has upon the explosiveness of mixtures of fire-damp and air, or of the causes of spontaneous combustion of coal and wood; and while exercising the utmost care required, as they believe, they may, in ignorance, be doing or leaving undone, things which result in a fire—a fire that is then said to be "purely accidental," and which it was "impossible to foresee or prevent."

Nearly every fire that occurs in a mine is said to be an "unavoidable accident," and so far as an accident is "an event that takes place without one's foresight or expectation; an event which proceeds from an unknown cause," most fires may be so designated; but the ignorance which makes them, in this sense, "accidents," is not unavoidable, and should not exist. I have frequently seen the fire-pot, or grate, that stands near the foot of almost every shaft in the anthracite coal regions in winter, placed so close to the solid "rib" of coal, as to heat it far beyond a safe temperature; and before leaving the mine, at the close of the day, coal would be piled upon it, in order to have it burning well in the morning. A change in the direction of the wind, or in the temperature at the surface, is sufficient to increase the draught, and fan up the fire to a furnace-heat; is it surprising, then, that several fires in our mines have been traced to this cause?

Underground boilers are a cause of mine fires still more fruitful than that just mentioned. The number and extent of the conflagrations due to this kind of "accident," in Pennsylvania, are enormous. In the immediate vicinity of Wilkes-Barre, Pa., alone, they have cost the companies millions of dollars. One would suppose that the enormous losses inflicted by such fires would have absolutely prohibited the use of the boilers or furnaces in coal mines, yet there are many of our mines still ventilated by furnaces, and not a few that have boilers underground. The fire in the Avondale Colliery, in which one hundred and ten persons lost their lives, was occasioned by a ventilating furnace. Wood was used in lighting up the fire, and the sparks from this were carried up into the wood-bratticed upcast shaft, igniting it and the "breaker" building which stood over the shaft. As the mine had but this one outlet, the one hundred and eight persons at work in it (and two volunteers, who subsequently entered it), were suffocated before they could be rescued. In this, as in nearly every case, the furnace was thought to be "perfectly safe;" it was at some distance from the shaft, and had been in use for some time without "accident" of this kind. The mine did not produce fire-damp, and, consequently, one source of danger was eliminated. In fiery mines when the air for the furnace is taken from the return air courses, there is introduced a source of accident of a very serious character. It is probable that even when the return air is not, in itself, explosive, it may become so by the presence of a very small quantity of coal-dust; and it is well known that, even without the presence of fire-damp, the finely comminuted carbon, whether soot or coal-dust, is very easily ignited, and this has, probably, been the cause of more than one of the mysterious fires that have occurred in our anthracite mines. Such a case was that known as the Empire Mine fire (Lehigh and Wilkes-Barre Coal Company), near Wilkes-Barre, Pa. The fire originated in an abandoned chamber, from which the coal had been taken, and which was made to serve as a flue for the smoke from a set of underground boilers. It is supposed that the soot collected in this large chamber, and became ignited from a spark, or that pieces of wood, dried to tinder, caught fire in the same way; in either event, the furnace was considered "perfectly safe," and yet it resulted in a fire that cost more than half a million dollars to extinguish. The great difficulty experienced in igniting anthracite coal, when it is desired to burn it, is relied on too implicitly as a safeguard against fire; and this misplaced confidence leads to the introduction of risks that would never be admitted in a bituminous coal-mine. I have frequently seen both ventilating and boiler furnaces separated from the solid coal by but a thin brick wall, and a few inches of space. The boilers which are always of the plain cylinder type, fired externally, are usually covered with a thin bed of sand, and a crack in the brickwork, or a hole through which the sand can run, may allow the fire free escape to the solid rib, or to the roof, that in some instances is a carbonaceous shell.

When the roof is not very solid it is frequently supported, over the boilers, on heavy timbers; and it is not unusual to find a mass of timber, that the heat has made as inflammable as tinder, supporting the roof only a few feet above the boilers. A single spark may ignite the mass, and the matter of surprise is, not how the fires originate in such mines, but how these so often or so long escape being burnt up. The fire which has now been burning in the Baltimore Mine, near Wilkes-Barre, for two years, and the efforts to extinguish which are said to have cost already nearly three-quarters of a million of dollars, was caused from underground boilers. These were, as usual, "perfectly safe," but the blast of air occasioned by a heavy fall of the roof in the vicinity, forced the fire from under the boilers and ignited some timber under the fall. As the cave extended over several acres of ground, and as the vein was above water-level and near the surface, to which the rock broke through, there was no means of getting at the fire, or of extinguishing it with water. That part of the mine had to be walled off by brick or earth walls, and, doubtless, the fire will continue in the portion "caved in" for many years to come. Underground boilers and ventilating furnaces have probably occasioned more fires than any other cause, at least this is the case in the anthracite mines of Pennsylvania.

Explosions of Fire-damp.—Not many years ago, while the Pennsylvania mines were worked along the outcrops of the coal-beds, it was commonly stated that anthracite did not yield this dangerous gas, but the mines were carried below water-level to a constantly increasing depth, but that some of the most fiery mines in the world are in this hard coal. The hardness of the coal is so great as to require the use of explosives to break it down, and it is not an uncommon thing for a vein to yield fire-damp in such enormous quantity as to ignite at every shot in headings driven out into the solid. At the Prospect shaft, near Wilkes-Barre—probably the most fiery mine in the coal field—the make of gas has been so rapid that with a current of air from 20,000 to 30,000 cubic feet per minute, passing through the gangway (12 feet wide by 7 feet high), it was impossible to proceed more than ten feet beyond the cross-heading connecting the gangway and parallel airway, without putting in bratticing to carry the air up to the face—or with such bratticing (dividing the gangway into two parts, each 6 feet by 7 feet), the velocity of air current being from 500 to 600 feet per minute—the gas would ignite at the face when the distance from the face of the gangway to the bratticing was more than fifteen feet. With such a prodigious discharge of carburetted hydrogen almost every blast would ignite it, and if the promptest measures were not taken, the coal was quickly aflame. The heat of the burning gas always tends to draw still more gas from the coal, and the longer the fire continues the more fiercely it burns and the more difficult it becomes to extinguish it. A number of fires have occurred in this and other collieries in the same field from this cause, and that notwithstanding all the efforts that it was thought possible to make to extinguish the fire. With a sudden fall of the barometer, or the striking of an unusually strong blower, the fire would gain the mastery, and several of the mines have had to be filled with water to extinguish the conflagration. There is still another and more mysterious cause of fires in mines, viz., spontaneous combustion. As this important cause of fires is but imperfectly understood by those in charge of our coal-mines, and as it is a matter whose interest and practical application are not confined to fires in mines, I shall enter with some detail into the subject. It may be remarked, at the outset, that what is known as "weather waste," is but a mild form of spontaneous combustion; we may, therefore, treat this part of our subject under the title of

Spontaneous Combustion and Weather Waste of Coal.[1]—Coal is a very complex substance, and though one with which we have long been very familiar, and which we make use of by oxidizing (burning), the subject of the exact conditions under which its oxidation takes place has received but little attention, and is, even yet, but imperfectly understood. We all know that at a high, but variable, temperature, the carbon of coal combines with the oxygen of the air, and forms carbonic oxide, or carbonic acid, as the case may be; but there are few who know at what temperature this absorption of oxygen commences, or what conditions facilitate it at a low temperature.

We are principally indebted to Professor E. Richters, of the Mining School at Wallenburg, for knowledge, so far as it goes, of this interesting and important subject. He has determined that at the ordinary temperature coal left in contact with oxygen, either pure or mixed with nitrogen, as in atmospheric air, absorbs oxygen, of which one portion combines with carbon and hydrogen, forming carbonic acid and water respectively, while another portion enters into an unknown state of combination with the coal, and proportionately increases its weight. Berthelot[2] has succeeded in demonstrating the fact that coal can be hydrogenized also, at a temperature not exceeding 527° Fahr. In absorbing hydrogen, in the experiments of M. Berthelot, as much as two-thirds of the coal was converted into liquid hydrocarbons of the petroleum class. On the other hand, we know that all coals, when freshly mined, give off a very noticeable amount of a hydrocarbon gas. In some mines, even in the hard anthracites of Pennsylvania, the escape of occluded gas is so energetic as to make a hissing or singing sound, that is easily recognized. This discharge of gas continues for a very considerable time, probably several weeks in some cases, after the coal is removed from the mine. In proof of this we have the record of a great number of explosions on vessels loaded with coal, and even with anthracite, days, and sometimes weeks after it was mined. It has also been ascertained that all coal, or at least all bituminous coal, and above all those soft varieties that are rich in volatile matter and poor in fixed carbon, lose a large part of their volatile constituents by exposure to the action of the atmosphere, especially when the coal is in a finely comminuted state, and is exposed to a high temperature and moisture. The gas thus evolved varies, both in quantity and in composition, according to the nature of the different coals; it contains carbonic acid, oxygen, nitrogen, marsh gas, ethyl hydride (C_2H_6), gases absorbable by sulphuric acid, and sometimes a small amount of carbonic oxide. By far the most abundant of these gases is free nitrogen, and as this has never been certainly proved to result from any natural process of decay, it is probably derived from the atmosphere.

This view seems to be confirmed by Richter's investigations on the weathering of coal, from which he concluded that more oxygen is absorbed from the atmosphere in weathering, than suffices to oxodize that portion of the carbon which is evolved in the state of carbonic acid. A portion of the balance, probably, combines with the hydrogen to form water, and another portion enters into an unknown state of combination with the organic substance of the coal, and still another portion is consumed in oxidizing the iron pyrites which are almost always found in coal. M. Marsilly (see *l'Eclairage du gas* de R. d'Harcourt) found that the long flaming coals, free from fire-damp, of the Grand Hornu, Belgium, when heated to 350° Cent. (662° Fahr.) evolve nitrogen to the extent of 31.83 to 44.27 cubic inches per lb. of coal, and one kilog. (2.2 lbs.) of *fat fiery caking coal* at the temperatures indicated gave off the following quantities of gas:

Degrees Cent.	*Degrees Fahr.*	*Litres*	*Cubic inches*	*Gas.*
70 to 150	158 to 302	0.46	28.07	Uninflammable gas.
150 to 180	302 to 356	0.2	12 21	Gas yielding a blue flame.
180 to 250	366 to 482	0.9	54.93	" a long illuminating flame.
250 to 300	482 to 572	0.51	31.12	" a longer and brighter flame.
300 to 325	572 to 617	0.5	30.51	" a still longer and brighter flame.
325 to 350	617 to 662	.0.23	14.04	" a very long and brilliant flame.

Marsilly concludes that coal impregnated with fire-damp gives off from 1 to 2 per cent. of uncombined hydrocarbons, below 626° Fahr., and the coal then completely loses its caking properties. These are the coals which deteriorate when exposed to the air in heaps. The long flaming dry coals, at 527° Fahr., evolve but little nitrogen, a circumstance which distinguishes them from the fiery coals. Heated from 572 to 1013° Fahr. (545° C.), they do not give off gas, and are not much affected by exposure to the air. Freshly mined coal is acted on most energetically by the oxygen of the air, and though, according to Richters, coal never entirely loses its power of absorbing oxygen, that power constantly diminishes by exposure to the air. According to the same authority, when coal is heated from 180° C. to 200° C., it at first gains in weight, more oxygen being absorbed than the weight of carbonic acid and water evolved; but on continuing this temperature, after a time both the weight and chemical composition of the coal will remain constant,(?) and the relation in weight which then obtains between its hydrogen and oxygen is that in water, from which it is inferred that the oxygen which combines with the carbon is evolved again as carbonic acid, and that, consequently, with the disappearance of the disposable hydrogen, the permanent absorption of oxygen should cease. It has also been found that the quantity of oxygen absorbed by different coals, under the same conditions, is proportionate to the quantity of water they absorb, which last does not appear to depend on the physical structure of the coal, compact bright coals sometimes absorbing from two to three times as much water as very loose, soft, and tender schistose coals; but coal from the same seam over a wide area absorbed the same proportion of water. This characteristic may prove to be of such general application as to afford valuable assistance in the identification of coal-beds where the measures are disturbed by faults, etc. Richters also found that coal absorbs three times as much carbonic acid as oxygen in a given time, and under the same conditions; and even coal that has been weathered till it will scarcely take up any oxygen will quickly absorb its own volume of carbonic acid. Numerous experiments seem to prove that sunlight always lessens or retards the absorption of oxygen by coal; a fact that may, in part, explain the generally admitted phenomenon of coal or wood not burning so well in the sunlight as in the shade. That some coals are capable of spontaneous ignition when allowed to accumulate in the form of dust or slack, and, sometimes when subjected to heavy pressure in the pillars of coal-mines, is a well-known fact; but to what this property is due has always been an open question, though it has usually been attributed to the decomposition of iron pyrites in the coal and shales accompanying the coal. The atmospheric oxidation of iron pyrites, by which the sulphurets are changed into sulphates, is a comparatively slow process; and, though undoubtedly capable of developing a large amount of heat in a confined area, it does not account for the majority of well-substantiated instances of spontaneous ignition of coal, both in the mines, on board ship, and in stock-yards. Richters has shown conclusively that the coals most liable to spontaneous ignition are not those which contain the largest percentage of iron pyrites, but that this property is principally due to the atmospheric oxidation of the organic substance of the coal. The following table gives his classification of eleven varieties of coal, according to the degree of their self-inflammability:

Table of Coals arranged according to Degrees of Self-Inflammability.

Degree of Self inflammability.		*Iron Pyrites. Per cent*	*Water Per ct.*	*Character of the Coal.*
CLASS I.—Difficulty self-inflammable. . .	1	1.13	2.54	Easily friable.
	2	1.10 to 3.04	2.75	Very compact.
	3	1 54	3.90	Very compact.
CLASS II.—Of medium self-inflammability. .	4	1.20	4.53	Firm, schistose, bright.
	5	1.08	4.55	Hard, but very brittle.
	6	1.15	4.75	Moderately tender.
CLASS III.—Readily self-inflammable. .	7	1.12	4.85	Outwardly very like No. 1.
	8	1.00	9.01	Modera'ly tender, schistose
	9	0.83	5.30	Moderately soft, schistose.
	10	1.35	4.85	Moderately soft, schistose.
	11	0.84	5.52	Not stated. Yielded only 2.5 per ct. of ash. From the same pit as No. 10, but from a different seam, are markable for its greater self-inflammability

[1] Many of the data relating to this subject will be found in the last edition of Percy's Metallurgy, 1875.

[2] Ann. Chim. Phys., 1870, and Bulletin Soc. Chim.

From the above-mentioned facts, which express the results of the latest and most reliable observations and direct experiments, somewhat contradictory as some of them seem to be, we may deduce many valuable practical lessons. Many varieties of coal deteriorate to a great extent when exposed to the air, and this deterioration is greatly favored by high temperature, and, in coals which contain sulphurets of iron, by moisture; in coals free from iron pyrites, this oxidation seems to be even more energetic when dry than when wet. It is always greatly increased in all kinds of coal by increase of temperature, and is more energetic when the coal is in dust or slack. This deterioration of coal has been aptly termed "weather waste." It is, as we have seen, not dependent solely on the physical character of the coal, though the harder the coal the less it is injured, and, in some cases that have come to my own knowledge, an exposure of eight or ten years of certain Lehigh anthracites had not affected the quality to any extent that could be appreciated in its subsequent use in blast-furnaces. In the case of coking and gas coals, however, the depreciation in the heating power, and in the coking and gas producing properties is very great; indeed, a very moderate exposure to the air, in heaps, at a high temperature and when moist (for these coals, for the most part, contain more or less iron pyrites) frequently entirely unfits them for use. A recent example suggests itself, in which a large amount—several thousand tons—of Albertite (a rich gas-producing mineral quite free from sulphur) was piled on dock in Boston. So rapid was the absorption of oxygen by this so-called coal that it heated and actually fused, running together round the edges of the pile, and finally even ignited. Its value as a gas coal was almost entirely destroyed.

The spontaneous ignition of coal is, doubtless, greatly facilitated by, though not altogether due to, the presence of iron pyrites; for the oxidation of the iron pyrites is attended with considerable development of heat, and by swelling, it splits up the coal, and renders it more pervious to oxygen. The real cause of spontaneous ignition is probably the oxidation of the organic substance of the coal; it is, in fact, a very energetic example of weather waste, and the precautions to take in each case are the same. In mines the crushing of the pillars, where they are left too small, and their gradual spalling off, from the oxidation of the coal and pyrites in the coal, cause an accumulation of fine coal around the pillars; this and the fine coal thrown back into the "gob" along with the shales (which contain most of the iron pyrites) and other rubbish, form exceedingly favorable conditions for spontaneous combustion. There is usually enough oxygen in the air of the goaves to support this slow combustion, while the velocity of the air current is not sufficient to carry off the heat, and thus prevent the weather waste from developing into spontaneous ignition of the coal. Spontaneous combustion is by no means confined to coal, but pieces of wood imbedded in the coal-dirt, rags or cotton waste saturated with vegetable or animal oils, are very subject to it; in fact this is the cause of a great number of fires on the surface as well as in the mines. As an instance of the facility with which cotton, saturated with oil, will ignite, I may mention a curious case that came under my observation some years ago. Two or three men were severely burned by an explosion of a powder-mill at Wilkes-Barre, Pa., and the remedy applied by the kind-hearted neighbors was to envelop the patient in cotton padding, saturated with linseed oil. They were greatly astonished to find that the heat of the body, after a time, ignited the cotton and oil, and the victim of well-meaning ignorance was with difficulty saved from cremation. Many of the unaccountable fires in the mines, both in anthracite and bituminous coal, are undoubtedly due to spontaneous combustion, either of the coal itself, in some of the bituminous coals, or, more frequently, from the more energetic spontaneous combustion of oiled "waste" or other easily inflammable substance. The fire that has now been burning since August, 1871, in the No. 6 tunnel, Summit Hill mines (Lehigh Coal and Navigation Company), is supposed to have been caused by spontaneous combustion, originating in the gob or rubbish in some abandoned works where the ventilation was very slack. It is exceedingly doubtful if our hard Pennsylvania anthracite will ignite spontaneously, even when they contain considerable quantities of iron pyrites, but it is an incontestable fact that piles of culm or coal-dirt, on the surface, in many parts of the anthracite regions, have ignited spontaneously. I attribute the ignition to the presence of the more inflammable rags or cotton-waste saturated with oil, or simply to oil saturating the fine coal, as can readily be conceived may occur in almost every pile of coal-dirt around a colliery. Many of you have, doubtless, frequently noticed the heating of culm-banks, but it is rarely that one actually ignites, which tends to prove that the anthracite coal itself, even in the form of dust, will not ignite spontaneously, but that the accidental presence of a more inflammable substance may readily cause a fire. Soot from anthracite coal, or indeed from any kind of coal, is less inflammable than ordinary lampblack, which ignites with such facility that even a few drops of water, oil, or other moisture falling in it, is liable to cause its ignition by the rapidity with which it absorbs oxygen, as several fires in lampblack factories in different parts of the country have proved. It is well known, also, that powdered charcoal will absorb oxygen from damp air so quickly as to ignite spontaneously; is it possible, therefore, to overestimate the danger of using chambers in the coal flues for underground furnaces? If it be necessary, which is rarely if ever the case, to have boiler or ventilating furnaces in a coal-mine, it is no more than ordinary prudence to line the flues with brick throughout, and take even greater precautions than would be taken in houses on the surface.

Means Adopted for Preventing Mine Fires.—Having thus reviewed the principal immediate causes of mine fires, it remains for me to mention the means adopted to prevent these causes from producing their natural effects, and finally to investigate the means of extinguishing fires when they do occur. The mere mention of the causes of mine fires suggests, in most cases, the preventives to apply. Where the cause is carelessness there must be strict and judicious rules and careful inspection, this will prevent many of these and other accidents that make the miner's calling a somewhat dangerous one. Ignorance of the nature and full bearing of the immediate causes we have just mentioned is the ultimate cause of most "accidents." Carelessness is usually, though not always, the result of ignorance of the results that may spring from the careless act. For example, it is too often either not known, or if known, not fully appreciated, that though the wood over the boilers is not at first easily ignited, and the new setting of the boilers allows no undue escape of heat and sparks, yet the wood in time becomes like tinder, and the walls supporting the boilers are liable to crack, and the accummulation over the boilers of coal-dust, and possibly light wood-fibres, from the timber supporting the roof, create a constantly increasing danger. The fire that results from these favorable conditions can scarcely with propriety be called accidental, though that term may satisfy the unquestioned faith of that patient and exemplary class, the stockholders of the mining company.

In fiery mines the practice of shot-firing is the cause of many explosions and fires. In anthracite coal it would seem at present as if the use of some explosive were absolutely essential for the economical getting of the coal, yet substitutes for explosives have been proposed and are actually in use for many purposes, but no effort seems to have been made by the owners of fiery anthracite mines to investigate or test such substitutes, or to encourage the invention of others. They seem to rest satisfied with taking the precautions which experience has shown to be sufficient, in most cases to control and extinguish fire when once ignited, but which experience has also fully demonstrated to be unequal to some emergencies, or to be subject themselves to unavoidable accidents. Of course it is in but comparatively rare cases that underground boilers, or ventilating furnaces, or powder shots result in fires, but the enormous loss incident to a mine fire makes the risk from these rare cases much too great to be undertaken by prudent managers; and so far at least as underground boilers and ventilating furnaces are concerned they are quite unnecessary risks. Steam can be carried to considerable distances (say 1500 to 2000 feet) through properly protected pipes, without any very great loss of condensation. Boilers on the surface are much more enconomical in installation, and in running expenses, as generally to compensate for this loss of steam; and where steam cannot be used—and in most cases where it can—compressed air forms a perfectly safe and equally efficient means of transmitting power. Compressed air is not an economical motor as compared with the direct use of steam, but it is a safe and convenient one for mine use, and after its use in the underground engines it serves for ventilation, while the exhaust steam is exceedingly injurious to the timber, and in some cases, to the roof-rock of the mine. Wire ropes can also be employed to advantage in some cases for the transmission of power in mines. Mechanical ventilators have been shown to be almost always more economical, and in every case more efficient, reliable, and safer than furnaces for mine ventilation. There is consequently no necessity for incurring these risks of enormously costly conflagrations. As already stated, the danger from spontaneous combustion of the coal in mines may be overcome either by a ventilation so active as to keep the temperature of all parts of the mine so low as to prevent ignition of the coal, or it may be prevented by an almost opposite course, viz., by cutting off altogether the ventilation of abandoned workings so that, from the absence of oxygen, no combustion can take place. In mines where the coal is subject to spontaneous combustion, both plans are adopted, with more or less success. If it were possible to keep the abandoned works always open, to prevent falls or crushing of pillars, or accumulations of fine coal in places where but little air can reach them, probably thorough ventilation would insure safety; but as these conditions cannot be secured, it has been found safer to prevent altogether the access of air to the parts of the mine where conditions favorable to spontaneous combustion exist. The method of walling off the goaves or old workings is objectionable in many respects. If the mine produces fire-damp, the walling off merely creates a magazine of a most dangerous explosive gas in the mine. If a fall of roof occur in the goaves, it may force this gas out into the working parts of the mine, and cause explosions; or, in many ways, a small but sufficient quantity of air may be admitted to the walled-off space to sustain in the most effective manner the slow combustion which it is desired to prevent. In the south of France, where the beds are very large, and the coal subject to spontaneous ignition, the system of mining known as by "remblais," where the space from which the coal is taken is filled with waste material, and the roof is allowed to settle down on this packing has been found to be the only really effective preventive of fires from spontaneous combustion. The packing effectually excludes air, and consequently no combustion can take place. No other system of mining than that of taking out all the coal, and either allowing the roof to fall as the work proceeds, or of filling the space from which the coal has been taken, is adapted to working in coals of this character. In chamber and pillar work, the crushing of the pillars, which cannot be prevented, is a constant source of danger, for it presents the most favorable condition possible for the spontaneous ignition of the coal.

The most efficient preventive of fire in mines, from whatever cause they may come, is to be found in education—in increased knowledge of the causes of fires and a better appreciation of the working of these causes. Our mine managers should be obliged to pass strict examinations, and no one should be allowed to undertake the responsible duties of this place without a certificate of competency, given by a qualified board of examiners. Nor is it sufficient that the managers alone should be better educated; the miners themselves should be taught the causes and preventives of the dangers they meet with in their work. Special, free, instruction upon these points might be furnished at every colliery, and this could doubtless be accomplished by encouraging the giving of public lectures, by practical miners and engineers, on subjects of interest to the miners, and by the giving of small prizes to those who pass the best examinations on subjects of daily practical application in their calling. I am well aware of the difficulty of exciting any interest among the majority of our miners in anything that is not actually their "bread and butter." They care little for the dangers they encounter, and do not appreciate the importance of knowing more than how to swing a pick or use a drill, and but little of these accomplishments. Nevertheless, I believe that the leaven of a small percentage who would profit by such instruction would finally leaven the whole mass, and the practical results of the increase in knowledge would be apparent in greater care and better mining, even by those who had not taken any part or interest in the lectures. Greater knowledge always makes better workers, and the mine-owners would find in this a good return for the small expense incurred. No startling results are expected from this suggested plan. A pretty intimate acquaintance with our mining classes, long ago dissipated the expectation of bringing about a millennium in the mining regions by means of education and instruction such as we have here suggested, but I nevertheless believe the modest results anticipated would abundantly justify the trial of some such plan as this.

Means adopted for Extinguishing Fires.—With all the precautions that the present condition of our knowledge suggests, fires will sometimes occur, and as there is, unfortunately, no prospect of the immediate application of all the preventives that we do know, fires in mines will continue to be common accidents. We will now review the more important means proposed for extinguishing them.

When blowers of fire-damp ignite in a mine they can sometimes be beaten out with wet clothes. In some instances the sudden vibration of the air, caused by the discharge of a small cannon, has been found quite effective. This remedy is applicable only when the fire has not had time to ignite the coal, and when the discharge of explosive gas is limited to the confined space on fire. When the burning gas cannot be beaten out by means of wet clothes, carbonic acid applied by portable fire-extinguishers, such as the Babcock, the Connolly, and others, can be used with advantage, as has been done in Pennsylvania during the past few years. The carbonic acid, in addition to excluding oxygen from the fire, tends in expanding rapidly, to cool down the inflammable gas to a point below the temperature of ignition; the force with which it is thrown against the burning gas also exerts a powerful extinguishing influence. The portability of the extinguishers, which are easily carried like a knapsack on the back, enables the workmen to take advantage of every current of air, and to apply the extinguisher wherever it will prove most effective. When once the fire has obtained such headway as to make it impossible to approach it close enough to allow the carbonic acid gas being thrown directly on the fire, recourse must be had to water, which under a heavy head or pressure can be thrown to a much greater distance than the extinguishing gas. Moreover, the carbonic acid would quickly make the air of a narrow heading irrespirable if the ventilation were not active; and if active the fire would extend too rapidly. This objection does not obtain against the use of water; it can be thrown from a considerable distance and with great effect. A single example will suffice. The Propect shaft, near Wilkes-Barre, Pa., already mentioned in this paper as an exceedingly fiery mine, is also a very dry one, scarcely any water being made, though the depth is 600 feet, and the gangways run out very near, if not quite, under the Susquehanna River. In order to combat successfully the fires that occur there so frequently from the ignition of fire damp by shot firing, the general manager, Mr. Frederic Mercur, an engineer of great experience and ability, had a pipe laid along each gangway (when the work was confined to driving gangways and their parallel airways), and strong rubber hose attached to the end, and at other points along the line of the pipe. The shaft-end of this 2½ inch pipe connected with a column-pipe, leading down the shaft from a reservoir on the surface. This gave somewhat more than 600 feet of head, or 260 lbs. per square inch pressure on water leaving the hose, a force sufficent to throw it with great force to a considerable distance. When the gas became ignited the water was immediately turned on (everything being kept constantly ready for such emergencies), and a few minutes usually sufficed to extinguish a fire that with less experienced men would have been considered ample cause for the abandonment of the works.

The skill which men engaged in this work of fighting fire acquire with experience, is not the least important element in the success which has generally attended Mr. Mercur's management of this trying colliery. But even experience and ability have at times been foiled by unexpected events, such as the breaking of the the pipe leading down the shaft, and other less important mishaps, which caused the few minutes delay that were all-sufficient to give the fire an irresistible and unconquerable force. In consequence the mine, though a new one, and not yet worked upon a large scale, has twice had to be drowned out to extinguish fires occasioned in this manner. The Pine Ridge shaft (400 feet deep), also near Wilkes-Barre, is scarcely less fiery than the Prospect, and as it makes a large amount of water, it was found sufficient to tap the base of the column-pipe from the pumps, and to lead the water, as in the other cases, along the gangways in iron pipes, with attachments for rubber hose at intervals in those parts of the mine where fires were likely to occur. When a fire has fully ignited the coal and obtained such headway that it is impossible to overcome it promptly by these means, a systematic method of attack is adopted. The fire must be confined by temporary bratticing or walls, so as to exclude air: the points of attack are approached in regular siege manner, a temporary bratticed approach being kept open and ventilated with a special fan; from this heading the men direct streams of water on the fire, and as they partly extinguish it, the loose coal is removed, and aceess given to portions still burning. The work is exceedingly arduous and dangerous, and the least interruption in it allows the fire to recover the ground that may have been gained from it. A better example of fighting the fire in this manner can scarcely be cited than that of the Empire Mine fire near Wilkes-Barre, Pa., which was fully described in the report, for 1874, of the very efficient State mine inspector for the district, Mr. T. M. Williams. In the same report is an account of the old Baltimore Mine fire, and the one in the Prospect shaft, to which reference has already been made.

In the case of the Empire fire, water was thrown upon it from no less than six underground pumps, and worked upon by a force of five or six hundred men, directed by the greatest experience and energy, for four or five months, yet one accident or another always prevented the final extinguishment of the fire. It may, therefore, be assumed as proven that when a fire gets beyond a certain stage, in most cases, it cannot be extinguished by throwing water upon it. The difficulties can be understood by a reference to the mode of fighting a conflagration in an anthracite mine. Let us imagine a fire in the chambers in a large anthracite vein, the pillows of coal all aglow and burning fiercely. When a stream of water is played on this incandescent mass a portion of the water is decomposed into hydrogen and oxygen, and probably this latter and a portion of the oxygen of the air form with the coal CO. This hydrogen and carbonic oxide burn again on the admission of air, making explosions sometimes of considerable violence. The pillars "spall off," and the pieces accumulate around their base in a mass of burning coal, so deep as to be impenetrable by the water, and therefore impossible to extinguish, so long as it gets the very small quantity of oxygen requisite to maintain slow combustion. The roof-rock breaks down also under the action of water and heat, and covers still further the burning pillars of coal, till finally the fire is under an immense covering of broken coal and rock. In this manner the men will sometimes be quite above the coal-seam, standing on the pile of waste coal and rock that has accumulated from such falls. It is then impossible to reach the seat of the fire except by laboriously attacking by regular approaches on the foot-wall, and carrying away the entire mass of rubbish as it is cooled by the stream of water. Since the fire generally occurs in "old workings," the pillars are not much more than sufficient to support the roof, and in most cases timber props have also to bear a portion of the superincumbent load. As the wooden props quickly burn out, the strain on the pillars is increased, and the spalling off, produced by both the heat and the water, soon brings them to the limit below which they will no longer support the roof, and a general crush occurs. After this there is no possibility of overcoming the fire in this manner, and the attempt is abandoned. If the fire has not obtained much headway, and other conditions are favorable, it is possible to extinguish it by this direct application of water, but the cases are not rare where the almost superhuman exertions of experienced men have failed. There remain but two remedies, either to close the entire mine, or to wall off the district on fire.

This latter course is usually adopted as soon as the fire has gained such headway as to satisfy those in charge that its extinction, by throwing water on it in the manner described, will be either impossible or too expensive, if successful. The simplest method is to fill the mine with water, either by allowing this to accumulate, if the mine be a wet one, or more commonly by pumping or turning some natural water-course into the shaft. Of course, there can be no doubt as to the result of this method. Wherever the water goes it extinguishes the fire. But it may happen that this is in portions of the mine above the foot of the shaft, where the water cannot reach, because the air cannot escape. In this case the fire may long continue to burn, deriving its oxygen from the air compressed in the "rise workings," and when the mine is pumped out, and fresh air admitted, the conflagration may break out again. Where the fire has occurred from spontaneous combustion, the admission of water sometimes aggravates the trouble, for, though it extinguishes the fire wherever it goes, it leaves in the wet coal-dust a condition of things very favorable to spontaneous ignition, and it not unfrequently happens that, on pumping the water out, fires occur at points where they did not previously exist. From these and other considerations, it would seem that, in coals subject to spontaneous combustion, drowning out is not a safe or desirable manner of extinguishing a fire, but, in nearly all cases where it can be applied, it is the cheapest and most effective means yet adopted. Where mines are extensive, or where there is a necessity for working the portion not on fire, or where the nature of the roof is such that the admission of water would cause it to fall, as is the case with many shales, it is evident drowning out is not a method that can be adopted. The system in most general use for extinguishing fires in large mines consists in walling off the portion on fire, trusting to the exclusion of air to secure its gradual extinction The products of combustion (carbonic acid gas and nitrogen), are most effectual extinguishers, and all that is necessary is to confine them, or, in other words, to exclude the oxygen, when in time the fire must inevitably go out. The time necessary to effect this object depends on the intensity of the conflagration, and the extent of the area inclosed. A mass of coal in full combustion requires a long time to cool below the temperature of ignition, and, even when the fire is actually extinguished, the admission of a little fresh air on the still hot coal is often sufficient to bring about spontaneous ignition. The time must be given for the combustible material, wood or coal, to cool off, before the fenced-off portion of the mine can be opened, and this delay is one of the chief objections to this remedy. To hasten the cooling, and also to hasten the expulsion of the air from the inclosed space, steam, carbonic acid, and the mixture of carbonic acid and nitrogen, known as "choke-damp," have been injected, with greater or less success. The *rôle* of steam appears to be principally as a cooler, and it is probably the most efficient agent that can readily be applied for that purpose, except, indeed, carbonic acid gas were allowed to expand from a state of very high compression (such as liquid CO_2) into the space to be cooled. At the Empire Mine, already referred to, after all efforts to extinguish the fire, by the direct application of water, had failed, a large part of the mine was walled off, and steam, from some sixty boilers, was forced in during many months. When examined some time after closing the mine, the fire was found completely extinguished in those parts where it burned most fiercely when inclosed, but it was thought that it still burned in the higher "rise workings," where the carbonic acid and nitrogen had not had time to accumulate. There was no question but that the steam had acted advantageously, but it is by no means certain that carbonic acid, allowed to expand from a liquid state into the space inclosed, would not have been quite as efficient, and economical as the steam.

Where carbonic acid has been tried, as has been done in a number of cases in different countries, in Europe, and in some mines in the country, it must be confessed the results have not been very satisfactory, but this is probably due principally to the defective manner in which it was applied, and particularly to the shortness of the time allowed for the cooling of the heated coal. The district on fire should be hermetically closed. If the gas can run out, as it will like water, from the lowest part of the mine, it will of course be inefficacious. In mines it is very difficult to make perfectly tight stoppings, and where the cover rock is broken up to the surface, air obtains entrance, and carbonic acid exit, through innumerable, unnoticed fissures. Moreover, where the fire exists under an accumulation of fine coal and rock, the carbonic acid really does not come in contact with the fire, so that its failure in many cases was probably due to causes which would have prevented the success of other methods; indeed, it has generally been tried only after the failure of everything else. The carbonic acid is usually generated by the action of sulphuric or muriatic acid on marble-dust or limestone, and is somewhat expensive where such large quantities are required. Mr. George Thompson, in a paper read before the British Iron and Steel Institute, gave an interesting account of the extinction of a fire in the Wynnastay Colliery, Ruabon, Wales, by the use of carbonic acid gas. The following is the description of the apparatus employed for the production of the carbonic acid gas:

"Two strong wooden boxes, 6 feet square by 2 feet deep, were provided, and lined with sheet-lead to resist the action of the acid. Pipes with taps were fixed into the upper side of the box, and manlids were provided, the latter for charging the box with limestone, the former for introducing the acid. Pipes with plugs were also fixed into the bottom of the box for the purpose of discharging the residuum, chloride of calcium, after the decomposition of each charge. Two cast-iron pipes, with separate valves, and also a valve common to both, were connected to the box to convey away the gas as it was produced. Small pipes, provided with taps, were inserted for allowing the air to escape, and also for attaching a mercury gauge during the operation to indicate the pressure of the gas. Whilst one box was giving off gas, the other was being charged, so that a continuous flow was kept up.

"The charge used was about 4½ cwt. of limestone, broken very small, and the 'manlid' being fastened down, the hydrochloric acid was poured in, and the mercury gauge was watched so as to keep the pressure tolerably equable, usually about 3 inches of mercury. We found, generally, that 120 gallons of the acid, of 1.12 strength, decomposed the charge of limestone, which, by calculation, gave us about 12.0 cubic yards of gas. The gauge indicated when the charge was exhausted, and then the valves, etc., were shut, and the residuum withdrawn, and thus the operation was repeated alternately as long as needful. Altogether we put down about 6000 cubic yards of carbonic acid gas, and we believe that it had a very important effect. The gas collected from all the pipes through the different stoppings from time to time would not support combustion, and the temperature within the stoppings continued very moderate. It may be interesting to state here that, in analyzing the gases within the stoppings, we found that a mixture of 5 per cent. of carbonic acid, with 25 per cent. of atmospheric air, and 70 per cent. of carburetted hydrogen, extinguished flame instantaneously. On adding more air to the mixtnre, and applying a match, it would not explode, but when pure oxygen was added, and a match was applied, the mixture exploded gently. Further, when this gas was deprived of the carbonic acid by means of caustic soda, and a match applied, it would burn when issuing into the open air."

Carbonic acid or choke-damp may also be produced by passing air through a bed of incandescent coal, mixed with limestone, of such a depth that the oxygen of the air will all be converted into carbonic acid, and not into carbonic oxide. The depth of the bed of coal to effect this purpose will be about 14 or 15 inches, and the greater the proportion of carbonic acid the better. If too little air is admitted, the gas formed may be in large part CO, but even a very small percentage of CO^2 will render this incombustible, mixed as it is with a large proportion of inert nitrogen. The application is quite similar to that of carbonic acid made from limestone and acid, with the additional drawback that it usually enters the mine hot, and therefore effects nothing as a cooling agent. To sum up, the records of a great number of fires, and of more or less successful efforts to extinguish them, seem to justify the conclusions that the use of the portable extinguishers is sometimes advantageous in extinguishing mine fires before they have attained much headway, that water under a heavy pressure is a much more efficient agent, and with energy and experience on the part of those using it, can be relied on to conquer, in most cases, when applied promptly and continuously. When the fire has gained such headway that it cannot be extinguished in this way, the burning district should at once be walled off, and the admission of air excluded. Carbonic acid or steam, or both, may then be blown into the enclosed space with advantage, steam being the most efficient cooling agent, and carbonic acid the best extinguisher. Neither the one nor the other can effect the extinguishment, except the admission of air be carefully avoided. When a mine is small, and the nature of the roof such as will not be much injured by water, and that the coal is not subject to spontaneous combustion, the quickest, cheapest, and most reliable method is to fill the mine with water and pump it out again. On account of the numerous modifying conditions which must be taken into account in each special case, it would be simply absurd to prescribe any one method as applicable in all. The best means to employ to extinguish a mine fire can only be determined after the most careful examination and study of the local conditions, and the object of the present paper has been simply to point out the means that have been adopted, with more or less success, in cases where the conditions have been those common in mining regions. It is safe to say that none of the chemical nostrums that are proposed from time to time by persons not familiar with mines are of any practical value whatever.

—*A paper by Richard P. Rothwell, M. E., Transactions American Institute Mining Engineers.*

MINING ACCIDENTS.

SOME notes on these matters are added here, compiled from the latest files of the mining press.

Coal Mine Explosions and their Prevention.—The calamities in coal mines, due to explosions of fire-damp, which have been observed to increase annually with the increasing output and the greater depths to which the pits are being sunk, form a subject deserving the greatest attention of colliery owners and others connected with the coal industry. Commendable interest has been displayed in France in connection with this subject, and in 1878 a commission was appointed to inquire into the causes of explosions in coal mines, and to suggest means of preventing or of modifying the effects of these disastrous occurrences. It appears that no efforts have been spared in collecting all available information bearing upon the subject. New inventions have been examined and subjected to careful consideration; the methods adopted in the principal mines of several foreign countries have been carefully studied, and numerous experiments have been conducted with a view of determining the direct and indirect causes of accumulations of fire-damp and their ignition. It would be too sanguine to expect the absolute prevention of coal mine explosions, but it is to be hoped that the exhaustive labors of the several members of the commission will result at least in a diminution of the danger which the miner now encounters. According to the results obtained, the idea that some mines contain specially bad gas is to be dismissed. Fire-damp will explode much less easily in a part of a mine where, from one cause or another, the air contains a large proportion of carbonic acid, or less than the normal quantity of oxygen, than elsewhere, and what is usually known as "bad air," due to inefficient ventilation, would therefore appear to prevent explosions to some extent. Another curious series of observations relates to the toxical properties of the gas and its products. If the proportion of fire-damp is below 9.5 per cent., carbonic acid and water are produced; if it is over 12 per cent., carbonic oxide is formed, and the presence of the latter is probably not without influence in increasing the number of deaths. As, however, it is very rarely that the atmosphere of a mine will contain so large a proportion of fire-damp, even at the moment of an explosion, as the latter percentage, it is argued that should carbonic oxide be found in poisonous quantities after an explosion, it will probably be due to the partial combustion of coal dust. Experiments have also been made to show that the temperature at which the explosive mixtures in mines are ignited is tolerably precise. The temperature at which mixtures of air and fire-damp take fire is 740° C. Such mixtures, however, differ from mixtures of other combustible gases in this important particular—that the ignition does not take place at the instant the general mass, or any part of it is raised to such a temperature. In order that explosions of fire-damp may occur, the gas must be submitted to the high temperature for several seconds. The delay in the explosion diminishes in proportion as the temperature is increased. A jet of fire-damp was discharged against an inverted iron crucible heated to redness. Under these circumstances, the explosive mixture remained only for an instant in contact with the red-hot iron and no explosion took place. When, however, the jet was directed to the interior of the crucible, the gas was held for some time in contact with the heated surface, and ignition ensued after a longer or shorter interval according to the degree to which the iron was heated. The bearing of this observation upon coal-mine explosions is obvious. When the wire gauze of a safety-lamp is heated to redness in consequence of the combustion of fire-damp in the interior of the lamp, an explosion is not always caused, since the surrounding gas does not remain long enough in contact with the heated metal; if, however, for any reason the contact of the external gas is prolonged, an explosion will result. The speed with which explosions are propagated is another interesting point worthy of notice. The commission point out that, according to some experiments by MM. Schloesing and Demondesir, not generally known, the rate of transmission is extremely variable according to the conditions of ignition. Thus an explosive mixture was placed in a long tube, closed at one end only. When the heat was applied to the open end the flame could be seen to traverse slowly without detonation; if, on the contrary, the heat was applied at the closed end a violent explosion ensued, and the flame traversed the tube at a rate estimated at 328 feet per second. With certain mixtures of oxygen and hydrogen it is estimated that the speed was increased to 5248 feet per second. From these experiments it is inferred that in a relatively still atmosphere the propagation will be slower and less violent than in agitated atmospheres; or again, supposing that a gallery had only one entrance and was charged with an explosive mixture, then if the mixture were inflamed by a pit-man entering the gallery, the combustion would be propagated slowly and without noise, while if ignition were caused by a pit-man working at the far end of the gallery, the combustion would be sudden, and be accompanied by a loud noise and violent mechanical effects.

The diffusion of fire-damp through the atmosphere of a mine takes place very slowly, but when once mixed the two will not voluntarily separate, after the manner of oil and water. The commission attach little or no practical importance to the influence of changes of barometric pressure in causing a disengagement of fire-damp, although it is admitted that sudden and considerable variations of pressure may have some influence, especially when the galleries communicate with old works by comparatively narrow orifices. The wind pressure on mouths of pits during storms has also been considered as exerting little influence in producing explosions. In regard to coal-dust, it is stated that though in itself it can never be the cause of other than slight and local explosions, it may greatly extend the fatal consequences of explosions resulting from fire-damp. In connection with this subject, the question relating to the safe lighting of coal mines is forcibly brought forward—a question which has already engaged the attention of English engineers to a considerable extent. The advantages of the incandescent lamps of Swan, Maxim and Edison are recognized by the commission, who, however, do not recommend their adoption, on account of the high tension of the electric currents employed, the latter being considered dangerous in fiery mines. Safety-lamps will therefore still continue to be used, and it appears that the Muessler lamp is specially recommended. The present system of lighting, however, notwithstanding the numerous improvements which have been made in the course of years, is still far from perfect, and the problem of producing a safety-lamp efficient in every respect is therefore still unsolved.

Mining Explosions and Mining Warnings.—The meteorologist who is at the trouble of giving warnings in the daily and other papers showing atmospherical changes that may affect mining operations, calls our attention to the result of last year's explosions, and we certainly agree with him that the small loss of life last year is matter for congratulation, considering the number of persons who were convicted of offenses, some of which were calculated to lead to serious consequences. The warnings appeared to be based on the action of the barometer. High barometric pressure, we are told, accompanied 22 of the occurrences, and low pressure 15. This, to some extent, would go to prove what we have often pointed out, that the barometer was not a reliable instrument as regards sudden changes of the atmosphere likely to influence gases in mines; that is, to indicate them before they really take place, and not coincident with them. Of the three heaviest explosions last year those at Whitfield and Lilydale took place at the time of highest barometer, and that at the Abram colliery with a low barometer. As to atmospheric pressure in connection with the explosions of last year, they go to support the theory that the most dangerous time is when the barometer is high. And we are told by Mr. Thompson, of Manchester, as the result of an extended period of observation as to explosions, that "the gas in the pits spoke out loud and clear long before any change could be discerned in the mercurial barometer." A careful collation of these atmospherical changes is by no means satisfactory as to their probable cause. The Government Inspector for Derbyshire, Mr. Evans, gives 16 non-fatal explosions in his district in 1880; and with respect to them he says: "It is curious to note that eight of them occurred whilst the barometer was rising, four whilst it was steady, and four when it was falling." Mr. Dobson, a high authority, considers that an altogether erroneous value was attached to a low barometer, for the explosion might be deferred until the storm had entirely passed away, and the mercury had regained the height and stability peculiar to settled weather. On the other hand, we have the views of Messrs. Scott and Galloway, from observations made extending over a period of four years, and they found that during that time 54 per cent. of the explosions occurred from a fall of barometer, 1 per cent. from a rise of thermometer and 27 per cent. from causes associated with atmospherical influence. The barometer has been looked upon as an instrument for indicating the changing conditions of the atmosphere, and indicating approaching liability to explosions in coal mines. But many of our ablest mining engineers do not consider it to be reliable, for changes take place before they are recorded. One of these gentlemen informs us that it has been found that in whatever degree the mercurial column may move, before that movement is perceptible the gas will have made its movement to the equivalent of such movement, and that instead of being an indicator of what is taking place in a mine as regards the exudation of gas, the barometer was only an indicator of what had taken place before its movements are perceptible.

But pressure is, of course, the great element for consideration. Gas exists in coal under considerable pressure, and no sooner is the mineral cut into than it liberates a considerable quantity of the gas, whether the barometer is high or low; but if there could be brought to bear on the face of the coal pressure equal to the gas escaping from it, there would be no escape at all. It has been held that the aqueous vapor in a mine, small though it may be, and consisting of two atoms of hydrogen and one of oxygen, may play an important part in forming the materials necessary for an explosion. When the air at a low temperature is taken into a mine, the aqueous vapor seizes with avidity the coal and goaves, until in a very short time, the mixture may be at an explosive point. To bring the gas up to an explosive point, there is another important element contributing to it in an atmosphere of low temperature—that is, when temperature is low, the aqueous vapor occupies a much less space and the atoms of oxygen are much nearer together, so that, space for space, under such conditions a less amount of gas will bring the mixture to an explosive point. So it is that in winter there is a keener gas, with a top on the flame, that will fire before it is half the length it will show in warmer seasons. Operatives vary a good deal as to the indications shown by the barometer being as quick as could be desired, but it is known that when coal falls or is cut into the gas is liberated, no matter what the state of the barometer may be. But, as a rule, as soon as there is a movement in the barometer, high or low, then the pressure on the space or pores through which the gas escapes is either less or greater, so that the quantity of gas will be determined by the variation. It has generally been considered that explosions took place with a falling barometer, but now it has been ascertained that many of these fatalities have taken place when the barometer was rising. With such interesting data as have been presented to us, in addition to our previous knowledge with respect to atmospheric influences in connection with explosions in mines, there is no doubt that the question of high pressure will receive more attention on the part of meteorologists in connection with its influence upon the existence of gas in mines. It would not, under any circumstances, be desirable to do away with the barometer at our mines, but at the same time, too much reliance should not be placed upon it, but all known precautions taken to prevent accumulation of gas. This can be most effectually done by sweeping all the working places with copious supplies of fresh air, and so long as this is done, there can be no accumulation of gas, and consequently no explosive mixtures. A mine manager should have no reason for consulting the barometer or thermometer, for it is his duty, strictly laid down by act of Parliament, to provide sufficient ventilation to dilute and render harmless all gases throughout a mine, and so long as he does that he need have no fear of an explosion.—*London Mining Journal.*

MECHANICAL APPLIANCES FOR MINE ACCIDENTS.

IN considering the general character of the special mechanical appliances best adapted to the purpose, the following requirements must be steadily kept in view: (*a*) Ease of transport; (*b*) adaptability to various situations; (*c*) rapidity of erection; (*d*) duplication and interchangeability of parts; (*e*) non-liability to derangement; (*f*) facility for repair.

The machinery and apparatus which it is most desirable to provide is principally: (1) Water-raising apparatus, for dealing with large quantities of water in a short time. (2) Portable boilers with fittings and steam pipes complete for promptly and efficiently supplying with steam at high pressure the pumping and other machinery; the boilers to be capable of being readily coupled together by interchangeable pipes, and to be prepared for transit by railway and over rough mining roads. (3) Air-compressing apparatus, for keeping back rising water, and enabling the mine to be entered before ventilation has been restored. (4) Air locks, with provision for quickly fixing them in the headings. (5) Ventilating apparatus, for promptly restoring ventilation after an explosion. (6) Temporary winding apparatus, for quickly replacing the winding gear over a pit when destroyed by an explosion, or to establish additional means of communication with the mine. (7) Diving apparatus, generally adapted for penetrating long levels under water. (8) Temporary workshop, fitted with complete sets of the tools likely to be needed. Through the kind assistance of several makers of the different kinds of machinery referred to, the writers are enabled to present descriptions and drawings of a few of the mechanical appliances which appear suitable for meeting the necessities of mine accidents.

It is well at the outset to note that such apparatus must not be judged by the ordinary rules of durability and economy in working, as the great object to obtain is handiness, portability, ease in putting together, and the greatest effect in the shortest time. It has to be noted that in colliery districts the source of power—coal—is readily obtainable, and the chief point to be considered is how to extract and apply that power with the greatest rapidity and efficiency; hence it appears that classes of water-raising apparatus which are not in favor where permanent and steady work are required, may be most suitable for the purpose under consideration.

The Pulsometer.—The Pulsometer (American), for example, has the advantage of needing only a steam pipe and delivery pipe; it may be lowered into water, and occupies but a small space, and when being lowered requires only the addition of extra steam and delivery pipes at the top of the shaft. When depth is great several of these pumps can be placed in succession. The pulsometer, is an instrument for applying the pressure of the steam directly upon the water to be lifted, the only working parts being the valves, and a small ball to direct the steam into the chambers alternately. The ball is self-acting, being drawn over by the increased velocity of the steam at the moment of the formation of the vacuum. An air-vessel to reduce the shock completes the apparatus, Fig. 1.

The Steam Ejector.—The ejector, another form of instrument for raising water by the direct application of steam without the intervention of moving parts, can be used; and in Fig. 2 is shown an arrangement suggested for the purpose by those familiar with its use. Fig. 3 shows an enlarged view of the ejector, which operates in the same way as the well known injector, forcing the water up the column A by the effect produced by the superior velocity of the steam jet B. It has no working parts, but is simply provided with means of adjustment. With some forms of the ejector the height of the delivery is limited only by the steam pressure obtainable. The enlarged view Fig. 4, shows such an instrument, and Fig. 5 shows its application when lifting to a great height.

Direct-Acting Steam Pump.—Some of the smaller forms of direct-acting steam pumps are capable of application on emergency, as shown in Fig. 6, where one is suspended from the surface. The same pump is shown in Fig. 7, fixed in a heading to force the water to the top of the shaft, steam being supplied from the surface. Other pumps can also be used in a similar manner.

The Centrifugal Pump.—The centrifugal pump is principally available where the height of the lift is small, but would be useful where the water could be got rid of by pumping from a lower level of the mine to another level at no great height above it, as shown in Fig. 8.

The Water-Spear Pump.—A form of pump which appears to be peculiarly well adapted for the purpose in view is shown in Fig. 9, where, instead of using wooden spears working within the pump to transmit the power of the engine, it is proposed by the designer to apply what may be termed a water spear by means of a pipe independent of the pump, and to attach the working parts of the pumps to a capstan engine by a wire rope in such a manner that the rope remains attached whilst the pump is at work, and is always in readiness to hoist the working parts to the surface, where they could be replaced by a duplicate set in a few minutes. The power is intended to be supplied from the surface by a forcing engine, the simplest form of which is indicated in Fig. 10, and all the operations could be carried on from the surface, thus enabling the pumps to be worked in any situation under water. In this way would be obviated the difficulties and delays occasioned by changing buckets and valves through door-pieces, and by drawing spears, as often found necessary in the ordinary system of pump-work, especially where dirty water has to be lifted. The mode of working may be thus described—on the surface, near the pit, would be placed a forcing engine capable of supplying all the power required for pumping; this engine could be of the form shown, in cases where time was of every consequence, or, if circumstances permitted, some other form of portable engine in which advantage could be taken of expansion. A capstan engine would also be needed for lifting and lowering the pipes, and for changing the working parts of the pumps as occasion required. The hydraulic pump would be lowered into the pit, and pipes added as frequently as required, both to the large delivery pump-trees and to the hydraulic forcing pipe. If needed, the pumps could be lowered at once to the bottom of the shaft. Where the water has to be followed where it is lowered, telescopic pipes at the surface could be used, of sufficient length to allow the pump to descend 30 feet or 40 feet without change. Such a pumping plant is calculated to work with but few interruptions, and the whole of the operations could be performed on the surface with facility and despatch, and without the use of steam in the pumping shaft.

Double Acting Hydraulic Pump.—In Fig. 11 is shown a double-acting hydraulic engine on the same principle, designed for use underground where power is available either from the column of the main pumps or from a forcing engine. The engine is shown in a horizontal position;

but for draining "dip" and distant workings it may be mounted on wheels, and made to follow the water as it is lowered, or in its compactest form it may be slung upright for use in a vertical shaft. This pump differs from that shown in Figs. 9 and 10, in being double instead of single-acting, and in the valves being worked by means of water pressure, in one central valve box; and it is perhaps more suitable for working under very heavy pressures.

Mounted High Pressure Boiler.—For the working of these and similar instruments to their better advantage, a greater pressure of steam is needed than is usually found at collieries; and, morever, it is probable that the local boilers will be engaged in other work, so that special portable boilers will be required, those forms being selected which do the most rather than the best duty. In Fig. 12 is shown a vertical boiler with internal fire-box, intended to be worked at a pressure of 150 lb. per square inch. The boiler is mounted on wheels, and is provided with trunnions to enable it to be laid horizontally when traveling by railway. Another figure was given, representing a portable boiler on the locomotive principle to sustain a pressure of 150 lb. to 200 lb. per square inch, and provided with wheels for traveling on roads, and also capable of being carried by railway without being dismounted.

Combined Engine, Boiler, and Air Compresser.—Whatever form of boiler is adopted, it is desirable that it be made of steel plates, with the object of attaining the greatest strength with the least weight; the boilers to be so fitted as to work seperately or in groups. A portable air compressor, with engine and boiler attached, is shown in Fig. 13; and in Figs. 14 and 15 were indicated other well known forms of air compressors, with engines combined such as those already referred to, but without attached boilers; a form of pump capable also of being used as an air compressor, and the same with arrangement of three combined, may be used where great pressure is needed. Air cylinders or other apparatus for enabling explorers to enter mines foul with choke damp should form part of the appliance provided.

Air Lock for Mines.—An air lock is shown in Fig. 16. The lock is of small size to facilitate fixing, and must be securely built into the heading in which it is to be used the materials for so doing should be kept with the apparatus, together with air proof sheeting in the event of the dam being porous. The boring apparatus, so ingeniously devised by Mr. Riches for use at the Tynewydd Colliery accident and described by him in a paper read at the last meeting of the Institution, would also be useful with certain modifications to enable it to meet a variety of circumstances.

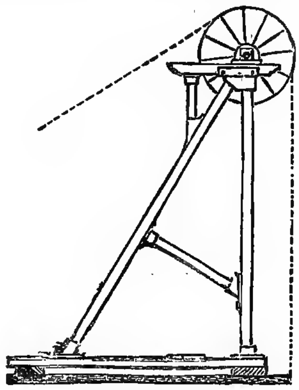

FIG. 17.

Portable Winding Gear for Mines.—As the winding gear and head frames are often injured, or are too much employed to be spared for special use, portable winding gear and engines will often be needed; a portable frame so made as to be rapidly put together is delineated in Fig. 17. It is essential that the whole of the apparatus should be so arranged as to be easily carried on railway trucks, a convenient form of which for the purpose is shown in Fig. 18. Although the machinery and apparatus indicated in the drawings are for the most part doubtless well known to every mechanical engineer, illustrations have been given to make the references to them more clear. It is necessary now to consider how the special appliances are to be provided and made available for the use of the mining community. It is not to be supposed that all that has been suggested can be accomplished without great consideration and much further information than could be obtained merely for the purpose of this paper, as to the special conditions of each mine, the needs of each past emergency, and the appliances that would have been best calculated to provide for them. The information so collected would lead to the designing of apparatus better adapted to the particular purposes in view than any now existing, nearly all of which has been constructed for working under other than the very exceptional conditions that obtain in the case of mine accidents.

It is hoped that these suggestions may lead to the organi-

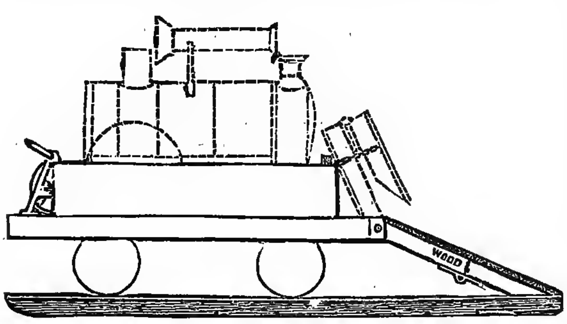

FIG. 18.

zation of an association of mine owners for mutual protection against the calamitous results of mine accidents, by establishing a central depot, with, perhaps, a branch in each mining center, containing a complete collection of the requisite special machinery and appliances, ready for use at a moment's notice. The cost of providing and maintaining the establishment would be met by a general subscription by those to be benefited; but the establishment should be made to a considerable extent self-supporting, by suitable charges for the use of the apparatus. In connection with these depots, competent men should be provided for fixing and working the apparatus; a few to be permanently engaged, while the others pursue their ordinary work, attending at intervals for training, and being "at call" at other times when needed. Had such an establishment been in existence, no doubt many valuable lives might have been saved, and much pecuniary loss spared to those engaged in mining operations; and though it is not suggested that accidents of the distressing character of those that have so recently occurred could have been averted, their sad consequences might possibly have been lessened, had appliances of the kind referred to in this paper been available. But while it falls within the province of the mechanical engineer to point out the appliances best adapted to meet the necessities of the various classes of mine accidents, it must rest with the mine owners themselves to carry the suggestion into execution.

—*A paper by Charles Hawksley and Edward B. Marten, Transactions Institution of Mechanical Engineers.*

PROSPECTING AS A PROFESSION.

THE majority of the prospectors or men who make the finding of mines the profession or business of their lives are those who have learnt what they know of mining and ores in the mines themselves. The causes which lead to their adoption of the business may be, individually speaking, many, but the primary cause affecting all alike is the fact that there are valuable properties in the shape of ledges carrying metal, waiting for the men who can find them, and that everything necessary to give a title to them is the discovery and compliance with certain simple forms. This done the prospector owns the ledge, and can sell it, develop it, or give it away, as his circumstances guided by his feelings, may dictate. As these ledges may be of a value ranging between nothing and many thousands of dollars, it follows that the hunt for them possesses all of the attributes of chance which make gambling so attractive. The prospector may discover and locate a property which will make him independently rich, or he may waste his time and money for months and years. As in other kinds of business, so in mining, one generally hears of the successes rather than the failures, for if you are talking to a successful man he likes to "brag," while to the unsuccessful man failure is not a congenial topic of conversation. It follows that among mining men prospecting is generally spoken of in connection with the strikes which have been made by the prospectors, and the months or years of weary waiting are as a rule passed over in polite silence, or spoken of merely to enhance by contrast the subsequent brilliancy of the fortune made. If one were to talk to mining men, especially in the new camps which are generally composed of prospectors, he would be apt to imagine from the stories he would hear that everything necessary to discover and locate a mine was to walk out of the camp and stake out the ground. As a matter of fact the successful prospector brings to his aid a training which is peculiar in many respects, and he possesses an amount of patience besides which that of Job was an airy figment of the imagination. I am of course excepting cases of the discovery of a mine by the purest accident, as when the *ranchers* built a wall for a *corral* out of pieces of rock taken from a ledge, and was told by the first miner that saw it that it contained rich ore or that other case of a man building the fire-place out of ore containing horn silver and finding the buttons in the ashes. But for the man who undertakes prospecting as a business he means to stick to, until he has found a mine which will make his fortune, there is hard work in plenty, and he will find that unless that hard work be done "according unto knowledge" his expenditure of time will not give him any great return. The prospector requires knowledge, and plenty of it, and he requires strength as well; the one that his strength may be profitably expended, and the other that he may be enabled to stand the terrible strain which the life he leads brings upon him.

As I have said prospecting is a business into which men generally "drift" by pure force of circumstances. Miners working in the mines go from one camp to another as a result of the stories told about rich strikes or because they hear that there is a big demand for labor. Arriving in the new camp they generally go to work at first for other men, but as time goes on and they hear the stories of those who have made rich discoveries they are tempted to see what they can do. They will take a "week off," and prospect in a desultory way in the immediate vicinity of the camp. Sometimes they find a ledge which has pay ore in it, and if they should do so they, as a rule, join the prospecting league. It is rarely the case that they receive much money at first, but it does not take many hundreds of dollars to confirm the prospector in his choice of a business. There is a fascination about going out and discovering a ledge which is valuable, that makes any kind of regular work extremely distasteful to a man. If a man follow prospecting for a year he is rarely willing to give up the business for any other, for the simple reason that all other forms of occupation seem to the last degree tame to him. As a rule prospectors do not accumulate very much money although they often make large sums. This is owing to two facts, first the nature or character of the prospector and second the kind of life he is obliged to lead. The rewards of the work being to the last degree uncertain, a man must possess, before going into it, that kind of disposition which will permit him to sacrifice the certain for the uncertain. He must be willing to take risks, to "chance it" in his luck. In other words he must have the gambling instinct largely developed. While the rewards are brilliant the prospector cannot shut his eyes to the fact that the toil may be long, and he can see in the case of others if not in his own that circumstances are apt to make that toil very wearisome. For "he who runs away may read" the statement written in the fashion of these men's lives that prospectors except after a sale have little or no money. As a rule they get nearly everything on credit as long as that credit lasts and hang around a camp before taking the plunge again, as long as it is possible for them to do so. Prospectors then must be willing to face poverty for a time in the chance of some day washing a "pile," because there is generally work to be had at wages or on contract if they are only willing to take it. Men with the kind of disposition which makes this life possible are men with but litle thought for the morrow. When they get money, as they often do, it comes in large lumps and they spend it lavishly. They generally pay all of their bills the first thing, not only because they are, as a class, a very honest set, but because they are wise enough to know that by doing this they make their credit good. Then with what is left they go on a spree, generally making their way to San Francisco or some other large place where with money in their pockets they proceed to "have a high old time." The money flows like water through their fingers, and at the end of one month or six, as the case may be, they make their way back to the camp with a large stock of stories of a somewhat dubious character as the result of their fun. The prospector "in luck" as seen in the streets of San Francisco is a man of mark. He generally goes to some tailor as soon as he arrives and purchases an outfit of clothes, which providing they be of a certain conventional cut can not be too gorgeous in color. He always, for example buys a sack coat, as he does not like the tails of a frock flapping around his legs. I remember one of them, a man named Reilley, who was one of the best prospectors I ever saw and deserved all his luck, of which he had plenty. Reilley as soon as he got to the city used to buy a suit which was gorgeous in the extreme. A tweed sack coat, a purple velvet waistcoat with brass buttons and a pair of those wonderful plaid trowsers which take two men to show the pattern, were always purchased first. A lot of white shirts with frills, a large soft felt hat and a pair of heavy boots in the tops of which the trowsers were generally tucked, completed the costume. In honor of his native land, I suppose, Reilley would always buy some enormous pin to stick in his shirt front, the color of the stone being green. A gold watch was attached to one of those immense cable chains made of large pieces of quartz showing pure gold, and this as it crossed the purple waistcoat had an effect which was to the last degree magnificent. He always bought two rings, one a diamond and the other the largest seal ring he could find. As he rarely wore any collar and never wore a cravat the effect of all this was startling. In the camps Reilley wore a full beard, but this he had cut when he arrived in the city, leaving a moustache and imperial, the former always being waxed ferociously. I can in my mind's eye, see him now; dressed in his wonderful costume, his great watch chain crossing his waist and having hanging to the end a pick about two inches long made of gold, his diamond rings flashing in the sunlight, his awe-inspiring green pin, his round good-natured face tanned to the color of leather by the fierce sun of the desert, his merry blue eyes looking at me over his altogether ferocious moustache! Truly he was a wonderful fellow to look at. While he was in the city he spent his money in the wildest way, literally throwing it in every direction. This kind of life would last as long as the money did, and then the pin would go, and then the seal ring. When he was reduced to the watch and diamond, Reilley would sell them both, generally realizing about five hundred dollars. He would then pay for his passage to the mining camp, buy an order on Wells & Fargo for two hundred, and have one last spree on what was left. This concluded he would pack up and start, and when he reached the camp would cash his order and once more go out to prospect for ledges. Having told about the somewhat ridiculous side of his character it is but fair that I should say more. This I do the more willingly because Reilley was not only a typical prospector but he was one of the pleasantest men I ever met. He was a thorough master of his business; keen-headed, manly, truthful, except perhaps in the matter of the value of the ore in ledges he had found which seemed somehow to increase every time he mentioned them; hospitable to the last degree, for whether it was champagne or water, game in a French restaurant or beans in the desert, you were always welcome to one-half of what Reilley had; and in short, "square" with him as with the great majority of the class to which he belonged, money was only good for the fun which could be got out of it. The reaction from the toil of finding the ledges showed itself in the kind of life he led when he reached the city.

And this brings me to the second reason why prospectors generally spend their money as fast as they get it. The work of prospecting is extremely hard and the privations of the life can scarcely be exaggerated. Not only is the existance a most lonely one, for the prospector goes upon his long trips with no other companions than his horse or his *burro* or jackass, but the labor of finding a ledge is very exhausting and the food is somewhat primitive. Sleeping out at night wrapped in his blankets, often cold, and often hungry, is it any wonder that when a prospector does make a strike by selling one of his properties he should plunge into the other extreme? But for the men who can resist the temptation to indulge in these wild sprees, prospecting offers a business which will probably result in the acquisition of a fortune. Given the necessary knowledge to engage in it and a determination to save money, the prospector, if he have very ordinary luck in time, "makes a pile." The education necessary is emphatically a practical one, and the best prospectors are those men who have learnt their business in the mines themselves. As they rarely carry with them more than the simplest materials for assaying or testing ores, they are obliged to have a sufficient amount of knowledge to recognize ores and to estimate their values the moment they see them. A curious instance of this fact was told to me once by a prospector who had been among the first to go to Virginia City, then called, Washoe. At that time gold was the only metal sought for and the prospectors had learned to distinguish gold-bearing quartz as soon as they saw it but they knew nothing at all about silver. "We didn't s'pose that black stuff wer' worth anything," said he, alluding to the silver ore; "an' we used to throw it away till one day 'long come a chap an' he says as how, says he, that ar black stuff were silver. Lordy, you oughter hev seen the boys' eyes bulge! Arter that we staked (located) black stuff whenever we seen it." It would be somewhat difficult to find the prospector of to-day who would not recognize and locate the "black stuff" as soon as he saw it. Of all the branches of knowledge necessary for the successful prospecting this of the ores is the most important. Not alone are there many kinds differing in appearance as radically as do the coal and granite, but the ores in one district differ from those in another in their importance and value. The prospector must not only know ores generally but he must know those of the district in which he is. It follows therefore that before a prospector can hope to engage in his work with any degree of success he must spend some time examining the district; that is, of course, if the district be developed. If there are mines opened in it, it will pay him well to examine them, not alone their ores but their walls as well. For the prospector must, if he would be successful, know as much about the barren *strata* next to the ledges as he does about the ledges themselves.

While it is generally the case that prospectors drift into the business from that of practical mining, urged to this change of occupation by a natural bent or a chance circumstance, it is certainly true that prospecting as a business offers inducements to any man who has the requisite knowledge. The number of ledges in the west which are valuable is unknown, but there can be no question that there are thousands upon thousands of them only waiting to be located and opened to yield up the treasures of gold and silver which they hold. This being the case it follows that there are many chances of making money waiting for the men who choose to look for them; and the experience of the great majority of the prospectors who have gone into the business is that it pays. Even those who have nothing now have had large sums which they have spent foolishly. If a man makes up his mind that he will adopt prospecting as the business of his life he may be reasonably certain, providing he will determine that when he gets money he will save it and invest it wisely, that he will be rich before he dies. He must however be the kind of man who can stick to a thing when he once gets hold of it, who can wait and wait patiently, who can live on hard fare with hope to season it, and who can control himself when he finds that he has suddenly made a large sum. If such a man becomes a prospector and lives to an average age, he will be wealthy before he dies. The training necessary for the business is varied, but as a foundation there can be nothing better than the ordinary course in a school of mines. This will teach a young man something of geology and mineralogy, and will make him familiar with the principles upon which the discovery of metals in the ores and the reduction of those ores depend. But the course is only a foundation for subsequent knowledge to be acquired in the mines. In the school the student learns the theoretical part of the work. He is taught, it is true, practical assaying, but when he finds himself in the mountains this is of little use to him for the simple reason that he has no tools or materials to assay with. I have often wondered why the mining schools do not make their instruction in the use of the blow-pipe more thorough than it is. In the hands of a man who knows how to use it properly, the blowpipe becomes a whole laboratory in itself, and when taken in connection with a few fluxes, will enable him to determine the character of any piece of ore he gets hold of. Not only can he perform qualitative analysis with it but he can do quantitative as well. Having passed through the mining school, the young man who wishes to be a prospector is ready to go into the mines. He will find it of almost primary importance that he work as a miner, learning by that greatest of all teachers, experience, how to handle a pick. His work as a prospector will necessitate the use of this and of powder as well, and he must learn practically how to put in and fire "a shot" or cartridge of blasting powder. Work around and about the concentrator will teach him to distinguish ore from gang the moment he sees it, and the picking over of the ore which has to be done to a greater or less extent will give him knowledge and experience of the utmost value. Although the prospector is not necessarily a miner he should know enough about mining to be able to open his ledge when he finds one and develop the property to some extent. It will pay him therefore to understand this being a mine, and he must learn the amount of carpentering necessary in making a hand winch. Time spent in a blacksmith shop learning to sharpen tools and to temper them when sharpened is time well spent, as he will find when he gets into the field. From other prospectors he can learn the uses of horn and iron spoons in the testing of ores and the

Mining Life.—A Prospector on Foot.

From "La Vie Souterraine," by L. Simonin.

numberless dodges and make-shifts by which these men make one thing take the place of another in such work. He will be surprised to find how many of the operations of a laboratory can be done in the field with no other tools than those provided by nature herself. As for example the crushing of ore which in the former we do with heavy iron pestles in heavier mortars of the same metal, in the latter we get along very well with two flat stones. And above all things he must learn to "average a ledge." The valuable ore on a ledge lies in bunches and small veins in the gang or barren rock. As the value of the whole body depends entirely upon the proportion existing between these two, it is of primary importance to the prospector who would properly describe his claim that he be able to determine this proportion by an examination of the ledge. There are many methods of doing this, one of which is described at length in the article headed "The Purchase of a Mine." But for the prospector there is no one equal to the effect produced upon him by a sight of the ledge. Knowing the character of the ore and its value, he should be able to tell at once from merely looking at the vein, the proportion existing between the ore and the gang in the vein matter. The knowledge necessary for this exercise of judgment can only be acquired from long experience and as a result of actual inspection of ore bodies. The would-be prospector should then never neglect an opportunity of improving and increasing his stock of information in this regard, and should bring his judgment to the test by ascertaining, whenever it is practicable, the result of working ores in the mill or furnace; and comparing it with his previously formed opinion. There is no better practice for example than that of estimating the yield in bullion of the ores which are mined, taking them in weekly or monthly lots. This, if steadily adhered to, will in time give a man an amount of knowledge upon the subject which he will find almost priceless.

Having secured his theoretical knowledge by study in the schools and supplemented it by his study and observations of the mines, the prospector is ready to begin his actual work. The first thing that we must do is to purchase an outfit. This must be adapted to the life he is going to lead and must be complete, or he will suffer severely for the lack of articles he should have procured. But as it must not be made too small so it should not be made too large, or he will find that he has burdened himself with a lot of things which are not of enough use to make their transportation profitable. A good outfit for the prospector—and parenthetically it may be said that this list as far as the personal outfit is concerned, is one well suited to the traveler in the mines—should consist of two pairs of heavy blankets, eight pounds in weight each. A buffalo robe or better yet, a blanket lined rubber *poncho* for sleeping on. A suit of strong gray *woolen* clothes, a pair of brown jean trousers, a change of woolen underclothing, woolen socks, a pair of heavy boots, a soft felt hat, three or four large handkerchiefs, a pair of buckskin gauntlets, and such toilet articles as he desires to take. These should all go into a strong canvas bag made with strings to tie up the open end. It will do no harm if this bag be made waterproof. He should have a breech-loading or magazine rifle of some kind or a shot gun. Around his waist he should wear a strong sash, and to it have attached his holster and his knife sheath, carry in the former a Colt's revolver, of heavy size, and in the latter a heavy hunting knife. His ammunition should if possible fit the rifle as well as the revolver. If he be a smoker, he will carry his tobacco and pipe. For transportation a good mustang, as free from tricks and bad habits as he can get it, should be bought. Mustangs are better than mules for mountain work because they have better backs for the saddle and larger areas of hoof, the latter being an important point when there is much travelling to do over sandy deserts. They are quite as sure-footed and will live on the same forage. He should buy a Mexican saddle fitted with rings, straps or thongs to tie on his pack, saddle bags, catinas, water canteen, &c. Speaking of this last, it should be large and be covered with thick felt. If it has a cork for a stopper, this should always be secured by a cord to the neck of the canteen that it may not be lost. One of the stirrups, preferably the left, should be fitted with a leather tube in which the barrel of the rifle may be placed, and there should be a strap fastened to the horn of the saddle, with which you can secure the stock by wrapping it round once and then putting the end of the strap over the horn. This tube and strap is the best method of carrying the gun or rifle yet discovered, as it is easy to cast the weapon loose and it does not pound itself to pieces against the saddle. The bridle should be made with a whip at the end of the reins and the long stake rope should be either attached to a halter worn by the animal or knotted in such a manner that it will not slip around the neck. While travelling the rope is coiled up and tied to a thong on the right of the saddle in front. If a staking pin be a part of the outfit the thong must be passed through the ring at the top and a small piece of leather sewn on the saddle flaps for the pin to go through in such a way as to prevent its jogging up and down. And by the way, I may mention here that the holster should have a hole cut in the end through which a small cord or a thong like a leather shoe lace should be passed and tied around the leg. Properly put on it will not hurt the rider while its usefulness as preventing the hammering of the leg by the heavy revolver will be found to be very great. For the work of prospecting a "poll," pick and prospecting pan made of iron should be carried. The pan serves for washing out sand or as a dish for bathing in. A frying pan, eight inches in diameter, made of wrought iron; a coffee pot, tin cup, fork and spoon; a good supply of matches in a tin case the shape of a bottle with a good cork in it or what is better still a wide mouthed glass stoppered bottle in a tin box; a pocket compass—and let it be a good one—and a spy-glass or pair of field glasses. For provisions the prospector takes with him bacon, flour, beans, tea, pepper and salt and a box of yeast powders. These should all be packed in bags which go into a canvass sack somewhat of the shape of that in which the blankets and clothes are put. A short time spent in the kitchen or in learning how to cook will pay the prospector as large an interest on the investment as that which he can get from any he can make. Sage bush cooking while not very good under any circumstances is execrably bad if the cook be a perfect novice, and as not only the comfort of the trip but oftentimes the health of the prospector depends upon what he eats, it will pay him well to make his food as good as he can. While the list as given above contains all that is absolutely necessary I cannot help urging that Chilli peppers and those strong red onions be added to it whenever it is practicable. The former in hot climates are almost a necessity, while the latter will at all times improve the fare to a very great and pleasurable degree. There is another use to which onions may be put which will often alone compensate for the trouble of packing them. Should the prospector run short of water he will, if he places a piece of raw onion in his mouth find that the torture of thirst is at once destroyed and that the swelling of the lips and tongue from the lack of water is prevented. With a plentiful supply, and one large onion will be sufficient for a day, he will find that he can resist the effects of a lack of water for some time, or if the fluid is scarce that he can get along with very little. This is often an important consideration. The onion will also prevent the lips cracking from the effects of alkali dust, or if they are cracked will relieve the pain. The prospector should carry some quinine with him and some pills to act upon the bowels as well as a remedy for dysentery.

Having collected his outfit he will proceed to pack his animal. Placing upon the mustang's back the blanket—a folded blanket is far better than a saddle cloth as it can be washed and hung up to dry—which has been carefully folded without wrinkles, he puts on the saddle and pinches it securely. The saddle bags are packed with the various small things which go into them, and the bag containing the provisions placed behind the cantle of the saddle where it is securely fastened by two thongs which are tied in such a way as to divide the bag into thirds. On top of this, the bag containing the clothing and blankets is placed and secured firmly in the same way. The pick goes into a strap made for it on the right saddle flap or skirt and is always put in with the point sticking out behind. It should be arranged in such a way that under no circumstances can this point strike against the horse's skin. The coffee-pot, frying-pan and prospecting-pan are lashed on the bags in a position where the rider will not rest against them. The tin cup, which should be one that was pressed into shape, may have a lanyard attached to the handle and be carried with the lanyard tucked under and around the belt or sash. The stake rope being coiled up and tied to the saddle and the rifle being put into place and fastened, the proprietor mounts. It is always well for him to wear spurs, as nothing else will have any effect upon a mustang. And then he leaves the camp to be gone any where from one week to six months, for if he can eke out his provisions by the killing of game he will stay in the field until he finds a ledge "if it takes all summer." He has started out prospecting, therefore the main work of his expedition is the finding of a ledge of paying ore. But while doing this he and his horse must live. Provisions for himself he has with him, but forage for his horse and water for both must be found. As grass is generally found in the neighborhood of water, the business of the prospector is to see where he can get the latter. He must before starting out in the morning make up his mind where he will camp at night, and there are certain indications given by the shape of the surrounding country which will guide him to a very great extent. The first of these is the character of the mountains. If they be snow-capped, water is almost always to be found at the base. But as the base of a mountain is generally a rather large extent of country, the prospector needs something more to indicate to him where he shall ride. This he finds in the natural water sheds or natural drainage of the district. Water is more apt to be found at the lower end of a valley or canyon, for example, than it is on a hill-side, and by taking careful observations with his glass, and ascertaining by the aid of his compass the direction in which he is to travel, the prospector will rarely fail to find a good camping ground. Having found one he will of course stay there until he has prospected the surrounding country thoroughly. Not only does he have the advantage of knowing that wood, water and feed are plenty, but he can save his horse a great deal of labor by relieving him of the weight which must be carried while travelling. It is always well to hide the things which are left in camp, and the provision bag must be tied up in a tree or *cached*, that is, buried under heavy stones, to keep it from the coyotes. When possible, suspending it in a tree is always the best, for the simple reason that while grizzly bears are not as plenty as blackberries in the mountains, all stories to the contrary notwithstanding, they are occasionally found, and it requires a much heavier *cache* than one man can make to be impervious to "cabb's" strong claws. Bears will dig up *caches* merely for the fun of doing it, apparently; and scatter the contents around even when they do not eat the provisions. Where there are bears, coyotes are as a rule, not far off, and they will eat anything that can be eaten. They are cowardly brutes, and while not dangerous, are often exceedingly annoying. When they are in the neighborhood it is always well to stake the horse rather than hobble him, and under no circumstances should the hobbles ever be placed on the hind feet. A mustang, as long as he can kick, can drive off any number of coyotes. This caution about placing hobbles upon the hind feet is almost superfluous, for a proper sense of his own dignity will as a rule prompt the mustang to enter a demurrer against anything of the kind, and the demurrer in question generally appeals to the judgment of the court with the directness and force of a stroke of lightning. If the provision bag be placed in a tree, do not suspend it by a cord passing over a branch and fastened to the trunk, but take the trouble to climb up and tie it to the branch. Grizzly bears are very cunning; "Heap wisdom in the old gray man," as the Indians say; and if they see a cord fastened to the trunk will tear it loose, thereby letting the bag fall.

Speaking of Indians reminds me that it may be the prospector will be obliged to traverse a bad Indian country, or he may be at work when they are on the war path. Should he know either one of these facts beforehand he will be wise if he takes a spell at work as a miner in some mine or joins the company of scouts generally raised in such cases. Foolhardiness is not bravery, and prospecting in a country where an Indian war is going on, is about as foolhardy a thing as a man can do. If he must do it, however, there are certain precautions which he might as well take, particularly as there is no one there to see him take them except his horse, and he will not say anything about them. In the first place then, he will travel chiefly at night or in the very early morning. Starting out at twelve and journeying until five or as long as the mists hold, will as a rule, be safe. Of course in order to do this he must know something about the country, the lay of the land and the places where water can be found. During the day he must hide somehow. He can only permit himself to kindle a fire at night, cooking then all of the provisions necessary for two or three days in order that the fire be built as seldom as possible. Even when he does kindle it, he must "mask it" as it is called. Taking his pick he digs a trench about five feet long and roofs it over with flat stones or brush, on which he piles dirt. With the stones he arranges a place just over the fire large enough to hold the coffee pot or frying pan. At the other end of the trench, if water be plenty, he makes a pile of loose brush which has been thoroughly wet. The smoke from the fire, which by the use of dry twigs or buffalo chips, should be as small in amount as possible, when it encounters this wet brushwood becomes cooled off at once and will not rise. The fire should always be built, if possible, in some place naturally screened by rocks or bushes so that the light cannot be seen from the neighboring mountains, and when one utensil is taken off of the hole another should be placed there instantly. If this is all properly done a man can cook within half a mile of an Indian and give no sign. As soon as the cooking is done the fire must be extinguished at once by heaping sand or earth upon it. Do not put it out by water, as heavy clouds of steam always rise up when this is done. As soon as the fire is extinguished mount your horse and ride on for a mile or two, or better yet, do your cooking just before you begin your night march. I have spoken of the necessity which exists in an Indian country of cooking as much as possible at once. Flour may be made into bread, beans may be boiled or baked, and both may be kept for a long time. Mr. J. S. Phillips in his chapter on Prospecting gives a most excellent suggestion which I can heartily endorse. He says "I boiled, when in security, one-fourth of a pound of tea in a quart of water, and after removing the tea leaves, continued the boiling of this strong tea water until it evaporated to about a pint, which I carried forward for use when required. It will be found that one teaspoonfull of this when added to a cup of water makes a much more palatable and refreshing beverage for washing down your frugal meal than water, and it will prevent the headache that would otherwise result." This suggestion of his about the using of tea makes me think of another which, whether there be Indians or not, should always be followed, After breakfast pour what is left into the canteen from the teapot, straining out the leaves, and add enough water to fill it. This cold weak tea is far more refreshing than water, and if it becomes lukewarm from the heat of the sun, can be drunk without nausea. If the water be bad, having alkali in it for example, it is almost undrinkable without the addition of tea. Under any and all circumstanees eat cooked food. No matter what the danger may be, the prospector must take time to cook. Not only are raw flour, bacon and beans excessively difficult to eat, how difficult no one knows who has not tried them, but they are dangerously unhealthy. A very short experience of them will bring on dysentery of a very bad type, and if the prospector gets sick in an Indian country, his chances are small indeed. It is true that there are very few sights more ridiculons than watching a stalwart man chewing raw beans or trying to eat paste, and the expressions of his face while doing it would make the fortune of a low comedian, but it is fun dearly bought at the expense of a bad attack of sickness. If it is positively necessary to eat one's food raw, at any rate leave vegetable food alone. The best thing to take under such circumstances is jerked beef, for while this is tougher than any known substance unless it be rawhide, and will cost many a jaw ache before one gets it down, it will not make the person eating it sick. If a man knows beforehand that he is to have great difficulties in making fires for cooking he should provide himself with a store of this jerked beef, and, if possible, with a bag of parched corn. This latter is very good food although somewhat dry, and will keep indefinitely. In travelling in an Indian country, the most common precaution is to avoid placing oneself on a skyline by riding on the crest of a hill. It is scarcely necessary to say, I suppose, that under any circumstances the person will avoid, unless it be absolutely necessary, the discharge of firearms.

There is a rule, and a good one, which should always be followed while prospecting. If you are overtaken by darkness before you have reached your camp, your horse will find his way better than you can and you will be safe in your trust to him. This applies equally well in a case where you are trying to find water, or where you are trying to reach a camp you have left in the morning. In the one, the horse will scent the water and make for it; in the other he will always find his way. In case you are obliged to camp without water, be careful to stake your horse securely, for if he can get away he will always go back to the place you have left in search of something to drink. This question of the supply of water is of all things the most important to the person travelling in the mountains or desert. In case none can be found, you can relieve the necessities of your horse to a certain extent by peeling the thick cactus and giving him the sponge-like stuff inside which is so full of sap. As nothing seems to hurt a mustang he can take this and live on it for a while. You must be exceedingly careful, however, not to let the avidity with which he takes it tempt you to suck much of the sap as it acts strangely upon the bowels. Wherever you find willows, cottonwoods, wild rye, or other plants you may conclude there is water, and you will often find it by digging a short distance. Do not, however, look on cactus or green-wood as indicative of the fluid, for if you do, you may dig for a week and find nothing.

It sometimes happens in the mountains that you wish to travel through snow in order to examine a ledge which crops prominently. In such a case you can make snow shoes by lacing willows into a kind of flat tray, two feet long by one wide. The interstices between the twigs should be not less than three-quarters of an inch in every direction, as while using the shoes you must permit the snow to fall through when the foot is lifted. In binding these shoes on the feet, the ball of the foot must be nearer the toe of the shoe than the heel, so that when the foot is lifted and advanced the heel will drag in the snow. Unless they are put on in this way the wearer will be continually tripping and falling down. In very cold climates it is necessary to place some extra covering on the feet. A piece of blanket, or in default of that, a gunny sack, cut into a triangular shape and wrapped over the boot, the two long ends being tied together, will be found to afford ample protection under any ordinary circumstances. As the feet must be kept warm in cold weather so the bowels must be kept warm when the weather is hot. It is a singular fact that the greatest preventive against dysentery or any form of cholera is a flannel band around the abdomen. This "cummerbund," as it is called in India, should be about ten inches wide and long enough to go once and a half around the body, the double being placed in front. It can be secured by pins or tapes, and the prospector should always carry a spare one.

Much of the work of the prospector is described in the article headed "Locating a Mine," and a reference to it will give a fairly complete account of how this work is done. But in considering such a subject as prospecting as a profession it is necessary to not only describe the knowledge and kinds of information needful, the method of obtaining them, the outfit which must be procured, the precautions which must be taken and the dangers which must be avoided; but some account must be given of the formations in which the prospector is apt to find the sought for ledges and their geographical distribution. There are also certain signs or indications found in the country over which he travels which will give him many hints of great value. First for a broad generalization. The mining history of the world has demonstrated one thing; that all systems or groups or fissure veins containing valuable metals are found at the junction, or in close proximity to that junction, or the primary and secondary formations. Sometimes in the former alone, sometimes solely in the latter, but generally in both. From this important fact we deduce the following rule: If we can not find a place at or near the junction or their two formations, we but spend our time foolishly if we prospect for mines. It is in this that the knowledge of geology which I have supposed the prospector to possess comes with the greatest value. By an examination of the country itself in a general way he is enabled to tell where to make his more particular search for valuable ledges. While this rule applies to copper, tin, gold and silver deposits, for the two latter we must discover something more; namely, evidence of metamorphic action. There must have been heat applied to the veins after they were formed. The effect of this heat upon them is but little understood, and it is not known why this action was necessary, but as a result of all experience in the matter it may be said there is "no metamorphic action upon the ledges, no gold and silver." While on the one hand if we wish to find gold, silver, copper or tin we look for a junction of the secondary with the primitive formations, and, in the case of the two former, for metamorphic action; on the other hand if we are searching for lead, antimony, zinc or mercury we must look away from the primitive *state*, anywhere from two miles to ten, and we do not need any evidence of the action of heat. These two general rules are almost infallible, and may serve to guide us at any time in our search for ledges. Now for the geographical distribution of the mining fields. In this country there are four in number west of the Mississippi river. The first begins at the Guadaloupe and Sierra Madre in Mexico, and thence runs in a northwesterly course through the territory of Arizona. The second begins north of the Colorado river where the Sierra Nevada rises and continues in a northwesterly direction for hundreds of miles. On the west it shows the talcose clay state of California overlying the granite and porphyry, while in the east there are numerous patches of clay slate and lime stone. This field has been marked by the development of the richest ledge the world has ever seen, the great Comstock in Nevada. It bends to the west through Oregon and to the east again in British Columbia, then running into the regions of perpetual snow in Alaska. Along this whole range on both sides, there are mines which we know of as far as the range has been prospected, and we may reasonably suppose that there are countless groups of veins whose existence is not more than suspected. The third is that which lies along the chain of the Wahsatch mountains. Beginning north of the Colorado, it rises east for some hundreds of miles, and thence north to join the Rocky mountains. It has been less developed than any of the fields, but has been marked by very rich ore where development has been made. The fourth is the range of the Rocky mountains with its various spurs. Beginning in the southerly portion of New Mexico, it runs north through Colorado and Wyoming, thence northwest through Montana and Idaho into British Columbia, where it turns to the north and runs parallel to the Sierra Nevada. In these four fields are to be found the best opportunities for the prospector. Up to the present time the exploration of them has not been more than begun, and where there has been one ledge found there are a thousand yet to find. Large areas of them have not yet seen the prospector at all, and their mineral treasures sleep undisturbed by his pick. The great transcontinental railways are cutting them, rendering the transportation of the products of their mines when opened, a thing easy of accomplishment. To the trained and competent prospector they offer opportunities of acquiring fortune which cannot be surpassed. He may find within them any climate he wishes to work in, facilities for mining which leave nothing to be desired and every species of metal known to men.

I have spoken of the fact that veins of the precious metals are generally found near the junction of the primitive and secondary formations. While this is true we need something more than the presence of the two formations to warrant the work of prospecting. We must find that distortion of the *strata* has taken place; that forces have been at work which would result in the formation of fractures into which the water carrying mineral could run. It is a favorable sign when we find that there are ledges interlacing the stratified rocks. The characteristic stains of oxide of iron disseminated through the vein and the pressure of sulphurets of iron, as for example, pyrites; are looked upon as being signs of continuance in the vein. When the talcose or argillaceous clay slates are greatly folded and distorted for long distances, it may be taken as a good indication of gold bearing veins. To the old prospector the appearance of the country and of the *strata* seen will tell a story. He will say that he prospects here because it is "likely ground," although in what the "likely" characteristics of the ground consist he is unable to explain. It is an undeniable fact that good mining ground is as easily recognized as good farming land, and that an old miner or prospector will rarely be deceived, but it would be impossible to describe this peculiar appearance upon paper. There are certain deposits which should be avoided.

Porous volcanic bed rock may be said to be one of the poorest grounds for the prospector. It is true that the copper mines of Lake Superior are found in this deposit, but they are, as far as I know, the sole exception to this general rule, and may therefore be considered, not unfairly, as the traditional one. The modern carbonates of lime and magnesia and the modern clay slates rarely show veins of the precious metals unless it be that a pocket of siver ore is found in the lime, and this does not happen very often. These deposits, however, form good ground in which to look for lead, iron, and coal—if the latter be the mineral sought for, the slates and shales of the carboniferous ore are, of course, the best of indications. A common practice is hunting for ledges in the neighborhood of others that are well known and fully developed. This practice is not one that can be endorsed. It rarely happens that two great veins lie alongside of each other, and it is much better for the prospector to turn his attention to places a few miles away. One of the most prominent instances of this fact can be seen in the Comstock Lode in Nevada. Although there are hundreds of locations in and around Virginia City, I never heard that any of them produced anything upon development, except those which are on the great ledge itself. Hundreds of thousands of dollars have been spent on these locations with no return, and although it will, probably, always be the case that men will take up ground in the vicinity of a great ledge, and although it is certainly a fact that the ground so taken up may be made the basis for fraudulent operations in the stock market, it is equally true that they rarely, if ever, turn out to be paying properties. It seems as if nature, when she made a big ledge of paying ore, became, as far as that particular location is concerned, exhausted, and that to find anything of value we must avoid the ledge in question. It is therefore the case that for the honest prospector, and I am supposing, of course, that the man who wishes to become a prospector is, and will be, honest, it is far better to go into "fresh fields and pastures new."

The amount of work to be done in a claim by the prospector is determined, first, by the law as settled by the government, and second, by his ideas as to what is necessary in order to sell it or invest capital in it. Both may be ascertained by an examination of the mining law, and other articles in another part of this book. For the mining men who have the necessary education and who are willing to undergo the severe training, and to live the life of hardship which prospecting involves, there are few professions or occupations in which more dazzling or richer rewards are offered in return for hard work. The great need of the present day, opportunities for men who have plenty of brains and resolution, but little money, of these prospecting may be considered to be as good as any. It may be learned while a man is supporting himself as a miner, it may be carried on in the same way, and the returns are almost certain, although they may be long delayed. When they do come, however, they more than make up for the hardships and the toil which have preceded them.

—*Alfred Balch.*

LOCATING A MINE.

THE vast mining interests of the United States have grown up from very humble beginnings. While we may trace, properly, mining in America to the copper mines of the Southwest, places in which ore was dug and smelted in order to get something stronger and more lasting than the rude stone implements made of iztli as the ancient Aztecs and the Toltecs before them called obsidian, for the use of men; there is no use of going back to unrecorded time to find the tiny shoot which has expanded into such an enormous tree, under whose branches so many men find shelter and employment. Great industries are like great movements in nature, they are marked by the same peculiarities and depend upon the same or cognate laws for their growth and their decline. As the scientists of to-day are as one in their position that to understand such a theory as that of evolution we must assume that it is going on around us, that new forms of life are constantly being evolved from lower forms by the process of natural selection, and that any statement which depends upon an assumption that the action of the law of evolution is at an end, that we are examining a final result rather than the working by causes leading to a result is necessarily an insufficient and circumscribed statement; so for us to assume that any great industry is merely the result of all that has been done is to limit ourselves in a manner not warranted by the facts. It is patent to the most cursory student that any great branch of human work embraces to-day not only the most advanced but the most primitive efforts of men in that direction, while we have the great Bessemer converters forcing out their streams of liquid steel, we have puddling furnaces and crucibles; and, if we examine the operations of the iron workers of India, China and Africa we find still more primitive methods in vogue. From the clay furnace, the tree-trunk bellows, the balls of ore mixed with rice straw of the Ashantee, to the smelting furnace, the puddling furnace, and the crucible is no greater advance than from the rude methods employed by the mound-builder to mine and reduce the copper of the Upper Mississippi Valley to the giant hoisting works, the stamp mills and the perfect plant of a mine upon the Comstock. To study the growth then of any industry like that of mining we must study all forms of it; the simple as well as the complex, the beginning of the science as well as the highest point of development reached by it. "Great oaks from little acorns grow," and if we would understand the oak we must examine into and try to comprehend the acorn.

It is this fact which gives the philosophical value to the work done in the location or discovery of mines. For no matter how great the mine may be, how valuable or how rich its product, there was a time when it slept undisturbed in the bosom of the earth, undreamed of by those who passed over it. There was a time when the first piece of its ore was examined by an eye quick to read the lesson written by old Dame Nature for him who could decipher the more or less obscure hieroglyphics—who can tell how many thousands of years ago! There was a time when the mine was located, when, commercially speaking, that mine had its beginning, when it became known. Following out the simile chosen at the beginning of this article, there was a time when the first step was taken, when the operation of the commercial law which has resulted in the great shaft, the long tunnels with their forests of timber, the powerful hoisting works, the reduction works, the mills, with their loud-sounding stamps, began. This time was when the solitary prospector, idly sitting upon some "cropping," perhaps, broke a piece of the ore in two and saw in the "gang" the rich streak which showed him that the piece of dull rock represented fortune. That was the first step in the great divorce suit instituted by man between the "gang" and the metal, the beginning of the mighty struggle during which nature was to be forced to yield up her treasures for the use and benefit of her creatures.

The actual work of the location or discovery of mines is done by a class of men called "prospectors" in the west. In the preceding article the men and their qualifications for their work are described; our concern just now is with the work itself. Mines may be divided into two great classes, the stratified and those which are confined to ledges. I am aware that all deposits of rock or mineral are, strictly speaking, *strata*, but I wish to make the difference between those deposits which cover large areas, and those which are more confined, plain. All deposits of ore have length, breadth, and thickness in common with all forms of matter, but the proportion existing between these three attributes varies enormously. In the great coal fields we have deposits which extend over large areas. Formed during the carboniferous period, there were thousands of square miles covered with the trees and plants which solidified into the coal we burn to-day. Hence it is that while the *strata* of coal have a dip in the synclinal or anti-clinal folds, that dip was given to them after they were formed, the original deposit of vegetable matter being flat, or nearly so. But in another class of mines, those in which we find silver or gold ores embedded in a quartz "gang," the ledge, whether formed by Plutonic action, by infiltration, or in any other way, was not formed horizontally. It was either shot up from below in a liquid form, or the crevice being formed by some convulsion of nature, the rock accumulated or was formed in it by some natural action. The question of the origin of these mines is one which will take far too much time to treat of here. But assuming that, in whatever way they were formed, the process took place after or before the formation of the country rock surrounding them, whether that rock be granite, porphyry, limestone, or any other found near them, we can see at once that, there is betweeen them and what I have called the stratified deposits of mineral, a wide difference. As there was this difference in the formation so is there a difference in the conditions under which those formations exist to-day, and this again implies a difference, which we find to exist, in the methods adopted for the discovery of these deposits. In other words, the conditions under which the various deposits exist although different, being fixed for each class; the man who would find those deposits must accommodate himself to the conditions. The sportsman who would shoot wild ducks does not hunt for them as he would quail.

Taking as an example of the stratified deposits one of coal in Pennsylvania, the work to be done by the prospector or locator—the man who is desirous of finding that deposit, is not difficult. The conditions under which that coal was formed being conditions which existed over a long period of time, all of the *strata* formed during that period present some of the same characteristics, whether it be the coal itself, or the shale or the slate. Each *stratum* was formed during a period of quiescence, a period in which there were no convulsions, as we have agreed to call the more violent and sudden operations of nature. The subsidence, or the upheaval was, it is true, going on, but it was going on very slowly. Had we been living during that period we would not have been conscious of the action, any more than those living in England are conscious of the subsidence going on there. After the *strata* were formed they were bent into the anticlinal and synclinal folds during the great crumpling process to which this continent was subjected, and then denudation planed off the tops of the synclinal ridges so that we have to-day cross-sections, as it were, of the *strata*, originally formed horizontally, one on top of the other. We may illustrate this by bending a jelly cake and cutting off the curve, we would then have a *stratum* of cake, one of jelly, two of cake, one of jelly, and one of cake. If we imagine a *stratum* of shale formed first, then a *stratum* of coal, and this in turn covered with a *stratum* of slate, then if we suppose these to be bent upward into a great fold and the top of the fold cut off, we will have in our cross-section a *stratum* of slate, one of coal, two of shale, one of coal and one of slate, again. While it is undoubtedly a fact that there are shales and slates which have no connection with coal; or which, to speak more accurately, were not formed during the carboniferous period, if we have the knowledge that we are in a region of country which exhibits deposits of the carboniferous, we may legitimately reason when we find our first *stratum* of slate that our *stratum* of coal will be found next to it, and that of shale in its proper place. It is scarcely necessary to say that this series is purely illustrative, and is not instanced for the purpose of describing the manner in which coal is always found to exist. It merely serves to point out the fact that the conditions under which the *strata* of the carboniferous age were formed having been the same, or nearly so, we may reason from the presence of one *stratum* that other and more valuable ones may be found.

The first discovery of coal in Virginia was made by a man named Bunson. He found a lump of black stone which he used to support a pan in which he was cooking, and he noticed that the stone itself burnt up, thereby tipping the "fat into the fire." At least, this is the story as told, and

"I tell the tale as 'twas told to me;
I cannot tell how true it be."

But whether Bunson lost his dinner and found coal, certain it is that coal must have been originally discovered in some way analogous to this. No amount of natural induction would ever teach a man that he could get warmth and heat out of a stone, and such coal must have appeared to the man who first saw it. Therefore, the first prospectors, the first locators of a coal mine must have discovered the mine purely by accident. Following them came the class of men, so largely represented by the prospectors of to-day, who, having seen black stones burn, when they found black stones tried them in the fire to see if they would burn. A step above these is the class who recognize coal as coal the moment they see it, and who, judging by the cleavage or the way in which it breaks, the appearance, the gravity, and any other of the attributes which experience has taught them coal always possesses, have no need to apply the fire test in order to know that it is coal which they have found. The methods by which these two classes arrive at the same conclusion are both outcomes of what might be called a rude experience. The first is the *experimentum crucis*, the experience formulated into a syllogism something like this:

Coal is a black stone which will burn;
This black stone burns;
Therefore this black stone is coal.

The second class reason in a more complex syllogism, but none the less as the result of experience which is personal. There is a third class of prospectors who reason from the experience of others. To arrive at their methods we must go back to our consideration of the conditions under which the coal was formed. During the carboniferous period, life, in both vegetable and animal forms, existed upon the earth. It is known that forms of life in all ages have left behind, embalmed in the rocks, unmistakable traces of their existence, and these traces we have agreed to call fossils. In the great book of nature, that page which we call the carboniferous period has upon it some characters which are peculiar to itself, interspersed with those which run through many pages. When, then, we find a part of some page, and on it find the characters which we know are confined to the carboniferous, we reason at once that it is the carboniferous that is spread out before us. As the conditions which brought about the forms of life seen in their fossils in the coal existed during the formation of the shales and the slates, we may expect to find those same fossils in those shales and slates. And, as a matter of fact, we do so find them. Observations of many men extended over many years, tabulated and reasoned from, have given to the student of geology and mineralogy a method of identifying the coal whenever and wherever he sees it. It is quite competent to imagine a man who had never seen the coal itself, but who had seen and studied pictures and casts of its fossils, a man, too, who did not know that coal was black, finding a piece of stone having in it a characteristic fossil and pronouncing it to be coal. But science has gone further than this. In the presence of the coal itself the student is no better off than the man who tries it by fire; the former identifies it by its fossil, the latter because it will burn. In the presence of the shale, the student has an enormous advantage over the tester by fire, because the fossils will tell him that it was formed during the carboniferous period, and he may expect to find coal near, while neither the shale nor the fossils will tell the fire tester anything at all. Hence it follows that the prospector for coal must be a man to whom the *strata* ordinarily associated with the coal will tell a story. The man who works by the light of the syllogism given above, must, before he can apply it to his work, find the coal itself. No matter how much he may wish to discover the mineral, the ground over which he walks is a book whose pages he cannot read. He cannot tell that he is near the discovery until that discovery has been made; within a few feet of the vein he is mentally miles away.

The process of examining a country for coal is one which does not differ from any other form of geological surveying. The pages studied by the prospector or the geologist are the "croppings" of *strata*, the edges where they have been cut by denudation or by glacier, and which have not been covered up by earth. There are few places, especially in mountainous or hilly regions where the rocks do not crop out. A ledge being seen, the prospector examines it; he breaks the pieces of rock in two with his hammer; he looks for fossils. In this period of the world's history, with the geological surveys which are carried on and maintained by the governments, we have the general character of almost any district ascertained for us. No man, for example, would think of looking for coal in the Laurentian belt in the northern part of New York and the southern part of the Province of Ontario. He would know beforehand that such search would be unavailing, and would result in disappointment. But to actually find the *stratum* of coal is the work of far more particular men, if I may be allowed the use of the expression, than the geological surveyors. The members of the survey are acquiring information by which they may map out a large district; the prospector for coal cares nothing about the district as a whole, his attention is confined to the one *stratum* he is in search of. He therefore examines more particularly, more closely than do the surveyors. He finds a *stratum* of carboniferous shale, but has no interest in the discovery beyond that which attaches itself to it as the possible indication of the presence of the more valuable mineral. The shale is valueless to him; to the surveyor it is as valuable as the coal being a stratum in the measures. In fact, if full of fossils it is more valuable. To the prospector the number of fossils found in the shale is significant. If they are few he reasons that the coal lies below the *stratum*, and to find it he must search away from the dip: if they are many he reasons that the coal lies above the shale, and he must look in the direction of the dip. The character of the fossils, whether vegetable or animal in origin, will tell a story, and the parts of vegetables, as the roots or branches of plants, will give him information. The deductions to be arrived at from these indications and the character of the fossils themselves, their description or their nature does not enter properly into such a subject as that which I am treating. These and other things are to be learned in the study of geology, whether that study take place in the class-room or in the mine; or better than either separately, in both. And this leads me naturally to the statement that the most successful prospectors are practical men—men who have learned the characteristics of the coal of whatever kind in the coal itself. The difference between this class and the purely scientific men is the difference which exists between theoretical and practical knowledge, the difference seen, for example, in the knowledge of a city possessed by a man who lives there, and one has spent many hours poring over a map.

There are other deposits of mineral which although stratified in the limited sense which I have used the word are not to be discovered by a study of fossils. In the search for them we are approaching the method of discovery which must be employed in the location of the ledge mines. We may properly divide the process of location of minerals into three classes: 1st. That in which the *strata* associated with the mineral we are anxious to find will indicate to us its possible presence; the mineral itself being one the deposits of which cover a large area. In this class the best and most striking example is the coal which we have just been discussing 3d. The mineral existing in ledges which are narrow although long, and whose width is wholly in the earth. A ledge of quartz is a good example of this variety. Formed in rocks which were there before it was formed, it is a wholly separate thing, and one which is not and cannot except to a very slight extent, be indicated by any other *strata*. In the case of a coal bed, if we find it on one side of a synclinal or anticlinal fold, we may conclude that we will find it on the other side, because we know that it was probably formed over a very large area. But in the case of a quartz ledge we never find it anywhere else; we never, so to speak, discover that there is a continuation of the story whose first chapters we found so interesting because so valuable. That ledge is by itself, is alone. Midway between these two classes is number 2 which has some of the characteristics of each. The *strata* in it were formed over large areas, and have been subjected to the folding process, and we may look for continuations of the *stratum* when once found. But we cannot discover it by the indications contained in the other *strata*, and fossils do not teach us anything. Of this class the best examples are some of the iron ores which, found in immense bodies extending over large areas are frequently of enormous thickness. In the location of iron mines the chief work to be done lies in the actual finding of them, and this is not as absurd as it at first sight appears to be from the fact of its being so perfectly self-evident. As the *strata* above and below a bed of red hematite for example will not indicate the presence of the ore in any way save possibly by the color, it follows that the prospector must look for the hematite until he finds it. Fortunately, and this may be generally said about all minerals belonging to this second class the characteristics of the ore are such that it can be identified at once. There is no such thing as mistaking it; that is by a person who knows anything at all about what he is in search of. As it generally exists in large bodies, it is as a rule easily found, and the work of the prospector is thereby lightened to no slight extent. In mines of this second class the color of the mineral is one of the chief guides to its discovery. The ores of iron, either red or brown hematites, or those of copper may be distinguished often at long distances by the sense of sight alone. When found the prospector examines them by breaking the lumps with his hammer and sometimes subjects them to some simple form of smelting. As a rule, however, he recognizes them at once by their appearance, and as their value is perfectly well known and varies but slightly, little requires to be done after the discovery. He has, of course, to examine the extent of the deposit as far as he can and to take such measurements as are possible under the circumstances. It is a characteristic of this second class that the values of the ores are known to be far more fixed than those of the first or third. Coal is coal of course, but all coal is not equally good or equally valuable. As to quartz mines they vary in value with a regularity which would be charming from its very invariableness were it not so extremely irritating to their possessors. But the ledges of this second class are always themselves worth just about so much. The presence of metal in red hematite for example is constant, and the value of the mine may be calculated almost mathematically by ascertaining the cost of reducing the ore in the place where it is found. This reduces the work of the prospector enormously. While he is obliged to find out when he discovers a bed of coal, whether it be hard or soft, "black" or "brown"; its heating power is short, and when he discovers a quartz ledge what the value of the rock is, if it is merely a pocket or is a permanent vein; when he locates a body of iron ore he can assume all of this for granted. The prospector for the minerals of the second class has certain facts, the knowledge of which guides him to a limited extent. He knows, in case he is in search of iron, that the bottom of the streams flowing over the bed are apt to be colored by the ore, and he can find this color particularly in the clays. But in the search after ores of the second class as in any other pursuit, special knowledge is necesary which can only be acquired by study or experience.

The prospecting for and the location of mines of the first and second classes is to a very great extent a sporadic occupation. There are few if any, men who pursue it as a settled business, one to which they devote their lives. The reasons for this are obvious. Lands containing the minerals in the Eastern states are generally owned by persons whose knowledge of them is confined to a more or less disheartening experience of their lack of value for agricultural purposes, or to companies formed for the purpose of developing those minerals. The man who finds the mine on the first has to settle with the prior owner of the land before he can acquire a title to the property. Then too, as the minerals themselves belong to classes which take up whole districts and whose presence is naturally expected from the known fact of the existence of other beds, the owners of lands are always on the lookout for such beds. These causes operating together make the profession of prospecting one which gives but few returns. In order to find a distinct class of prospectors, of men whose sole business is to find and locate mines we must find some place where the fact of the discovery of the mine gives the title to the property because it is only in such a place that the prospector is repaid by his work for his work, and it is only in such a place that the title to the mine becomes a piece of property that can be realized on at once. A region which will support a class of prospectors must also be one in which the existence of other mines can only be inferred from those already found. You must be able to suppose, not to conclude, that because you have a mine, another can find one. It must be that each mine is complete in itself, and as its existence could not be predicated from that of any other so its discovery can be no guarantee that others will be made. It is only in this way that the finding of mines can be made a business because it is only in this way that there can be any reason for such a business. In the coal regions of Pennsylvania property in the neighborhood of coal mines has a value simply from the fact that it is in that neighborhood. Men reason that land near a coal mine is apt to contain coal, and an examination of the physical character of the country will enable them to reason with considerable amount of certainty about their chances of discovering a new bed or the continuation of an old one. But prospectors can only exist as a class where there is none of this reasoning possible because they make a business of hunting for and finding mines, the previous existence of which had not been suspected. In order then to have a class of prospectors you must have natural conditions and artificial conditions, not only must the ore bodies be unrelated to each other but the laws must be such that men finding them will receive a reward in the shape of acquiring property at once. In no part of this country are these conditions so perfectly carried out as in the mineral regions of the West. The law gives, under certain easily fulfilled stipulations, absolute property in the locations made to the prospector; and from the existence of a thousand known mines you could not predicate that of the thousand and first with any degree of certainty. It follows then that in the west we might naturally look for the prospector in what may be called his most perfect state of development, and as a fact we there find a class whose sole business is the hunting for, and the location of ore bearing ledges and veins.

The work of the prospector in his search after mines is very peculiar. As far as the mine itself is concerned, he starts out on his hunt without any very definite idea of where he is going to find it. He "concludes" or he "reckons" that a given range of hills are "likely looking," and he proceeds to prospect them. The chances that he fails in his search or that he succeeds are about even. The only indications from which he can reason at all are of the slightest possible character. If he knows that there are what are called recent placers on some river he may conclude that somewhere along that river there are free gold-bearing ledges, but beyond this he has little to guide him. The work of prospecting divides itself naturally into the three kinds of mines, prospected for, placer, pocket and ledge. That "all things may be decently and in order" I will take them in the series as named.

The outfit of a placer miner or rather of a man who prospects for placer mines is of course selected with a view to the kind of work to be done. Placer mines as they are called in the west, or "diggings" as they are more familiarly styled, are places where the gold having been torn from the ledges by the process of denudation, generally carried on by means of water, and swept down by the floods has finally found a resting place. Gold being very much heavier than the quartz or other rock associated with it soon sinks to the bottom of the water. If the stream be very violent it will, especially if it be in small pieces, be carried along until it comes to some place where there is an eddy or a pool, in which the water lingers for a time. Here it will sink at once and rest upon the bottom. The water still moving has power enough to carry the clay and the lighter pebbles along with it leaving the gold and larger stones behind. This process of separating the gold from the rocks in which it was originally, may have been carried on on a very grand or a very small scale. In the one case, millions of tons of rock have been torn away and ground to powder by the action of the water, reducing high mountains during the process to small hills or cutting them away altogether.

On whatever scale the work has been done the subsequent action upon the gold and the rock is the same. It is always swept down by the water until it finds a resting-place, while the small pebbles and the clay are carried away. It may be that the gold is deposited all along the stream during the long years which succeed each other in uncounted decades while this work is going on, and then comes some great flood strong enough and fierce enough to tear up all the gold so slowly deposited and sweep it with the large stones further down. But sooner or later it finds a place from which it is never moved except by man. These places are called "placers," whether large as in the case of the gravel mines of California, or small, they are always the same. They are the resting-places of the gold, the places where it has lodged after denudation has torn it out of its quartz, and water has carried it far away from where the ledge in which it was formed or originally stood. To find these places the prospector doth seriously incline. Loading up his pick, shovel and pan, together with his food, he starts out to hunt for some "diggings" as he calls them. He could not tell you why he selects a particular spot as a "likely location," but experience has taught him where to look with best chances of success. If he finds an old river-bed whose sides show in their water-worn condition where the water ran in the old days long before the time of man, and following it up he sees that these sides suddenly widen out until they form a basin and then contract again, he will say at once, "Thar wer' a mighty big eddy here onct;" and he will be right. If he finds a place where the old river ran over a high ledge of rocks, either as a water-fall or a sharp rapid with a pool below it, he will "reckon it's a kinder likely spot," and he will begin to dig. Hundreds of signs speak to the old prospector trumpet-tongued, and guided by their silent voices he begins his search for the yellow metal.

Taking his pick he loosens the soil and shovels it out. He knows that somewhere beneath the surface of the ground and the centre of the earth is what is called the "bed rock;" that is the *stratum* of rock or clay below which the old river did not dig and above which it deposited the gold. This may be anywhere from five feet to two hundred, but as a rule it is not anything like the latter distance down. Reaching the bed rock in time, his first work is the looking for large nuggets. Of course while sinking the shaft he has kept a bright lookout for the "color" as he lovingly calls the gold in his quaint slang. Should he find pieces of the yellow metal large enough to be picked out with his fingers, he at once concludes that his claim is enormously valuable. This, however, is rarely the case, for as a general rule he must resort to the pan to separate the gold from the gravel. "Panning," as it is called, is the simplest of all operations to look at, and while not difficult to learn is yet one in which there is a certain knack which takes time to acquire. The prospector knows by looking at the kind of dirt likely to contain gold, and he rejects what he finds on top of his shaft without the slightest hesitation. But when he begins to get down below and to find a kind of clayey sand having in it more or less black sand, he separates that carefully from the gravel and fills the pan. Taking it to the side of the stream, if stream there be in the neighborhood, he first picks it all over carefully to separate the pebbles. This is often done in a quicker way by filling the pan with water and then using the fingers as a kind of sieve, allowing the finer stuff to pass between them as they are shaken to and fro in the water. Having got the pebbles out the prospector stirs the masses of clay with his fingers until the water is fully charged with it, and then, after allowing that water to settle for a moment, he pours it carefully away. He repeats this operation until the clay is all dissolved and washed out of the mass in the pan. This as a rule reduces the amount of stuff in the pan to no slight extent. Then the real work of separating the gold begins. Filling the pan with water and taking it in both hands, generally resting the elbows on the knees as he sits on some convenient stone, the prospector gives a peculiar circling motion to the water. It is done in such a way that each time the little wave comes around the pan, a small amount of the sand will be swept over the edge. If he has a partner, and prospectors after placers rarely travel alone, this partner pours in more water. A constant repetition of the process results in gradually reducing the bulk of stuff in the pan until when he pours the water off after a scientific twist which spreads all the stuff left over the bottom in a thin layer, he can see specks of gold shining in the sunlight, and he knows beyond a peradventure that he has found a placer which is valuable. Having found their placer, his partner and himself proceed to locate it legally by complying with the regulations of the mining district in which it is situated, or doing what is required by the United States law.[1] And it should be mentioned here that among mining men the district regulations are often somewhat different from those of the Government, so that it will often pay the prospector to familiarize himself with them. These differences between local and general law while permitted by the latter are far less frequent now than they used to be. Miners have discovered that the law

[1] See chapter on Mining Laws.

passed by the Government is so practical and so just that there is no necessity for any change.

The second class of prospectors in the far west, those who hunt for pockets, are the most improvident and the most peculiar of all men in the business. A "pocket" is the technical name for a small or large deposit of nuggets of gold. How pockets originated or what brought the gold together in the manner in which it is found is a question which cannot be answered here. The theories upon the subject are as many as theories generally are in cases where men are at a loss to explain anything. Certain it is that pockets exist and that large sums of money have been taken out of them. They are of two kinds, those found in old or present water-courses, and those on hill-sides. The first were of course created by the same action which has brought about the existence of the placers. They are generally holes in the rocks at the foot of some waterfall into which large nuggets have fallen. The search after them is the same as that after the placer mines. Hill pockets, or mountain pockets as they are sometimes called, are holes upon a hill-side in which gold has accumulated. Their origin is to the last degree mysterious. The hunt for them, however, forms the occupation of a class of men called "pocket hunters," and is carried on in this way: The prospector starts out armed with his pick, shovel and pan. He has absolutely nothing to guide him in his choice of ground to be tried, and one place being as good as another, his route may be traced by the little holes out of which he has taken a panful of dirt to wash. We will suppose that after a more or less prolonged search, he finds in one pan of dirt a few specks of color. If this be at the base of a hill, and he generally tries the dirt in these places, he proceeds to wash dirt taken from holes ten feet apart in a line horizontal to the spot he first found the color. He may find gold in several of these places, but he prosecutes his search until he establishes two points beyond which he does not find the gold in the dirt.

Between these two points is the base line or an imaginary triangle, the apex of which is, he hopes, the wished for pocket. The theory upon which the pocket miner works is simple in the extreme. He reasons that the gold in the pocket being slowly distributed in the form of float or fine gold by the action of denudation and as slowly washed down hill by the rain, gradually widens out as it moves covering *a larger or smaller*, a constantly increasing area. Having a base line for this imaginary triangle of, let us suppose, one hundred feet in length, he strikes a line twenty feet up, and this he proceeds to test by washing pans of dirt taken every few feet across it until he has established two points as before, beyond which he fails to find the gold on either side. This gives him a second line, which may be called a sector of his triangle. If this second line is shorter than the first and if it corresponds to the first; that is if a line bisecting the first and second would run up the hill, the prospector assumes at once that there is pocket. But should the second line be longer than the first, there being no natural configuration of the surface of the ground to account for this, as for example gullies or ridges, the prospector finds himself at a loss. Assuming, however, that he finds everything all right in the second line, he takes a third still higher up. The first and the second together will give him very close instructions as to the length of the third line and where to locate it. The first being one hundred feet, and the second forty, he aims to make the third about ten. Having done so he begins his search for the pocket itself and when he finds it, as he almost surely would under such a combination of circumstances as I have imagined, he may find that it is what is called a "washed pocket" or one in which denudation has dispersed all the gold; or on the other hand he may find that it is an exceedingly valuable deposit. Large sums of money have been taken out of pockets discovered in this manner. It is scarcely necessary to say that of all modes of livelihood adopted by men, pocket mining or prospecting is the most precarious. While the pocket miner must find ten or even twenty thousand dollars worth of gold which he gets out in a day's work, he is much more apt to go months or even years without finding any. The class of pocket miners is one which is rapidly dying out, and one of them is rarely seen now. It used to be recruited from placer miners, and the men who went into it were generally old. It was noticeable, however, that a pocket miner who was once successful rarely if ever gave up the pursuit.

The third class and highest development of the *genus* prospector is that the members of it search for and discover ledges containing the precious metals. The work is exceedingly hard and full of strange vicissitudes, for to-day the prospector may be so poor as to find it difficult to secure credit for a side of bacon while to-morrow he may be worth thousands of dollars. In beginning the search or the prospecting trip, the prospector secures what is called his "grub stake." This generally consists of a side of bacon, a bag of flour, one of beans, some tea or coffee, some sugar and salt, and a few chili or red peppers. His personal outfit consists of a gray suit generally covered with one of brown jeans, a pair of blankets, a felt hat, strong boots, revolver, ammunition, knife, canteen, pipe, tobacco, fire bag containing matches, a rubber blanket or a buffalo robe and one or two personal conveniences of some sort or other. His camping outfit includes an iron pan which may be used as a frying pan, a plate or a pan to wash ore in; an iron pot of the kind known as a Dutch oven, a tea pot and tin mug. For the actual work of prospecting he takes a pick, shovel, a horn spoon, as an ellipse cut from the outer curve of a horn, is called, and sometimes a small pestle and mortar. If he be well off when he starts he is apt to add to his stores a small quantity of mercury and a large iron spoon. If he be the possessor of a horse or mule he packs all these things upon it, but if not he secures a *burro*—the Spanish name for a donkey—and makes the animal carry the "plunder." Some prospectors carry a heavy hammer with them. Starting out he leaves the mining town for a trip which may last anywhere from one month to six or as long in fact as the provisions hold out. He has nothing to guide him in his search beyond the fact that he believes that there may be locations in the district into which he is going. To a certain extent his search might be called an indefinite one from the fact that the ledges may be discovered in one place as well as another, and, therefore, all places are alike at first. The greatest assistance given to the prospector come from the "float." A ledge of rock "cropping out" or appearing above the surface of the ground at the top of the hill gradually crumbles by the action of water and air upon it. This action, scientifically considered, is a form of denudation ordinarily called by both scientists and miners, "weathering." As the pieces of the vein fall off or become loosened, they, aided by the rain, move away from the ledge, and as a matter of course always roll down hill. These pieces are called "float rock," and the name is applied to them irrespective of the mineral contained in them. There may be "barren" float or "country" float just as there are "barren" ledges or "country" rock. The prospector never passes one of these accumulations of float at the foot of a hill or on the side of the mountain without taking the precaution of breaking and examining a number of stones. In fact the prospector is always breaking stones; now a spur or point of some ledge projecting from the earth and now a loose pebble which he finds laying on the surface of the ground. We will suppose that he finds in a piece of float he has just broken in two, the wished for ore. He recognizes it as quickly as one would recognize the face of a friend after a mask is taken off. The next thing the prospector has to do is to "trace the float" or find out where it came from. In this he has one almost invariable rule to guide him. Wherever it was that the float started from it did not come up hill. If he breaks a number of pieces of float and finds that they all contain the same ore and if he sees by looking up the hill side that the stones are pretty regularly scattered over it below a line about half way up he may conclude at once that the ledge is there. If he finds the stones are all over the hill side as far up as he can see, he concludes that the ledge crops out on top. He can tell by examination whether the float has been there for a very long time or if it be comparatively recent.

In either case he simply walks to where the ledge is, and as a rule he generally finds it pretty easily, and proceeds to "locate" it. But it may be that the prospector finds his pieces of float in a water course either ancient or present; or at the mouth of a *cañon*. In such a case the work to be done by him is much more complex and difficult and involves the expenditure of a greater or less length of time.

The search for the ledge after finding the float may take a month or a year. In fact instances are not wanting in the history of mining in the west where men have spent five and six years hunting for a ledge where the float was particularly rich. Should the float be discovered in the bed of a water course or at the mouth of a cañon, up that water course or cañon the prospector goes. He is particularly careful to examine all loose stones found on the way because he reasons that where one piece of float exists it is probably not alone; and the discovery of other pieces will always prove two very important points, namely that he is on the right track and that the piece of float found by him at first was not "a stranger." The greater number of pieces of float found the nearer the prospector reasons he is to the mine. At length there comes a point beyond which he cannot find any. He then begins the search after the ledge on each side of the water course or cañon and this search is conducted in the same way that he works when hunting for one of whose existence he has received no intimation from the discovery of float. He walks over the ground breaking off and examining a piece of any spur or ledge of rock he may see. Sometimes but rarely he may remove the surface soil with his pick and shovel in order to find what kind of mineral is in the bed rock. Working in this way and in a direction at right angles to the "strike" or longitudinal line of the *strata*, he examines everything in sight until he either gives up the search in disgust or finds the ledge. It may be said here that the former is a rare termination to the trip, for prospectors are of all men the most patient and unwearying in the prosecution of their work.

Having found the ledge either by walking up a hill to where it is or by tracing float and examining the district for a time extending over months, the work of location begins. This may be properly divided into three parts. An examination of the ledge to ascertain its value, compliance with the necessary forms to secure possession, and the securing of facilities for working. To take these in their order, the prospector secures from as many points as he may small pieces of ore or ledge matter. These he selects from the most promising points laid bare by weathering or by his efforts with the pick. Placing them between two flat stones he pulverizes them to the size of peas. He then mixes them thoroughly and spreading them out selects half. These he pulverizes more finely and mixing again, again takes a half or a third. He continues this work until he has got about ten ounces of what he considers a fair average sample of all the rock chosen at first. Pulverizing this yet more finely, in fact as fine as he can get it, he washes it in a pan or horn spoon—"horns" it as the miners say—in order to find the color if there be free gold in it. If it contain sulphurets he roasts it in his iron spoon over the fire. As free silver is seldom found except in the form of wire in the clay seams it is recognized at once by its appearance. Whatever method be taken to assure himself of the value of the ledge, the prospector always depends to a considerable extent upon the appearance of the ores. He is familiar with the look of chlorides, sulphurets or carbonates, and an examination of the ledge will determine for him by the eye, the proportion existing between these and the barren "gang" or rock surrounding the ore. Valuable ore being always mixed with gang vein matter or barren rock—these all mean the same thing when used in this sense—the proportion existing in the ledge between the ore and the gang is a very important point to ascertain. The prospector measures the thickness of the ledge and traces it as far as he can find the croppings. He also examines the "walls" or ledges lying on each side of it and endeavors to find a ledge or ledges parallel to it at a short distance away. He then "locates" the mine using the word in a strict sense; that is, he proceeds to comply with the directions of the law in order to make it his property. He measures off a parallelogram fifteen hundred feet long by six hundred feet wide and builds piles of stones at each corner. In one or more of these he places a notice of his location. When he returns to the nearest recorder's office he files a copy of the notice of location and a description of the claim, and he then has complied with all that is necessary to make that claim his property. Certain amounts of work must be done each year in order to hold it, but these are prescribed and set forth in the Mining Law and the decisions of the Land Office. The prospector may also claim a mill site within easy distance of his ledge as well as a water right if he can find one. The mill site must not exceed five acres in extent and must be upon non-mineral ground. As the possession of a mill site and the water right increases the value of the property greatly, they are almost always taken up or located when it is practicable. The prospector then has found his mine, and by that act together with compliance with certain formalities which are very simple, has become its owner. He may sell it, develop it, lease it, or allow his title to lapse. It may make him very rich or he may find that he has lost his time and labor. What becomes of the property after he has got it is of no interest to anyone but himself, and the consideration of such a point must be made under some other heading than that of the location of a mine.

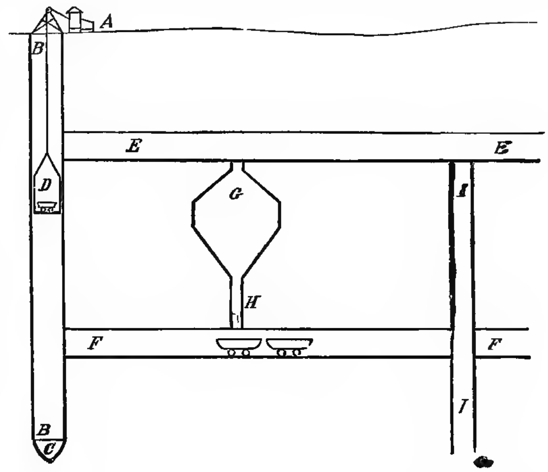
—*Alfred Balch.*

THE OPERATION OF A MINE.

A GREAT business, a great ship, a great army must be managed by some one. There must be some one man to whom questions may be finally referred; who shall decide all points one way or the other. That man must have various qualities of mind or he cannot grapple with the problems submitted to him, he must have knowledge or he is powerless before the questions which present themselves, he must be decided or his decisions are valueless because there is nothing permanent about them, he must be candid or he will persist in mistakes and will not save himself by changing his policy before it be too late. He must be a business man, a practical man, a theoretical man, an executive man. In few words, he must be an efficient man. These are briefly the qualities which must be found in a mining superintendent. The business connected with the mine being of great extent he must be able from previous knowledge and training to settle questions appertaining to it at once and with a due regard for the interests of all parties or there is a waste of money. There being an enormous amount of machinery employed, he must understand not only the operation of such machinery when put up but the method of constructing it. He must be a surveyor and understand the questions which are studied by the civil engineer because he may be required to build roads and bridges or to construct canals; and in any event he is at all times required to know the state in which the mine under his charge is. He must be a miner, for otherwise he cannot know when the men employed are working to the best advantage. Questions of *strata* or of the policy in connection with faults occur in the management of mines, therefore he must be a geologist or he is powerless to meet them. The ore varies in value or changes in character; he must be a mineralogist to know what to do and why he does it. At this point, too, he brings chemistry to his aid, and in his laboratory finds out either personally or from his assayer, what conclusions to draw as to the practical working of the ore from the indications given by, and the results of, the tests. While he may not be able to make these tests himself or it may not pay him to so employ his time, he must be competent to draw conclusions from them. He has to superintend the building of furnaces and he must therefore know the value of mortars, the pressure of air blasts, the strength of fire-brick, and the angles of incidence which effect heat. His furnaces have to treat ores and he must understand the value and proportion of fluxes and be prepared to vary them when the character of the ores change. The mine itself is a vast underground working having in it avenues called shafts, streets called levels, workshops called "breasts," "faces," or "stopes." There are many men employed in these places, he must know to supply them with air. Enormous amounts of bad air and noxious gases are set free, he must know how to get these out. His mine may heat and he must know what to do to cool it. The men employed may strike and the superintendent must understand the problems of political economy which are included in the relation of labor and capital. In fact the list of the different branches of theoretical and practical knowledge which he must possess is almost endless, and the reason why is very simple. As interests involving vast sums of money are committed to his charge, unless he understands and can decide rightly in the questions created by them, he will be inefficient and worse than worthless in his position.

In view of this fact can the practice of employing any man as a mining superintendent who is destitute of the special training necessary for such a position be looked upon as being wise? Is it possible that men who have a part of the training only, business men or geologists, or engineers, or machinists, or chemists, or miners, can succeed? It must be remembered that as the successful management of a large mine involves questions which relate to each and all of these special branches of information, the chemist may be confronted at any time with one only to be settled by the machinist, or the business man with one which must be referred to the geologist. The mining superintendent must be a "many-sided" man if he would be a successful one in his position, he must be prepared to treat two subjects, one after the other, as different as are the calculations of an eclipse and placing of a market value upon a wheat crop. In order to treat the questions which have to be settled by him; in other words, to write an article under such a title as that at the beginning of this, it is necessary to divide the subject into two parts. These may be stated as, 1st, the mining of the ore or those questions which affect the mine itself, and 2nd, the working of the ore or those which arise in the separation of the valuable metal and its preparation for the market.

First then, as to the mining of the ore. The obvious commencement of mining upon any ledge or ore body is digging the ore out. Given a ledge or ore body the first work is that of making a hole. But as such a deposit can not be called a mine and as the really important questions of mining are only presented for solution after that deposit by the work done upon it, has become a mine in the strict sense of the word, it follows that in order to examine these questions in detail it is necessary to presuppose the mine to have been created by the development of the deposit. Supposing then that this has been done and that the property consists of deposit, shaft or tunnel, levels, breasts and stopes, what are the points which naturally arise in the mining or getting out of the ore. And here again the question which is obviously the first to be settled is that of how to dig or tear the ore from the deposit of which it forms a part. If the ore be soft and easily worked, this is generally done by the manual labor of wielding the pick. The miners cut the ore away in the breasts with the pick alone. But if it be hard the drill is brought into play and three miners working together, two strike while the third turns the drill in the hole. The invention and perfection after many changes of the diamond drill has brought machinery to the aid of the mine owner, and the amount of drilling or "boring," as it is generally called, done by them is vastly in excess of anything which was done before. They are most valuable parts of the "plant" or stock of machinery owned by the company, and are to be found in all mines the character of whose ore warrants their use. The holes having been drilled or bored, cartridges of some explosive are placed in them and fired, the result being the tearing out of large masses of the ore. For a long time powder of the ordinary kind was the only substance obtainable for the purpose but as mining became more and more of a settled industry carried on under more perfect scientific methods, explosives of far greater force and efficiency were discovered and applied. Nitro-glycerine, blasting powder or dynamite are now used almost exclusively. They are exploded by a fuse or by electricity, and are vastly more valuable than the common powder. The actual work of mining or getting out ore from the deposit is pretty much confined to the two methods of picking and blasting. There are cases of course where a deposit is found in such a shape that the breaking of the ore with sledge hammers is all that is necessary, but as such deposits are exceedingly rare, we may conclude, for practical purposes of inquiry, that the pick and the drill in whatever form the latter may be used, are the representatives of the methods employed. And speaking of the latter, a word should be said about the power drills worked either by compressed air, steam or transmitted power, those in which it is sought to imitate the action of the hand drills. The distinguishing characteristic between these and the "diamonds" is the fact that they are made to strike instead of bore. As a rule they are not very effective from the fact that so few of them "clear" themselves; that is, get rid of the rock pounded up by them, effectually. They have their uses, however, the greatest being for employment in shallow working where the holes sought to be drilled are not very deep. The ore having been torn from its bed has to be carried in some way to the shaft. This is generally done in cars running on rails or "trams," pushed by men or hauled by horses or mules. These cars run along the levels and the ore is either loaded into them by hand or allowed to run into them from the "chutes." If the ore is being cut from the face of a level, the former method is the one necessarily resorted to but in every other case the latter



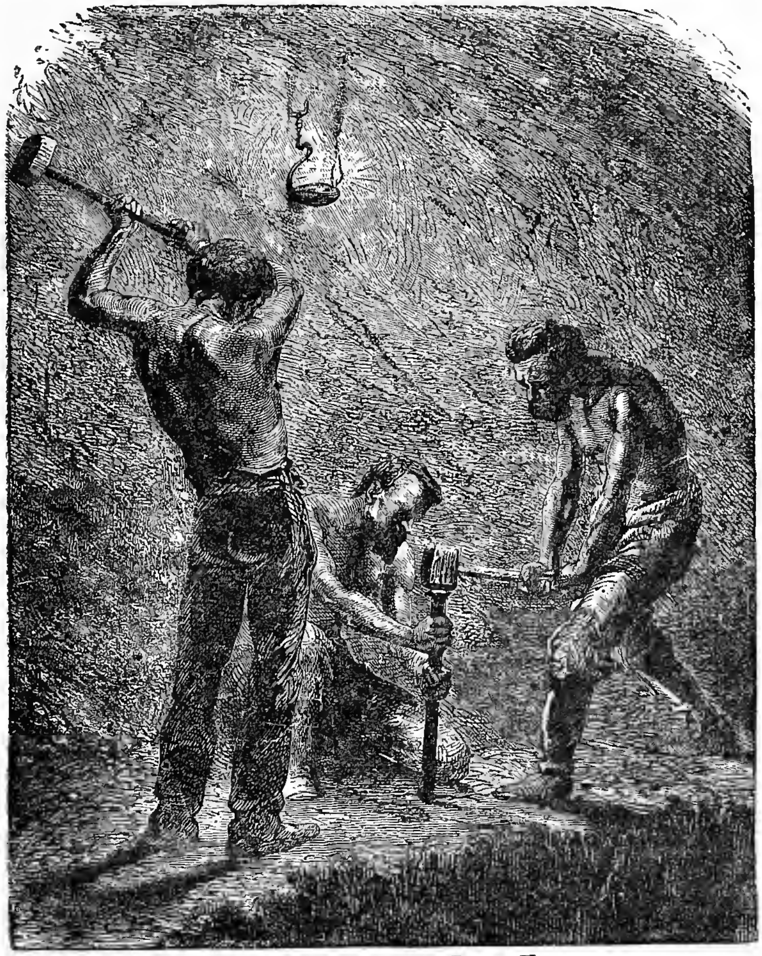
is the one adopted. A reference to the cut will explain this. Let A represent the hoisting works, BB the shaft, D the cage having in it a car or wagon, EE Level No. 1, FF Level No. 2, G the breast or place from which the miners are cutting ore and H the chute. In the cut this is all represented as though the deposit were perpendicular while as a matter of fact deposits generally dip at a more or less acute angle. But the work in any case is the same. The ore which is taken out from the end of Level No. 2 must be loaded into the cars by hand. But that which is cut in the breast G will, if allowed to do so, roll down the chute H by the force of gravity. Any simple gate will stop it and when the cars are placed underneath the chute the opening of this gate will allow the ore to roll out and fill them. The labor of handling the ore then is reduced to the lowest point, and as labor saved is money saved, the use of levels and chutes is easily seen. The ore having been got into the cars, they are hauled to the shaft and run into the cages in which they are hoisted to the surface. The spot where the ore is placed ready for sale, if it need no smelting or working, as for example, coal; or when it is heaped to wait for further treatment, is called the "dump"—the etymology of the word is apparent as it is there that the cars are dumped or emptied. This dump may be either a pile upon the surface of the ground or it may be a lofty structure of wood built for the purpose of allowing the ore in subsequent operations to move by the power of gravity exactly as it did in the shoots. So far the questions which have arisen have not been very important. Any miner knows how to operate a drill or fire a cartridge, construct a chute or load cars. But when the ore is removed a space is created which brings with it very serious questions. As each stratum rests upon that beneath and in turn supports that above, when one is removed the pressure on the lower one and the support given to the upper one ceases simultaneously.

This at once brings us to the important subject of timbering the mine and "leveling" all cuttings. The timbers placed in a mine are so placed for the purpose of supporting the stratum above, called technically the "hanging wall" or "roof." Their number and size depend entirely upon the nature of this hanging wall, its strength and cohesion. This, in turn, depends upon the kind of rock it is composed of, as some kinds of rock are more liable to break and fall in than others, it follows that they need more support. If, for example, a seam of coal be overhung by a stratum of poor shale, as fast as a few feet of the coal are worked out timbers must be inserted in their place. But if you are getting out iron ore and you have a heavy and tough limestone for your roof, few timbers are required, as the pillars left will support that roof. For in cutting out ore, no superintendent will allow all of the deposit to be extracted. Certain parts of it called "pillars," "columns," "buttresses," and a large number of other terms, are left in place. Their object is to support the roof and to prevent a "cave," as the falling of that roof is called. No part of the work of a mine Boss is more important than the determination of what proportion of the deposit to leave in this way and the number of timbers required. Timbers can only be used as auxillary to the pillars, because it would be impossible to substitute them entirely for the ore body. The pressure of the superincumbent strata is so enormous that the strongest timbers are crushed, or bent and broken by it. I have seen an oak timber, twelve inches square and five feet long, crushed down until it was only three and a half feet long. I do not mean bent but absolutely shortened by the force exerted upon it, the ends jammed together in the same way that a piece of rubber may be squeezed in a vice. Such a pressure as this is one which defies all calculation; we can only state it by stating its effects. The superintendent of the mine must then examine his hanging wall, and determine as the work goes on how many and of what size are the timbers required. But as there is pressure downward in a mine when the ore is removed so there is pressure upward. The "floors" of the levels or the breasts "heave," and they have to be constantly cut down or levelled in order to permit of the work of active mining being carried on. This, however, is properly a branch of the "dead work" of the mine, and will be alluded to more at length when I reach that division of my subject. In timbering a system has been devised and patented, in which each timber forms a part of a whole series of supports. Under it the timbers are all cut of one certain shape, and are put together in the mine in the same way that a piece of machinery is "assembled." Each one placed in position is at once a supplement to those placed before, does its own share of the work, and prepares the way for the next in order.

No matter how thoroughly the timbering may be done, there is always danger, and as the area of the worked portion of the mine increases so does this danger increase. That this should be the case is almost self-evident. As there must always be a difference in the amount of support given to the superincumbent *strata*, between that furnished by the ore deposit itself and that of the aggregate of the pillars and timbers; and as the more extensive the working the greater becomes the sum of this difference, the danger of caving must always be in direct ratio to the area of working. Then, again, the superincumbent *strata* themselves aid in the work of their support. We have already seen that there is a difference between a strong bed of limestone and a *stratum* of poor shale. If we suppose the superincumbent *strata* to be of any thickness, it follows that they will be supported to a certain extent by their own resistance to breakage. But the larger the area excavated under them, the less will the *strata* be able to resist the tendency to break down in the centre; the greater becomes the leverage exerted upon them at the edges of the excavation. As the pillars of ore left behind contain valuable mineral, and as they sometimes amount to more than a half of the whole deposit existing in the worked region, it follows that their extraction is work which will pay. There comes a time then in the history of the mine when it is desirable on the score of safety, as well as that of economy, to do something which will at once replace the ore taken out, and allow that which has been left behind to be extracted. There is another danger about these worked areas which is found in coal mines. It is that they become reservoirs or places in which the dangerous fire-damp collects. The superintendent then determines to "pull down the roof." In order to do this, he causes the pillars to be removed one by one, replacing them as far as may be necessary with timbers. Upon this work, as it is excessively dangerous, he employs only his most experienced men. Having removed the pillars, or such of them as he considers safe to move, he may do either one of two things. He may shut up that part of the mine and trust to time and the pressure upon the roof to gradually fill up the excavated portion. In this case he simply lets the thing alone, and after a longer or shorter period natural forces bring about the desired result. Or he may decide that he will hurry the thing up. In this case, he has a number of cartridges inserted in the roof of the worked district, and connected by wires. Causing all the men to leave the mine, he explodes these himself, or has them exploded in his presence by some one else, in each case the operation being performed at a distance by electricity. There being no support for the roof, for so far as practicable even the timbers are taken out, the explosion of so many cartridges at so many points brings the whole roof down in pieces. As broken stone will always occupy more space than that taken by the stone when unbroken, the excavated area is filled up. It must not be supposed that this process of "pulling down the roof" is one which moves all the superincumbent *strata*. On the contrary, the *stratum* affected by it is that one generally immediately overlying the ore deposit. In time, if the mining in any district be very extensive, the whole district will undoubtedly sink, but this requires a long period, and is an operation of extreme slowness. When the roof is pulled down, the superintendent, if the mine be one of coal, orders all approaches to the deserted district to be sealed up with walls built of stone and mortar, in order to prevent the dangerous gases collecting in the interstices between the stones, and so preparing for an explosion. In mines where such gases are not generated, this precaution is one which is of course unnecessary.

From the time that the miner has got down in the shaft a sufficient distance to begin the first level or cross cut to that when the property is abandoned forever, the ventilation of the workings is a great and almost constantly increasing difficulty. Not alone is it a task of great magnitude to persuade the air to enter the mine but in these days of extentensive workings and liberal use of explosives the difficulty of forcing the bad air and the gases generated by the ore or by the explosive agents out of the workings is a very great one. Fortunately experience has shown that currents of air can be made to move from one place or another, can be directed in such a way that they will search out the most obscure corners, provided the persons managing them know how. There are two principles which are relied upon to ventilate a mine, that of heat expanding the air and the abhorence of a vacuum by nature. Add to these a system of pumping or forcing air into a place and we have the three ideas upon the expansion of which into practical methods all ventilation of mining properties depends. There are various causes which develop heat in mines. The lamps or candles by the light of which the miner works, the heat given out by the bodies of the men as the result of that work, the oxydation of sulphur if any be present in the mineral or in the walls, being among them. There may be, too, the heat of thermal springs or, if the mine be deep enough, that which is found in the rock. If we suppose a shaft to be sunk say two thousand feet and if in the centre of that shaft we placed a tube or box or any substance, wood for example, which runs from the surface of the ground to the bottom of the shaft there would at once be created a circulation of air. The air around the sides of the shaft being heated by the walls would rise and the vacuum so created would draw the cold air down through the box. But if we kindled a fire below the box the current of air would be down the shaft and up the box. The system of ventilating a mine by heat is simply the one which we have imagined expanded to the extent necessary to ventilate the whole mine. If we run off at one side from the bottom of our shaft a level of five hundred feet in length and carried the box into the face of it we would have precisely the same thing taking place as before. The air as heated by the walls would travel along the level and ascend the shaft while the cold air would come through the box. If instead of constructing a box we placed a division in the shaft cutting it into two equal parts the cold air would descend on one side and the warm air would ascend on the other. Suppose however that we had two shafts one at each end of the level. Then the air would come down one, traverse the level and go up the other. The direction in which it would travel would depend upon the size of the shafts or the amount of heat generated. If the shafts were of unequal size, the air would come down the smaller and go up the larger. If it is the same, the air would move in the direction of that shaft the centre or equilibrium of heat was nearest to. If the centre or equilibrium of heat was exactly in the centre of the level and if the friction on the air was exactly equal in each shaft, then we could cause the air to move whichever way we pleased by building a fire at the foot of the shaft we wished it to ascend. Keeping that fire burning for a day would be sufficient to cause the air to ascend that shaft in preference to the other for all time because the cold air constantly descending through one shaft would cool that shaft off and so move the point of equilibrium of heat nearer to the other. The ventilation of a mine where pumping is not necessary is merely an expansion of the system which has just been outlined. But there are two most important variations possible in the application of this that it is well nigh impossible to lay down any one rule. The experienced and able superintendent will select that which under all the conditions present seems to promise the best results; and if he finds, as he sometimes will, that the system adopted at first is deficient, he may change it or resort to auxiliary methods to aid it. It is generally the case that auxiliary heat, in the shape of fires maintained at the foot of the shaft or that portion of it through which the air ascends, is employed. There are other methods too, such as the employment of a descending column of water, falling through a pipe and impinging into a trough, which will force the air into boxes from which it may be taken to various parts of the workings.

The most important of these, however, is the pumping or forcing of air into the mines by the employment of pressure blowers or air pumps. The operation of these may be seen



Mining Life.—Boring a Blast Hole.

—*From "La Vie Souterraine," by L. Simonin.*

system. We may either take the fresh air in through a box to the workings or we may take the foul air out. Each has its advantages. In the first we find the introduction of the fresh air and the removal of the foul easier than in the second. In the second the foul air and gases generated by explosions are carried off at once and are not forced to travel through the level to the shaft. We may dispense with the box or "Solar" as it is sometimes called and force the air to travel into one level, thence through the breasts into the other and thence out. In this case the levels themselves are made the channels or pipes for the air. The best method when it is practicable is to draw the foul air through the boxes, it being of great importance to remove the gases and heat as rapidly as possible. It may be said, however, that the determination of a method of ventilation so entirely depends upon the peculiarities of the mine to be ventilated to great advantage in the deep mines of the Comstock, where millions of cubic feet of air are forced into the deep workings during every twenty-four hours. If pumps be employed they should be double acting, that is the piston head should be solid and valves placed at each end of the cylinder. If blowers are used they should be chosen among the "pressure" blowers for the simple reason that fans have rarely enough power to do much good. A case in point occurred in one of the Comstock mines. The supply of air being insufficient a large and powerful fan was added to the blowers and pumps already in use. The men complained that the supply was less than before and an investigation showed that the air was actually being forced out through the fan although this was running at a high rate of speed. As the pumps and blowers may be employed to force the air in, so they may be used to draw it out. This however, must be considered a wasteful application of power as it is more difficult to create a vacuum and cause the air to move into it than it is to move the air itself. It sometimes, but rarely happens that the conditions found in a given working will necessitate this method of ventilation. Such conditions being purely and necessarily special do not call for more than an allusion in such an article as this.

Speaking of pumps for forcing air into the mine brings us naturally to those which hoist out water, that bane of miners! No consideration in the working or operation of a mine is more grave than this one of the removal of the water. It is of such importance as to sometimes, and in fact, not seldom, cause the abandonment of the property and is one of the risks which can never be estimated beforehand. When contemplating a purchase of course if the mine be entered by a tunnel, as speaking in general terms, it always will be when it is practicable, the question of drainage is simple in the extreme. All that must be done is to allow the water to run through the canal cut for it in the bottom of the tunnel. But in the mines where shafts have been sunk, the water must be hoisted out by pumping. And just here it may be proper to say that in the writer's opinion there never was a more perfect machine devised by man than the Cornish pumping engine. If the requirements for perfection in any mechanical contrivance be cheapness in working, ease of graduation or the amount of work done, simplicity of parts and adaptability to the end in view then the Cornish pumps must be pronounced to be perfect. No other word will describe it. The reader by referring to the cut will see at the bottom of the shaft B B a rounded place marked C. This is the "rump" or "rumph," the basin into which all the water in the mine is allowed to run. Into it open the suction pipes of the pumps, and from it the water which is pumped out is taken. It should be large enough to receive the water from the mine and to allow it to settle before being removed. The suction pipes from the pumps which lead into it should of course be carefully screened in order to prevent the possibility of small stones being sucked up into them. The rump should also be made large enough to permit of the bailing of the water by large casks, in case such a proceeding becomes necessary, for it sometimes happens that a subterranean body of water being tapped during the working, the mine becomes flooded and the pumps are utterly insufficient to clear it. An example of this was the flooding of the Savage mine in the Comstock. In such a case bailing must be resorted to. And incidentally it may be pointed out that in such a case the pumps used in many of our mines, pumps to which the steam is carried by a supply pipe from the surface become perfectly worthless, owing to the fact that the steam is so cooled down in the pipe as to lose its pressure. The Cornish pump on the contrary will work even if its rod be in the water half or three-quarters of its length. For the drawing of the mine into the rump it is necessary to cut canals in the floors of the levels. These are called "channel-ways," and should be large enough to permit any ordinary amount of water passing along them. If cut in the centre of the level the channel way must be covered with boards in order to prevent the falling into it of lumps of ore and dirt. In fact whether it be made in the centre or at the side it is always good policy to cover it in. From the levels to the rump the water must be taken in pipes of some kind, or if the shaft be timbered it may be allowed to find its way down between the timber casing and the walls. It is good policy, however, to construct pipes either of wood or metal for it to run through, as it is often of such a character as to rot the wood rapidly, and it is far cheaper to renew the pipes than it is to replace the casing of a shaft. There is use to which this water may be put which is worthy of allusion and comment.

So far we have been considering the working of a mine through a shaft, a system of levels and stoping from level to level. But it sometimes happens that we wish to sink "winzes" or small shafts within the mine which do not reach to the surface. These may be sunk for the purpose of connecting two levels, or for purposes of discovery. In the cut 1 I represents a winze connecting levels 1 and 2 and prospecting into the ore body below level F F. In sinking them the winze "chamber" or place large enough to work in, is first hollowed out, and then the work is done in the same way as that of sinking the shaft. For a short distance the hoisting of rock out of a winze may be done by an ordinary hand capstan or crank barrel, such as those used to lift water in buckets out of wells. But when the winze is sunk to any depth, this becomes far too laborious work to be performed by hand and it is necessary to employ power of some kind. If the amount of air available in such a place is sufficient, an engine is of course erected and run. But, as often happens, this is not the case and we have our choice of four methods. A horse power, transmitted power by wire ropes, compressed air and the weight of a body of water. Of these the transmitted is the best power when it can be applied, the compressed air if the work be light and the pressure of the column of water conducted in a pipe from the surface and utilized in some form of water engine when the work is very heavy. In case the water be used, it is advisable to construct an additional rump near the engine and to pump from that in order to save the power necessary to lift the water from the deep workings. As the power secured in this way costs first what it takes to raise the water to the surface again, any saving in this is a direct saving. One of the most expensive divisions of labor in a mine is what is ordinarily called "dead work." It is that work which is done in order to allow of ore being extracted, and may be compared to the building of a bridge in order to reach a desired spot. It is a means to an end. While the object of mining is distinctly that of taking out ore, it ofttimes, in fact almost always happens that a great deal of labor must be done and large amounts of money expended, before the ore can be got at. This is the dead work, and in nothing does the superintendent show his ability more than in the way in which he plans out and has this work done. He must avoid on the one hand the doing of so much that the profits of the mine are swallowed up and on the other, of doing so little that the mine is in danger of becoming "boxed," that is, of getting into such a state that the ore can be neither cut nor removed in the cheapest way. Theoretically speaking the ventilation and drainage are properly parts of the dead work, but their importance is such that they have been by common consent relegated to separate divisions. We have already had in the leveling or "plaining" of floors of the levels, cross cuts, breasts or whatever part of the mine where a heave has taken place, a reference to the dead work. The extension of levels so that when a portion of the vein or deposit is worked out, a fresh portion is ready for working, is dead work. To look at it in a general way a mine always consists of three parts, that in which the ore has been extracted, that from which the ore is being taken, and that from which it is to be taken in the future.

The preparation of this third division for the miners, getting it into shape for easy access, ventilating and draining it, is all dead work. A good superintendent always keeps mine, by doing this dead work ahead of the actual work of extraction of the ore. It is of course the case that during the time the dead work is being done, there is often some ore extracted, but it is rare that rock which is not ore has not to be taken out also.

The ore being ready for hoisting to the surface some power with which to do this is necessary. At first when the shaft is not very deep, hand capstans may be used, or a horse "whin" employed. But as time goes on steam must be brought into play. The boilers have to be put into place, the great hoisting engines built and the "pit head," "derrick" or whatever the structure over the shaft which carries the enormous "sheaves" or pulleys over which the cables run, may be called, erected. The superintendent must know how to plan these things in order to obtain the requisite amount of power. As their size varies with each mine it is very difficult to say much about them, except in a general way. Such a question as the pressure of steam to be employed is, for example, settled almost entirely by that of the value of the fuel available. With the kind of wood which engineers are often forced to use in the West, a low pressure is all that can be obtained. With good coal, a high pressure may be utilized. It would expand this article far beyond its limits were I to attempt to go into the respective merits of high and low pressure hoisting engines. It is proper, however, for me to mention one fact. The weight of the descending cap and wagons can be utilized whenever there is a double shaft, and it is therefore always wise to have such shaft when the mine will warrant the necessary expenditure. I so state the proviso advisedly. There is often the mistake made of beginning with an expenditure for hoisting works and shafts which subsequent developments do not justify, and a superintendent should know his mine thoroughly before advising such an outlay of the company's money. The character or details of the engine employed, the style used and the expense necessary to secure it, each superintendent must decide after examining the mine and the work to be done. There are many hoisting engines adapted for different kinds of work and it would be impossible to distinguish between them when writing generally as I am now.

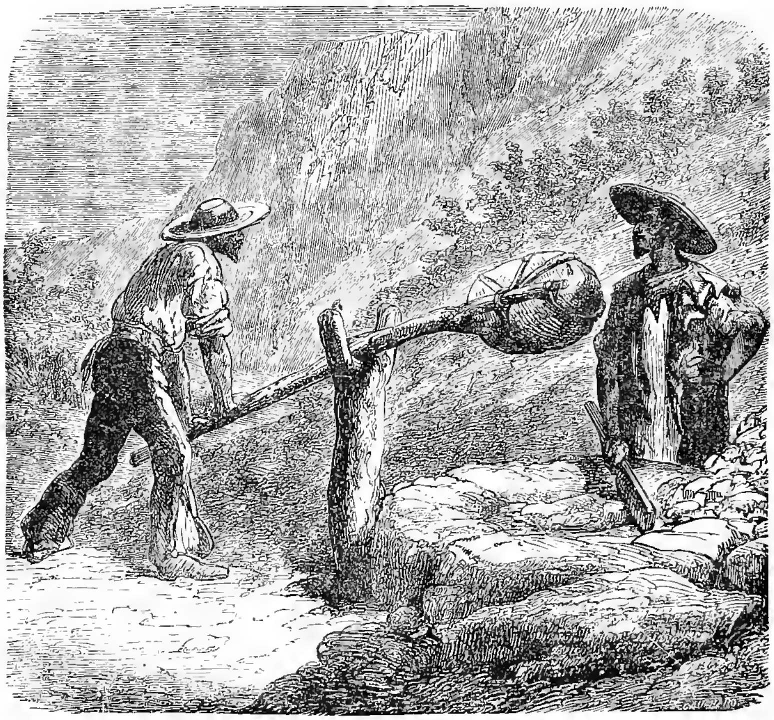
The ore being upon the surface of the ground we must face the question of "what will he do with it," to quote from Bulwer. And this in turn is governed by the character of the ore itself and the uses to which it is to be put. It may be all ready for use, as is coal; or the first part of the work may only have been done, as in the case of iron. I shall not attempt to give full and minute instructions for reaching the products of mines after they have been extracted and hoisted to the surface. Such instructions would be far too technical for the general reader and may be property sought for in works upon practical metallurgy. But I shall in a general way indicate the processes necessary for the handling of ores and the reasons why those processes are employed. Beginning then with that to which the least work is done, coal has simply to be screened to separate the different sized lumps, and is then ready for sale. It sometimes happens when the coal is "dirty" or largely mixed with shale or slate that it must be picked over by hand, but this is rarely the case except when the seam is very narrow. Coal that is mined then is ready for market. Taking the ore of quicksilver as one which after it is mined, one operation has to be performed before it is ready for market, we find that when the cinnabar or sulphuret of mercury, the ore usually found, is to be treated, we have to build a furnace. The treatment of the ore depends upon two facts. First, that mercury is a metal easily sublimed or turned into vapor; and second, that sulphur in combination with it will unite with lime in the presence of heat and set the mercury free. Proceeding then from our knowledge of these two facts, we mix the cinnabar, previously broken into small pieces, with quick-lime and expose the mass to the action of fire. The reaction which takes place is precisely that indicated by the two chemical facts to which allusion has been made. The heat causes the sulphur to leave the mercury and to unite with the lime, setting the mercury free in a metallic state. It then causes the mercury to become a vapor to turn into fumes. Having secured the metal in this form, all that we have to do is to cause it to condense back in a fluid shape and the operation is conducted by simply cooling it. Practically, a reverberatory furnace is built and the mass of ore mixed with lime is placed upon the hearth. The mercurial fumes are conducted away from it into the condensing chambers through which as they pass they are met by sprays of falling water. These chambers are so constructed as to cause the fumes to pass slowly through them and to give the water sprays a chance to extract the heat and so cool the metal. The bottoms of the chambers, technically called the "tanks," are shallow basins partly filled with water into which the mercury in a fluid state falls. When the mercury is secured all that has to be done is to place it in the iron flasks in which it is sold and send it to market.

In the consideration of this system in securing the mercury which exist in the ore in a marketable state, we have touched upon a simple example of the principle upon which the reduction of all metals depends. It was when we spoke of mixing the ore with lime. Ores of metal are bodies in which the metal exists in combination with other chemical substances, and with gang, or other matter which contains no mineral. The gang may be removed mechanically as when we crush rock containing free gold, we may wash the gang out in a pan. But when the metal is chemically combined with other things we must supply during our operations some substance which will extract the combining chemical elements and leave the metal. The substances so supplied are technically called "fluxes," and depend for their operation upon the laws of chemical affinity. It is not necessary to go into those laws here. It is sufficient to say that the affinity existing between A and B is greater than that between A and C under certain conditions; and that given those conditions, we can cause A to leave C and combine with B. It often happens that this action will take place more rapidly in the presence of heat, and we therefore build furnaces or structures in which we may cause heat to aid this action. When we supplied the heat to the mixture of cinnabar and quicklime, we caused the sulphur in the cinnabar to leave the mercury and combine with the lime. This the sulphur did, because in the presence of heat its affinity for lime is greater than for quicksilver. Many people imagine that furnaces melt ores in some such way as grease may be melted in a pan. This is a mistake. The furnaces simply permit the combining element present in the ore to leave the metal and combine with something else; and the metal set free is melted and run into convenient forms.

Iron ore being upon the surface and ready for working requires sometimes two processes before it is ready for market. It must be roasted if it contain sulphur, and then smelted. In the first place the ore being piled in loose stacks or placed in roasting furnaces is exposed to the action of a slow fire for some time. The sulphur in it being heated becomes sublimed, and either by burning unites with the oxygen of the air or is driven off in sulphur fumes. Having been roasted, the ore is mixed with proper proportions of flux and is smelted. If the ore be a carbonate of iron, the combining element of the carbon unites with the oxygen forced in by the air-blast and burns away. But in the treatment of such an ore we have to get rid of the gang, and this is so intimately mixed with it that we never hope to do so by mechanical means. We therefore ascertain what chemical elements are in that gang and supply in the fluxes used some material which by uniting with it will change the form in which it is, permit the metal to separate from it and enable us to remove the two separately. If the ore be that which is often found and worked, the carbonate of iron mixed with argillaceous earths and clays we add lime stone, and if there be no silica in the ore, a certain amount of sand. In the presence of heat the argillaceous earths and clays, the lime stone and the silica unite to form a fusible glass-like substance called "slag," having a different specific gravity from the iron. The carbonate of iron having the carbon burnt out by the oxygen in the blast and being melted by the heat of the burning coal, sinks down to the bottom of the furnace to which place the slag also runs. But the specific gravity of the slag and the iron being different they form two layers in the furnace which may be compared to water and oil in a glass; and they may be tapped and drawn out separately. The questions of most importance in the smelting of iron ore are those which relate to the building of the furnaces, the proportions and kinds of fluxes used and the economical use of coal.

To settle these questions the superintendent must know how to build a furnace. The importance of this knowledge is very great, for upon the shape given to the furnace depends the amount of metal which can be worked. Some ores require greater time for their passage through the furnace than others; or must be exposed to the action of the fluxes for a longer period. The internal shape of the furnace will, to a large extent, regulate the rapidity with which the ore goes through. As the object in every case is to pass the ore through with the greatest speed consistent with its reduction, the superintendent will, in building his furnace, make such changes as may be necessary to suit the particular kind of ore which he is dealing with. The kind of fuel obtainable brings with it the question of whether a hot or cold blast is to be used to obtain the best results from the working. It may be said generally, that the hot blast, or the air forced into the furnace raised to a temperature of about 600°, will enable the superintendent to use ordinary coal in place of coke or charcoal. It is said that "hot blast" iron is inferior to "cold blast," but I am not certain that this has been conclusively proved. At any rate, as the object of the superintendent is always to get the largest return in money as the result of the operation of the mine as a whole, the blast used, and the iron made, will depend upon the individual conditions under which the particular mine is worked. Fluxes being of enormous importance, the superintendent will not only look out at all times for a convenient source of supply, but will examine into the proportions being used with great care, in order to see exactly where his work stands, whether he is working the ore to the best possible advantage, and at the least possible expenditure of money. The result of the operation of the furnace in metal and slag will teach him a great deal. If he finds his metal too hard, for example, he will know that the iron, after reaching a metallic state, is exposed to the action of carbon for too long a time. He must then hasten its passage through the coal. If he finds that the slag is sluggish, and will not run over the "slag-stone" easily, he knows that the proportions of the flux to the ore must be varied in some way. It would be impossible for me to go into a list of the indications which point to a change in the treatment of the ore being necessary, for the simple reason that were I to do so I would write a whole book instead of a single article. Suffice it that I point them out in this general way as an example of the method by which the superintendent ascertains if the work be going on right, and, at the same time, as an instance of the kind of questions which the superintendent has to smelting of such rock will cost more than the metal yielded by it will amount to. But if two and a half tons of the rock be taken, and the ore separated out, we get one ton of ore to smelt in the furnace and a ton and a half of gang which we throw away. Smelting that ton of ore may pay very well. This is what is called the concentration of ore. The primitive method of doing it was the picking over and sorting of the ore by hand, which was a very slow and costly process. As there is a difference in the specific gravity of the ore and the gang, advantage is taken of the fact to separate them, and machines more or less complicated, and working with water or without, have been devised for the work. Some of them are very effective. It is always a measure of economy when the ore is such as to permit of its being done, and the conditions are favorable, to concentrate the ore before treatment in the furnaces, and it will often make the difference between a paying and a non-paying property.

To the three classes already specified we must add a fourth, that in which the ore after it is extracted from the mine has to be worked, but in which the plant for such work

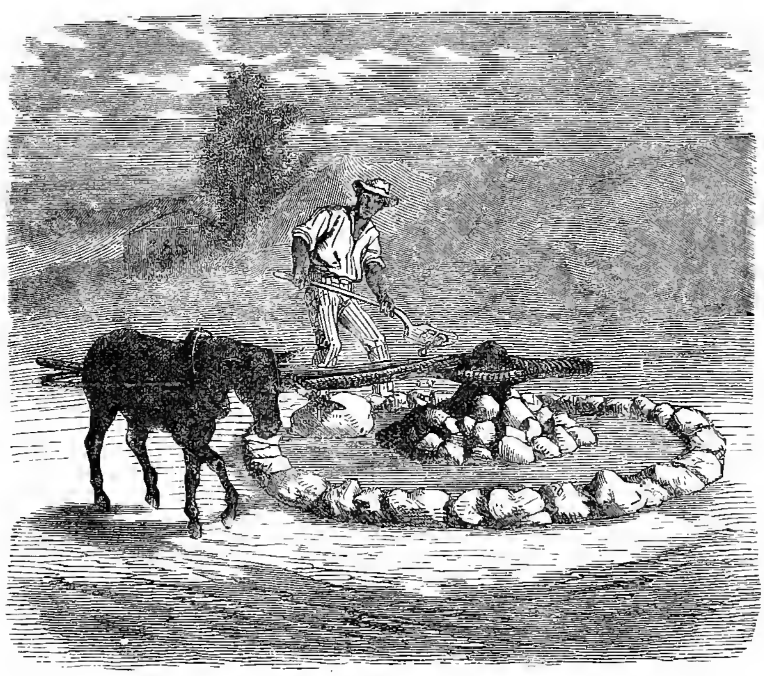


Mining Life.—Crushing Ore by the Old Mexican Process.
—From "*La Souterraine*," by *L. Simonin*.

meet. This latter contains, inferentially, a description of the kind of man the successful superintendent must be.

All deposits of ore which have to be treated by fire in order to extract the metal contained in them, are treated by modifications of the two processes described, roasting and smelting. The details of the treatment vary with the minerals, as do the fluxes employed, and the shapes of the furnaces. We have, then, three classes of ores; first, those which are ready for sale as soon as mined, second, those which have to be roasted, and third, those which require smelting. There is a process often necessary for the economical treatment of ores which applies to those of the second and third. It is a part of the preparation of the ores for the furnaces, and is called "concentration." It is applied to such ores as consist in the veins or deposits of ore intermixed with gang. With such ores it is of course perfectly apparent that the treatment in a furnace should only be applied to the ore itself, and not to the gang, as that contains no valuable metal. Supposing that in a ton of rock, as taken from the deposit, there is forty per cent. of ore and sixty per cent. of gang. It may easily be that the does not include a smelting furnace. Such ores are worked by crushing and mixing direct with some substance which will combine with the chemical form of matter in combination with the metal. An example of this class is the ore carrying the precious metals in combination with sulphur. The ore is mined, roasted and taken to the mill. Here it is broken with some crushing machinery into lumps about the size of an ordinary potato, and then placed in the battery. Heavy stamps being caused to fall upon it, pound it into a fine powder, in which condition it passed through the screens, as the fine sieves are called. From there it is taken to the pans, where, being mixed with mercury by the action of the revolving mullers, the amalgam or paste composed of mercury, gold and silver is formed. The whole mass being removed to the settlers, the fine gang, vein matter, and in fact everything except the amalgam, is washed away, and the amalgam is then taken and "retorted." That is, it is placed in a retort and heated, when the mercury sublimes and passes away in vapor only to be condensed and used again, while the gold and silver are left behind. These being melted, are formed into the familiar "bricks." It will be noticed that in this process the ore was roasted to drive off the sulphur, being as far as that part of the work is concerned, treated as though it had to be smelted. But should the ore be a quartz carrying fine or native gold, this roasting would not be necessary. In the treatment of the ores of the precious metals, there are various modifications demanded by those in the character and kind of ore to be worked. Among these may be mentioned chlorination and treatment by the special processes and methods.

The opening of the mine, its ventilation and drainage, the extraction of the ore and its treatment, have all been described generally, and this part of the duties of a superintendent has been sufficiently indicated. But there are other points which arise in the management of a great mining property which must be alluded to briefly, and first among them is the question of labor. Good miners are men who are always worth a great deal of money, and who cannot always be got, especially in new districts. While they do not necessarily know very much about the many questions which serve to worry the minds of the superintendent and those who have the mine in charge, they should understand their business thoroughly. Experienced miners will save large amounts of money to the owners during the year, and for this reason. They know how to manage that portion of the work committed to them. An inexperienced or green hand will often do more damage than he does good, and he rarely is able to give the "Underground Agent," "Captain," or "Mining Boss," as the assistant superintendent underground is called, the information about the workings which is of so much value. He does not do his work as well as a rule, and he requires constant supervision.* A very necessary part of the work of a mining superintendent is the laying out of roads and the building of bridges if any be needed. This comes directly into the question of the transportation of ore after being mined. If the pit head be on top of a hill, and the mill or furnaces be at the bottom, as in such case they almost always are, the transportation of the ore may be effected by wagons over a good road. This should be built in such a way that no ordinary rain will wash it into heavy gutters. It is well, if it be possible to have it wide enough for the passage of two wagons at once, but if this be impracticable, places at which the wagons may pass each other in ascending and descending should be carefully built. The grade should not be too steep or the wagons will be racked to pieces and yet should be steep enough to give the animals used little to do beyond steering the wagons down hill. When the hill side is straight, it is often economical to construct double "teams" or railways and to allow the loaded wagons to pull the empty ones up. If it be impracticable to build a road or if the ore have to be carried across a "bassanca," canon or deep gully, it will often pay to send it in buckets suspended from rollers which travel upon a single rail and string piece supported by posts. The power in this case is furnished by a long and endless wire rope passing at the mill or mine around a drum. An important consideration for the mining engineer is often the supply of water for the mine and mill. This has sometimes to be brought a long distance, as that which is pumped from the mine is rarely available for the boilers from the quantity of chemical substances contained in it. If possible the water should be got from a spring which does not dry up at any period of the year and the ditch, pipe or flume used to bring it to where it is wanted should always be constructed large enough to give all that is necessary for some years to come.



Mining Life—Arrastra or Mexican Mill for Treatment of Gold and Silver Ores.

From "*La Vie Souterraine*," *by L. Simonin.*

A powder house or place in which to keep explosives should always be constructed. If there is a deserted drift or tunnel, by placing in it two heavy gates or doors at least ten feet apart it forms an excellent magazine. It should always be ventilated by openings or grates in these doors. If a house has to be built it should be so at a distance from the works and pit-head and should be solidly constructed of stone and surrounded by a wall. The keys of the gate and door should always be in the hands of the clerk of the mine or the storekeeper, who should be responsible for the powder and should never be allowed to issue it except in person.

A capable superintendent should see that arrangements for the introduction into the mining camps of such things as groceries and dry goods by storekeepers are made, although it is a mistake, unless we find that the men are outrageously fleeced, for him to advise the company to run a store.

* See Article on Labor Problems, close of this Part.

Miners are as much given to lying as are other men, and stories about the amount of profit made by the store out of them are sure to set afloat and frequently give no small aid to those who wish to start strikes. If the company own the ground around the mine, as they often do, it is well to let it to the miners to build houses upon. In such case a small ground rent should always be charged in order that the men may not think that they own the lots in fee. An agreement should be made by the company to take the improvements made at a fair valuation in case the men leave, or what is better yet the custom should be known to prevail. The ground rent and the purchase of the houses built gives the superintendent a check upon the men and enables him to insist upon the premises being kept in good order. Such things as drainage and the supply of water should as a rule be attended to by the company, enough being charged in each case to give a fair interest on the money expended. That nothing can be worse than for the company to do things for the miners for nothing—may be laid down as a general rule. The exception to this, for like all rules it has an exception, is the furnishing of a hospital and medical attendance free for those who become injured in the mine by accident or as the result of any cause directly connected with the mine. When there are several mines near together, the companies can unite to fit up a hospital for the benefit of all employed. The physician who attends to the hospital will of course have a certain amount of practice among the miners and their families, but as this is insufficient to support him, the company should supplement it by such payments as may be necessary. Reading clubs and free libraries should be encouraged to the utmost; or if the latter are not free the charge for them should be of the most nominal kind. When the men get up clubs or libraries, the Superintendent should, without interfering with them in any way, make his approbation of such things strongly felt by liberal donations of books. As the libraries should be encouraged, so the liquor saloons should be discouraged. A man who as soon as the monthly pay day comes, after squaring up his account proceeds to spend every cent he has left on whiskey or gin, may help to increase the profits of the saloon keeper, but he is not much good under ground. Not only does he "lay off" until the spree and its effects have passed away, but, when he does go to cutting again he is not trustworthy. It is scarcely necessary to say that a superintendent who drinks himself cannot preach the value of temperance very loudly. Of course, if there be many children in the camp, the company will see that a good school is provided. It will receive more than the money expended in the increased value of the labor of the boys when they come to take their place under ground. It is of some importance for the superintendent to remember that he represents the company to the men, and that his influence whether for good or evil, cannot be overestimated. He rules a large body of men, and if he be fit for the place, he rules them wisely. He is not there simply to make the greatest output possible for any one year. He is there to manage a great property, and to manage it so that it will always be worth as much as when he took hold of it, except of course in the one matter of the amount of ore in the mine. He can only so manage it by remembering that an important diversion of the interests under his control consists of the labor employed. If he treats the men in such a way, and he very easily can, as to bring about constant strikes he is unfit for his position. If on the other hand they are satisfied, the company will find that in choosing him they made a wise choice, and that the financial result of his management is one which shows a comfortable balance on the credit side of the ledger.

—*Alfred Balch.*

THE MINER AND THE CAPITALIST.

IN the old days, "the days of 49" as the song has it, the plant required by the miner in the West was a pick, shovel and pan. When he found his placer he, aided by his partners, constructed a "long tom" or a sluice-way, and in time, perhaps, built a ditch and flume. But in mining the days were essentially those of small things. The man who could not afford a "tom," or the expense of mercury for the "rifles," could make ways with his pan alone if the claim was good. He could save some money and in time, as the result of those savings, could construct the things necessary for increasing his gains more rapidly. Any man could begin by himself with a fair chance, providing he brought strength, sobriety and shrewdness to his aid, of making a handsome amount of money. But as time went on and the "diggings" got worked out, the search for the precious metals began to assume a more business-like character. It was no longer that the miner of to-day acted as a teamster next week only to return to mining in a month or two. What had been an incident in a man's life became his life's business. The form of mining changed when the quartz ledges, or "reefs" as they are called in Australia, were discovered. It was found that expensive plants were required to work them, and the reign of the capitalist and the company began. It became necessary for the men who found the mines to have money before they could develop them, as hoisting works cost more than a pick, and stamp mills were more expensive than pans. It was discovered that the ores which contained the precious metals must be reduced by expensive processes before they could be made to yield the gold and the silver. The time had come, in short, in the history of Western mining, when it was beginning to be a business in which vast amounts of capital were to be invested, and financial questions were to be considered in connection with it; when the President who looked after the business interests of the company, never having handled a pick in his life, was to be as important a person to the stockholders or owners as the superintendent. This change in the process of mining brought about a separation between the men interested. Those who found the mines, the prospectors, and those who operated them when found became two distinct classes.

As the prospector is poor; that is, as he rarely has, even under the most favorable circumstances, more money than what suffices to support him; or, as is generally the case, he is obliged to labor for that support, the question of how the prospector shall reach the capitalist, how the man with a valuable property, requiring money to make it yield its treasures, shall reach the man who has the necessary money and is willing to devote it to this object is one of great importance. It is of importance to both prospector and capitalist, for the union of the money and the mine will result in benefit to both. The prospector gets his mine as the result of a search which consumes more or less time. Having located it and filed his location, he becomes the sole owner of that piece of property which may be worth millions or may not be worth anything. By law the prospector, in order to hold his property, is obliged to do a certain amount of work every year. He must either spend within each twelve months one hundred dollars upon the mine, or he must put in labor to this extent. There is a conventional amount of work recognized in many mining districts as being equivalent to this hundred dollars, the sinking of a shaft, or driving of a tunnel eight feet by four, being supposed to cost ten dollars a mining foot, so that sinking such a shaft ten feet would be considered as an expenditure of one hundred dollars upon the claim. This assessment work, as it is called, ceases after a United States Patent is obtained for the property, but a locator or his assigns could hold a claim to doomsday without a patent if they did one hundred dollars worth of work on it each year. The requirements of the law, in the matter of assessment work, have had an exceedingly good result. In the old days (prior to 1872) when all that was necessary to hold a ledge was to locate it, the prospectors in mining districts were as a rule, mine poor. They owned so many locations that they never considered it necessary to do anything to any of them, and the ledges remained undeveloped while their owners strutted about, the imaginary owners of millions they never took any steps to get. Under the present law, the assessment work compels men to limit the number of claims held by them, for the simple reason that they cannot afford to do the work or spend the money necessary to hold them, upon any very great number. This again, by concentrating their attention and their efforts upon a few ledges, has led to the development of those ledges; and just here it may be said that a mine which has just been located is worth but very little money except in very rare cases. A ledge of rock may be exceedingly rich, very thick, have clay seams and walls complete, may crop out for three or four thousand feet and yet be a property which is not valuable. I concede that this would be an extreme case, but it is a possible one. Prospectors are far too apt to consider that any kind of a claim, if the surface indications are good, is worth a great deal of money. The sums which they mention as those for which they would sell are ridiculous. Fifty thousand, one hundred thousand, two hundred thousand, half-a-million or a million, are words which flow as readily from their lips as though they were talking about grains of sand rather than dollars, each one of which has in it one hundred cents. They do not seem to realize that they are simply showing their own folly. They will point to some "coyote hole" of a shaft about ten or twenty feet deep, and talk about the mine! They will tell you that they have ten thousand tons of ore in sight when there is neither shaft nor tunnel, sunk or driven. They will talk of a property worth a hundred thousand dollars when that property is absolutely without development, and their knowledge of it is confined to surface examination of the croppings, the "horning" of a dozen specimens and perhaps three or four assays. They do not seem to realize that all of this kind of talk is not only foolish and unbusiness-like, but that it injures them. Business men with money are not fools; on the contrary they are as a rule exceedingly "level-headed" individuals. Having made their money by shrewdness and forethought, they have learned the lesson thoroughly that when a thing is bought for a dollar, it is so bought because it may be sold for a dollar and a half.

There are unfortunately far too many instances in the mining history of the West, where the business men of the East have succumbed to the glamor which mining seems to be able to throw over the great majority of those who come in contact with it. They have spent their money foolishly, and have purchased, for large sums, properties which had nothing more to recommend them than the two facts that they were in a good neighborhood and the surface indications were favorable. In some cases these purchases have turned out well, but in the great majority they have been speculations which have ended disastrously for those who have gone into them. It may be conceded that the prospectors who have thus sold have attained what might be called their first object, that of obtaining money for their claims; but on the other hand, every claim so bought which has turned out badly has injured the district in which it was located far more than ten times the sums paid for it. And that this is a fact may be demonstrated with but little trouble. It is a common saying that "capitalists are like sheep, where one goes another will follow." This is true, but not in the derogatory sense in which it is generally used. Capital seeks interest as naturally as gold seeks quicksilver; the man who puts money out does so because he expects to see it return with increase. Capitalists then are men who have a keen sense of where their money will so increase, and when B finds that A has invested money in any business and secured an enlargement of his wealth, the attention of B is drawn to that business with a certainty and to a degree which nothing else will secure. No descriptions of a channel for the profitable investment of money, no laudatory articles in newspapers, no assurances from friends or acquaintances, no talk of this or that reason for the investment of money, will speak half as loudly to B as will the knowledge that A has put in a dollar and received in turn a dollar and a half or a quarter, ten cents or five. In the one case B listens—if he listens at all—with a half-hearted interest; in the other, his attention is instantly aroused. Now as every man, who has ever been in a mining district, will conclude at once, the number of properties in one which is fairly prospected and which is rich, that will pay if capital be judiciously invested upon them, is as a rule very large. The original location of the "Roaring Tiger" is, we will suppose, on a good ledge, with walls, clay seams and everything else which makes a "true fissure vein" complete. Upon opening the mine it is found to widen as it goes down, the ore is easily mined and worked, the milling results are handsome, wood and water are plenty, labor can be got easily and, in short, the property is one which will give a handsome return for the money invested. We will further suppose that the money necessary to develop it has been invested by A, that hoisting and reduction works have been built, and that A is receiving for his outlay handsome returns. But there are extensions 1, 2, 3 and 4 on the "Roaring Tiger" west, and 1, 2 and 3 east; and there are parallel ledges carrying the same kind of ore, and with the same or better indications after the "prospecting development" has been done.

A cannot handle the extensions let alone the other veins. For these to be developed and made profitable B and C and D and the rest of the alphabet must come in, examine the properties and invest money in them. A then is but the pioneer of the capital in his relation to the whole district, and if the pioneer report the country a fraud, as he will do if he loses the money invested, it will be many years before B, C and D are seen in the neighborhood. But this may be carried out still farther. B is a friend or an acquaintance of A, and is attracted to the district by A's success in the original location of the "Roaring Tiger." As he was attracted by the success of A so his success in turn attracts C, and D is brought in by the knowledge that C has made money. The investment in the district by each capitalist then, after the first, is at once the result of the previous successes made there and the cause of investments by others. Of course the same causes which led to the original investment by A are still operating in the case of B, and they have weight in B's mind. But as any man who has ever attempted to place a mine or sell a location knows they do not operate to the same extent. The first capitalist may get a venture into an untried field by the reports of its wealth, the second always requires to know how the first succeeded. No amount of description, no matter how rose-colored, will weigh in the mind of the second against a failure of the first. The first sheep on trying to jump the wall got knocked back, and the second respectfully declines to make a battering ram of himself.

Every miner knows, and I am writing now for miners who have good properties which they wish to see developed, and in which they hope to interest capital, that each mine, unless it be a first extension, and not always then, stands alone. It is impossible to reason with certainty that because the "Roaring Tiger" is a good mine, the "Purring Lion," which lies beside it, is also good. That the same work which demonstrated the value of the first must be done before the value of the second can be ascertained or known. It is true that capitalists do not always know this, and that as a result of their lack of knowledge, the "Purring Lion" is purchased simply from the success of the "Roaring Tiger." No men are quicker to laugh at such purchasers than the miners in the district, where the properties are located, and they often conceive and express no small amount of contempt for the "Eastern sharps as bought a coyote hole in the croppings." But they permitted the property to be sold in that condition. There is a fellow feeling among them which leads one to endorse the claim of another. They shrink from doing anything which does not seem to be square, they would hesitate a long time before they would talk to a man who had an idea of purchaseing Jack's claim with half of the frankness that they would talk to Jack about the property. They have an idea that the capitalist has plenty of money, and they know that Jack has got a "damned small pile." In default of the purchase of property owned by themselves they are willing to help Jack to a sale of his, and they are naturally anxious that the money shall be invested in the district. And so they stand by and see the money invested by the capitalist with a full knowledge, not that the investment will be a dead loss, for I am not supposing for a moment that Jack's claim has more "salt than sugar" about it, but that the investment is not warranted by the development of the mine, and is consequently a very risky one. Now I am not advocating any low down tricks, and there is no one who would more heartily despise a man who came to him and told him that Jack's property was not all that it was claimed to be. I believe in white dealing as much as any man living. But I know that the feeling among the miners which permits Jack to sell his claim when it is nothing more than a prospect is a wrong feeling and which works infinite harm to Jack first and to every man in the camp afterwards. And I know that there are hundreds of districts in the West that have been ruined by the fact that the prospects owned by the Jacks and the Toms and the Petes have been sold for sums of money which were in excess of their real value.

Every miner who reads this paper knows this as well as I do. Now what I want to do is to show the miners who know this how to avoid having this fate or that which is akin to it, the retarding, the setting back of a district for those in which they now are.

And in the first place I will say that a good mine is generally worth a large sum of money. I say generally because of course it is not impossible that the vein may pinch, or that there may be a "horse" coming in or something else may be found out which will prove the property to be worthless. But, generally speaking, a good mine is undoubtedly worth a large sum of money. The prospector who owns the mine or his partner who advanced the "grub stake" and paid the fees for registration, have put in time and money, and have secured as the result of such investment a piece of property. It is right and just that they should get a return for that property, that it should pay them, and pay them handsomely for the work done and the money invested. But when the property is first acquired, it is not a mine, it is only a prospect. The difference betweeen these two is enormous. A good mine is generally worth a large sum of money—a good prospect is never worth more than a small sum. Take a mine of free milling ore for example, which has a shaft or tunnel exploiting it below water line. Let there be a ledge of six feet in thickness at the lowest point reached against a thickness of four feet on the croppings. Let there be in it two levels, one cutting the vein north and the other south, supposing the strike to be north and south, and let the two aggregate five hundred feet of cutting. Let the walls be good walls, clearly defined and with the clay seams complete. That mine is a good mine to sell and is worth a large sum of money. Why? Because it has been proved to be worth it. It is not a risky speculation when a man purchases it and the man who sells it gives an assumed value for what he gets as well as a prospective value. It may be that in the next fifty feet down the ore will pinch or it may in the same distance widen still more. The risk of the one may legitimately set against the chance of the other by the purchaser. In any event there are just so many tons of ore in sight, and each ton of that ore will yield just so much when milled. But suppose that some mine is a prospect only with perhaps a cutting into the vein ten feet deep, showing the ore below the weathered rock. It is worth very little. Why again? Because it has not been proved to be worth anything. The risk of its pinching is enormously increased, for the state of the vein below the water line is not known, while the chance of its widening out is enormously diminished. And there is practically no ore in sight. The purchase of it becomes an exceedingly risky speculation, and the man who sells it gives prospective value only. It may be worth a great deal it is true but it may not. Nothing is known, nothing is sure; it is all speculation and all risk. Now it is a commercial and natural law which, like all natural laws, cannot be broken with impunity by any one; that in proportion to the risk must be the profit. If men take great risks commercially they must have the chance of wishing enormous profits. It is therefore the case that when the capitalist takes all the risk he must and will, unless he be a fool, take all the profit. It is another commercial law, or rather an extension of the first, that in proportion to the sacrifice shall be the return. With these two laws clearly in our heads let us see how the miner and the capitalist, the man who found the property and the man who has money to develop it, and who wishes to purchase it, stand in relation to the two periods in the history of the mine to which allusion has been made. As the prospect is prior in point of time to the developed mine, I will reverse the order in which they have been maintained, and take the prospect first; and for the sake of convenience I will call the commercial laws to which I have alluded, number one and number two.

The prospector found the mine, let us suppose after a search which took one year's time. He spent then 365 days on it, and his time and labor being worth, say fifteen dollars a day; in that the mine cost him $5475. It will be noticed that I put the price of his labor at a high figure. This is done because the knowledge which enabled him to find the mine is worth just so much money, while his labor might be worth anywhere from two to six dollars a day, his knowledge makes his time worth more. It cost him or his partner something to buy food for him during this time, and I will put that down at a high figure also, ten dollars a week. There are very few camps where a man cannot in these days buy grub for a week for ten dollars. This added to the former sum amounts to $9125. Then there are recording fees which will bring it up higher, and the time spent by the prospector in talking to the capitalist or in writing to him; the time, in short, it took to bring about the sale. Putting these and all other expenses down liberally $10,000 will cover everything the prospect has cost the man who found it up to the time of its sale. Under law number one, $10,000 represents the risk to the prospector; under law number two it represents the sacrifice. Now the proportion which exists between risk and profit is a direct proportion, and the proportion which exists between sacrifice and return is well known. In this case the sacrifice having been made the prospector has a right to look for a return, and that sacrifice having been a risk, he has a right to expect a large return. Had he sacrificed his time in the employment of others, he would have been fully compensated by a payment of the $5475, because there would have been no risk. I am supposing that he would have lived during the year at the expense of his employer. In that case law number one would not have applied, as there would have been no risk. The difference, then, between the amount he has a right to receive for the prospect and the $5475 is a difference caused by the operation of law number one. In other words, it is because he has taken the risk of losing the $10,000 that he should receive more than $10,000. And it is in consequence of his taking this risk that he has acquired a property which is worth more than $10,000. Suppose he had made an agreement by which for a year's work, boarding himself, he was to receive a mill worth $10,000. He would have taken no risk, and the mill would only be worth $10,000 when he got it. So then, when he has sacrificed $10,000 to get the prospect, and has risked the loss of that amount, he has a right to receive, and does receive in property, a great deal more. Now comes the question of how much more and this is governed in the same way and by the same law. If he has got such a prospect as the one which I have described, that is a prospect which, when developed, is legitimately worth say $100,000, his risk, as soon as the value of that prospect is ascertained is annihilated, and for his sacrifice he gets a large return. But while the prospect remains undeveloped his risk continues. Not to such an extent as formerly, because the prospect when located and examined, as well as it may be on the surface, is most certainly worth more than no prospect at all. Before he found it his sacrifice was all risk, now for his sacrifice he has a piece of property to which there is some risk attached. In proportion to that risk is the value of the property, and if we can ascertain the risk we can determine the value. And at this point we must consider the interests of the capitalists. The risk of the capitalist who purchases the property is here precisely the same as that of the prospector who sells it. The sacrifice of the prospector is, in case of sale, at $10,000, transferred to the capitalist, and the risk of the investment goes with it from the former to the latter. The sacrifice, as far as the prospector is concerned, has the element of risk taken from it and becomes the same as that which would have been made by him, had he worked a year for the mill. He gets paid for his time but he does not get paid for his risk, and he therefore loses that which he had a right to receive. On the other hand as the risk is less when the claim is located than it was before it was discovered, the capitalist when he pays $10,000 makes a sacrifice which has less risk attached to it than was attached to that made by the prospector. If he then only pays $10,000 he gains what the prospector loses, namely, the degree in which the risk is lessened from the time when it was all risk to the time of the sale. It is right and just that he should pay for this exactly as it is right and just that the prospector should be paid for it. But while, if the risk taken at first by the prospector were annihilated by the development of the mine, the capitalist would pay $100,000 for the property; every particle of risk which remains will reduce that amount. Supposing the sacrifice to be $10,000 and the value of the mine when located and developed to be $100,000; supposing, too, the development of the ledge which annihilates this risk to be 200 feet of shafting and 500 feet of levels, 700 feet in all. Putting this at the assessment values as already given it would amount to an expenditure of $7000. It costs $7000 to annihilate the risk remaining after the mine is discovered, and this makes the mine worth $100,000. The sacrifice is $17,000, $10,000 at first to discover the ledge and $7000 to develop the mine. All the risk then is represented by $83,000, what proportion of this exists after the location and before the 700 feet of work has been done? In order to get at this we must remember that the risk is constantly decreasing during the process of development, and that it is decreasing much faster than the work is done. The difference in the risk between the time the shaft is begun and the time it is down 200 feet is much greater than between the time the shaft is sunk to this point and the end of the first level of 200 feet to the north. This is apparent at once. The shaft shows the vein does not pinch at the water line, and that it is a fissure vein, while the level merely shows that the vein does not fault below, a fact that could have been assumed with considerable degree of certainty from the croppings. The expenditure of $2000 on the shaft has lessened the risk enormously, far more, in fact, than the expenditure of $2000 on the north level, and the expenditure of the $2000 on the north level lessens the risk far more than the expenditure of $3000, driving the 300 feet of level to the south. The north level tells us that the vein does not fault, a fact we could have assumed from the croppings; the south level merely repeats this assurance, gives us more ore in sight. Reversing the calculations on the respective amounts of the risk as removed by the three parts of the work, and applying it to the $83,000 which represents the whole risk, we find that each section of the work represents a constantly increasing risk. We have four sections, the drift to the south, the drift to the north, the shaft and the hunt for the mine. If we may assume that the drift to the south increases the value of the mine by the amount of ore it brings into sight we may say that the risk is but little changed by it. That is, the south level does not so much decrease the risk as it increases the known value of the mine. If we suppose that the ore in sight is worth $50,000 of the whole value of the mine, the south level has given us $30,000 of value in right. The north level has given us $20,000 worth of ore in sight, and by proving that the vein does not fault below, has taken away $10,000 of risk. This leaves the shaft and the location representing $40,000—of what? of risk, because the main object accomplished by the shaft is the proving that the mine is a good one, or in other words, annihilating risk; until that is proved the location has but little value except that of risk.

Now let us go back a little bit. The sacrifice of the prospector was $10,000, and the risk was enormous. For that sacrifice and that risk he got the location. The location with a 200 feet shaft in it represents $40,000. That shaft increases the sacrifice to $12,000, making the risk represent $28,000. The question of what part of this attaches to the location and what to the shaft may be reasoned as before. At 190 feet down the shaft, which at 200 feet makes a property costing $12,000, worth $40,000, certainly makes that property worth $39,500. Ten feet then increases the value of the property $500. But ten times ten feet makes much more difference in the value than ten times $500. The property which with a shaft 200 feet deep is worth $40,000, with a shaft only 100 feet deep is not worth more than $15,000. $1000 for the shaft has annihilated $4000 worth of risk. Following this up we would arrive at the statement that before any development is made on a location, the claim itself is not legitimately worth the amount of the sacrifice, supposing the sacrifice to be such as we have mentioned, and this is unquestionably true. The sacrifice has been made, but the risk is so great that the property is not worth in its then condition, the amount of that sacrifice. A claim which has merely surface indications, which has not been developed and which has only been located and thereby become property, is not worth, under commercial laws, the amount sacrificed to obtain it.

I began this article by stating that I was writing for miners and prospectors, for the men who find the claims rather than for the men who would purchase them. It may be urged at once by the miners who read what I have written, that I am not practical enough, that I do not give what they would have a right to expect from the title of this article; the information by the aid of which they may sell their properties. I think, however, that I have done so, and for this reason. I think that it is of primary importance if two men would consummate a sale of property, that they should, as far as possible, find out what each thinks of that property. If I wish to buy a saddle from a storekeeper, I ask him the price and he tells me. By the fact of his telling he conveys to me his estimate of the value to him of that saddle. As I began the bargain he assumes that I want the saddle and that he as seller shall put a price upon it. In the sale of the saddle I give him money which I have got by writing this article, for example, and buy the saddle, and he gives me the saddle which he bought and paid for, at a sufficient increase to give him a profit and in turn buys my money. Each of us is both buyer and seller, while I begin the negotiations which lead to the sale. But suppose he begins them, he asks me what I will give for the saddle. He has a saddle and he wants my money now; before, it was I had my money and wanted his saddle. The sale is the same in each case, but the causes which lead to the sale are different. It is I who fix the price in the second case as it was the storekeeper who fixed it in the first. In each case there is a reserve veto. If the storekeeper tells me a price at first which is more than I care to pay, I do not buy. If I offer him less in the second than he is willing to sell for, he does not sell. But in each case the one who begins the negotiation attempts by his first question to find out what the ideas of the other are in connection with the sale or purchase of the saddle. Now, it is perfectly evident that it would be of great advantage to me when I asked the storekeeper what was the price of the saddle, to know exactly what that storekeeper thought that saddle worth, just as it would be of great advantage to the storekeeper when he offered the saddle to me, to know just how much I wanted the saddle; in other words, to know what I thought the saddle worth to me, and the reasons why I fixed the sum in my own mind at which I would buy. Now, to apply this long illustration: The prospector with a claim or mine is in the position of the storekeeper having the saddle to sell. He has got something he wants to dispose of, or with which he wants to buy money. The capitalist is the man who has that money. It is of great advantage to the prospector to understand how the capitalist will reason about the claim or mine offered to him, and if he will read over what I have written again he will see how that reasoning is done. I have heard prospectors say that capitalists wanted the mine for nothing, and were not willing to give a decent sum for it. I have generally found that in such a case the sum asked was out of all reason and that there was little, if anything, to show in the mine. It may be accepted as a truth beyond all question that a good mining property can be sold at any time for a handsome profit on the money spent to acquire it and a fair return for the risk taken; but it is equally true that a prospect alone is worth but very little. It is true that capitalists will sometimes foolishly purchase claims for sums which are absurd; and it may be that their purchase will turn out well. But the men who do so, certainly do not do very much good to the districts in which they purchase, and their number is necessarily small. How many undeveloped mines are there west of the Mississippi River, which, if developed would prove to be valuable properties? Who can answer that question? No one. There may be ten thousand; it is far more likely that there are a million.

From where is the money to come which in the next hundred, or two hundred, or three hundred years, will develop these mines? From capitalists, from men who have money before they invest in the mines. Is it reasonable to suppose that the uncounted millions necessary to do all of this development will be invested on guess work? Most certainly not. It is but a few years since the capitalists in the East first began to put money into mining claims, and already they have learned a lesson or two about the value of prospects. No man who is caught once gets caught again. But as the time goes on more and more capital turns towards the mines, capital which will be invested wisely, judiciously, on business principles and in accordance with commercial laws. The class of fools still exists and always will, but the class of fools never built up any great industry. It behooves the prospectors then to find out what they must do to attract the attention of business men to their properties and having found this out, to do it. To sell their saddles they must put themselves in the place of the men they wish to purchase them. And what they have to do is develop their claims, to sell mines instead of prospects. It is of primary importance if they would take advantage of the tide of wealth which is now setting towards them, that they should have the value of their properties proved beyond the peradventure of a doubt. Take the example which I have been reasoning from. The sacrifice of $10,000 by itself was not worth the money. With $7,000 added to it it was worth a golden return, a fortune. It may be objected at once that the prospector rarely has $7,000 to put out upon a mine, and my reader may mutter to himself or comment to his partner that they know the value of development just as well as I do. In the first case, I may say that my experience is, and I think the experience of every miner will confirm mine, that the class of prospectors who make money in mining are those who when they get a claim they think is worth money stick to that claim, work when they can afford to in it and when they can not, go to work for somebody else until they have got together enough to give them food during another spell. I know one case where two men worked in this way on a claim for four years. They were partners in it, and as soon as they had a grub stake and enough to buy powder they would go to work tunneling. During that four years they ran a tunnel eleven hundred feet long, tapping the ledge at a depth of twelve hundred and fifty and drove nine hundred feet by levels. When they struck the ledge they were offered $72,000 for the mine which they refused. They waited until they had driven the levels and when they sold, got $250,000 in cash and fifteen per cent. of the stock. Now I know that those men had no help from any one. It is true they were good miners, and could get work at any time and make good wages. After they struck the ledge they sold some of the ore, and this gave them some money, but while they were driving that long tunnel it was all barren work. And what those men did other men can do. There is another class of prospectors that I never saw make any money, except by accident. It is the class of men who are mine poor, who have so many claims they can barely pay or do the assessment work and who sit around and talk everlastingly about capitals, waiting for some fool to come along and buy on the strength of what they say exists below the croppings. This is the class the members of which are all millionaires and owe ten dollar store bills, who would be insulted if you offered them five hundred or a thousand dollars for any one of their claims, who talk—heavens, how they do talk—of some one of their locations and say it is worth a hundred thousand or swear with much profanity that they will not sell under half a million. If you are a miner, my reader, you know these men, for the camps are full of them. I remember one of them who wanted to bond a claim to me for $150,000, on which the fees for recording were actually not paid. It is true he kindly said that if I would advance the $12 necessary I might deduct it from the $150,000 to be paid to him when I sold the mine. I suppose it is scarcely necessary to say that that mine was not bonded. Half, aye, nine-tenths of the growling heard in camps comes from just such men, yet I leave it to any white man on earth to say whether capitalists who know the value of money are to be blamed for respectfully declining such bargains as these.

Prospectors must learn that their claims must be developed before they can realize from them sums anywhere near what the properties, if good, are worth. And now to give them a few hints on what else must be done: as the majority of prospectors know how to develop a mine and how to make it show what it is worth, there is no need for me to take up space describing this. But to get a mine in condition for sale while the actual development is of primary importance, there are other things which will facilitate the transaction enormously, and the first of these is a note book containing a full and accurate record of the mine from the day of its discovery. The measurements should be put down exactly as they were found to be when made with the tape, not as they may be guessed. These measurements should be taken as least once a week during development, and should include the amount of work done in sinking or diving, as well as the width of the vein. Notes of the character of the rock found during the week, its hardness, and anything else noticed about it should be kept. The conditions of the walls and seams should be recorded from time to time; the finding of water and the time taken to free the mine of it should be included in the log. Kept in this way the note-book becomes a complete history of the mine from the day of the location of the claim to that of the sale. It forms a record which is of enormous value to the parties to the transaction. The entries in it as to the amount of ore worked at the customs mills, if any has been so worked, and the mill returns will do more to sell the mine than most prospectors imagine. It is, of course, easy enough to "cook" such a book, but as the purchaser may say that he will have thirty or forty tons worked himself, and will so say if he be wise, such "cooking" only results in proving to his satisfaction that the ore has fallen off in value as the work went on; a conclusion which will end the transaction as a rule. In keeping such a book then, as in other things, "honesty is the best policy;" a maxim none the less true because trite. The note-book should include every piece of information about the mine which comes to the knowledge of the prospector, it should record failures as well as successes. As a rule I have found that as much information is to be derived from the one as from the other. A valuable adjunct to the note-book, one which might be almost called a companion volume in stone, is a complete series of specimens. This should embrace those taken from the cropping, from the walls, the seams, the "horses," if any be encountered, and the vein; and should represent as fully as may be the mine in its different stages of development. It is as important to save specimens of the barren "gang" as of the ore. The object of these is the same as that of the note-book, to give to the purchaser every particle of information possible about the mine, each specimen should be carefully labeled. Doing this is neither short-sighted policy nor unwise. Supposing the mine to be a good one, and I am, of course, imagining that it is an honest property, the more information about it accessible to the purchaser, the speedier is his recognition of its merits. A man who knows his business when buying a mine can, of course, find out by examination a great deal about it, because a developed mine is a piece of property that tells its own story. There is always, however, the work of becoming acquainted with it to be done, and this the owner should, if possible, prepare in advance. There is the same difference made to the purchaser when this is done that exists when a man receives a letter of introduction to another from a mutual friend. He can, of course, go to that other and introduce himself, but his business is greatly facilitated when he has the letter given to him beforehand. The preparation of a mine for sale in this way will often turn the scale in favor of that property as against another of equal merit, and the prospector should, therefore, always when it is possible so prepare it. Assuming that the mine itself is found to be satisfactory both in its development and probable value as an investment, there are certain questions which have to be asked by the purchaser and answered by some one, therefore the owner of the mine should prepare himself with the answers beforehand. These are inquiries into the economical working of the mine when purchased. First among them are those which relate to the mill. As a matter of course the prospector when he has been able to do so, has located a mill site himself, which he includes in the property he offers for sale. But when this is not possible he should ascertain where a mill site can be purchased and should bond it for some reasonable figure. The supply of water and its cost, either when bought or the expenditure necessary for a ditch, if one has to be built, should form an item in the note-book. The supply of fuel, its cost and its character whether good or bad, should be examined and noted in the same way. Where the timber for the mine is to be procured, its value on the spot and the cost of transportion should be ascertained. Each and all of these things will, of course, be verified by the purchaser, but the owner of the mine should prepare the way for him by ascertaining all of the information beforehand. A man who buys a mine can find out all of these things for himself, but it will lessen the work to be done by him and shorten the time necessary for the transaction greatly if he is at once referred to the place where he can get the desired information. For example, suppose the supply of timber must be procured from a place distant twenty miles. The purchaser can find this out by inquiry, but it will take him more or less time.

If the owner of the mine has the information ready for him, he has nothing to do but to verify it. In the one case there is vexatious delay; in the other there is nothing but a legitimate expenditure of time. The fullest possible information on the question of labor, its supply, cost and efficiency should be prepared. This is of so much importance that the work necessary to prepare it is time well spent. It should include a full description of the policy and terms of the miners' union if one exists in the place. As the purchaser of the mine will probably wish to have a milling-test made of the ore under his own supervision, the owner when it is practicable should know where he can get transportation for the ore at once. The negotiations which lead to the sale of the property are rarely carried on without some preliminary talk on the subject, and the owner has time enough and sufficient notice of the necessity for such transportation to enable him to make arrangements for it. In this connection I should say that he should also know where the men to get out the ore may be found and what it will cost to employ them. From his own experience of the mine he will know with considerable certainty, how much labor will be required and how long it will take to extract a given number of tons of rock. There is one point I must urge in the strongest manner I know how. In all such arrangements and in all advice given to the purchaser by the owner, the latter must act and advise as though he were doing it all himself. It often happens that the work done in a milling-test for example is paid for by the purchaser owing to the inability of the owner. In such a case the owner should identify the interests of the purchaser with his own. He should guard him as far as possible from those who would, if they could, fleece him in transactions. If labor is required and the owner knows that Bill is a good miner, Bill being a personal friend of his, it is right and proper that he should recommend Bill for the job. But if the price of labor in the district be four dollars and a half a day or ten dollars a mining foot in blasting out ore, he should not allow Bill to charge five or ten and a half. He should not allow himself to reason that Bill is a good fellow, poor and needs the money. Not only is it honest for him to guard the interests of the purchaser, as his own, and therefore right, but it pays. The principle of allowing Bill to make the extra fifty cents which if the owner of the mine wish he can almost always do, will when carried into other things represent the district to the purchaser as more expensive than it really is It seems a very small thing to say that fifty cents a ton more on forty tons only amounts to $20, a sum the purchaser will not miss and which will do Bill a great deal of good. This may all be true. But when the owner talks to the purchaser about ten or twenty thousand tons of ore in sight, only needed to be mined and worked to yield its treasures, he does not realize that the purchaser being a business man, calculates the expense of the mining in his mind, and that the fifty cents a ton which did Bill so much good and did the purchaser no harm becomes five or ten thousand dollars, a sum sufficient to turn the scale and make a man decline a sale.

It may be said with truth that money is never so useful as in selling a mine. If the owner can afford to pay for the experiments needed to prove the value of his property himself, he is in an infinitely stronger position than he is when he is forced to ask the purchaser to pay for them. The majority of men are unwilling to put out money for what may not bring any return, and they will therefore hesitate over the preliminary expenses, while perfectly willing to pay a very much greater sum if the experiments are satisfactory. My own belief as to what is fair in such matters is this. If the owner of the mine pays for the drilling test, including expenses of transportation, etc., the purchaser should agree to pay that money in case the test is satisfactory. And for this reason:—The owner of the mine has proved its value to his own satisfaction by the work done upon it during the development. Any work done during the negotiations is done for the benefit of the customer, and if that work succeeds in placing his mine in the relation occupied by that of the owner towards the property; in other words, if the work convinces him of the property's value, then he should pay for it, because there was no need of the work being done to convince the owner. On the other hand it is fair that the owner should advance that money if he can, because the result of that test is a part of the risk, and it is not fair to ask the purchaser to assume any risk before the actual sale of the mine.

A few words on the last branch of my subject, what it is necessary for the owner to do when he seeks the purchaser, and I have done. I will suppose that Jones, who owns the "Roaring Tiger," in New Mexico, wishes to get acquainted with Smith, the capitalist in New York, and dispose of the property. And first I should say that this applies to all sales of mines. It is a mistake for Jones to sell the "Roaring Tiger outright. He will, of course, be obliged to sell the control because Smith will not invest in the mine unless he acquire this; but he should retain an interest, from twenty-five to forty per cent. of the stock. The reason why he should do so is, that supposing the "Roaring Tiger" to be a really good mine, he can rarely get its full value; in fact, I may say he can never get its full value. In selling the control and retaining the interest, he should always stipulate what amount of working capital Smith is to raise in addition to the sum paid for the control, and that amount should be sufficient in his opinion, as formed from his knowledge of the mine and the expense of working in the district, to make the property a paying one. To return, however, to the question of how Jones is to make the acquaintance of Smith and interest him in the property. The first step is, of course, for Jones to come to New York, as it is pretty certain Smith will not go to New Mexico. Jones brings with him his note-book, kept as I have described, and with every particular of information in it he has been able to acquire. In negotiating the sale of a property at a distance the note-book becomes of infinitely greater value than before. Jones also brings a full series of specimens, or as full as he can. He should by all means avoid the mistake of bringing only those that are rich, for he will find that if he shows rock which goes thousands of dollars to the ton and none of less value, Smith will have nothing to do with him. Having arrived in New York, he gets at Smith in the best way he can. If he knows anyone who knows Smith, of course the work is easy. If he does not, the best thing he can do is to walk boldly into some office and state his business. It is probable, in fact, certain that, he will meet with rebuffs, but if he be the kind of man I am supposing him to be, he will keep this work up until he succeeds. Every prospector knows what a job it is to find a ledge; how many weary miles of country have to be walked over, how long and careful is the search sometimes when "tracing float." Well, when Jones comes to New York he has to "prospect" for Smith before he can "locate" him, and if he only prospects long enough he will find him to a certainty. Having found him, he should remember that Smith is probably a busy man and has no time to waste, therefore he should make his story a short one but one that covers all points, and he should tell that story without any previous "chin;" Smith does not want to talk about the weather, nor is he interested in the inconveniences of an emigrant trip. The morning paper has told him what the weather for the day will be and he never travels by the emigrant train. Jones having told his story, Smith, if he be the right Smith, will feel sufficient interest in it to make further inquiries. He will send out some one in whom he has confidence to examine the mine or he will go himself. The sum of money to be paid for such part of the property as Jones wishes to sell being different in every case is of no interest to us here. It is sufficient that a general outline of the considerations which affect the mind of the capitalist and of the work to be done by the owner have been given at some length, and it would be useless, in fact, impossible to attempt to make the instructions minutely particular.

—*Alfred Balch.*

THE PURCHASE OF MINES '

MINING as a business in this country received an enormous impetus a few years ago. The growth of mining for coal, iron and copper in the east was one which was necessarily slow from the fact that it was parallel to and coexistent with the growth of the country itself, and mines that were known had to wait until there was a demand for their product before they could be worked.

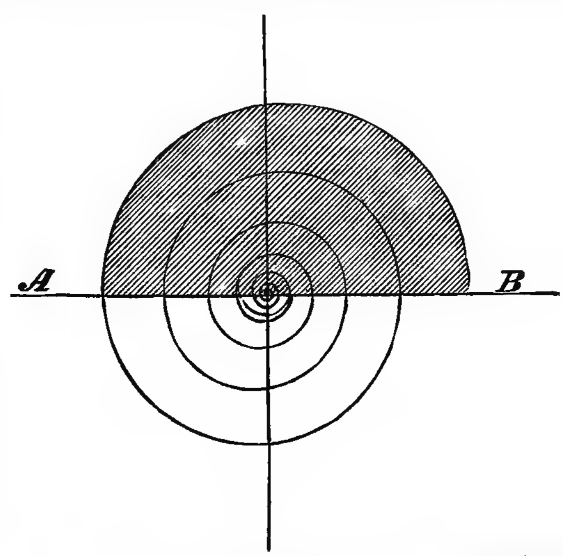
This did not apply to the mines of the west, those which yielded gold and silver; for the simple reason that there was always a demand for the metals contained in them. But when gold was first discovered in California in 1848, and the rush began in '49, the country was not as wealthy as it is now, the means of transportation were exceedingly primitive and business men found that there were chances enough for the employment of capital at home without looking for them so far away. People too, were not then as accustomed to travelling as they are now, and the conservative men in the community shrank from any such radical changes in their habits as that involved in a transfer of their household gods to the Golden Gate. Hence it was that the tide of emigration which flowed westward at that time was chiefly made up of the more adventurous and daring spirits, and this in turn produced in the minds of those who were left behind, the idea that it was a somewhat wild and foolish kind of person who would engage in gold mining. This feeling was anything but decreased by the fact that those who returned from the west on visits, by their habits, their stories and their methods of looking at things, convinced those who saw them that they were very wild persons indeed. But as the years rolled on the wealth of the east increased enormously, and there was a revolution effected in the methods of transportation. People travelled more, and the country, as the newspapers in their growth began to give more and more news about it, became in the minds of the people less and less of a number of parts widely separated and with but slight connection. It was impossible for a man who read day after day of what had taken place the day before in California, to look on California as being very far away, especially when he was conscious that eight days' time would land him in San Francisco. Time and the altered conditions then, had destroyed one of the great bars to investment in the west on the part of eastern men when, in 1875 the Great Bonanza was discovered in the Con. Virginia and California on the Comstock. The wildest stories were told about it, but the truth was wild enough. Over seventy-nine millions of dollars were taken out of the two mines and paid as dividends to the stockholders, and that they were so taken was the result of shrewdness and skill in management aided by a judicious use of capital. This was a proposition which eastern business men could understand. It was one which they could look upon without the feeling which had accompanied the idea of gold and silver mining in their minds for such a long time, namely, that the business was one in which it was all speculation and little certainty. It presented to them the proposition, as it had never been presented before, that intelligence and money invested in mines stood more than a fair chance of bringing ample returns. And as a result of all this the business men of the east began to turn their attention westward. They found that the case of the Great Bonanza was not a solitary case; that there were hundreds of mines of the precious metals which were yielding dividends as the result of money invested. And so began a rush of capital into the mining regions which was as strange in its way as the rush of emigration in '49. Men with money having been slow to believe anything now believed everything. Hundreds of thousands of dollars were brought into the districts, their owners fairly hunting for properties in which to invest. In their estimation and from their standpoint a mine was a mine, and provided they bought a mine they were satisfied. It was not to be supposed that a state of things which included the purchase of properties for large sums by men who knew absolutely nothing at all about what they were paying for, —should not include cases of gross fraud. The capitalists were cheated right and left, sometimes consciously and sometimes unconsciously. Ledges upon which no work had been done at all or which did not contain a pound of ore were sold for sums which were, in view of the facts, wildly absurd. The capitalists were crazy, and full advantage was taken by the prospectors of their craze. But along with the sale of properties worth nothing went that of properties worth a great deal. Mines having paying ore in them were bought, opened, worked and dividends got from them. It was this that saved the business and that kept up the flow of money to the west. Eastern men found that there was an opening for capital, and that returns could be got from its investment by that surest of all tests, experience. But they found too that the business must be conducted in a business way to make it profitable; that if it were not so conducted it would burn their fingers badly, and that such burns were very painful. Perhaps it would be more correct for me to say that they are finding this out, for the process of discovery and the learning of the lesson is not yet completed. The fools who think that "croppings" are equivalent to a mine, who think that assays will give them the value of a property, and who imagine that all that is necessary to acquire a fortune from mining is to buy a ledge, are not all dead yet, but they are, fortunately, rapidly dying. The injury they have done to themselves is as nothing to the injury they have done to the districts and to mining. For every dollar they have lost through their own blind and insensate idiocy, they have kept one hundred out of the districts and have thereby retarded to that degree the development of mineral wealth. They have never done the least amount of good either to themselves or to others by their investment while they have done an infinite amount of harm. I heard one of them say once that he considered gold mining the greatest fraud on earth, and I found that he based his opinion upon the fact that he had bought a ledge which turned out to be perfectly barren on the strength of some assays made from a piece of rock said to have been taken from it. I did not report the $60,000 he had paid and lost, but I did very much regret the fact that he had it in his power to make such a statement upon such apparently good grounds to those who did not inquire into the case.

The origin of all the losses made by eastern men in their purchases of mining properties has been the fact that they have attempted to engage in a business about which they knew nothing at all. And the odd part of it is that they only show the effects of this extraordinary idea when they invest in gold or silver mines. If one of them bought a locomotive he would never dream of acting as an engineer, or if he bought a steamboat he would not examine the boilers himself. In the one case he would hire an engineer, in the other a boiler inspector to do the work for him. But if he buys a mine he seems to consider that he is perfectly able to examine and determine upon the property or to run it after he has acquired the title. This is absurd. The knowledge necessary to examine a mine properly is only acquired after years of study and work, and no more comes by inspiration or revelation than does that of how to manage a bank or run a ship. The purchasing capitalist should be content with paying for his mine after it has been examined by an expert and pronounced to be worth the money; and when he gets it he should employ some one who knows how, which he does not, to operate it for him. It is no more difficult to find honest and capable men who understand mining than it is to find the same class in any other occupation. If the business men in the east will bring to the investment of money in mines, the same shrewdness which they show in other things, they will find that the business is one that will give handsome returns. Nothing is more fatal to their success than the idea that mining is a kind of investment which will run itself or which is not governed by the same business principles applicable in any other occupation. Mining is not the wild speculation which so many people imagine it to be; it is, on the contrary, a business which is as safe as the raising of wheat. It is true that a vein may fault and the mine come to an abrupt end, or the vein may pinch and "peter" out; but for that matter, the crop may fail from drought or may be eaten up by grasshoppers. Each variety of business has in it ups and downs. The only point is that business men should learn that proper precautions will reduce the proportion of the latter to the former enormously.

As I am writing this article to tell men how to buy a mine I will assume that the capitalist has had his attention called to a piece of mining property, that he is disposed to purchase it, and that he has the money both for the purchase and for the development and working of the mine when purchased. It is hardly necessary to say that what applies to one imaginary purchaser applies as well to a company. The mine having been found, it is necessary to determine as nearly as possible its value as an investment or the chance of getting a return for the money placed in the mine for the mine itself. This question properly divides itself into three, each of which may be considered as a factor seriously affecting the final result or the return of the money invested with increase. 1st, The ore body and questions which affect it. 2d, The working of the ore. 3d, The property acquired by the purchase. All inquiries necessary for the proper investment of money in mines are embraced under these three heads, and although in some cases the line of demarkation between them is not very distinct, I shall treat them as though it were.

First then as to the ore body itself. Gold and silver sometimes occur in a native or metallic state, but they are more often found in the former ore, that is in chemical combination with other elements. These ores are generally called after the combining element rather than the metal, as when we speak, in this connection, of carbonates and chlorides, we mean the combination of carbon or chlorine with the metal. I am of course talking in very general terms and not in any purely scientific way. Taking as an example a ledge containing the chlorides of silver, it would be found that the ledge is a body of quartz having in it small veins like their slabs, nodules or bunches of the ore. The vein matter is called "gang" or "gangue" and this gang is worthless, being barren quartz without any ore in it. But the valuable ore is contained in this gang. The result then of this preliminary examination is learning the lesson that the ledge is not a homogeneous body of ore, and this is one of the most important distinctions between a gold or silver mine and one of iron. If we find a deposit of one of the hematites we find that the ore is, to a very great extent, the same throughout the whole thickness of the vein, and if we arrive at the value of one piece by an assay, we can estimate from that the value of the whole. But if we assay a single piece of ore from a ledge containing this chloride of silver, we can predicate absolutely nothing from the result. This has been one of the hardest lessons for eastern business men to learn. Knowing, as many of them have known, that a sample from an iron mine or coal vein represents fairly the whole deposit, they have reasoned that a sample from a ledge of silver or gold ore is equally significant. They have not realized that the conditions of the existence of the ore in the ledge are different conditions; and have therefore attached to the assays of the silver bearing ledge the same value they knew from experience, was attached to those of specimens taken from a bed of iron ore, and in doing this they have given to the assays a significance far in excess of the fact. An assay of ore is, as most people know, an examination by fire and chemical reagents of a piece of ore. In making one the assayer takes a piece of ore about the size of a hazel nut, and ascertains by methods of no particular interest here, what it contains. As far as it goes it is absolutely correct, for the assayer finds out to the thousandth part of a cent, the amount of gold, silver, copper, lead, iron or any other metal contained in the piece assayed. He tells you that the ore assayed goes 7000 ounces to the ton and he is perfectly correct in what he says, for a ton of that kind of ore would undoubtedly yield 7000 ounces of silver. But from the fact that the ledge is not homogeneous, when the assayer tells you the result of the assay he tells you absolutely nothing about the ledge except the fact that it did at one time contain a lump of ore, that lump which he has assayed, which was valuable. Suppose that you have a ledge of quartz containing among other things some ruby silver. It would be quite possible to take from it two specimens for assay, one of the gang and one of the ruby. The result of the assay of the first would be *nil;* that of the second would be far up into the thousands. It would be as absurd to reason that the ledge was worth nothing from the first as it would be to reason that it was worth thousands of dollars to the ton, from the second. It must not be supposed that I am decrying the results of assaying, for I am not. I am simply trying to explain why those results have not the significance which has been attached to them and why the purchase of a mine upon the information derived from assays is a foolish purchase. In their place assays are of enormous value, and it would be impossible to mine successfully did we not have them. They may be compared to a compass on board ship, for they point out to us where to go; but he would be a most unwise captain who, because he had a compass, thought it unnecessary to take any observations of the sun.

As the ore exists in the ledge in combination with the gang and as the ore is valuable and the gang worthless, it follows that it is the proportion existing between the ore and the gang, in the ledge, which determines the value of the ledge. If there be a great deal of gang and very little ore, the ledge is worth but little or may be commercially worth nothing at all. If the reverse of this be true, the ledge is worth a great deal of money. Now comes the question of how to ascertain this proportion. We have already seen that an assay being the determination of the value of a particular piece of ore, is worthless in revealing the value of the whole ledge. But we can by taking proper precautions make this assay give us this information. If we submit a specimen to the assayer which contains an average amount of gang and an average amount of ore, the result will be what we wish to arrive at. Suppose that the proportion of barren gang to the valuable ore is as six to four; if we prepare a specimen having in it sixty per cent. by weight, of gang and forty per cent. of ore, the result of the assay of that specimen will be the value of the ledge. And the value of the result of such an assay will depend entirely upon the care and thoroughness with which this average specimen is prepared. As to the fact that it is only in this way that the value of the ledge as a whole can be ascertained, nothing is more common than to hear men say who have ledges for sale that their specimens are average specimens. As a matter of fact I do not believe that an average specimen was ever found in any mine in the world. It seems to me that as the proportions of the gang and the ore are constantly varying, the supposition that a single piece may be found which will in itself represent all of these variations, when tried by the almost theoretically accurate test of a fire assay, is an absurd one. At least I never heard of an assay of a single piece of rock which experience proved to have represented the value of the mine, nor did I ever know any person who had heard of one. In order then to get an average specimen we must do one or two things, either work a quantity of rock sufficient to represent the whole mine, in which case we get an average result of working; or mix together all the varieties of ore and gang and find the value of the specimen, in which case we simply work on a small scale an average lot of rock. Taking the latter first, in order to prepare such a specimen we must take a very large number of small pieces of rock. The best way to secure these is taking a pick and cutting a small ditch or groove across the face of the ledge. This should run from one wall of the ledge to the other, and should be about one inch wide and one deep. A large number of these grooves should be cut, not less than fifteen, and if the



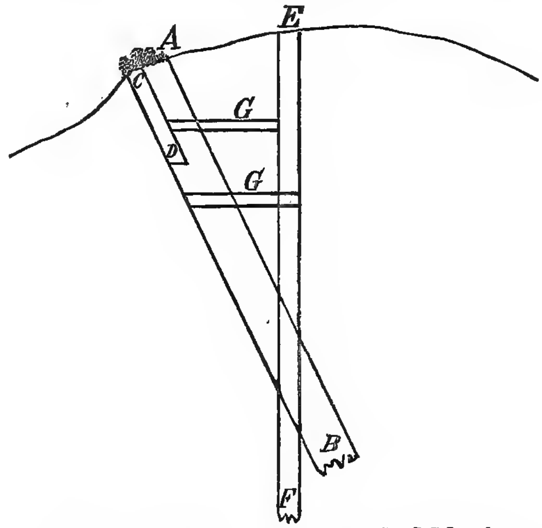
Watch spring Coil, A B line dividing the centre—Shaded half taken for further experiment.

ledge crops out for the full length of the claim, they may be cut every hundred feet. The stuff which is cut out of them should be reduced to the size of hazel nuts and spread out upon a flat surface. It should be heaped up and spread out again a great number of times, and finally should be worked with the fingers or a small stick into a figure resembling a watch-spring lying on its side. It should then be divided by a line through the center and one half carefully removed and placed by itself. The remaining half should be reduced to the size of peas by pounding it in a mortar or on a flat stone. This should in turn be heaped up and spread out as before, and one-half be taken in the same way. The half now taken, a quarter of the original should again be worked by mixing and spreading out, and by the same method reduced one-half. The person who is conducting this test should be careful each time to sweep up all the dust, and should see that this dust becomes fairly scattered during the process of spreading the stuff out. The process is continued until the amount is reduced to about five ounces, which is carefully gathered up and saved. The second half of the first separation should now be taken and treated in the same way until it is reduced to five ounces, which should be added to the five already obtained. The ten ounces should then be placed in a mortar and reduced until the stuff is as fine as flour. It is then mixed thoroughly in the mortar and spread out on a large sheet of white paper, until it is not more than a quarter of an inch thick. Two lines at right angles to each other should then be drawn and the opposite quarters of the mass taken and thoroughly mixed. This will give the two halves separate. Each half should be treated as the whole mass was until two specimens, each containing one hundred grains, have been separated out, and these specimens should be assayed. If the two assays correspond within a few cents to the ton, it may be concluded that the work has been done properly, but should there be any great difference between them there is nothing to be done but to begin all over again and cut fresh grooves across the face of the ledge.

It should be remembered that the more places from which the ore is taken, or in other words the more grooves cut, the better and more reliable is the final result. This method is the most reliable one which can be applied to a ledge before any work has been done upon it. Should there be a shaft extending say two hundred feet down, and two levels upon it is, say five hundred feet in all, the ledge may be said to be prospected and we may apply a milling test to it. This is much more expensive than the former and much more valuable as a means of determining the value of the mine. To make it we take from fifty to one hundred tons of ore secured in this way. Beginning at the top of the shaft, we cut lumps of ore from the vein the whole way down. Upon each level we cut out ore along the top, being careful to take it from the full width of the vein, and we cut a full section of the vein across the two faces of each level. The ore so secured is carried to a customs mill and, taking the precaution of having the batteries and pans or furnaces thoroughly cleaned, then worked. While the ore is being crushed a spoonful of the "slime," as the crushed ore mixed with water is called, is taken every ten or fifteen minutes from in front of each stamp, and thrown into a bucket. Being thoroughly mixed it is then dried and subjected to the same process as that already described in order to get specimens for assay out of it. In a milling test, however, we generally make ten assays and average on the results. Examining the batteries after the operation of crushing is at an end, in order to see if, as sometimes happens, the gold or silver in a metallic state has refused to pass through the screens, we take the birch or result in metal of the working and ascertain its value. Supposing that every part of the test and the preparations for it to have been carried out properly we will have arrived at a very close estimate of the value of the ore in the mine. These tests, particularly the last, are troublesome to make, take time and cost money, but it is time, trouble and money well spent to make them. The purchase of a mine is an operation which involves the expenditure of a more or less large sum of money, while its development and working is apt to cost a great deal more than its purchase. It is rarely that a mine can be made to pay without the expenditure of fifty thousand dollars, and it far oftener costs a hundred and fifty. These outlays are legitimate if warranted by the condition of the mine, but it is of primary importance to ascertain if that condition will so warrant them. Economy here may well be said to be "penny wise but pound foolish" policy. Supposing that the ore is found to be all right and to warrant the belief that the mine will pay as an investment, the next question in order is the state of the ledge. A ledge of quartz may be compared to a leaf of a book. It has a leaf on each side of it, of barren or country rock, called the "walls," and it may run all the way down to the binding, or it may be merely a margin pasted on. All that we can see at first is that like the other leaves it has an edge. To drop the simile, all we can know from the "croppings" or appearance of the ledge at the surface of the ground is that there is a ledge there. We may conclude that if the ledge is continuous, if it is the same width or wider a thousand feet under ground, and if it carries the same proportion of ore and gang throughout, that it is a good property. But it may be a "pocket" ledge, that is, it may end when we get fifty or a hundred feet down; or it may fault or be cut off and disappear. The ore may give out and the gang alone remain. Now these points must be ascertained if possible before purchasing the property, because upon them depends the value of that property. As far as faults are concerned, they may generally be discovered if they exist by an examination of the surrounding country. The question of whether the ledge is a pocket is one of infinitely more complex character, to the solving of which must be brought far more reasoning power and closer observation. As each mining district possesses peculiarities of its own, the expert, before attempting to reason about a ledge, especially if that ledge be undeveloped, examines all the mines he can get into in that district. By such examination he will be enabled to determine what are the peculiar features of ledges there. Having done this, he returns to the ledge he thinks of purchasing or of which he is to recommend the purchase. He examines the walls to find out the kind of rock they are composed of. If he finds the same kind of rock on each side of the ledge, and if he ascertains that the strike of the ledge is different from that of the walls, he concludes that the ledge is probably a fissure. If in addition to this he finds that the walls next to the ledge are smooth and have a soapy feel, and he sees clay seams between the ledge and the walls, his previous conclusion is confirmed. Should he on the contrary find that the strike of the ledge is the same as that of the walls, that the ledge lies between two *strata* of different rock and that there are no clay seams he will, as a rule, be inclined to look on the property with anything but favorable eyes, because he will feel almost certain that it is a pocket. The ore itself will tell a tale to him. If he finds that it is equally distributed throughout the gang and is a variety of ore which in that district has been found to be permanent, he will reason that the ledge probably carries the ore all through it. But in the examination of the ledge the two most important points to be determined are the existence of faults, if any, and if it be a fissure vein, a careful examination will generally determine these sufficiently to warrant a purchase of the mine or a refusal to have anything to do with it.

It will be conceded I think that examinations of the ore and the ledge such as those which have been generally described, are somewhat more satisfactory than those made as a rule by investors, for the simple reason that they are more thorough. But the ore and the ledge having been proved to be all that is desired, more has to be done before the mine can be properly bought. There are the questions which relate to the working of the ore. As the metal has to be extracted from the ore before the mine can pay, the cost of doing this will often prevent the mine being a legitimate commercial investment. This cost divides itself into two parts, that of getting the ore out of the mine and that of working it after it is so got out. The would be purchaser should inquire carefully into these points if he would not find his money evaporating into thin air. The cost of getting the ore out includes the price and value of the labor to be obtained. The rate of wages should be ascertained and the contract prices of work be got at. As a rule in mining it is better to have work done by the piece, as it often happens that in trying to save the profit to the contractor the owner loses more than he makes. If there be a miners' union in the district the purchaser should make himself thoroughly familiar with its workings and the rates established by it so that he may find out whether he is to make a profit himself or pay all his money to his men. The history of that union in the past will give him a fair insight into its policy in the future. As mines require timbering, the cost of the timber and the expense of transportation must be ascertained. In making an examination into this branch of the subject it is necessary to find out from the character of the walls, how much timber will probably be required. The ore must be hoisted out so the cost of hoisting engines must be known, and the freighting rates to the mines from the shops. The rate at which rails can be laid down at the mine for use in tunnels and levels should find a place in the note book. If steam is to be used to hoist, the price and heating value of the fuel to make that steam; and the source and character of the water, whether it be water that will corrode the boilers rapidly, must be ascertained. The cost of blasting powder, of picks and drills and of all other things must be known; and in case of the picks and drills the rapidity with which they will wear out as governed by the hardness of the rock. The ore being upon the surface of the ground it has been mined and now must be worked. The first thing to discover is how it is to be worked to the greatest advantage. Does it require a crushing mill pans and settlers, or is it a smelting ore, and are furnaces needed? Will it pay better to work it on the ground, or ship it and have it worked anywhere from one to one hundred miles away? If a mill or furnace is to be built the purchaser must find out where the mill site is to be secured and its cost. He must know the supply of water if there be one, and the cost. If the ore must be smelted, he must ascertain what kind of fuel he requires, and the cost, of laying it down at the furnace. Its value, too, must be known. If the ore has to be carried from the mine to a mill or furnace, the question of the facilities for road making comes in and must be answered together with that of the cost. All these and many other points must be inquired into before the question of whether it will pay to work the ore which is satisfactorily found in this ledge which is probably permanent, can be answered. It does not do to buy the mine first and to find out these things afterwards, because when this is done, it often happens that the purchaser is forced to resolve to let his loss on the purchase of the mine end his connection with it. Nor does it do to buy the mine and then spend money making experiments on working it. Before one dollar is paid for the transfer of the property a clear and plain answer to the question "will the ore pay after it is mined and worked a sufficient return to give me fifteen per cent. on the purchase money" must be had. There must be no If, or But or Perhaps about it. It must be known in the same way that the probable return from a purchase of wheat land is known. Giving the mine, if the vein proves permanent and no unforeseen accident occurs, I can make just such an amount by the expenditure of just so much money. When mining is gone into in this way, it is a business and not a speculation.

There is a third branch of the subject-matter of the purchase which must be inquired into before that purchase can be made. It is that of the property transferred. And the first thing to be ascertained is the question of title. It often happens in a mining district that claims being hastily made and carelessly stated, overlap each other. A search through the recorder's books must be made to see if the property to be bought is claimed by any one else, and if it is, whether that claim is good. It must also be found out whether the assessment work, providing the claim is not patented, has been done during the previous year or two, and if that work is recorded by the United States surveyor in the district. The question of title having been satisfactorily settled, the "plant" or stock of tools, machinery, etc., transferred with the mine must be examined. If there be a mill, the engine and boilers should be inspected, the pans and settlers cleaned and viewed to find out if they are in good condition. If there is a furnace, it should be examined with the same object. The work done upon the mine in sinking a shaft, mining a tunnel or driving levels should be surveyed in order to find out if it has been done properly, or is sufficient. There is such a thing known as getting a mine into such a shape as to prevent the cheap extraction of the ore, and in such a case it is often necessary to do all the work over again. Supposing, for example, that the ledge dips at an angle of 53°, and that a slope two hundred feet in depth has been sunk in the foot wall. It may be known the "output" through the slope is, say, ten tons a day. But the purchaser may intend to put up works which will reduce one hundred tons per day. In such a case he finds that he cannot get such an output through the slope, and that it is necessary to sink a shaft to strike the ledge at say, six hundred feet, and run level on to it. In that case the slope is of no use except, of course, for ventilation. Or it may be that the work done in sinking a perpendicular shaft



A B Ledge C D Slope. E F Shaft. G G Levels.

was done at one end of a claim, and that in order to work the mine to the point of output wished it is necessary to sink nearer the centre. Or the tunnels and levels may be too small. These points must all be examined into and answers arrived at before the value of the property can be known with any degree of certainty. Careful and accurate measurement of the ground and of the ledge must be taken in order that the details of the property purchased may be known to the purchaser.

It may be laid down as a general rule applicable to the purchase of all ledges containing gold and silver, that it is unwise to buy mere prospects or locations. It is of course, the fact that a ledge which has been only located and on which no work has been done may be bought for far less money than one the value of which has been proved by development, but on the other hand it pays the capitalist to expend more money and take a smaller chance of loss. All that can be said of any ledge when it is located is, that the prospects warrant the finding out whether it is a mine. From the fact that every dollar expended upon the development at first is not only so much towards the preparation of the mine for working, but is also a reason for the expenditure of another dollar, it follows that the work of development is work for which there is always a reason. The indications found in the croppings are such as to warrant making a cutting, say ten feet deep. If the ledge is found to be at this point, one which looks well, it is right and proper that the shaft should be commenced and sunk, say, ten feet more. The croppings warranted the first excavation, that in turn warranted the second. And this process of reasoning is one which is constantly being applied as the work goes on. Each foot sunk is a step towards the development, and a reason for taking another step. But from the fact that the croppings can only be properly looked upon as sufficient to warrant the commencement of development, it is unbusiness-like to purchase a ledge upon the strength of what they may reveal. The capitalist who pays anywhere from fifty to two hundred thousand dollars for a claim, does not pay that money for the privilege of proving the ledge to be barren. He pays that money for what he believes to be a mine, and it is only when he gets a mine, a piece of property which will pay him his money back with interest, when worked, that he is warranted in paying the money at all. It is then of primary importance for him to know that he is buying a mine. Until the ledge is developed he can not know this with any degree of certainty, and he has no right, speaking in a business sense, to pay a heavy sum for the chance of finding this out. It often happens, however, that prospectors have acquired the titles to properties which show well upon the surface, and as the result of assessment work, the prospectors themselves being too poor to do the necessary work of development. In such a case, the position of affairs is this. Here is a valuable property, for I am supposing that the ledge is really a good one, and will pay if developed and worked, the owner of which is unable to do anything with it. Such a property the owner will try to sell, as he is conscious of the fact that it will remain forever in his hands unexplored. If the capitalist knew—which he never can know with certainty—that the ledge is what I have supposed it to be he would be perfectly justified in purchasing it. But as he can not know this he is not so justified. On the other hand, if the ledge be really valuable it should not be sold by the prospector as though it were of little worth. At first sight this appears to be somewhat of a deadlock, but like most deadlocks, there is a way out of it. While the capitalist is not justified in paying for that ledge as though it were a mine, he is perfectly justified in paying to find out if it be one. His possible loss then is confined to what money he puts out for development, an expenditure he can stop at any moment, if the indications be such as to show him that his money is being wasted. If we suppose that the water line for the district is one hundred and fifty feet down, two hundred feet of shafting will generally prospect a ledge pretty well. If to this be added five hundred feet of levels, that ledge may be said to be fairly opened. Now taking assessment values as a basis, we can call this seven hundred feet of work, $7000, and supposing the plant necessary to do it cost $3000 we have $10,000 as the sum to be expended At the risk of being charged with reiteration I must once more point out the fact that each $1000 expended gives at once direct return in development and is a warrant for the expenditure of the next. It is this fact which makes it proper for the capitalist to agree to spend his money. If he buys the ledge outright for $10,000, and it is a mighty poor ledge he could get for that, he has lost his money if the vein pinches. He has nothing to warrant the payment, except the croppings and surface indications. But in the case of the spending of the money for development he is constantly receiving new proofs of the wisdom of his expenditure, or, on the other hand, if he does not receive such proof, he can at any time decline to lose any more. The capitalist should then, if he find a ledge which from its surface indications he believes to be a good one, but which needs developments the owner is unable to make, be willing to make such developments. In such a case he agrees to spend so much money upon the ledge for development, or such a part thereof as the result of that development shall warrant. He at the same time bonds the mine for a certain fixed sum, to be paid for the controlling interest or for the whole property in case, upon development, the mine shall turn out to be a good one.

The deed should always specify the amount of development which is to be done, as well as the time it is to be done in. As for example, the shafting is set down at two hundred feet and the levels to be driven at five hundred; when this seven hundred feet of work has been done, the capitalist must decide as a result of an examination of the mine in its then state, whether it will pay the purchase money as agreed upon. If he declines to do so, the property reverts to the original owner whose title becomes as clear as if the capitalist had never acquired a prospective interest in it, and had never expended a dollar upon it It sometimes happens when such an arrangement is made that the mine, when developed, turns out to be worth less than the sum agreed upon as its purchase price although still a valuable property. Supposing that the purchase price named was $100,000; the mine may easily turn out not to be worth this but to be a good investment at $50,000. On the other hand, it may turn out to be a mine which would be cheap at $200,000. One of these chances may be fairly set against the other. The capitalist however should be careful before agreeing to a purchase price, to examine into the property as thoroughly as may be possible, and to set that price at a sum which in view of all that he can discover about the ledge seems to be a fair and reasonable one. Even if the first of the two results of the development of the mine mentioned be the one which is arrived at; if the property turn out to be worth less than the sum agreed upon, the capitalist rarely loses his money as invested. If he declines to pay the sum originally specified as he has under his bond a perfect right to do, he will often, if he make a fair offer for the mine succeed in purchasing it for a less sum. The difficulty of finding a purchaser for a mine is such that the prospector is rarely unwilling to sell at a fair figure. It sometimes, and I might say often, happens that the prospector will offer to give the control for the development. That is in consideration of a specified sum being spent in the development of a mine and in the purchase of hoisting and reduction works, he will transfer anything over fifty-one per cent. of the property. And just here let me say a few words about acquiring the control. Nothing can be more foolish and more of a mistake than for the capitalist who purchases an interest in a mine to invest his money for other men to manage. Time and time again has experience proved that this is the most ill judged proceeding any man with money ever went into. The way in which it is generally brought about is the purchase where there are several owners of the interest of one. The capitalist if he go into mining at all should in all cases have the control of the property, and for a very simple reason. The men who find the mines, the prospectors, rarely if ever can be considered business men. They may be and probably are perfectly honest, but they do not know how to handle money in a way which will make every dollar pay for one hundred cents worth of work or supplies. When such men are placed in control the shrinkage in sums of money placed in their hands and the waste, not as a result of dishonesty but simply from a lack of knowledge, becomes very great. It is therefore necessary that business men should attend to regulating the expenditures upon the mine, because if they do not, those expenditures will be far in excess of what is legitimate and right in the premises. To return however to the proposition stated at the beginning of this digression, that of the prospector giving the control for the development, While this offer is often made it is one which is, except in very rare cases, unwise for the capitalist to accept. And for this reason. Nothing is apparently fairer than for the owner of a ledge to say "I have a ledge which I own. From the surface indications I think that it is of value and will if developed pay handsomely. You from your examinations agree with me. I have the ledge but no money; you have the money but no ledge. You take your money and work my ledge for the benefit of both and I will give you a larger interest than that which I retain to pay you for doing this." But when we examine into this proposition we find that it is not one which is either wise or business-like. The arrangement is never made unless the capitalist agrees to do a certain specified amount of work or spend a certain specified sum of money. As the essence of the fact that it is legitimate business for him to agree to begin the development and carry it on providing at every point the development made warrants further development being made, lies in the proviso, and as such a contract as that which we are considering is without this proviso, it follows that the purchase of the control for the development does not differ except in name from the purchase of the location. No matter how little the ledge as you go down may warrant the doing of further work, the sum mentioned in the agreement must be spent of course; the capitalist can at any time cut the gordian knot by refusing to pay any more money, but if the prospector be of the opinion, as he frequently is, that the full amount of work mentioned will, if done, prove the value of the mine to be great, he can seriously annoy and embarrass the capitalist by law suits and other vexatious proceedings.

There is in mining, or rather the investment in mines, a fundamental commercial law of which all these directions as to purchasers may be said to be the "croppings." This law is the one which teaches us from experience, that mines of the precious metals have been formed in such a way as to make them uncertain properties. All the directions given have had as their sole object the giving to the capitalist of greater certainty in business operations, greater security for his investments. In obedience to that other commercial law which reaches the possible profit always in proportion to the certain risk, mines which pay, generally pay handsomely for the money invested. It is possible by taking due precautions, to determine to a very great extent what this risk is, and it is therefore wise to take those precautions. The difference in the risk of purchasing a mine which has been developed sufficiently to prove that it is a mine and not a pocket, and that taken in the purchase of a location upon the strength of the croppings and surface indications, can scarcely be over stated. But supposing that the ledge be proved by development to be a mine, that the ore is abundant and valuable and that it can be worked at a profit; there is still a question which is of great importance, namely what that profit will be. It is a known fact that property in a mine differs from that in land, for example, in one very important particular. If a man owns a lot in a city that property is, barring such an accident as the swallowing up of the city during an earthquake, property for ever. As long as men live on the earth and congregate in that city so long will that piece of ground have a value. That value may vary but there will always be something left. But in a mine this is all changed. There will come a time when that mine can no longer be worked, when from natural causes it must cease to pay, when it costs to get the ore out and separate the metal from it just the sum represented by the metal when separated. The ultimate value of that mine then, is represented by the sum which can be taken out prior to that time. There are many opinions as to the depth which mines may be worked, but we will suppose that under all the conditions existing in a certain district a particular mine can not be worked at a greater depth than 3,000 feet. The claim is 1,500 feet long. We will also suppose that the ledge of paying rock is five feet thick. We have then 22,500,000 cubic feet of ore which we can take out. When this is done, that mine is at an end; it has as far as the question of property is concerned, ceased to be. Now if the amount of money paid for the property be represented by x and the amount expended for plant for the extraction and for the working of the twenty-two and a half millions of cubic feet of ore be represented by y, then x + y will represent all the money put into or expended upon the mine. The amount of money which that mine must yield in order to make it a paying and legitimate business investment is (x + y) a sufficient sum to answer the requirements of interest. In other words that mine must pay back all the money invested in it together with an increase or its purchase will result in a loss. As the time in which this must be done is limited from the fact that the existence of the mine is limited, it follows that the purchaser must see his way to such a return clearly from the start. The fact that the mine may not be exhausted during his life does not alter this conclusion in any way because, supposing the commercial life of the mine to be ten years, and the purchaser to die at the end of five, the mine is a property at the time of that death being but half worked. Practically this question resolves itself into that of the dividends which the mine must pay or the interest on the money invested which it must yield. I have already placed that at fifteen per cent. of the purchase money, because although this is rather high there are so many risks to be looked on as possible that it does not seem to me it should be reduced. As the result of all examinatious then the purchaser must see fifteen per cent. on the investment in sight from the start. If he does see a higher per centage so much the better, but he must not see a lower, if he would go into an investment in a mine with the same degree of certainty and guided by the same amount of business caution asked for and shown by him in other business transactions.

In conclusion, I have but one word more to add. There is a class of men in the community who have given the best years of their lives to the study of mines and mining. They are as a rule honest, capable and trustworthy. The employment of them by capitalists who wish to purchase mines will save thousands of dollars and will give results which are out of all proportion to the money paid. The substitution for their trained experience and their knowledge, of the "common sense," by the light of which so many men have purchased mines in the past is a substitution which is characterized by no sense, common or uncommon; and which is the most expensive folly the mind of man ever conceived or acted upon.

—*Alfred Balch.*

SALTED LEDGES AND WILDCAT MINES.

FRAUD in mining is as confidently expected by some people as is the rising of the sun in the morning. They will tell you that the man who touches a gold mine has lost whatever sense he ever had, and they will repeat with much cynicism the trite saying about "a fool and his money." As there have been many instances of fraud in the business, few if any of those who speak so sneeringly of it lack an example to which they may triumphantly point as an instance in point; and as you listen to the story of how Smith was taken in, and done for by that guileless prospector Jones, you are forced to admit that Jones stocked the cards on Smith and got away with the pile. In all honesty it is but fair to say that the *genus* Smith who has lost its money, has by its own folly in many cases, prepared the way for the work subsequently got in on it by the *genus* Jones; and that if Smith had displayed ordinary caution, Jones would have had no chance. It is, however, unquestionably true that the losses by fraud in mining have been enormous, and that many men have cause to regret that they ever put one dollar into the business. It cannot be said that mining has been marked by any unusual number of frauds; that is, distinguished as one form of business among other forms, by fraud. It is probably the fact that as much money has been lost in every variety of occupation among men by dishonest practices as was ever thrown away in mining, but it is unquestionably true that there is about mining frauds a brilliancy of execution and a clearness of cut in the pattern, marking them among frauds in general with a degree of distinctness which attracts the attention at once. A "salted" ledge once bought, the money has gone forever, and gone too, in the intensely aggravating form of a lump. The sum lost is generally large, and there is rarely, if ever, any redress. The owner of the ledge can contemplate his property with the disgust which animates the soul of a man who knows he has been cheated, intensified by the reflection that he will have the greatest possible difficulty in persuading others to share his loss in any way. The annoyance, too, is cumulative. I have known a man who had bought a property at a price about five times what it was worth, keep his temper beautifully until he learnt that to retain possession of it he must do one hundred dollars worth of work upon it each year, when he lost his philosophy and broke out into strange oaths. The government assessment work was the last straw. The peculiarly disagreeable character of mining swindlers is due to the fact that money once paid, one must pay more in order to have even a chance of getting back any at all. Whether this demand for more takes the form of the disbursement necessary to purchase hoisting works and mills or the miller, but no less inexorable cry for "more mud," it is none the less disagreeable. Nothing dampens a man's willingness to pay out money more than the knowledge that he has already paid and lost in the operation. And in gold or silver mining the loss, if loss there be, is generally a positive loss and one about which no man can make any mistake. It seems to partake somewhat of the character of the gain. That is in bullion which has a value the moment it is taken out of the "chill" or iron mould of the brick. There is no question about a market, it can be sold at once; taken to the mint the gold twenties are poured out for it as soon as its value is known.

The frauds in gold and silver mining may be divided into two great classes indicated by the title of this article. The "Salted Ledges" are the frauds perpetrated by Jones, the sale to Smith of ledges which have no valuable mineral in them. The "Wild Cat Mines" are the frauds perpetrated by Smith upon the public at large through the medium of the stock market. The two classes may be said to be the positive and the superlative of mining frauds, for the first is to the second in importance what a retail business is to a wholesale. While thousands of dollars have been lost through the Salted Ledges, millions have been thrown away in the Wild Cat mines. Taking the lesser of the two evils first, the conditions necessary for the sale of the Salted Ledges are a flow of capital into mining, the success of some of those engaged in it, a ledge of some kind to salt, shrewdness on the part of the men who negotiate the sale and credulity, and a lack of knowledge on the part of those who pay the money. Given these conditions fraud is always possible; and given these conditions, fraud will always be practiced. In order to illustrate how it is done, a story may be told, which is strictly true, except in the names given; these, for obvious reasons, being fictitious. In mining camps in the West the men generally assemble in some place for an hour or two during the evening and there tell yarns. Among these none is more popular than that of the "$100,000 Picnic;" and you can rarely get any number of Pacific Coast miners together without hearing it if the conversation turns upon the tricks which have been played upon the "mining sharps" from the East. In 1867, as the story goes, Mr. Henry Thompson arrived in the city of Albany with a mine for sale. Having succeeded in getting some introductions to capitalists, Mr. Thompson being a most plausible talker, told them of his errand and of the property he had for sale. This was situated in Idaho, and, being undoubtedly the finest mine in the territory was appropriately named the "Flower of Idaho." It was owned by Mr. Thompson and his two partners, and consisted of a ledge of quartz carrying ore of high grade. Although the ore was scattered through it very irregularly, Mr. Thompson stated that taking the ledge all through, the rock would run from $50 to $250 a ton with one average, say $112,50. Mr. Thompson expressed himself as exceedingly anxious not to overstate anything. One of the capitalists, Mr. John Smith, a gentleman who had made a great deal of money in railroads and who was looked upon, and justly, too, as being one of the shrewdest men in the State of New York, listened to Mr. Thompson's story with eager ears. He had heard that other men were making money in mines; he had read as what man had not in '76, of the enormous yield of the Great Bonanza in the Comstock. Naturally of an enterprising turn of mind, Mr. Smith had some of the specimens produced by Mr. Thompson assayed and the result showed that the half had not been told by this honest miner, for some of them went high up into the thousands. Mr Thompson gained not a little credit too by telling Mr. Smith that the higher assays were not to be depended upon as they could not be taken as representing the ledge. Having secured in this way a character for fairness which shone with a golden tinted splendor, Mr. Thompson pointed out the profits of the enterprise by telling Mr. Smith that the cost of mining and milling would together amount to about $25 per ton. The high estimate was given he said because labor and transportation in Idaho were very expensive. Mr. Smith asked how many tons could be extracted in a day, and Mr. Thompson replied, still speaking with that moderation which had characterized him all through, that twenty to thirty was not a large estimate. $2,000 to $3,000 profit a day was enough to make Mr. Smith open his eyes. But Mr. Thompson's story was not yet told. He had not come East to tell a mere "prospect of which he spoke with proper contempt," he had a mine which was fairly opened. His partners and himself had sunk a shaft 100 feet and had driven a level 250 feet so that the vein was in a condition to be examined. More than that. He had a little money, and if the purchasers would sign a contract to buy at his figures, $100,000 in cash and 30 per cent. of the stock, providing an inspection of the mine by their own expert confirmed the story as told, he would pay the expenses of that expert to and from the mine. He did not ask Mr. Smith to buy, but he did ask him if he thought well of the property as described, to select an expert and let him view the mine. He also explained that while he was able to pay the expenses he was not able to pay the salary of the expert and he therefore expected Mr. Smith to assume this part of the burden. The story as told and the proposition as made captivated Mr. Smith, and he called a meeting of those of his friends whom he was willing to let into a "good thing," and laid the proposition before them. Thompson told his story once more, and explained that the contract must contain a clause binding them if they purchased the mine to raise $250,000 as working capital. Mr. Smith showed the result of the assays he had had made and offered to subscribe $100,000 out of the $350,000 necessary to carry the whole thing through. "Money talks" as they say in the betting ring. Mr. Smith was known by every one present to be a man who had been the architect of his own fortunes, and his ability and shrewdness were universally acknowledged and respected. It did not take five minutes to have the amount necessary subscribed and the contract giving $100,000 in cash to the owners of the mine for 70 per cent. of the property and the raising of the working capital was signed before those in the room left to go home.

Then came the question of an expert. And, just here, a most fortunate thing happened. Mr. Smith's son, John, Jr., had first graduated with credit from a school of mines which I will locate in Kamskatka for fear of being invidious. He had taken prize after prize, could talk learnedly about various strange things, and delighted his father who was naturally proud of the boy's ability, by the perfect familiarity he showed with the specimens which had been exhibited by Thompson. This latter individual had told Mr. Smith that John, Jr. was wasted in the East, and that his true field of usefulness was aiding in the development of the great mining industries of the West; that West that Mr. Thompson was pleased to call Boundless. Mr. Smith noticed, with pleasure, that Thompson, who was so evidently a practical man, seemed to esteem highly the opinions given by John, Jr., and he did not fail to observe that he had also on one or two occasions confessed that he was wrong after arguments held with "the boy." Mr. Smith, naturally, was anxious to give his son a start, and when he proposed to his associates that John, Jr. be sent as their representative they agreed at once. The same proposition having been made to Thompson, he replied, "It ain't for me to say who shall go, Mr. Smith. I'm ready to take any one you say; but I should like to have your son with me as I believe he'll keep your interests in sight, an' I know he'll be pleasant like to travel with." And so it was settled; Thompson and John, Jr. left Albany for Idaho. During the trip Thompson beguiled the time with stories about mines and mining, in many of which he was forced to allude to the dishonest tricks which had been played. These he reprobated, not from any high moral standpoint, but from a business point of view, claiming that they did not pay. Arriving at the terminus of the railroad Thompson and his companion were met by Brown, one of the partners in the mine, with a wagon in which to make the rest of the trip. The drive took two days, through magnificent scenery, and the weather was delicious. About the food there was just that suspicion of roughness which is so delightful; the pan of bacon and beans stood beside the canned meat and vegetables on the table. Brown proved himself to be a most entertaining fellow, although somewhat more volatile than the sober Thompson. He, also, told stories about the way in which unsuspecting Eastern men had been fleeced in fraudulent ledges, and his outspoken admiration of smartness gave Thompson a chances to once more repeat those little observations about the shortsightedness of dishonesty. John, Jr. fell in love with the country, and thought his companions two of the most delightful men he ever met.

Reaching the mine at last, John, Jr. went into it. He found that Thompson's statements in Albany had been short rather than in excess of the truth. The shaft was 108 feet, or eight feet more than had been claimed, while the level exceeded the length stated by thirteen, being 273 feet long. The next morning Thompson said to him, "Now, Mr. Smith, I reckon you'd better kinder let me show you about the mine, an' then leave you to yourself. You kin examine the property an' make up your mind 'bout it any way you like, but I ain't got no call to point out much to you. I'll answer any questions you may hev to ask, but I want you to do the work without help. Then when you gits back you kin kinder bet in your 'pinion,' an' you can't say as how I influenced you."

"I shall want to do some assaying," said John, Jr., after expressing his opinion of the perfect fairness of Thompson's plan.

"Certainly," said Thompson, "don't forget the assayin'. Only we ain't got no place fur you here. We've got horn spoons, but they ain't the most reliable things in the world."

"I ought to have brought a furnace and things with me, I suppose," said John Jr., in the tone used by a young man when he thinks he has made a mistake which causes his seniors to think him "green."

"Waal," said Thompson, "I had a right to tell you. I 'spose you've got a place at home?"

"Yes, father fitted up a splendid laboratory for me."

"'Spose, then, that you take your specimens all the same. Brown here will make a lot o' little bags an' you can seal the specimens up. Then, when you gits East, you kin assay 'em at your leisure. Number the bags an' keep a record an' you'll get along all right, I reckon."

It was so determined. John Jr. took specimens from the vein and the walls; he examined the country for faults, he worked hard at measurements. The evening of the second day as he sat tying up the specimens in the bags and sealing them with his ring, he said, "I find this ledge to be one of the most interesting deposits I ever saw. It lies in the fracture of an anti-clinal fold, and is, I think, an alluvial deposit of quartz which has been subjected to metamorphic action. The marks of the great denuding agencies are plainly visible and it gives every indication of permanence, for I find that the quartzite visible near the surface gives place to true quartz below. It is really delightful to examine a formation which is so thoroughly scientific in its character."

"Jes' so," murmured Brown, respectfully, while Thompson added "Thar's heaps in these yer veins 'round here, Mr. Smith, as we miners can't see."

A week having been passed at the mine, John Jr. announced that he was ready to return. He told Thompson that if the assays were all right the mine was as good as sold. The bags containing the specimens were placed in two grain sacks which were at Thompson's suggestion sealed up. During the journey back, John Jr., also at the suggestion of his companion, looked after them himself and never allowed them out of his possession until they reached Chicago, from which place he shipped them to Albany in a strong box by a different route from that traveled by himself. As Thompson said "This thing's business with me, Mr. Smith; an' thar's a sight dependin' on them bags, so I don't wan't no chances took." Arriving in Albany, the assays were made by John Jr. in the presence of the men interested, and at Thompson's suggestion portions of the specimens were sent for independent analysis by assayers in New York. The reports confirmed each other and Thompson's statements; the capitalists, feeling that they had a good thing, came to the front, the $100,000 was paid, the mine incorporated, the 30 per cent. of stock issued to Thompson as representing the ex-owners, the $250,000 was raised for working capital, and Thompson left for the West. A short time afterwards a superintendent was sent out and the Company were greatly astonished to hear from him that the "Flower of Idaho" was a worthless ledge of quartz which would not average ten dollars to the ton!

The way in which the swindle had been worked was simplicity itself. By making a bread seal, Thompson had been able to open the bags while John Jr. was on a hunt after a mythical grizzly of which Brown had told him and after which Brown took him, the day before he left for the East. Having opened them Thompson substituted for a part of their contents some rich ore procured from a mine at some distance away. Then he sealed them up again. When John Jr. and Brown returned Thompson was engaged in cooking, and the seal was burnt. John Jr. had been deceived for the simple reason that he had trusted to his assays to tell him the value of the ore. The true history of the mine was somewhat different from that told by the guileless Thompson. It had been opened to its then extent by men, who, having become convinced that it was worthless, had abandoned it in disgust. Thompson, who was a gambler by profession, had with his partners taken possession of the property and had spent enough money upon it to clear it of water, when they had sold it in the manner described.

Although there was no Thompson, Smith or Brown in the original transaction, and although the "Flower of Idaho" was not sold in Albany, and although John Jr. did not graduate in Kamschatka, this story is strictly true. It illustrates well the methods taken to dispose of salted ledges although the salt in this case was placed in the bags rather than in the mine. Instances have not been lacking where the latter work has been done by men who desired to sell worthless and fraudulent claims. In such case the ore is procured from a mine somewhere in the neighborhood, if possible, and mixed with that on the dump. The faces of the levels and the sides of the shafts are "plugged" at intervals; that is, holes are made in which the valuable ore is placed. Great skill is sometimes shown in this plugging operation, and a very natural appearance is given to the deposit. But as a rule, the men who are deceived are those who have made the salted ledges possible. They are those, who, without any previous training have attempted to purchase mines by the guidance of "common sense." To them there is no difference in the appearance of the salt and the surrounding vein matter, and they cannot tell when they see a hole drilled before their eyes, and a shot fired, that the ore torn out has previously been put in for the purpose of being torn out. The men who sell the fraudulent veins are quick to "take the measure of the emigrant's foot" as they term it and know well just how far they can go and how barefaced they can make the swindle.

It is not very often, however, that men attempt to salt a developed mine. As a rule they confine themselves to some ledge on which they own a claim, and for a very simple reason. The smaller the area of observation of the value of a ledge the greater the ease with which that ledge is salted. If a ledge be found that has not more than twenty or thirty feet showing on the surface, it is comparatively easy to prepare it for sale to an "emigrant," as the late arrival from the East is called. The owner gets some weathered ore from some mine in the district which carries the same kind of gang. This he scatters along the ledge and around it. Then procuring some that is not weathered, he proceeds to make a cutting in the ledge of say, ten feet deep. In this he places some of the salt, mixing the remainder with the rock thrown into the dump. He generally fills up the place where one blast has been fired with the mixture of salt and vein matter. Now, to a person unaccustomed to mines, a vein prepared in this way is not only enticing, but exceedingly deceptive. It is almost impossible for him to tell that it has been salted, and although the steps to be taken to reveal the fraud are as simple as anything in the world, he will rarely take them. He sees the vein and the rock lying all around it; he has some of this rock assayed and he concludes at once, being guided by sense of a most common kind, that the claim is valuable. In his "Roughing It," which, by the by, is the most reliable description of life on the Pacific Coast ever written, Mark Twain gives an account of a mine, or rather ledge, in Virginia City which was salted with half-melted Mexican dollars. The man who salted it must have been green at his business, for he could scarcely hope to persuade any one, even the most typical emigrant that ever crossed the Sierras, that Nature created silver with a mint stamp upon it! And yet I do not know. The folly shown by men who have invested in mines has been so monstrous as to almost come up to the swallowing of such a yarn as this.

But the salted ledges are as nothing when weighed in the balance of fraud compared to the wild cat mines. While it is true that the stock-markets have enabled the man interested in mining property to find money to develop those properties, it is also true that they have made it possible to float mines and mining stock which are absolutely worthless. In such a business as the dealing in the stock of mines there are necessarily enormous fluctuations in the value of the securities, and as a result speculators gather around the exchanges like flies around a honey-pot. As all men have in them the desire for gambling implanted to a greater or less extent,—that is, the desire to make money rapidly, and the willingness to risk money in order to so make it, such chances as those given by a stock market when securities are varying ten or twenty dollars a share in an hour, are too good to neglect. The result of this is that men with money come in and furnish the wherewithal to carry on the game. Many of them have other occupations, and merely risk a few thousands or hundreds "as a flyer," as they term it. These men rarely if ever know very much about the value of mining property, and they will place their money in any stock that promises to give a return or to rise in value. It is this class that the fraudulent promoter of mining companies is in search of. This fraudulent promoter whom for the sake of convenience I will call John Stone, having used up the names of Brown, Smith, Thomson and Jones, secures a ledge somewhere. He is careful to get it in an old camp where there are well-known mines, or in a perfectly new one. He incorporates the mine and has the certificates of stock printed. Then he pays the necessary fees to have the mine listed on the Board. Altogether his expenses amount to about $1500 so far. He may or may not have paid anything for his claim, because he can always find some man who has a claim he is willing to throw into the pool for the sake of a chance in the steal. Having listed the stock he proceeds by the aid of brokers who may or may not be in collusion with him, to deal in it. One broker sells and another buys, and in this way it is given a showing on the lists. In the meantime he gets up a flaming prospectus which he scatters broadcast throughout the community. The letters from the mine are printed in the stock papers and advertisements are inserted calling attention to the unexampled opportunities for investment offered by the "Untamed Feline M. and M. Co." The process may be longer or shorter according to circumstances, but sooner or later the public bite. The cost of making them do so is variously estimated at from five to twenty thousand dollars. When the public begins to buy the stock it is fed out to them cautiously at first, but as time goes on in constantly increasing blocks. When they are loaded up, the time comes for the first assessment, which the letters from the superintendent excuse on the ground that a "bone" has been discovered in the mine, or the sinking has opened a subterranean body of water and the mine is flooded, or the ore body is slower in coming into sight than had been expected, or an out-house has burned down, or the mule owned by the company has died of colic.

It does not matter what the story is, the result of the assessment is always the same. Some men allow the stock to be sold and content themselves with the first loss without striving to make it larger. Others pay up and hold on, hoping that the next news heard will be that of sudden development of ore. In time the process is repeated again and again until finally the mine—on the street—has been exhausted and the operators turn their attention to some new one. It sometimes happens that Johnston in picking out a ledge to work in this way stumbles by accident upon one which is really valuable, In such a case his astonishment and confusion are really comic. He is so amazed at finding that the property is worth something and will pay if honestly managed, that he is positively at a loss to know what to do with it. In one instance that I know of a mine that had been begun as a swindle turned out to be extraordinarily rich, and the Johnston in the case promptly substituted for the superintendent in charge, a man who had been working for him as a superintendent of mines for over twelve years, one who had never worked for him before; naively remarking that in that mine he wanted a superintendent who knew "something about mining." This method of floating a mine on the public is one which is as common as are wild cat mines. There is another and quite as effective a fashion. It is that in which the mine is never listed upon the stock boards at all but is "placed" as a property to be listed. This method depends for its success upon the amiable principle of dividing or seeming to divide, the results of the steal. There are a large class of men to be found hanging around every stock exchange who are ready to work as tools for any scoundrel who wishes to employ them. They are generally those who have lost all they had in stocks and now wish to get even. If it is necessary that others shall lose in order to permit of this, they are willing to watch those losses with perfect equanimity. These men Johnston employs as "cappers" for this game. He tells them that he has the stock of this new and terribly valuable mine for sale and that he intends to let a certain number of men into the pool. That is, that a certain amount of money being necessary to start the pool, or in other words, to enable the men in the pool to work the market, he is willing to sell a certain amount of the stock, to those who will buy it, for less money than it will be sold for when it is placed in the Board. He is willing to give the cappers a percentage on sales, either in cash or stock. Armed with the information thus given to them the cappers start out to place that stock among their friends, and as each one generally knows several men who have more or less money to spare, a good deal of stock is disposed of in this way. The cappers, when they approach a man, always point out to him that they are giving him a chance to buy "on the inside prices." That, purely from love and affection for him, they have brought this chance to him, and really, without wishing to influence him, they can not understand how any man in his senses can decline such an opportunity for making money as that offered by the "Untamed Feline." The rich they tell him is *nil* as when the mine is listed, which it will be as soon as the pool stock is sold—and, by the way, there is not much of that stock left—the shares they offer him at $2 will be placed on the Board at $5. That prominent stock operator, Mr. Johnston, who is so rich, is heavily interested and will not allow the stock to be sold for less than $5 when it gets into the Board. Now all of this kind of talk when translated means that the stock sold at first is so sold because the pool wants money enough to work the market in the manner described, and the reference to that prominent operator, Mr. Johnston, simply implies that that prominent operator who is so rich does not consider the mine good enough to make it worth while going into it. It sometimes happens that the individual who is approached by the capper is really honest enough to believe that the money received for the pool stock is to be expended for that mysterious operation he has heard men call "development." But it is not unusual for the capper to make no bones about telling him that the mine is to be sold to the general public through the market, and that the pool stock is sold to obtain the money necessary "to work the street." It is pointed out that when the stock begins to go at $5 a share, the purchaser in the pool will make $500 for his investment of $200; and the strange assurance of safety for him in going into the fraud is given, that his stock will be sold to people who are to be deluded into purchasing it through the use of his money and that of others. A fraud is made to guarantee the safety of a fraud. It would seem as though the veriest fool that ever lived would decline to touch such a thing as this, that he would say he would at least have the management of any cheating schemes he placed money in. But experience has shown men to reason in some strange way that when a person makes them a partner in a scheme of rascality, he cannot mean to cheat them! And so the game goes on, the pool stock is sold and the mine is never even listed on the Board.

It is extraordinary how successful this method is among small speculators in mining stocks. They invest their money with a fatuous kind of idiocy which would be amusing were not the results so disastrous. The aggregate of the money so lost is something amazing, and were it to be stated in a lump sum, supposing it to be possible to get the statistics for making such calculation, would astonish every one who saw the statement. I have not the slightest doubt that the amount of money thrown away in such schemes as the one which I have described would, were the facts known, be found to equal that which has been paid as dividends from all the gold mines ever worked. This statement seems to be wildly extravagant, but it is one which is made after a good deal of reflection. The operation of placing mines among people in the shape of sales of pool stock is one which is going on all the time. There are men who have made large fortunes out of it, and many of them do nothing else. The loss of money through it may be compared to a leak in a reservoir, the amount of water lost in any one minute or any one hour is small, but it is going on day and night, week in and week out, through all the months in the year and years, as time flies by, are filling up into decades and centuries. And in this sale of pool stock in mines there is not one leak but many. It is going on in San Francisco and New York, in Chicago and Philadelphia, in St. Louis and Boston; in short, wherever there is a class of men with money willing to risk that money in small amounts in a business of which they know nothing.

There is yet another class of mining swindles in the operation of which neither the stock board nor the cappers are employed. They might be called the "advertisement frauds," as they are worked chiefly through the medium of advertisements in newspapers. In one of these cases, the Mr. Johnston who is manipulating the mine hires an office and advertises liberally in the papers. He selects, as a rule, those journals which will reach, as he thinks, that class in the community which invests money as a permanant thing. He has no wish to touch the pockets of business men, because he wants investors who will be content to let well enough alone as long as a reasonable showing is made, and who will not be so fearfully particular in their questions. Among the papers particularly affected by this Mr. Johnston, the religious journals stand first. He knows that people who take them have developed in them to an extraordinary degree that queer belief that things seen in print are always true, and that they attach a kind of fetish-like solemnity and reliability to a line of words appearing in the ———, whatever the religious paper may be called. In writing his advertisement, Mr. Johnston, while careful to describe the advantages to be derived from an investment in that particular mine, contrives to give to the description an air of sober probability which is exceedingly taking, and which is calculated to deceive the very elect. As a fact, the deception of the elect is the object aimed at. If he can secure an office in some building devoted to or identified with a semi-religious business, he is willing to pay a handsome rent. If he cannot, he gets one as near as possible. In his office he has a handsome array of specimens placed on tables or in cases, and finely executed plans of the work already done and to be done in the mine. The work to be done is often shown in dotted lines, but I regret to say that I found in one instance a discrepancy existing between the state of the mine as it really was and the plan as shown. The mine did not have the amount of development shown in the office plans, as I knew from personal knowledge, and as this trick was played once, I can conceive that it may have been played again. However, to return to the advertising fraud. Having prepared his web, the spider patiently waits until some foolish fly walks in. The fly in question is often some clergyman with either money to invest of his own or of some one else; his ward, for example, if he be a guardian. The spider explains to the fly the value of the mine, shows him specimens which, as he is utterly unable to understand anything about them, prove exceedingly convincing, and points out with honest pride the amount of work done. He explains that as soon as the development has reached a certain point, which he indicates with a pen-handle, the "out-put" through the shaft will amount to enough to justify dividends which, he casually mentions, will be large. The fly gathers from the explanation of the plan that the shaft is the hole in the ground, and not caring to ask what is meant by the "out-put," regards the word as an assurance of large returns for the investment. Ultimately the fly makes a purchase, and having done so, congratulates himself upon his wisdom. It will often happen that the spider, if the crop of flies be large, or if he have money enough of his own, will declare a dividend and pay back a portion of the money.

In such a case, the flies fairly swarm around him, and he keeps the game up until something happens or he thinks that he has made about all there is to make. Then he disappears and the flies swarm together, refusing to be comforted and indulging in that useless recrimination common among flies in all ages. For the successful carrying through of the advertising fraud, it is imperatively necessary that the spider prevent the flies selling stock to each other. As long as he can control the transfers, he is comparatively safe, because the value of the stock remains a credit value. The instant that the stock is sold by one fly to another, inquiries are made as to the basis upon which this value rests and these result generally in the discovery by the spider, that it is time for him to fold his tent and silently steal away. This word "steal" comes in well here. The barefaced character of some of these advertising frauds was once brought to my notice in a curious way. I found that the agents of two properties, one supposed to be situated in Colorado and the other in New Mexico, had their offices in the same building and in adjoining rooms; and that in the prosecution of their business they were both using the same set of specimens. The specimens, by-the-by, came from a mine in Utah! If my reader will pause for a moment and think, he will see that this case contains elements of a strongly humorous character. It may be said that while giving so many instances of fraud and descriptions of how frauds are carried on, I should say something about how to prevent frauds being practiced upon my readers. This I can do by simply repeating the old English proverb "never buy a pig in a poke (sack)." In other words do not put your money into that which you do not understand; do not engage in a business of which you know nothing without at least getting the advice of some one who does know something. And as far as mining is concerned, do not take the advice of a man as ignorant as yourself. Do not imagine that because a man has made money by an investment in mining stock he is thereby qualified to direct your investments. Put it down to his luck if you like, but do not put it down to his wisdom. Understand me, I do not mean that because a man makes money in the mines you should therefore believe him to be without knowledge of mines. But I do mean that the simple fact that he has so made money should not be allowed to convince you that he has this knowledge.

If you know that from his business training he is a man likely to have acquired such knowledge, then the fact that he makes or has made money may be looked upon as an additional reason for trusting to and following his advice, but it must be remembered that it can only be an additional reason to some one possessed before; can only be evidence corroborating that which has already been given as evidence in chief, and can not, or rather should not, be taken as that evidence in chief. It is perfectly evident that when the blind leads the blind both are apt to "fall into the ditch," and the man who invests his money on the strength of advice received from men who know no more of the investment than he does himself, has certainly not increased the wisdom of the investment. He has, it is true, secured some one to abuse if the investment turns out badly, and this may or may not be a comfort to him in such an event, but it is undeniable that abuse of even your dearest friend is but a poor substitute for a bank account. There is another thing. Advice in such cases as generally given, is gratuitous, and of all worthless things in this world gratuitous advice is the least valuable. It may be laid down as an axiom that "nothing for nothing and but little for sixpence" is the rule which governs the business operations of men. When a man is paid for the advice given by him, he is justified in putting forth the effort or making the sacrifice which will place him in possession of the information upon which to base that advice; and his counsel therefore becomes of value. But when he is not so paid, he does not make the sacrifice or put forth the effort; and his advice becomes guess-work. As a general statement it may be said that one man's guess is as good as that of another, and that when you go to another man and get a guess from him, you might have stayed at home and done the guessing yourself.

But a mine may be listed on the stock boards, its stock may be sold and purchased in open market, the ledge may be a good one, the ore may pay, the company may own hoisting and reduction works, and the property may be one which could declare and pay dividends; yet that mine must be set down among the list of wild-cat investments. In this case it is because the management of the mine has become a wild-cat management, one that works the property for profits on the street. The reason why this may come to pass is very simple. As the ores of gold and silver lie in the ledges in irregular masses, and as the proportion of paying ore to barren ledge matter or gang, is one which is constantly and everlastingly varying, it follows that the value of the rock as extracted, or of the mine at any one particular moment is constantly changing. The value of a coal mine is governed by the market, or in other words by the price and demand existing for coal. The cost of extracting the mineral being known, the profit depends upon the price at which the mineral may be sold. But in a gold or silver mine the conditions of value are different. There is always a demand for the product and the price is always about the same. The value of the mine depends then upon the yield. If gold mines existed under the same natural conditions as those found in seams of coal, gold mining would not be attended by any risks at all, for the seam of coal is generally about the same thickness, and the coal has about the same value; so that, barring "faults" in the measures, given the market value of the coal, and the cost of production, the value of the mine may be calculated in the turn of a hand. As the natural conditions found in gold mines are different from those in mines of coal, it follows that the value of the mine can not be so calculated. That value is always changing as shown by the change in the prices given for the stock.

A sudden discovery of a body of ore—technically a "bonanza"—will affect the value of the mine at once, and the stock will rise. A sudden discovery that an ore body has been worked out and come to an end will also affect the value of a mine, and the stock will fall. The desired point in the history of a mine to reach is the payment of dividends; the point which it is not desired to reach, is the levying of assessments. Between these two, there are an infinite number of marchings upon the scale over which the pendulum swings, and the stock of that mine varies in price as the pendulum goes in one direction or the other with the delicacy of a thermometer. But it is perfectly possible to make that stock so vary by inducing the public to believe that the pendulum is moving, when there is in fact no movement at all, or if there be a movement, it is one in an opposite direction to that which is generally supposed. It is this that makes the "milking of the street," to use the expressive slang of the victims, possible.

It would seem at first as though from the fact that so many men are employed in mines, all of whom must have knowledge of what is going on, and of the work done, that the discovery of paying ore could not be concealed. But under the present methods of mining it is quite possible to keep the information as to the value of the mine in the near future a secret confined to a small number of persons. The diamond drills will bring out in their long "cores" a perfect section of the rock they have been boring, and assays of these cores will tell the superintendent or the assayer what there is beyond the place where the men are working. No one else can know anything of it. As the superintendent is always appointed by the Board of Trustees, he naturally reveals to them the information given by the assays to him, and as he can operate the mine in any way he chooses, he may manage it in such fashion as to permit the Trustees to work the stock as they see fit. Suppose for example that the superintendent discovers from the cores which come from the sinking of the shaft, that the working is near a valuable body of ore. Suppose too, that he is sinking a "winze" or underground shaft, five hundred feet distant from the main shaft and that the cores taken from the bottom of this winze show the same kind of ore. He reasons at once that he is near a bonanza, or ore body. He communicates his conclusion and his reasons for arriving at it to the Trustees. If that information was in turn communicated to the public, the stock would rise at once. The Trustees, however, want to make as much money as possible—the superintendent "stands in" on the game—and they accordingly set rumors afloat to the effect that the mine is in a bad way. Some accident happens conveniently to the pumps, and the water collects or a fire breaks out and some machinery or buildings burn down. Any excuse will do for an assessment, and the assessment is promptly levied.

Under its influence the stock goes down, and in a cautious way the Trustees buy that stock up as it falls in price. The work of sinking the shaft and winze having been discontinued, the miners know nothing about the bonanza and there is nothing to check the fall in the price of the stock. When this operation has been continued long enough, the work on the shaft and the winze is resumed and the news comes that the mine has "struck it rich." Up goes the stock in the market, a "boom" is begun and carried on and the trustees gradually unload the stock which they had bought at an enormous advance. The money has been made by them in the street. It is this fact that the Trustees are always placed in possession of information about the mine in advance of the public that makes the "control" of a mine so valuable. The Trustees are elected by the votes of the stockholders as representing the shares in the property, and if there be one hundred thousand shares, fifty-one thousand will elect the board. The representatives of that fifty-one thousand; the men in other words, who own those shares are the men who will have during the year following any election the knowledge of the real condition of the mine. So valuable has this knowledge been found to be that an active fight is often made for it by stock operators, and I have personally seen one of these fights in which the price of the stock of a certain prominent mine rose from $20 a share to $273 before the control was finally obtained. Of course this method of "milking the street" can only be looked upon as a very dishonest thing. It is a deliberate robbery carried on under forms of law and is one for which no remedy has as yet been found. It is difficult perhaps to suggest a system which would put an end to it from the fact that men if they wish to cheat will generally find means to do so. It may be said however, that a State Mining Board or Commission such as that which exists in the majority of states for the regulation of insurance companies; and a law requiring the publication of reports once a week of all assays made during the week, such report to be certified to, under oath by the superintendent, and assayer, and a false oath to be treated criminally as perjury, would probably do some good. It would certainly make men more cautious than they are now about the information furnished by them.

Or to put it in another way, if a law could be contrived that would make it an exceedingly dangerous thing to engage in the manipulation of stocks by false reports, for every one engaged in it, the result could not be anything but good. Until such a law is framed, passed and put into operation the business of using the information derived from the control of the mine will continue to be as flourishing as it is at present. While the chances taken by men with money when they place that money in mines are great from the fact that mining is under any circumstances a precarious business, the investments are legitimate because the possible returns are in proportion to the risks of loss. But when those chances are increased and complicated by wild cat management, they are not only very greatly increased and complicated but the legitimacy of the investment is almost wholly destroyed. In the case where the chances of mining are alone taken, the majority of the risks may be guarded against by proper precautions, care in examination and conservative management. But when the investor is exposed to the robberies which are the result of wild cat management, he is powerless. No amount of precaution will save him from the lies which are told and which affect the value of his property as soon as uttered; no care in examination is of any use when that examination cannot be made; no conservatism in management can be shown by the man who has nothing to do with that management and against whom that management is arrayed. But it may be said that if there were no fools there would be few if any knaves in this world. It is undoubtedly the fact that the men who make the sale of salted ledges and wildcat mines possible are the men who buy them. And that they do so buy them is the result of an idea which is of all ideas the most absurdly ridiculous. It is this. People have a belief that mining is a thing which is utterly different from anything else in the world in one respect, that it does not require the same care in investment and the same caution before engaging in it as is demanded by other forms of business.

This idea is a form of lunacy. The men who would laugh in your face if you suggested to them that they should attempt to argue a case of theirs in court; or who would look on you as a fool if you advised them to attempt the care of one of their children suffering from small-pox; or who would make remarks derogatory to your sanity if you asked them to buy and run a steamer, will calmly go into the business of mining when they know absolutely nothing about it and will actually expect to make money in it. Why they should do so, why they should select mining as the field in which they are to display their absurdity, no one knows. That must be added to the long list of the mysterious things which no one can account for. But that they do so can be seen every day. From the business man who invests a few hundreds in a "flyer" in the mining stock market to the capitalist who pays his tens of thousands for a ledge which he finds is worthless, all seem to be moved by the same craze, the craze for investment in a business about which they are wholly ignorant. Is it then any wonder that they lose their money, any wonder that the investments turn out badly? Mining is a business in which money can be made as surely as in any other, provided men will take the precautions necessary to insure the safety of their investments. Without these precautions it is about as risky as it is possible to imagine, and as long as men will persist in going into it without taking these precautions so long will it be that they will lose their money.

—*Alfred Balch.*

GOLD MINING FROM THE INVESTOR'S POINT OF VIEW.

GOLD-MINING is popularly considered as a speculation, almost as a species of gambling by some nervous people, and is certainly never regarded in the light of a sound investment or a steady-going business enterprise. Why is this so? Why, for instance, should a man run more risk in investing his money below ground than above it? Agriculture is not regarded as a speculation, though it is in reality far more of a speculation than gold-mining, for it depends upon seasons, which can neither be foreseen nor controlled, and the market value of the produce is liable to fluctuations such as gold never experiences, nor is ever likely to. Why then should gold-mining be deemed speculative? Simply because those who invest their money in a gold-mining enterprise cast their usual business-like shrewdness and caution to the winds, and rush headlong on the bidding of some superficially attractive prospectus, without devoting to it a particle of the inquiry and common sense which they would exhibit over the purchase of the smallest retail business. Those who cater for the public taste in gold-mining shares are quite aware of this fact, and with characteristic sharpness, they avail themselves of it. The result is that numbers of companies are floated, and vast sums of shareholders' capital are sunk, and upon undertakings that never deserved the slightest expenditure of either their time or their money. And then the gold-mining industry generally gets branded as a speculation, a thing to be avoided by all sensible sober men. While this state of feeling exists, and so long as investors are content to blame anybody else rather than themselves and their own ignorance, bogus affairs will continue to spring up and grow at their expense. The promoter, or some capitalist representing him is necessary to the formation of a company under the present circumstances. Heaping abuse on the heads of promoters will never save investors from losing their money. Their one and only safeguard is to use their own common sense in judging of the merits of a concern, instead of rushing like a flock of sheep through a gap in a hedge, and expecting to find ready-coined gold on the other side waiting for them to collect it. It must be remembered too that many a property which would give handsome returns to an individual capitalist or miner possessing the requisite knowledge, would fail to pay in the hands of a company, by reason of the cumbrous and costly machinery, I mean financial machinery, with which a company is necessarily burdened.

With these introductory observations, I will proceed to indicate the heads upon which, as it seems to me, the capitalist should thoroughly assure himself before investing in gold-mining shares.

Title.—The first consideration is the title on which the property is held. When a freehold is acquired from a private individual, the greatest precautions are necesary to ensure that his rights are unimpeachable. Several lamentable instances have occured where the purchasing company has maintained possession of the acquired property only after long and costly litigation, and instances are not wanting where the company has been quite ousted by the conspiracy of the vendor and his confederates, when the property had been rendered valuable by the expenditure of the company's money. Preference should generally be given to concessions held direct from government, supposing that the conditions are sufficiently clear and just. Of course discrimination is necessary with governments as with individuals. Governments which have exhibited dishonest tendencies, or have repudiated their obligations, should be avoided as much as dishonest individuals. It is a usual thing for a government to demand the deposit of a caution-money as a guarantee for the performance of the contract on the concessionaire's part; when this is more than a nominal sum, the honesty of the government will be a matter for particular consideration. The duration of a lease or concession for the working of a gold-mine should not be less than 21 years.

Mining Laws.—A point very generally overlooked is the nature of the Mining Laws and Regulations of the country in which the gold mine is situated and under which it is to be worked, as well as the manner in which these laws are administered. The laws must be sufficiently liberal to admit of the adoption of whatever machines, appliances, and processes may be found requisite, such as the right to acquire by purchase, a fair price as between the two parties, land which may be necessary for the erection of works, the storage and conveyance of water, and the deposit of refuse. They must contain no arbitrary restrictions or local prejudices, such as would interfere with the full liberty of the company's officers to carry out necessary operations, and full protection from the local officials must be given for conducting the operations. This question of mining laws is one that demands the most serious attention from investors. It is one too that has received far too little consideration from foreign states, whose mineral resources have been left undeveloped largely on this account. For it must be remembered that the richer the mine, the greater is the likelihood that unprincipled men will avail themselves of any flaw that exists in the laws to enable them to oust the purchasers, or to make onerous terms in various ways, and place the company at a great disadvantage. Another point, which, though not coming strictly under this section, demands equal attention, is whether the local government ever has, or is ever likely to, impose special taxes upon industries working under foreign capital.

Climate.—The climate of the country has a direct influence upon the success of an undertaking. Operations carried on in a notoriously unhealthy climate have many drawbacks. Additional expense is entailed for tending the sick, the work is liable to be seriously interrupted, wages are likely to be high in proportion to the work, and the effective work of the men is greatly reduced. In the first place, a man of any position in the ranks of the gold miners will require an exorbitant salary to reside in, or even to visit, a locality where he may live only a few months or even weeks. During his illness, things have to take pretty much their own course, and the result of protracted illness is to undermine the energies and abilities of the man upon whom the success of the undertaking may be said absolutely to depend. Effective gold mining is in a great measure a matter of personal experience gained on the spot. When the superintendent has to be frequently changed on account of illness or death, the advantage of his experience is thrown away, and his successor has to go through almost the same stages before acquiring the same local knowledge.

Other climatic conditions must not be overlooked. Great heat or drought may suspend operations for a lengthened period by cutting off the water-supply. Excessive rainfall may create floods of such a nature as to prevent locomotion for a considerable time, and cause great destruction to dams, water-wheels, and machinery, or necessitate an expenditure of capital to establish preventive measures. Extreme cold may interrupt the working by freezing the water, and rendering the appliances temporarily useless. The presence of these unfavorable conditions will demand a very rich ore, and unusually good circumstances in other respects, in order to compensate for them. They may even occur in such an aggravated degree as to render the richest mine quite unprofitable to the shareholders.

Water-supply.—Water is useful and necessary in almost all industries, but in gold mining it is absolutely indispensable. As a motive power, it is the cheapest that can be obtained, and is always desirable on that account; but of course very cheap and abundant fuel will counterbalance a lack of water for this purpose. In the treatment of the ore, however, no available substitute for water has yet been found. Nor is the purity of the water a matter of indifference. Water intended for use in the treatment of the ore cannot be too pure; dirty water, water obtained in draining the mine, or water containing considerable proportions of salts in solution, is quite inadmissible for this purpose, though it may be applied to driving the machinery, and thus render a larger quantity of good water available for the washing processes. The source from which the water-supply is to be drawn is, therefore, a question for primary consideration: whether it can be obtained from the surface, or whether it must be sought for below, or whether both supplies are to be brought into requisition. The existence of a river or stream in close proximity to the mine is a great advantage, provided that drought or frost do not render it useless for a considerable portion of the year, and that it is not subject to excessive floods at other seasons. If there be a river at some distance, it will be a question whether the ore should be carried to it, or the water be led to the ore, with a consideration of the relative facilities, cost, and advantages in either case. An approximate idea should be gained of the annual rainfall, and whether it is pretty equally distributed throughout the year, or whether it comes as a deluge for a short period and leaves the remainder of the twelve months dry. If the rainfall is considerable but spasmodic, it may be stored in reservoirs for subsequent use. The engineer reporting upon the mine should study the country in relation to its suitability for making such reservoirs, and permitting the water to be conducted to the point where it is to be applied. Sometimes mountain lakes prove most valuable in this respect. The cost of the construction of the reservoirs and conduits, if necessary, will have to be taken into account and provided for. It will be found to vary much, according as ditches, wooden flumes, or iron pipes are the requisite channels; and the expense of maintaining them in repair must not be lost sight of. Where no surface-water is obtainable, it may be feasible to procure a supply by sinking a well. In this case, all possible data should be collected as to the probability of finding a suitable and sufficient flow, and what the cost is likely to amount to. Well-water may be found very acceptable as an auxiliary supply in some cases; but when the working of the mine has to depend entirely upon it, common sense would demand that the company should have abundant and reliable evidence of its existence, before entertaining the acquisition of the property.

Timber.—Timber may be considered as a two-fold necessary; heavy timber for constructive purposes, and inferior wood for fuel, unless other fuel is available. The mine may require a large amount of timber for supporting the walls and roofs of the workings, and a considerable quantity is sure to be needed for building the works, if not for making dams and reservoirs. It is important to know not only that there are plenty of trees, but that their wood is applicable to the purposes intended. Many a tree is worthless as timber on account of its inherent defects, its liability to decay, or the rapidity with which it is destroyed by insects. Many trees are equally worthless as firewood; and some are too valuable for other industrial purposes to be obtainable at anything like a reasonable price. The question of the cost at which the timber can be procured, and of the certainty of securing an ample supply, should be inquired into with great care. It is an advantage to the mine when suitable timber is growing on the surface of the property itself, and is included in the purchase. When it has to be brought from a distance or imported, its cost of transport will be a heavy item. Insufficient supplies of timber would render some mines quite unworkable.

Fuel.—The question of fuel has been touched upon under the heading, Timber. It is employed in two capacities: for the purpose of raising steam to drive the machinery, and for the purpose of roasting portions of the ore. In the first application it may be in a great measure rendered unnecessary by a bountiful supply of water for motive power. In the second application, it cannot be so replaced. A certain proportion of pyritous ore occurs in every gold mine, and some process of roasting or oxidizing by means of dry or wet heat, is essential for extracting the gold from it. There are many mines where such a state of things would render the undertaking a complete failure. Fuel is therefore a necessary more or less requisite in all cases. When firewood is not to be had, coal or other fuel may be obtainable at a reasonable figure, including its delivery at the actual point where it is to be employed.

Transport.—The accessibility of a mine, and the extent to which a country is opened up, are matters of no mean import. All the materials requisite for the mine must be carried to it, building materials, machinery, fuel, and the miners' necessaries. The transport of the extracted gold from the mine is an affair of little difficulty under any conditions of travel; but when it is inconvenient or impossible, from want of water or other causes, to treat the ore at, or close to the mine, it may be necessary to transport the ore a considerable distance, and the question then becomes a vital one. Even where this is not the case, but when the gold exists largely in the sulphides (pyrites), and no means is at hand for treating them on the spot, their conveyance to a better adapted locality may have great influence upon the success of the undertaking. The existence of roads, waterways, or railways available for the purposes of the undertaking, is therefore a prime necessity. When the construction of roads is necessary and possible, their cost should be estimated and taken into consideration in judging of the merits of the enterprise.

Labor.—In an industry entailing the employment of so many men, the labor question is one that is sure to demand the closest attention, and the greatest exercise of judgment. The first consideration will be whether the native labor is available, and here many questions will propose themselves. In some instances, the natives are sufficiently numerous, but are prevented by caste or prejudice from engaging in mining operations; in other cases, they may be a pastoral or agricultural race, that has never performed mining tasks, and will need to be taught before it can be utilized; again, feasts, fasts, and religious observances may prevent work being carried on with anything like regularity, and where more than one race or religious sect is employed, the difficulty will be increased; also the ignorance or laziness of the native laborer may render him virtually worthless. The presence of plentiful, cheap, and really efficient native labor is one of the greatest blessings under which a mining enterprise can be started. When it does not exist, it may be deemed necessary to import foreign labor, than which no greater disadvantage can be. By importing foreign labor, I do not mean the drafting of men from one portion of a country to another but the introduction of men of different race, religion, and relation, such as Chinese into India, or Mexicans into Africa. One consequence of such an importation is very likely to be frequent collisions between the strangers and the natives, giving rise to many troubles, both direct and indirect. Another consideration will be, whether the climate is suited to the habits of the imported laborers; if it is unsuitable, there will be difficulty in getting the men to remain, unless at very high wages, and their effective capacity will be much reduced. So also with the food: a race accustomed to live on fish would object to being kept on rice, and one habitually consuming large quantities of meat would not content itself with maize, unless this disadvantage were compensated for by increased wages; and, in that case, probably the men would regard the emigration as a means of making money wherewith to improve their condition on returning home, and would therefore be continually shifting. This would deprive their labor of that advantage which is gained by generations following the same occupation under one another's guidance, and each new comer would need the same amount of teaching as his predecessor. Then again, in a half-settled country, where alluvial gold deposits chance to occur in the neighborhood of the mine being worked, it will be found that the strangers will remain at wages just long enough to acquire the necessary knowledge, and to be a sufficiently powerful body for self-preservation, and then they will quit servitude, and go in search of gold on their own account. This is an especial danger in employing Chinese labor, and the experience gained on this point in Australia and California should be a sufficient warning to prevent the experiment being repeated elsewhere. Of course there is no objection to the introduction of foreign labor when the requisite conditions can be fulfilled. Other conditions being equal, the rate of wages will decide whether the mine can be profitably worked or not.

Cost of Necessaries.—In some new and thinly peopled countries, commodities of all kinds are excessively dear. Then the market prices of the ordinary necessaries of life, such as food and clothing, run very high, and the rates of wages may be expected to rise in proportion. The high price or scarcity of other articles, such as illuminating materials, tools, ironwork of all kinds, mercury for amalgamating, carpentry, &c., will tend to swell the incidental expenses, and therefore require the mine to be all the richer in order to support the increased cost of getting the gold. The question of the suitability of the food for the laborers employed has been already alluded to, as affecting both the nominal price of the labor, and the amount of work done for the money.

The Mine.—A so-called gold mine may be either of three things. (1.) It may be a recent alluvial deposit, that is to say, a mass of auriferous material which has been broken up, and its gold liberated by bodies of water still exist, though perhaps a little changed in position. Such is an ordinary "alluvial" or "placer." (2.) It may be a similar deposit formed by rivers and lakes which have altogether ceased to exist, and have, in very many instances, been subsequently covered to a varying depth by a flow of igneous rock. This is termed a "deep lead" or "dead river." (3.) It may be a mine proper, where the gold is secreted in the interstices of quartz or other rock. This distinction is necessary as a preliminary step to a discussion of their features and requisites, as the mode of working differs not a little.

(1.) *An Alluvial or Placer* is worked by removing the whole mass, and passing it with water through a long series of apparatus where the gold is arrested. The first essential is an abundant water-supply, the consumption of water in this operation being immense, as the whole mass of the deposit is transported by its agency. The next consideration will be the position of the deposit, whether it lies actually upon the surface, or is covered with more or less loose earth: if the latter, whether this loose earth must be removed, or whether the deposit can be worked from beneath it, and what the cost of supporting it or removing it respectively will be; whether the deposit can be directly dislodged by the application of water under the pressure of considerable fall, or whether it must be dug out by manual labor before being brought under the disintegrating and separating influence of the water; whether the position of the deposit in relation to the source of the water supply will permit the water to be carried in open ditches and wooden flumes, or whether it will have to be conducted in pipes, and what the probable cost will be,—where the distance is great, a large margin must be allowed for loss by evaporation and leakage, when estimating the supply. Another requisite, without which the preceding are useless, is an abundant space for the deposit of the immense quantity of earth which is disturbed and transported. There must be a possibility of depositing this refuse where it will do no harm, either to private property or by stopping up water-courses. An alluvial without this accommodation is utterly valueless, because it cannot be worked. The space where the refuse is to be deposited must necessarily be on a lower level than the alluvial, in order that the refuse may be carried to it by the flow of the water. Where this space has to be acquired at the hands of private occupiers, its actual undisputed possession should be considered as necessary a preliminary as the very title deeds of the property.

(2.) *A Deep Lead or Dead River* demands much the same conditions as the preceding, but in a magnified degree. The difficulties of tracing the deposit, estimating the extent and richness, and working it are all increased. Sometimes, too, the auriferous material is cemented together in such a way as to need the appliances of a reduction works, in order to recover the gold, thus adding to the cost.

(3.) *Mines*, or undisturbed deposits of mineral, are much more frequently made the object of joint-stock enterprise in this country than either alluvial or deep leads. The first question relating to a mine is its accessibility, or the opportunity which it presents for opening it up. The most desirable condition is where the mineral can be attacked by a level adit, driven with just sufficient rise as it advances to permit the water which is met with to make its escape. The greater the amount of ore lying above this adit, the more valuable is the mine. When the mineral has to be reached by sinking a shaft, great additional and permanent cost is incurred by raising all the material from a depth, and for pumping machinery to keep the workings dry, and there is always the risk of a flood, a waterspout or a hidden reservoir suddenly filling the mine with water, and suspending operations for a long time, or even for ever. But though great preference is due to a mine that can be developed by adit levels, most mines sooner or later have to be worked by means of deeper drivings, and this must hardly be considered a fault, when other conditions are favorable. The character of the ground has great influence upon the cost of working: soft ground may cost less for excavating, but will require all the passages to be kept open by means of timber, which may add immensely to the cost if timber is not readily and cheaply procurable. On the whole, with modern drills and explosives, hard rock that needs no timbering is generally to be preferred. But a certain quantity of timber is always necessary in the veins or lodes themselves, and where these are of great width, the consumption of timber is enormous, and the cost is proportionate.

The Ore.—The extractable proportion of gold in the ore and the cost entailed in getting it out, will vary greatly with the character of the ore. Sometimes the gold occurs almost entirely in the free state, that is to say, associated with no metallic mineral, but only with such minerals as quartz. In this case its extraction and recovery are very simple and inexpensive, and, under suitable conditions, an extremely minute quantity of gold, in other words, an exceedingly poor ore may give handsome returns. Frequently a large portion of the gold is intimately associated with ores of the baser metals, particularly with sulphides, and arsenides, and indeed occasionally the ore contains no appreciable quantity of gold in a free state. It must not be supposed that the gold is *chemically* combined with any other substance, but the microscope has proved that the tiny atoms of gold are sometimes completely enveloped by a film of other mineral, so thin as to be beyond actual measurement yet sufficing to exert considerable influence on the mode of treatment. But I wish here to call particular attention to the fact that, in Hibernian language, gold is not always gold. However rich the ore may be, it is like one-half of a bank note, utterly useless without the complementary half, or the possibility of getting the gold out. While the gold is *in* the ore it is of no value to anybody; it becomes valuable only when it is got at; consequently in judging of the worth of ore the basis for the calculation is the gold that can be extracted from it, and the cost at which this extraction can be effected. Where the ore is refractory, and needs roasting or other processes, the cost and provision of the necessary materials, labor, and plant will demand consideration, as well as the working expenses of the process. From a careful perusal and comparison of the preceding paragraphs, it will be evident that a rich ore is *not* the only desideratum; 3 oz. of gold per ton of ore under unfavorable conditions may be far less remunerative than 3 dwt. under favorable conditions; and the intended investor must look a great deal farther than at the assays of the mineral, which are a groundless basis, if he wishes to place his money in a sound undertaking. It must not be expected that any mine will satisfy in the highest possible degree all the conditions I have alluded to. But no mine is worth the serious attention of a capitalist, if the report made upon it does not afford a reliable statement of its position in regard to these several points; and it will remain with the intended investor to exercise his criticism and judgment, and to decide finally whether the undertaking possesses sufficient favorable or satisfactory points to make it worth the price which is asked for it, and the additional expenditure necessary to make it productive.

—Compiled from a pamphlet on gold mining, by Albert G. Lock, F.R.G.S.

THE PROBLEMS OF LABOR.

THE Superintendent of a mine as representing the company owning it, at the beginning of his term is met with the great labor problems which affect the business. The mine to be properly worked must be supplied with a large number of men, and those men must by of different trades. Mining employs first, the miners themselves or the men who actually tear the ore out of the deposit. But supplimenting these come the carpenters, the blacksmiths, the engineers, the furnace men, the millwrights, the mill hands and the representatives of all the trades which find employment in and around a great mining property. As the men employed are skilled workmen, for there is but little about a mine that mere laboring men can do as compared with the tradesmen, it follows that there are degrees in the efficiency of the labor to be obtained. Strictly speaking, there are degrees of efficiency in the commonest labor, because one man is necessarily stronger or weaker than another, can work a longer or shorter time, and his work is done more or less thoroughly. But the degree in efficiency apparent where skilled labor is employed is very much greater than that seen in ordinary labor, and so it is that the training which the workmen employed have received, either in that mine or others, becomes one of the greatest problems in the labor question as they affect mining. Poor miners are the most expensive men ever employed, for they cost infinitely more than they bring in. As the trade under consideration becomes more difficult to learn this lack of skill in its representatives becomes more costly. The mining carpenter, or the mining blacksmith for example, may by their inefficiency cause the loss of thousands of dollars. The work done in a mine can be compared to a great structure, each part of which is supported by, and in turn supports other parts. Every expenditure of strength in mining is the result of former expenditures and prepares the way for expenditures in the future. As this is the case, inefficiency in the labor employed, bad or careless work, may be the cause at any time of loss which casts into the shade the cost of the work itself. And it is this fact coupled with one other which gives their great importance to the questions of labor which affect mines. That other fact is mines must "go on" continually, that any stoppage is enormously expensive, that the property is either being improved or decreasing in value. There is no middle course possible. If a man owns a field he may cultivate it or not as he pleases. If he does not, the field becomes from the fact that it lies fallow, more valuable than it was before. But if a man own a mine, he can not stop work upon it without the property decreasing in value. Water collects in it, the roof caves, the floor heaves, the timbers rot; in short, the mine is injured. Not alone does he lose the interest of the money invested in the mine; but the property actually deteriorates in value. When then through those results of labor difficulties, which we call strikes, the mine is shut down, the owners of that mine lose enormous amounts of money, and as the loss is a cumulative loss, as every day which passes before the mine is worked again increases that loss; the conditions which lead to the causes of that loss are conditions which must be studied carefully. The labor problems in connection with mining may be stated as coming generally under the following heads: the supply of labor, the efficiency of labor, the just demands of labor, the price of labor, the union and the regulation of labor, so that the men may be in the best condition to work well.

As the number of men employed in and about a mine is very great when that mine becomes developed, the supply of labor is one of the most important of those questions which affect the economical working of the property. This is particularly true in new mining districts where the population is small and the demand for men is great. In such districts it often happens that miners are sought for, but not obtained, and the superintendent is forced to see the property remain without the development which it should receive for pure lack of labor with which to do the work. In such a case he is obliged to face the question, of what may be done to substitute for the skilled labor required of unskilled men, whose work while not as efficient as that of the trained miner is yet work, and to a certain extent this may be done, but when it is done the arrangement of the work and the system under which the mine is managed, is necessarily subject to change. The most perfect system of mining yet devised by man is the contract system. Under it, the hardness of the rock and the difficulty of getting it out, the conditions under which the mining is done in any particular part of the workings, and the amount of dead work it is necessary to do in order to keep that part in its then state of development or to increase that development, being known the superintendent lets out the work to the "contract gangs" or "shifts" the corps of men who do the work.

Having stated the conditions under which the work is to be done, the size of the cutting to be made, the amount of dead work to be "carried" or performed during the cutting of the ore, he states the price at which he will pay for each cubic foot. These contracts should always specify the exact amount to be paid for the work, and the prices as so fixed should be invariably adhered to. Nothing is more calculated to bring about disagreements between the superintendent and the men than the kind of contracts which give any chance to either party to change the terms after the work has been done. It may be that the work has been far less difficult than was expected at the time that the contract was made or it may be that it was far harder. In the one case the men who have taken the contract will make very high wages during the month—all contracts should be made for a month—while in the other they will make but little. Aside from the fact that this will average up in the long run, and that each party to the contract will come out even at the end of the year, nothing is more difficult than to fairly adjust the honest differences of opinion existing between the employer and the employed in such matters.

While it naturally seems that handing a man three or four hundred dollars as the result of a month's work is giving him too much; that is, is paying him more than the work is worth, on the other hand giving him but thirty or forty seems like too little. While the miner in the first place might be willing to concede that he was getting more than he had earned, he certainly would look on the second payment as being less than he was entitled to.

Now I think that every superintendent who has seen the contract system in operation will concede that the trouble brought about in the raising of the second sum, by the cutting down of the first, even when that cutting is done with the full consent of the miner, costs more in the end than the amount of money saved. If in nothing else, in the time taken up. A good superintendent is generally worth and paid a large salary. He is paid that salary by the company for his skill and ability in managing the mine and, as a rule, the management of the mine will take up all the time that he has to spare. If that time be employed settling the differences which arise between the shifts and the "underground adjust," "mine boss" or "assistant superintendent," as the superintendent's chief assistant is variously called; the company can scarcely be said to be getting the full worth of their money. These disputes as to the value of the work done are generally intensely vexatious, and a small sum will often bring about a serious difficulty with the men. Not only is the time of the superintendent wasted but the time of the miner as well. In mines where the contract system is in operation payments of wages are always one month behind. That is, the work done in April is paid for on the last Saturday or Friday in May. This month is taken up in calculating the amount of work done and deducting the charges against the men. The clerk of the mine generally has the pay roll made up on the 15th of May, and the men are then notified what the office calculations of the amount coming to them amount to. I never saw a month pass when the calculations already made by the miners did not differ from those made by the office, nor did I ever hear of any man who had seen one. From the 15th to the 20th are the adjustment days, two words which are coupled with as much profanity as any two in the language, during which the superintendent's time is taken up almost wholly in listening to the claims for more money as advanced by the miner and the reasons of the mine boss for estimating the work at the price named. The miners lose their time, not alone those who have a difference to adjust but those who hang around to hear what the result of the discussion is, as well. And whatever that adjustment may be it fails to give satisfaction. The men accept it, because they are forced to, but they do so with much grumbling. A superintendent once said to me, "I dread adjustment days, they break up the work of the whole mine to that extent that the output looks as if we were ruuning on half time." Another evil, and a great one, is the amount of drinking done during adjustment. The men having nothing to do, resort naturally to the dram shops or saloons and pour down liquor, thereby rendering themselves unfit for work. When they begin again under the settled contract system, whether the payment be by percentage or so much a cubic foot, none of these difficulties arise. The miners when they take the contract know exactly—in the latter system—what they are to receive, and the calculation being simply a matter of measurement, which is made by the mine boss, or the clerk of the mine, in the presence of the shift, or of the leader as representing the shift, few if any disputes arise. Even iu the mine, changes to the shifts for blacksmith work, powder, cars or "vibbles," the tallies which are returned to the leader can neither be disputed nor gainsayed. Adjustment days become an exploded terror and months may pass without an appeal being made to the superintendent. To return to the question of the supply of labor when unskilled men must be employed. I have seen most excellent results from a modification of the contract system. The skilled miners were made the sub-contractors for the work, and that work was done by them under the specifications as made by the mine boss in regard to measurements. They employed their own men on percentages which were recorded in the office, and payments were made direct to the men under those percentages as agreed upon. The advantages of the system are almost self-apparent. Every part of the work was done under the direction of a skilled miner, who was responsible for it, and the unskilled labor received an amount of direction and supervision which could never have been given by the officials of the mine. Some such system as this must be adopted in the working of a mine when the supply of skilled labor is deficient; for if, as is undoubtedly the case, the system of daily wages is a bad one when skilled miners are employed its evils become intensified when skilled labor is all that can be obtained. The skilled miner may "shirk" when he is on wages, and as a general rule will do so; but what work he does do, will be properly done. The unskillful laborer will shirk and do his work badly into the bargain. The supervision of the work, done in a mine, is divided into so many parts, the work is being done at so many different points at once, that unless the company were to employ an inspector or "viewer" for each face, breast and stope, it would be impossible to tell whether that work was going on right.

And it is this fact which makes the contract system of all others the fairest. Under it a man is paid for what he does, not for what he is supposed to do. If he chooses to work hard, he gets more money; if he does not so choose he gets less. He is paid, too, in proportion to his skill. A good miner is a man who has learned to utilize his strength to the utmost and to get the largest return from his labor. Such a man deserves to receive more money; his work is worth more to the company than that of the man who has not so much skill. While this is generally true of all trades, it is especially so of mining. If a compositor sets up, corrects and distributes a stick of matter, his work as far as that stick is concerned is at an end forever. The time he took in setting up, the state of the proof or the time taken to distribute, providing always that the distribution be clean, can have no earthly effect upon the next stick passing through his hands But with the miner it is different. As each section of the work prepares the way for those following, and as the ease and economy with which each section can be done depends upon the manner in which all previous sections were done, the state in which the miner leaves the sections is a thing which is of direct pecuniary concern to the company. This fact is generally recognized in the eagerness with which superintendents will hail the chance of employing good men. But as the value of the work done by those men may be said to be constantly varying between that which is worth most, the work of the typical miner, the man who knows his trade thoroughly, who works hard and who guards the mine carefully; and that which is worth least, the work of the shirking "ne'er-do-weel," who leaves his seam half worked, his timbers half put in, and sends his kibbles out half filled; so the payments should vary. In mining as in every other branch of human industry it is impossible to devise a system which will perfectly meet all cases arising under it. The best that we can do is to employ the one which meets the largest number of these cases; and I think the contract system may be said to be the best yet devised for the industry. I have already spoken at some length of the necessity of "fixed contracts," but it may be as well to describe more in detail what this contract system is. Under the contract system the owners of the mine furnish the property to be worked upon and supply that part of it necessary for the working, in which capital is required. As for example, it costs a great deal of money to purchase the hoisting machinery necessary to lift the product of the mine to the surface; therefore the company supplies the hoisting engines. They sink the shaft, drive the levels, supply the ventilation and drain the mine. The mine is then in a condition to be worked, and the contract system begins. The miners possess the labor necessary to work the mine, and the company says in effect to them, "We will pay you for that labor as shown by results. We will declare upon what conditions that labor is to be performed and what work has to be done in our opinion to prevent the mine becoming diminished in value. For such amounts of work done by you under those conditions we will pay the price agreed upon by both parties to the contract." The miners then become men working for themselves, in the same way that a job carpenter works for himself, and in proportion to the work done is the amount of money paid. The price of that work is settled by the company and is regulated by the hardness of the ground, the conditions under which the work is to be done and any other considerations which affect the net amount of effective work a man can do in a day's time. The price having been settled by the company the miners may take the contract or leave it, as they see fit. There is no compulsion in the matter one way or the other. If the price named, or any price is too little to pay for the work, the miners will refuse to accept the contract, and in order to have that particular work done, the price must be raised.

If on the other hand the mine boss fixes the price at a sum in excess of its real value, the contract is taken at once and the company loses money. As a rule, the mine boss fixes a price beyond which the company will not go and the men then have a chance to "bid down," the one offering to take the contract at the least sum securing it. It is always well to settle the order in which the "shift options" are to come, that is the order in which the shifts may take the contracts beforehand, and the drawing of numbers is as good a way as any for this unless the men agree among themselves to some other method. In any case shift with option number one, must have the right to accept a contract or decline it before shift with option number two. Of course if the first shift accepts the contract and the second underbid, the second gets it; but the system of options will prevent a great deal of confusion. The awarding of the contracts goes on something after this fashion. The clerk of the mine calls out, "Face of level number two. Ten feet. Same size. Dead work the same. Fifty cents." This means that the face of the level number two is to be driven in ten feet, that the size of the level is to be maintained and that the dead work, such as cutting the canal for drainage, is to be the same. Fifty cents is given as the price which will be paid for each cubic foot of rock extracted. The clerk then calls the numbers of the options until the leader of a shift answers "aye." The clerk then says "number 16 has it at fifty cents. Any bids?" Number 17 may say "forty-five cents," being an under bid of five cents, and number 18 may say "forty," a second underbid. The lowest bidder gets the contract, and the price bid by him is the price at which the work will be reckoned. Of course the figures given above are purely illustrative. Having secured their contracts the shifts begin the work. The company charges them, or should charge them, for every thing they require. Blacksmith work in sharpening picks and drills, cartridges of powder, charges for cars in which the rock is carried to the surface are all paid by the shifts. This is not unfair, because the price at which contracts are taken is settled with a view to such charges, and the fact that the charges are made induces the men to be economical with supplies. At this point comes in the chance given to the miners by the contract system of making a great deal of money or very little. As the character of the vein or seam often changes within a few feet, and as contracts are, or should be, always made "on the face" or in view of these conditions of the place to be worked it follows that if the rock becomes softer the men get ahead faster, while if it becomes harder they get ahead more slowly. As the amount of money received by them depends wholly on the amount of work done as judged by the result, if the one change takes place they make more and if the other they make less. The charges against the shifts are best based upon the "tallies" or little pieces of wood having upon them the name of the leader or the number of the shift. These should be of different shapes or colors to prevent confusion; as, for example, a round "tally" may be given for blacksmith work in sharpening a pick or drill, a square one given for a cartridge and an oblong one for a car.

The numbers or names should be stamped into the wood rather than painted. At the end of the month these are counted by the clerk and returned to the shift, the leader of which gives a receipt for them, and in accordance with the terms of that receipt finds the amount deducted on pay-day from that due to his shift. The individual sums due the members of a shift should always be settled by percentages, and it is well to have the agreement in writing so there may be no dispute. Men may change from one shift to another at the end of the month, but the Superintendent should not allow such changes to be made, except at such times. The principle upon which the contract system is based, and which it is always well to keep in mind, may be divided into two parts; first, that a thing once settled, is settled forever, as far as that month is concerned; and second, that once a month the details of the system may be completely changed around and modified to suit the changed conditions of the mine. It is upon this principle, or rather upon these two principles, that the whole value of the system depends. It is given enough rapidity to make it a thoroughly business method of carrying on the work, and enough elasticity to enable it to adapt itself to the ever varying state of the property.

In mines where wages are paid, the men receive just so much money per day of so many hours, and the amount of work done by them depends upon their individual honesty, or the amount of supervision exercised over them. As it is a fact that not one man in a thousand will work for others with anything like the zeal he will display in working for himself, it follows that to get from the miners under wages anything like the amount of work which should be furnished for the money paid, a close supervision must be maintained. For reasons already stated, such supervision is an excessively difficult thing to keep up, and unless the number of viewers be very large, the men will have plenty of time to shirk. In this connection I may say that while Cornwall has given us many things in mining, which are of the utmost value, the practice of putting white jackets on the captains of the mine is an absurd one, for the simple reason that the men can see a captain long before he can see them, and hence his inspection or "viewing" becomes of little account. The radical difficulty about a wages mine, is the fact that it works against the interests of the men as well as the company. If the wages are settled at $5 a day—any sum will do as an example—the skilled miner gets nothing for his skill, experience and knowledge. The amount received by him is the same as that paid to another man who has just begun cutting, and whose work is not worth half the value of his. He loses the money he has a right to expect, as the result of his training and experience. On the other hand, the company gains when they pay him only $5 for labor worth $3 and experience and skill worth $4, but they lose heavily when they pay $5 to the man who has but the $3 worth of labor to give in return, and is totally without the $4 worth of experience. The aggregate of the sum so paid is far greater than the aggregate of that saved. It may be objected at once by the miners that if this be true, miners as a class are better off, because as a class they receive more money. I confess I do not agree with this view, although I have heard some of my mining friends urge it very stoutly. It would be a sound view were all miners part of one great firm, turning their wages in, and drawing money out, in proportion to the value of their work. But this is not, and never can be, the case. My reasons for thinking the wages system bad for the miners, I can briefly state as follows: First, it is right that every man as he goes through life should receive a constantly increasing sum for his labor. A man's work should be paid for in proportion to his strength, or that which enables him to do the work at all, and in proportion to his knowledge or that which makes his work valuable. If you will think for a moment you will see that these are the only two considerations which enter into the value of the work as done. Strength on one hand, knowledge on the other.

It is a physical law that the time of a man's greatest strength is between twenty and forty-five, and that after that period his strength declines. But suppose you put a man of twenty-five who knew nothing of mining into a coal seam along side of a miner of fifty, which would cut the most coal? The miner, every time. Why? Because with less strength, but with greater knowledge, the miner would make each blow of the pick tell, while the laborer would lose half or three-quarters of his work. Knowledge, then, comes in and replaces strength. But in the infinitely complex industry, which we call mining, knowledge is worth far more than strength. Take one instance. What man on earth who knew nothing about mining would leave a breast after a month's work in it, in such a condition that miners would be willing to go into it and begin to blast? Not one. The work of the miner then must be such, that after he has worked out a place, others can safely work beyond him. Knowledge alone will bring this about; strength will ruin the mine. Knowledge then is more valuable than strength, and being more valuable should be better paid. But this knowledge can only be got by experience, and experience takes time to acquire. Therefore as men get older they should be better paid. As under the wages system they are paid the same, this is the method of reasoning by which I arrive at my first objection to wages. My second objection is the fact that the wages system prevents the young men receiving a reward in direct proportion to the quickness with which they learn their trade. Take two young men, just out of their time and beginning cutting. One of them will learn with extraordinary rapidity the various kinds of knowledge which go to make up the miner; the other will stay just at the point where he left off. In my opinion the first should receive something more than the second because his work is worth more to the Company. Under the wages system he receives the same. Not alone does he not receive anything more for his improvement as a miner, but the wages system takes from him all inducement to improve. To improve oneself, to increase one's stock of knowledge requires effort, and that effort will not be made unless a man receives something for it. If a miner knows that everything learnt by him will return to his direct advantage, he will try to learn. But if on the other hand, he knows that his labor of learning is labor wasted, he will not make the effort. It is true that even under the wages system the young man who works to improve himself, who labors to make himself a better and more valuable miner, will, some time, receive a reward for that labor. In time he will attract the attention of the superintendent and will receive advancement. But the time is a long time, and when he does receive the advancement, the other men whom he has passed in the race are sure to accuse the superintendent of favoritism. "So and so is the boss' pet," they will say. Under the contract system the miner gets a reward at once for every particle of knowledge which he has and the men are the first to find out his merits. I have seen a man of twenty-two the leader of a shift which was never empty. He could get the best men in the mine to work with him, and he always had more applications than he had places. When at the age of twenty-four that man was made "night boss," the superintendent simply confirmed the choice already made by the miners. His advancement by the way did not stop there. At the age of thirty-five he was made superintendent of the mine he had gone into as a boy to drive the horses before the cars, twenty years before. But, it is urged, the wages system makes the Company pay out more money in the long run than the contract system. To a certain extent this is true. It obliges the Company to pay the same wages to the poor miner as to the good; in other words the wages system is the system clung to, and believed in, by the "no-account" men. It is the system of the drones. In it the Company is always trying to get the wages down to the amount represented by the average value of the work done by each man, and as the poor miners are always in excess of the good ones, the rate while not much above that which should be paid to these inefficient men is very far below that which should be paid to the efficient. On the other hand the miners are always trying to raise the sum paid to each to the amount which the work of the good man is worth. In this struggle the great majority of the troubles of the miners and the companies are born. It must be remembered that many of the men, who are poor miners at forty years of age, had they been subjected to the spur as applied by a system which gave them a tangible reward for improvement, as soon as that improvement was made, would have been far more valuable The numbing effect of the wages system upon the faculties is shown disastrously in their case.

I have mentioned the struggle which goes on between the miners and the company and the cause which leads to it. It is necessary to consider this struggle more at length and the machinery employed on each side, by the aid of which it is conducted. First and foremost in such consideration comes the complicated question of the miners' unions. I say complicated because the question of the union is generally so considered. To me it seems that the question is an excessively simple one, if a person will but take the trouble to examine it. Some light may be thrown upon it by an examination of how the union, as it exists to day, came to be formed. The union may be traced to the benevolent clubs which were common in English mines many decades of years ago. The miners found that if they wanted to provide against the effects of accidents, the troubles attendant upon those accidents were lessened. A contribution of a shilling or six pence a month gave a man medical attendance and allowance when he was sick, or paid for a decent interment when he died, and gave a small sum of money to his widow. The results of the clubs were found to be so excellent that men who had once joined them rarely left them. But as time went on the miners made a second discovery. They found that while coöperation between them would provide for illness or death, the same coöperation made their voices far more powerful in the conduct of the mine. The owners of the mine on the one hand had money, and wanted labor as cheap as they could get it; the miners on the other had labor and wanted all the money which could be got for it. While the discharge of one man would not affect the owners at all, if the whole force quit work it would affect them a great deal. And so the miners said "we will band ourselves together and act in all things as one man." This they did, and the owners found that the operation of a mine had a new element introduced into it. It is undoubtedly a fact that the union has done an enormous amount of good. It has brought about discussion among the miners, out of which discussions have arisen improvements in mining; it has forced owners to pay more attention to the wants of the men, their safety, and their comfort; and it has proved a check upon the owners in many ways. In all of these things it has done good. On the other hand it has done an enormous amount of harm to the men, as well as the owners. Having great power, it has often used that power without proper caution. It has often refused to acknowledge the fact that the question of wages is one which is governed by other things beside the willingness of the company to pay. To tell a miners' union that the rate of wages governed in Pennsylvania by the rate of discount, as established by the Bank of England, would seem to the members of that union a wildly absurd statement, yet it is one which is susceptible of proof.

The miners' union forces us to regard labor as being one individual factor in our calculations. While we may say that the union has ruined the business, and in some respects this is true, it is yet a fact that the union exists, and that it will exist to all time. While miners themselves are forced to concede that the union has done harm to them in the past, they are conscious that it has, on the whole, done more good than harm, and that the balance must therefore be strong in its favor. As this is unquestionably true, it follows that in the consideration of the union, we must accept this fact as one prior to any such consideration, and base all our reflections upon the continued existence of that union. Capital being governed by certain commercial laws well understood, although, perhaps, not formulated, by every capitalist: it follows that capital will always work in the same way. The first and most imperative of these laws is to guard capital against loss. The second is to so manage capital as to secure interest or increase for its use. When men place large amounts of money in mines, and an investment in a mine is necessarily a large one, by the owners, although strictly speaking the size of an investment has nothing to do with the operation of the two laws mentioned; they require that it be safe and that it yield interest or profit. We have already seen that shutting down a mine makes that mine less valuable than it was before, and that the decrease in value is one which is cumulative. A strike on the part of the men employed threatens the safety of the capital invested or exposes it to a chance of loss. But a strike brings the output to an abrupt stop.

As the profit or interest upon the mine depends wholly upon the out-put, the strike causes the interest on the capital or profit of the investment to cease. When, then, a strike occurs, the company has both of these imperative commercial laws urging it to bring about as soon as possible a termination to that strike. Were it not for the operation of these laws, the company would allow the men on strike to stay there until they got tired. As there are these commercial laws affecting capital, so there are the same laws affecting labor. The miner has his strength and his knowledge, which may be called his capital, and he wants that strength and knowledge secured from loss, and as large a return as possible in the shape of wages or profit. He goes into a strike, as a rule, because the profit derived by him from his strength and knowledge, is not as large as he thinks it should be. The result of the strike upon him is the same result seen in the case of company representing capital. As when the strike began the company found its capital exposed to loss from the decrease in the value of the mine, so the miner finds his capital exposed to loss indirect and direct; indirect because his capability for work is decreased by idleness, and the habits he too often forms during the strike; and direct because, as his capital consists of his strength and knowledge first, and his savings second, he is obliged to live on those savings. The fact that the union funds support him does not change this, for he gets out of the union only what he put in. If he is supported by the funds of other unions, then it is merely an amplification of the first state of things. The operation of the second law during a strike, is the same in the case of the miner, as in that of the company. The interest or profit of the company depends upon the out-put; when that ceases the interest ceases. The profit of the miner depends upon his wages, when they cease it comes to an end. The strike, then, affects both parties to it in the same way, and as that effect is in each case a bad one, both parties are anxious to end it.

The courses which force the termination of the strike are to be found, as a rule, in the operation of the first law, that which governs the loss. The company may be obliged to yield rather than see the mine deteriorate any more in value, the miner may be starved out. But the causes which bring about the terms of settlement are to be found in the second law, and as a rule these causes are those which affect the company, and not those which affect the miner. It may be laid down as a principle, applicable in all cases, when business is carried on, that there is a point beyond which disbursements cannot be made. If the company pay wages which swallow up all the profits of the mine, there is no return to them for the capital invested. As the mine may be supposed to represent the capital invested in it by the company and the labor or capital invested in it by the miners, so the capital invested in the mine may be said to be the aggregate of both. The profit of the working is to be divided between the two, and the share which goes to the company being called interest, and the share going to the miners being called wages. As it is right that the latter should have a part of this profit in the shape of wages, so it is right that the former should have a part in the shape of interest. If the demands of the striking miners are such as to give them, should the terms be agreed upon, all this profit, the company will never accede to them. If on the other hand the company are receiving more than a fair share of these profits they will accede to the demands of the strikers at once.

I may be asked why I have gone into this long examination of the different theoretical interests which affect a strike. My reasons for doing so are simply these: It is necessary before we can cure a disease to know what conditions brought that disease into existence. For the company on the one hand, to say that a strike is simply folly on the part of the men, that it is brought about by the machinations of those who delight in making trouble, that if it were not for the demagogues it would never have happened is as absurd as it is for the miners on the other to say that the refusal by the company to accede to their demands is dictated wholly by a desire on the company's part to grind them down. Each of these accusations may have in it a certain amount of truth. It may be that the strike was folly on the part of the miners, that it was brought about by interested men and that had it not been for the demagogues it would never have taken place, but to suppose that a large body of hard working men, men who fully realize what it is to pay for the support of their wives and children out of their wages, will go on strike simply because others tell them to do so is to suppose a thing which is utterly ridiculous. So it may be that the company desires to receive as large a share of the profit in the shape of interest as it can, but to accuse it of a desire to degrade labor by grinding down the miners is folly of the wildest sort. Yet these are the positions generally taken by each party in the fight, and half the difficulty experienced in adjusting matters amicably arises from the fact that each party proceeds upon one of these absurd assumptions. As a matter of fact there is at the base of the strike on the part of the miners a belief, either true or false, that they are not getting as great a share of the profit of the mine as they are entitled to, and the refusal of the company to accede to their demands arises wholly from a consciousness that were they to do so their share of the profits would cease. It all comes down then to a question of profits or to the question of how much money is got from the operation of the mine. If both parties to the strike, the company and the Union, will recognize this fact and will in their arbitration meeting calmly ascertain and consider what the profits are, a piece of information not at all difficult to get, and will then quietly determine the proportion which should exist between the interest which goes to the company, and the wages which go to the men, they will find little or no trouble in arriving at a solution of their difficulty. But if they go into a conference or arbitration meeting for the purpose of indulging in mutual recriminations, for the sake of making charges of personal animosity and personal feeling against each other, that strike is apt to last until both parties learn more sense. I remember being present at an arbitration meeting of the representatives of the Union and the Superintendent at which the speeches made were of the most bitterly personal character on each side. Accusations of a desire to grind down the laboring men—it is extraordinary how fond the Union orators are of this phrase—on the part of the company, and of rank folly, black ingratitude, and a wish to create trouble on the part of the miners, were freely made. The meeting got more and more stormy and the prospect of a settlement seemed to be very remote, when an old miner got up and made a speech which I thought the best one I ever heard. It ran something like this: "I come here, men and Mr. Chair, for to find out if I were goin' to work agin. I didn't come here for to call no names 'cause my old woman an' me can git up that kind o' 'musement any time we likes. Now ther's a good many old women in this yer camp as can do that kind o' work a heap better nor me, an' I moves you Mr. Chair as how we gets them old women in here to 'buse each other while we goes out into the yard an' settles this yer question o' goin' to work an' what the company will give a day." It did a man good to hear the laughter which followed this speech, laughter caused the more readily as I afterwards found out, from the fact that old Sandy's wife was a notorious shrew. The old man's speech was effective, though, and the question of wages was settled before the meeting broke up. Once or twice during the discussion things began to wear a threatening aspect, but an allusion to Molly always brought good humor with it. I have often thought of Sandy's speech since that time.

But at best the system of strikes in order to increase wages is a make shift system. It is a mistake which is brought about, by that other mistake, the system of wages itself. As long as the work of men is given a fictitious value, instead of being estimated at its real worth, so long will it be that the company will estimate the value below, and the men estimate it above, the proper point. The company as controlling the disbursements has a powerful weapon in its hands, while in the union which controls the labor it meets a "foeman worthy of its steel." But of the two, the men suffer the most. The company may lose the interest in its money and lose a part of that money in the decrease in value of the mine; between the men and the gaunt twin wolves of poverty and starvation there ever stands the daily wage. The struggle may be kept up a month, three months, even a year; but a time comes when they can no longer hold out. Then, broken down by their suffering, and dispirited by their failure they are forced to yield. They cannot stand the looks of the wife as she sees them come home day after day, only to tell that the strike is not ended; they cannot face the cries of the little ones for food when there is no food to give them. The storekeepers can give no more credit, the cupboard is empty, even bread cannot be had. They are starved out. All the misery and suffering and pain has been of no avail, the company have held out and the union is broken down. Such a failure means much. It means that the power of the union has proved naught, that they have been leaning on a broken reed. To restore that power will take years of time during which the company, the check of the union having been removed, will manage things as it sees fit. And all this misery has been incurred and this failure has been brought about from what? Simply that the union made its demands such that the Company could not accede to them. While the union has great power, its members should recollect that an unwise use of that power will react upon them. They should be careful to examine into the question of profits before committing themselves; they should see that the question of wages has two sides; and if any man begins to talk about grinding down the laboring man, they should promptly rule his speech out of order.

There are other considerations which affect labor in relation to its efficiency and value which the superintendent is forced to consider. And first among these may be placed that of temperance. In some respects miners are like sailors, their pay comes to them in large sums and at comparatively long intervals, and their labor is very hard. It follows that drinking prevails among them to a greater or less extent. Not only is this bad for the men themselves who spend their money foolishly, but a drinking miner is never a desirable man to have in the mine. His work is rarely good work, and he can not be trusted to take those precautions, or to see them taken, which are the sole safeguard of the property. His judgment cannot be relied upon. It is therefore wise for a superintendent to encourage among the men, both by precept and example, anything which will aid in decreasing drinking. Temperance societies and leagues have done a great deal of good, and when it can be arranged that the men find a direct advantage in joining them, their work is made easier and their influence increased. This may be done by the company in the form of donations of books to the library or by giving picnics or pleasure excursions to the members. I have seen one mine where the company established a "sick fund" in connection with the temperance league, the benefits of which were only to be obtained by a membership in good standing for six months or more; and the result was most excellent. For the young men, amusement in any form outside of the bar rooms, should be encouraged to the utmost. Base ball clubs, reading rooms, debating societies and other forms of recreation all produce good results.

It should also be known that drinking men are not wanted, and that the first discharges will be distributed among them. In fact, every exertion possible should be made to discourage intemperance, if nothing else, on account of the fearful risk which accompanies it. A glass of beer too much may make an engineer run a cage into the "sheeves" and the safety clutches may not work. I remember an instance of this kind that resulted in the death of eleven men. A timber badly placed may bring about a "cave." The risks necessarily taken in mining are too great to permit of their being increased by any habit which can be cured. A superintendent's power is very great, and his influence is still greater. Both are never better exercised than on the side of temperance. It is wise economy for the company to see that money for school-houses is not wanting, and that churches do not remain things to be built, for lack of funds. Few expenditures give larger returns than those made for these purposes. In fact the more steadily the company keep before them the idea that the miners are men and not machines, the better work they will have done and the more valuable will become their property. It pays, and pays well, to see that the men have comfortable quarters although the ownership of the houses by the company, and their lease to the men is not as a rule a wise practice, as it is frequently charged that the company's rents are exorbitant, and an excuse is given for the reputation of that little statement about grinding in connection with the poor man. If one of the men employed, however, wishes to build, it is wise for the company to advance a part of the money necessary, providing always that his character for sobriety and industry will warrant such an advance. It must always be understood, however, that such advance is the direct result of the personal character of the man to whom it is made, and is a recognition of the qualities in him which go to make up the miner who is valuable to the company. It should never be understood that the men have any right to such an advance or loan. It is well, too, for the company to require a man to save up a part of the money necessary, before they consent to advance the remainder. The company should always see that facilities for saving money are given to the men, and if there be no savings bank in the place, should always act in that capacity, paying the regular interest on deposits. This work is troublesome, and takes time, but it pays in the better character of the labor; while it would be wildly absurd for the company to interfere directly in purely personal matters among the men, it is certainly a fact that a good superintendent can do a great deal among them by his influence, if he will take the trouble to exert it, and such influence when exerted for their good is not only increased but gratefully acknowledged. A liberal policy on the part of the company pays better than any investment they can make. When the mine is running smoothly, and the men are contented, the largest out-put is obtained and the work is done in the best way. When there are constant squabbles and fights going on, the work of the mine is badly done. It is as easy for a superintendent to work in one direction as in the other, and upon the direction in which he works will depend in a great degree, the final result of the operation of the mine, the dividends paid to the stockholders.

It will be gathered easily from what I have written, that it is my opinion that liberal treatment of the men combined with a proper system in the management of the mine will produce the best results for the owners. This, as a general proposition, will not probably be disputed by any one. But I have written to little purpose, if I have not shown my belief in the contract system, and my utter lack of belief in that of wages. I regard the contract system as being the wisest because its benefits are equally felt by the employer and the employed; and as being the best because under it the difficulties between labor and capital are adjusted as fast as they arise. Strikes, where it is in operation, are rarely made because there is rarely felt to be any need for them. The miner by his acceptance of the contract regulates at what price he will work once every month. The company by the price placed upon the work, states once a month what they can afford to pay. A difference in the values is not allowed to remain in existence constantly rolling up like a snow-ball until its very size compels attention; it is settled at once, and when it is small. In the contract system the ounce of prevention is always being applied, and the necessity for the pound of cure is never felt. It brings about a state of things in which the mine goes along smoothly and easily, with no friction and no trouble. The men are contented, and the superintendent is satisfied. More work is done, so more money is paid; the company has a larger output for sale and the men get more wages. Better work is done and the mine is left in better condition for the future. I believe that in the contract system one-half if not three-quarters of the problems of labor find their solution, and I believe that the wages system would create those problems in a mine in which the superintendent was an archangel and the men taken from the Hosts of Heaven.

PART X.

METALLURGY AND METALLURGICAL PROCESS—THE LATEST DISCOVERIES—THE INDUSTRIAL APPLICATION OF METALS—MINING TOOLS—METALLURGICAL MEMORANDA.

PROCESSES of metallurgy have proved the salvation of many American Mining Districts. Many of the gold fields of Georgia, the gold gravels of North Carolina, the gold fields of Nova Scotia are to-day worked at a profit where ten, twenty, thirty years ago they would have bankrupted their owners and left them unhappy victims of glittering imagination. Nowhere in the world have the processes for operating mines been more quickly adapted to the wants of the work, and new and wonderful ways contrived to overcome new and wonderful difficulties. Every year brings cumulative evidences of our progress in this direction, and the great spirit of private initiative that animates our mining men is producing the most valuable and praiseworthy results; In PART X., of the MINES, MINERS, AND MINING INTERESTS OF THE UNITED STATES some metallurgical processes are set forth that will be found of interest, together with a careful gleaning of the field of recent metallurgical discovery and experiment. The chief industrial applications of metals, their properties, and some papers that were procured too late to find a place in the PART properly belonging to them, make up the contents of PART X.

IRON.

WITH respect to its useful properties, iron occupies the first place among the metals. By far the strongest, and, at the same time, one of the lightest, its applications in the arts of construction are much more numerous than those of any other metal. Being capable of assuming, according to the treatment which it undergoes, the forms of wrought iron, cast iron, and steel, it is susceptible of the widest variations in its characters. Extracted from its ores in the form of cast iron, it is melted with comparative facility, and, according to the mode of operating in the foundry, may be made to yield castings which are easily filed and turned, or may be rendered so hard that no tool is able to touch it. By judicious treatment with heat and atmospheric air the cast iron is converted into steel, the strongest, and one of the hardest and most elastic of all materials, as well as the only one of which a magnetic needle can be made. Continued a little further, the joint action of heat and atmospheric air converts the steel into wrought iron, possessing great strength and toughness, yet soft enough to be turned, bored, and punched with ease, and, especially when heated, to be rolled and twisted into the most varied forms without cracking. With less disposition to melt under the action of heat than any other common metal, wrought iron is sufficiently softened at a bright red heat to be *welded*, or joined to another piece, in the most perfect manner, without the use of solder of any kind. Being capable of acquiring and of losing the properties of a magnet with great rapidity, soft iron (wrought iron) is the only material which is adapted for the construction of electro-magnetic and magneto-electric apparatus. It is not too much to assert that scarcely a step of importance has ever been made in the industrial progress of any community to which some one of the three modifications of iron has not been indispensable. Possessed of so many valuable qualities, iron is still the cheapest of all the metals, since the ores from which it is extracted are scattered in profusion through the crust of the earth, and can be made to yield the metal in abundance by a moderate expenditure of time, labor, and fuel.

The difficulty of separating the iron from the other substances with which it is associated in the ore, is of course greater in proportion as these foreign matters are more numerous; thus, when the iron is combined with oxygen only, as in the magnetic iron ore, red hæmatite, and specular iron ore, the metal may be extracted at once in the form of malleable iron, by merely heating the ore in contact with carbon (charcoal), which combines with the oxygen; and this, which is the primitive process for obtaining wrought iron, is still followed in places where the above ores can be readily obtained, and wood is abundant for conversion into charcoal. Even brown hæmatite and spathic ore can be treated in a similar manner if the water and the carbonic acid which they respectively contain be previously expelled by calcination. But in the clay iron-stones and in blackband, the earthy matter (clay, &c.) which is present renders such a process impracticable, and it is necessary to raise such ores to a much higher temperature, in contact with lime, to liquefy the clay so that it may be separated from the iron; when the high temperature causes the iron to combine with the carbon of the fuel, forming cast iron, from which the carbon is removed by a subsequent process, in order to obtain wrought iron.

Extraction of Iron from its Ores in the Form of Cast Iron.—The ore to be smelted is broken up into lumps about twice the size of a fist, and in some cases it is found advantageous to prepare it for smelting by a preliminary process of *calcining* or *roasting*. For this purpose the ore is mixed with small coal, and built up on a foundation of lumps of coal, into huge pyramidal heaps or *clamps*, which are kindled at the windward end, and allowed to smoulder for months, being prolonged, as may be requisite, by fresh additions of ore and fuel at the opposite extremity. The ore may be calcined with an addition of only one-twentieth of its weight of coal, if it contain, as is the case with blackband, a large proportion of bituminous or combustible matter, whilst a clay ironstone may require as much as one-fifth of its weight of coal. This calcination in heaps is a very uncertain process, on account of the irregular distribution of the heat; some parts of the ore being scarcely affected, while others are over-heated and melted so that they can be smelted only with difficulty. This plan is only adopted in districts where fuel is very cheap. During the process of calcination the ore loses about one-fourth in weight, in consequence of the expulsion of water and carbonic acid, and the combustion of the bituminous matter. A portion of the sulphur from the pyrites contained in the ore is also burnt off during the roasting process, entering into combination with oxygen from the air, to form sulphurous acid gas. Many ores are rendered much more porous by this process, and are then more readily smelted. The expulsion of water and carbonic acid would, of course, be effected by the heat of the smelting furnace if this preliminary roasting were omitted: but the sulphur would not be removed to the same extent, and, since this is one of the most damaging impurities in iron, the roasting is a necessary preparation for ores containing much pyrites, and is always practiced in Scotland. During the calcination of the ore, the oxygen of the air combines with the protoxide of iron (ferrous oxide) which is contained in it, converting it into the sesquioxide (ferric oxide), which is less liable to enter into combination with the silica present in the ore, and thus to cause a loss of iron in the slag during the subsequent smelting process. In South Wales the ore is roasted in furnaces, or *running-kilns*, resembling lime-kilns, into which it is thrown at the top, alternately with layers of small coal, the roasted ore being raked out at the bottom of the furnace. Calcination has been much less practiced since the introduction of the hot blast.

Process of smelting[1] *Iron Ores.*—Since this operation re-

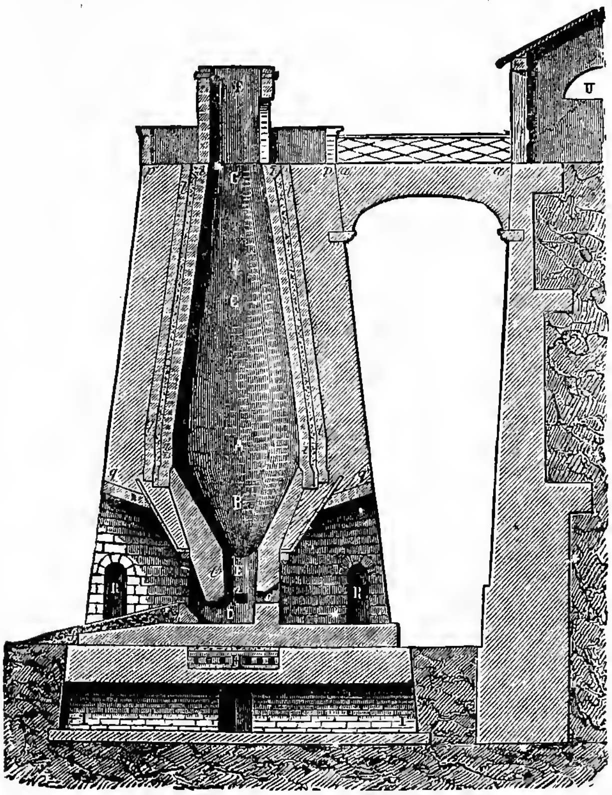

Fig. 1.—Blast-furnace for Smelting Iron Ores.

quires a very high temperature, it is carried out in a *blast furnace*, which does not depend upon the draught of a chimney, but has a strong blast of air forced into it from beneath.

[1] From the German *Schmelzen*, to melt.

This blast varies much in form and dimensions according to circumstances, which will be better understood when the smelting process has been described. Fig. 1. shows a common form, and exhibits the essential features of its construction. The chimney, *tunnel-head* F, has three openings at the side, closed by iron doors, through which the ore and fuel are introduced into the furnace, when they fall through the *throat* or *tunnel-hole*, G, into the *body* C, which is generally of a barrel-shaped form, widening as it descends, and thus allowing a free descent of the materials until they reach the *boshes* A, after which the furnace contracts rapidly, as at B, in order somewhat to check the descent of the solid materials, and attain its smallest diameter at the top of the *hearth* E, which is at its upper part a nearly cylindrical passage, but is made almost rectangular at the lower part, into which,

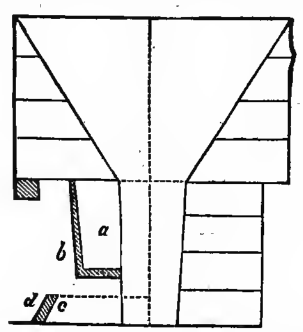

Fig. 2.—Boshes, Hearth, and Crucible of Blast Furnaces.

through apertures *o o* in the walls, a blast of air is forced. The blast-pipes, or *tuyerès*, are usually three in number, and are situated on three sides of the hearth. The fourth side is constructed differently from these three, its upper part being formed by a heavy block of stone *a* (Fig. 2), called the *tymp-stone*, which is supported by a cast-iron *tymp-plate b*, built into the masonry of the furnace, whilst the lower part is enclosed by the *dam-stone c*, faced externally with a thick cast-iron *dam-plate d*. That portion of the hearth which is shut in by the dam-stone is called the *crucible*, for it is here that the cast-iron produced in the furnace accumulates in a melted state, covered with a layer of melted earthy matter or *slag*.[1] The space between the tymp and dam-stones is rammed up with good binding sand, in which an opening is made, just above the dam stone, through which the slag is allowed to flow out of the furnace. The melted cast-iron is never permitted to rise to the level of this opening, but is run out once or twice in twenty-four hours through a *tap-hole* at the bottom of the crucible, which is rammed up again with binding sand.

The dimensions of blast-furnaces vary much according to the conditions of their working, but some idea of them may be acquired from the following:—

Height of blast-furnace, from 45 ft. to 100 ft.
Height of boshes from commencement of hearth, about 15 ft.
Greatest diameter at the boshes, from 13 ft. to 18 ft,
Diameter of chimney at charging-platform, about 10 ft.
Diameter of hearth, 3 ft. to 9 ft.
Depth of crucible, from 8 to 10 inches.
Total depth of hearth, 6 ft. to 8 ft.
Depth from tuyère holes to bottom of hearth, from 12 to 36 inches.

When the coal and ore are soft, and easily crushed, they are liable to obstruct the passage of the blast if there be too much pressure from the column of material above, so that the furnace must not be so high as when harder materials are employed. But in such a case, the diameter of the hearth and body of the furnace may be increased, whereas when hard ores and anthracite coal are employed, the diameter must be reduced, sometimes to one-half, and the height increased. The compression caused by the weight of materials in the furnace sometimes amounts to one-fourth of the bulk of the charge, so that 7,500 cubic feet of materials measured in the charging barrows may be thrown into a furnace of

[1] From the German *schlacke*, dross.

6,000 cubic feet in capacity. The tuyères,[1] or *twyers*, through which the blast of air is forced into the furnace, are formed of conical tubes of cast iron (*a b d c*, Fig. 3), having double walls between which water is introduced through the pipes *t t'*, and made to circulate as shown by the arrows, in order to keep them from being melted. They are between 2 and 3 inches wide at the opening into the furnace, and are built into the walls, as shown in Fig. 4, which represents a section of the hearth at the level of the tuyères. The openings are inclined somewhat in different directions, so that the blasts coming from them shall not exactly meet each other. The air is forced into the tuyère through a movable nozzle (B, Fig. 3) of copper or sheet-iron, connected by a leathern hose (A) with the pipe coming from the blowing machine, with a large forcing

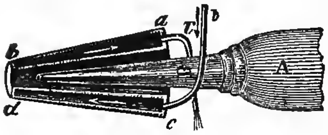

FIG. 3.—Tuyère of blast furnaces.

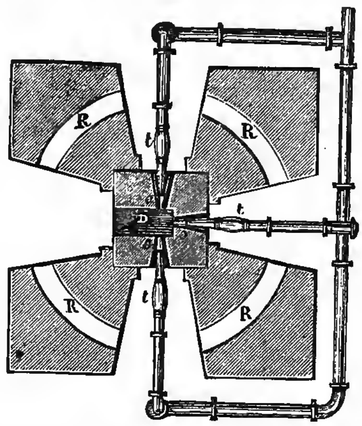

FIG. 4.—Arrangement of Tuyères in Blast-furnace. *t*, Pipes conveying the blast. *o*, Openings in the sides of the hearth D. R. Arched passages for the labourers.

pump worked by steam power, and capable of supplying air, at the rate of from 4,000, to 10,000 cubic feet per minute, to each furnace. The pressure of the blast as it issues into the furnace usually amounts to 2½ lbs. or 3 lbs. upon the inch, but it is sometimes increased to 5 lbs. In charcoal furnaces, the fuel being very porous, a pressure of 1 lb. upon the inch is sufficient; in furnaces fed with coke, about 3 lbs. upon the inch; but where anthracite is employed, the blast has a pressure of 4 lbs. When a blast of high pressure is employed, it becomes necessary to stop up the space between the tuyère and the nozzle of the pipe conveying the blast. The elbow pipe, which connects the blast-pipe with the air main (Fig. 4), has usually a small peep-hole closed with glass or mica, so that the temperature of the hearth, as indicated by the color of its glow, may be observed by looking through the tuyère.

In some modern furnaces the number of tuyères has been much increased. *Rachette's blast-furnace*, which is used in the iron-works of the Ural for smelting magnetic ore, and yields 30 tons of iron in 24 hours, is a furnace of a narrow oblong section, with eight tuyères on each side. It widens as it ascends, unlike the older blast furnace, so that the width is greatest at the mouth, which causes the charge to sink more uniformly in horizontal layers. When the air is blown into the furnace at the ordinary temperature of the atmosphere, it is spoken of as a *cold-blast* furnace, whilst a *hot-blast* furnace is one in which the air is heated to 500° or 600° F. (about the melting point of lead), by being forced through a considerable length of red-hot iron pipes, before it enters the furnace. At first sight it would appear to be immaterial whether the blast of air be heated before or after it is forced into the fire, since, in either case, the same quantity of heat must be lost in raising the air to the temperature of the fire itself, whether a part of this heat be produced by fuel burnt in order to warm the iron pipes, or the whole of it be produced by fuel consumed in the furnace. In the stoves for heating the blast, however, the carbon of the fuel is converted into carbonic *acid*, whilst in the blast-furnace it is converted into carbonic *oxide*, combining, in the latter case, with only half as much oxygen as in the former, and producing less than one-third as much heat, so that 2 cwt. of coal burnt in the stove will go as far above 7 cwt. burnt in the furnace. Moreover, when cold air is blown into the furnace, it must pass through a much larger quantity of the heated fuel before it is raised to the temperature of the fire than would be the case if it had been heated before entering, so that the hot blast has less cooling effect upon the fire, and a much higher temperature may be produced by the same consumption of fuel, or a fire sufficiently hot for smelting the iron ore may be raised with a smaller consumption of fuel than when a cold blast is employed. The economy of fuel is still greater when the blast is heated without any extra expenditure of fuel, by employing the waste heat derived from the furnace itself. An improved method of heating the blast consists in employing two chambers of fire-brick, in which fire-bricks are loosely stacked. Into each of these chambers, alternately, the flame of a coal fire is passed until the bricks are heated to redness; the fire is then diverted into the other chamber, whilst the blast is sent over the hot bricks, when it becomes heated to 1,300° F. before entering the blast-furnace. By the time this chamber has been cooled, the other is heated and ready to do duty again. These *regenerative stoves*, as they are called, have been employed, with great advantage, in other cases.

In the construction of the blast-furnace, very infusible materials are necessary, especially in the crucible and hearth, where the highest temperature prevails. For these portions of the furnace, millstone grit or Newcastle sandstone is sometimes employed (though fire-brick has been lately used), but the upper part or body of the furnace, which is not exposed to so high a temperature, is lined either with fire-brick, or sometimes with blocks of *slag* from the furnace itself, which undergoes an alteration in structure, rendering it less fusible, when exposed to the heat of this portion of the fire. The fire-brick lining (*i l*, Fig. 1) of the furnace is double, a space of about three inches being left between the two portions, and rammed up with powdered coke or sand, which yields to the expansion of the brick-work, and hinders the conduction of the heat to the external part of the structure. Much attention is given to the slope of the boshes, for if this be too steep, the materials will fall too quickly, and if it be not steep enough, they will stick to the sides, and form obstructions or *scaffolds*, preventing the descent of the materials above. Three or more blast-furnaces are generally built in a row, and vaulted passages are left around the hearth to allow easy access to the tuyères and the crucible. When the masonry of the blast-furnace is slight, it is strengthened by iron hoops and bars (*cupola* furnace), or it is sometimes cased externally with boiler plates riveted together.

The *fuel* of blast-furnaces in England is almost exclusively coal or coke, for charcoal is far too expensive for general use, though its freedom from sulphur enables a better quality of iron to be manufactured with it. In Austria, charcoal from wood or peat is the only fuel employed and iron of the finest quality is the result. The Swedish iron works also use charcoal only. In hot-blast furnaces, coal may be employed without having been coked, because the higher temperature which prevails in the furnace allows it to become converted into coke in the upper part of the fire; but for cold-blast furnaces, coke is the ordinary fuel, a hard-burnt, dense quality being preferred. For lighting or *putting the furnace in blast*, much time is required, since there would be great danger of cracking the lining by a sudden application of a very high temperature. Before the dam-stone is fixed in its place, fagots are kindled in the opening below the tymp-stone, so that the flame and heated air may be drawn up into the furnace and gradually warm it. After a few days, a quantity of coal or coke is thrown at the throat of the furnace, and gradually increased until the furnace is filled; the blast is then gradually turned on, and when the fuel has sunk down sufficiently, the smelting operation is commenced. The drying and warming of the furnace occupy a month or more, according to its size.

For the convenience of charging the furnace with fuel

[1] From the French *tuyau*, a pipe.

and ore, a gallery runs round it at the level of the tunnel-hole, to which the materials are brought in iron wagons or barrows, either up an inclined plane, or along a railway carried from the slope over against the furnace. From three to six cwt. of iron ore, according to its richness, is thrown on the top of the burning fuel, together with about one-third its weight of limestone or quicklime, which is employed as a *flux*,[1] to bring the clay of the ore to a liquid state in the fire, in order that it may be separated from the iron. Upon this a charge of fuel is thrown consisting of about four to six cwt. The descent of the charge in the furnace is very gradual, from forty to fifty hours being usually occupied in its passage from the top to the bottom. After an interval of half an hour or so, fresh charges of ore, flux, and fuel are introduced, and the furnace is thus fed, night and day in many places, for six or seven years, before it is found necessary to *blow it out* in order that its lining may be repaired. The melted cast iron which is produced runs down into the crucible, together with the liquid slag, formed by the action of the lime in the flux upon the clay in the ore. The cast iron, being the heavier of the two, accumulates at the bottom, and above it five or six times its bulk of liquid slag, which flows over a notch in the dam plate, and is generally received in iron moulds and cast into large blocks of fifteen to twenty cwt. each. At intervals, of twelve hours, generally, the furnace is *tapped* by opening the tap-hole with an iron rod, and a *cast* is made, that is, the liquid cast iron is run out and cast into *pigs*, or rough half-round bars, either in thick iron moulds, or in trenches excavated in strongly binding sand, and communicating with a central channel into which the cast iron flows from the furnace. The pigs of iron are about three feet long and four inches in diameter, and weigh two and a half cwt. About five or six tons are usually run out at each tapping.

The *foundry iron* intended for the manufacture of castings is generally run into sand moulds; but *forge iron*, which is to be afterwards converted into wrought iron, is cast in iron moulds, partly to avoid contamination with the sand, and partly to render the metal brittle, so that it may be easily broken up for the puddling process which it next undergoes. The blast is suspended during the operation of tapping, and turned on again at the end, in order to force all the iron and slag out of the hearth.

Steel.—The difference between steel and wrought iron (or soft iron, as it is sometimes called) is chiefly seen in their behaviour when raised to a high temperature and suddenly cooled by being plunged into water; when wrought iron undergoes little if any change; while steel is rendered almost as hard as diamond, and so brittle that it snaps off if an attempt be made to bend it. If this very hard brittle steel be again heated to a temperature far short of redness, and cooled, it becomes much softer than before and extremely elastic, so that when forcibly bent it springs back into its former position, whereas wrought iron would retain a permanent bend. It will be remembered that cast iron is also greatly hardened by being suddenly cooled, but it cannot be rendered elastic like steel. The property of being hardened by chilling is dependent upon the presence of carbon in the metal, for chemically pure iron does not exhibit it, though all specimens of commercial wrought iron are slightly hardened when so treated, because they contain a small proportion of carbon. It is, therefore, difficult to define the exact limit beyond which wrought iron passes into steel. Bar iron, containing as much as two parts of carbon in a thousand of metal, would be so decidedly hardened by chilling as to be termed a *steely iron*, and a slight increase in the quantity would produce a *mild steel*, such as the *homogeneous metal* of which cannon and armor-plates are forged. A proportion of carbon, amounting to three parts in the thousand, is contained in the Bessemer steel rails, and in the steel of which spades and hammers are commonly made. Twice this proportion of carbon, or six parts in a thousand, is contained in steel ramrods; and the steel employed for tools commonly contains ten or twelve parts of carbon in a thousand. When the carbon amounts to fourteen parts in a thousand, the steel becomes more fusible and resembles white cast iron.

Bar iron, which contains only a minute proportion of carbon, has a tensile strength of about 57,500 lbs. (nearly 26 tons) per square inch[1]; but when the proportion of carbon amounts to three or five parts in a thousand, its tensile strength is increased to 90,000 or 100,000 lbs. (40 tons or 45 tons) per square inch, while it is still soft enough to be easily punched and flanged. Such a metal is well suited for boiler-plates and similar purposes. For armor-plates designed to protect ships, by offering resistance to blows from shot at high velocities, it appears to be desirable that the proportion of carbon should not exceed two parts in a thousand, for, although an increased proportion of this element is attended with increased resistance to tension (or to a force tending to pull the particles of the metal asunder), as well as to penetration by dead pressure, it renders an armor-plate more liable to fracture under the sudden and powerful blow of a shot.

In addition to hardness and increased tensile strength, the presence of carbon confers another valuable property upon the iron, namely, the capability of retaining magnetism. When a bar of soft iron is placed in contact with a magnet, or in the axis of a coil of wire through which a galvanic current is transmitted, the iron bar acquires all the properties of a magnet, becoming capable of attracting iron filings, and, if freely suspended, of pointing, like a compass needle, north and south. It loses these magnetic properties as soon as the permanent magnet is removed, or the galvanic current is discontinued in the surrounding wire. A bar of steel, however, would retain its magnetic properties. Just as all specimens of commercial bar iron are slightly hardened by chilling, in consequence of their containing a minute quantity of carbon, so they are all slightly retentive of magnetism in proportion to the quantity of carbon present. In the manufacture of electro-magnetic instruments of various kinds, the action of which depends upon the sudden loss of magnetic power by a bar of iron when the galvanic current is interrupted, it becomes of great importance to select the softest commercial iron, so that it may lose its magnetic power as quickly as possible. On the other hand, the hardest steel is selected for the production of permanent magnets, and it has been noticed that the addition of the metal tungsten to steel increases its power of retaining magnetism.

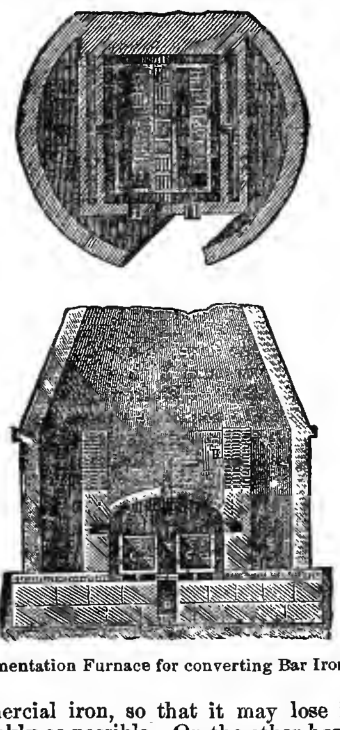

Fig. 5.—Cementation Furnace for converting Bar Iron into Steel.

Steel rings when struck, much more than iron, and this property is relied upon by the steel-maker as one of the tests of its quality.

[1] From the Latin *fluo*, to flow.

[1] The British Board of Trade gives 5 tons per square inch as the *working strain* to which it is safe to expose bar iron in actual practice.

Conversion of Bar Iron into Steel by Cementation.—The process of *cementation* by which until lately nearly all English steel was produced, consists in heating bar iron in contact with charcoal, in a closed chest, until it has acquired a proper proportion of carbon.

The cementation furnace (Fig. 5) is dome-shaped, like the furnace of a glass-house, and is enclosed in a conical jacket of brick work which serves to carry off the smoke from the flues. The hearth of the furnace is divided into two parts by the grate G, traversing the whole length (13 or 14 feet) of the furnace, in which a coal fire is maintained, the flame of which is made to circulate above, below, and around the fire-clay chests or *pots*, or *troughs* C placed one on each side of the grate, before escaping through the flues in the wall H and through the opening M. These troughs are 10 or 12 feet long. and about 3 feet in depth and width, so that each will contain seven or eight tons of bar iron, together with the charcoal necessary for its conversion into steel. A small opening is left at about the middle of one end of each chest, through which the end of one of the bars undergoing cementation is allowed to project; this *proof-bar* is withdrawn from time to time, through a small door in the wall of the furnace, for the purpose of watching the progress of the cementation. There is also a small door in the wall of the furnace, a little above the top of each trough. through which the bars of iron may be introduced and withdrawn, a larger door being made in the middle of the wall to allow the passage of the workmen. The nature of the *cement* or carbonaceous material employed varies in different works, but the bulk of it nearly always consists of ground charcoal from hard wood, with which there are sometimes mixed a little common salt and some ashes of the charcoal. The salt and the alkaline matters contained in the ashes are believed by some persons to have a beneficial effect in converting into a glass the silica which is contained in the charcoal, and thus preventing it from imparting silicon to the steel. The bars of iron should be of the purest description if the best steel is to be produced. They are about three inches broad, and one-third of an inch thick.

In order to fill the troughs, the workman stands upon an iron platform between the two, and sifts the cement powder into them, so as to form a layer of about half an inch in depth, upon which the bars are arranged, standing upon their edges, at about an inch apart. More cement powder is now sifted over these, so as to fill up the intervals between them, and to cover them entirely to the depth of about an inch. Upon this a second layer of bars is placed, then more of the charcoal powder, and so on until the trough is filled to within a few inches; it is then covered in with four or five inches of fire-clay or some similar material, well rammed down, and the fire is gradually applied during the first two or three days, to avoid the risk of splitting the troughs. A temperature high enough to melt copper (estimated at about 2,000° of Fahrenheit's scale) is required to enable the bar iron to acquire a proper proportion of carbon, and the troughs are maintained at this temperature for a period proportionate to the hardness which the steel is required to possess; four days being sufficient for producing the steel of which saws and springs are made, while six or eight days are required for shear steel, and ten days or more are required for the very hard steel of which cold chisels are made. The fire is then gradually let down, to avoid sudden change of temperature, so that some days elapse before the troughs are cool enough to be opened. About three weeks are commonly occupied in the conversion of the bar iron into steel—one to get up the heat, one to keep it at the required degree, and one to cool it down; so that only about sixteen cementations can be executed in a year by a single furnace. The bars are found to have upon their surface bubbles or blisters of considerable size, whence they are called *blister steel*. On breaking the bars, the fracture exhibits a silvery lustre and a well-marked crystalline structure. The proportion of carbon which has entered into combination with the iron depends upon the duration of the cementing process, but it rarely exceeds fourteen parts in a thousand parts of the metal. The chemical changes which are involved in the process of cementation are not yet thoroughly understood. The passage of the infusible solid carbon into the interior of the solid iron bar obviously requires explanation. It might be imagined that the external particles of iron which are in contact with the charcoal, becoming surcharged with carbon, impart a portion of that element to the next layer, and so on, until the particles in the very centre of the bar had acquired a proper share of carbon; but such an explanation would require that the outside of the bar, at the close of the process, should be very much richer in carbon than the inside, and we have no evidence that this is the case.

The following explanation appears more probable. The small quantity of oxygen contained in the air remaining in the trough, and present in the pores of the charcoal, enters into combination with the carbon to form carbonic oxide gas ; this gas, in contact with iron at a high temperature, gives up one-half of its carbon to the metal, and becomes converted into carbonic acid gas; but this carbonic acid, in contact with the strongly-heated carbon, is reconverted into carbonic oxide, which again transfers one-half of its carbon to the metal, these changes recurring many times in the same order until the whole of the iron is converted into steel. The observations of chemists during the last few years have shown that red-hot iron allows the passage of gas through its substance, and that this metal has the power of absorbing a considerable quantity of carbonic oxide, which renders it easy to account for the transference of carbon from the charcoal into the interior of the bar. Other gases containing carbon are capable of imparting that element to iron; thus, if coal gas, which contains carbon in combination with hydrogen, be passed for an hour through an iron tube containing some soft iron wires heated to bright redness, the wires will absorb carbon from the gas and become converted into steel. The blisters, which are distributed sparsely and irregularly over the surface of the bars, are commonly believed to be due to the action of particles of oxide of iron, or of slag, accidentally occurring in the iron bars, upon the carbon combined with the iron, giving rise to carbonic-oxide gas, which escapes as a bubble through the softening iron. As might be anticipated, the blistered steel, in its present condition, is only fitted for very rough articles, such as shovels; its largely crystalline structure renders it deficient in tenacity, and the bars are further weakened by their want of uniformity and by the presence of the blisters.

Conversion of Blister Steel into Cast Steel.—The blister steel is broken up into pieces of a convenient size for packing close together, and about 30 lbs. of it are introduced into a tall narrow crucible (Fig. 6), about two feet high, made of fire-clay mixed with black-lead, and provided with a closely-fitting cover. Some steel-makers add a little bottle-

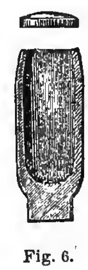

Fig. 6.

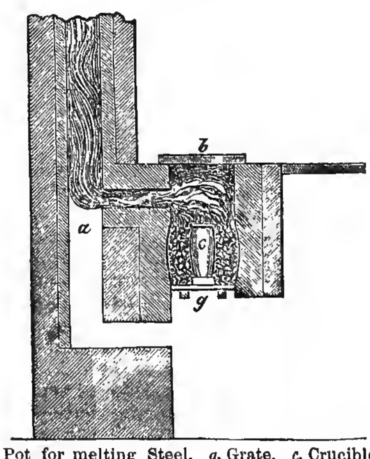

Fig 7.—Furnace and Pot for melting Steel. *g*, Grate. *c*, Crucible. *b*, Cover of Furnace. *a*, Chimney.

glass to fuse over the surface and prevent oxidation of the steel. The crucibles are placed in a small furnace (Fig. 7) holding six, twelve, or more, about one foot wide and two feet deep, the opening of which is usually on a level with the floor, to facilitate the lifting of the crucibles. Several of these furnaces are connected by flues with the high chimney of the works, so that a powerful draught may be produced. Hard coke broken into small pieces is employed to raise the crucible to a bright red heat; the steel is then introduced, the crucible covered, and the furnace filled up with coke; when the steel is melted, the crucible is lifted out with a pair of tongs, and its contents poured into a rectangular or octagonal mould of cast iron which has been previously heated and is placed vertically for the steel to be poured in. The mould is made in two halves, closely fitting together, so that it may be opened for the removal of the bar of cast steel, and is coated inside with coal-tar soot. The quality of the cast steel produced is in some measure dependent upon the temperature at which it is poured, so that an experienced workman is employed for the purpose. For the production of large castings of steel in this way, the requisite number of crucibles must be emptied into the mould as nearly as possible at the same time. At the factory of Krupp at Essen, near Cologne, a casting of 16 tons may be produced in this way, 400 men being well drilled to co-operate in emptying 1,200 crucibles, so that the melted steel may flow in an uninterrupted stream along the gutters leading to the mould. Great alterations and improvements in the manufacture of cast steel will probably result from the introduction of the regenerative gas-furnace of Siemens, in which steel may be easily melted in large quantities. Cast steel is much more uniform in structure than tilted steel, and has a very compact granular texture, without lustre, indicating high tenacity, as may be seen on inspecting its fracture; though here, as in the case of bar iron, it must be borne in mind, that when fracture takes place slowly, it will present a more or less distinctly fibrous appearance; the granular structure becoming evident only on sudden fracture. The higher the quality of the steel, the finer is the granular structure exhibited by sudden breaking. The lower qualities somewhat resemble bar iron in fracture. When produced by the process just described, cast steel has the serious defect of being brittle at a high temperature, so that it is forged with difficulty, and does not admit of being welded. But a method of correcting this was patented by Heath, in 1839, which consists simply in adding to the cast steel, in the melting-pot, about one-hundredth of its weight of *carburet of manganese*, the result of the action of heat upon a mixture of black oxide of manganese (ore of manganese) and charcoal, or some other substance containing carbon, such as coal tar. After this addition, the cast steel possesses much more tenacity at a high temperature, and can be welded either to itself or to wrought iron, so that it may be employed for the fabrication of many implements which were formerly obliged to be made of shear steel. Thus, the blades of table knives can be made of cast steel welded on to an iron *tang*, as that part of the knife is called which is fixed into the handle. Another important consequence of the introduction of Heath's process has been a reduction of about one-third in the price of cast steel, by enabling it to be produced from an inferior quality of bar iron, instead of the very expensive descriptions which it was necessary to employ previously to this discovery.

The mode in which this addition of manganese acts to produce so great an improvement in the quality of the cast steel is by no means understood. It does not appear to depend upon the formation of an alloy of manganese with the steel, for the bulk of that metal is found in the slag from the melting-pots, only a minute proportion entering into the composition of the steel; but that even this small quantity affects the quality of the metal, appears to have been proved by the observation that the manganiferous steel, if melted a second time, becomes as red-short as if no manganese had been added, probably because the small proportion of that metal is removed by the oxygen of the air when re-melting. It is commonly believed that manganese has a particular tendency to encourage the removal of sulphur, phosphorus, and silicon in the slag both from steel and iron, though its precise mode of action has not been defined. For the manufacture of some tools requiring rough usage, such as the chisels of planes, it is customary to employ a bar of iron faced with steel, the cutting edge being, of course, made upon the steel side, which receives great support from the wrought iron. To produce such a compound bar, a bar of iron is polished upon that surface which is to be faced with steel, heated to redness, sprinkled with borax to cleanse the oxide from its surface, and placed in the ingot mould destined to receive the cast steel, which then adheres firmly to the polished iron, so that the two may be forged together.

Production of Bessemer Steel.—It has been already stated that Bessemer's process for converting cast iron into malleable iron depends upon the removal of the carbon by forcing air through the liquid metal, and if this process be arrested before the removal of the carbon is completed, the metal will have the composition of steel. Another process by which this kind of steel is produced consists in depriving the cast iron of nearly the whole of its carbon, so as to obtain wrought iron, which is then converted into steel by adding the proper proportion of carbon in the form of *Spiegel-eisen*. The *converter* (Fig. 8) in which this process is carried out is made of wrought iron boiler-plate, and lined with fire-clay or other refractory material to protect it from oxidation. It is sometimes large enough to contain ten tons of cast iron for a charge, and is suspended on trunnions so that it may be easily tilted for charging and discharging. A six-ton converter is 11 feet high, and 5½ feet in its widest diameter.

Through the bottom of this vessel there are several openings to admit the blast of air, which is blown in at a pressure of fifteen or twenty pounds upon the inch through 35 holes, from 7 tuyères with five holes each. (The number of tuyère holes employed varies, in different works, between 35 and 150, their diameter varying from ¼ to ⅝ inch.) The converter having been heated by burning a little fuel within it, is charged with pig iron which has been previously melted in a separate furnace, a pig iron containing a large proportion of graphite and silicon and a small proportion of sulphur and phosphorus being selected. The air, bubbling through the liquid metal, induces an intense combustion of the iron, producing a large quantity of the black or magnetic oxide of iron which is carried up by the force of the blast together with the nitrogen of the air, which does not act upon the iron. The bubbles of this gas being forced up through the melted metal, effectually mix the unoxidized portion with the melted oxide, which converts the carbon of the cast iron into carbonic oxide gas, and the silicon into silicic acid, the latter combining with some oxide of iron to form a slag which appears as a froth at the mouth of the converter.

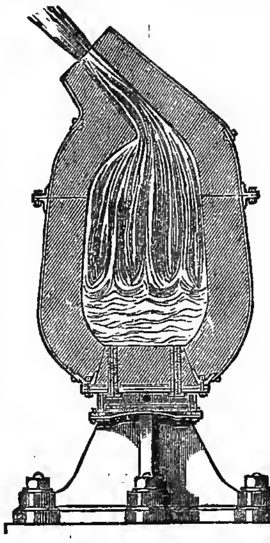

FIG. 8.—Bessemer's Converting Vessel.

The silicon is always oxidized before the carbon, and during the first ten minutes or so, very little flame appears at the mouth of the converter. Since, in this process, a portion of the iron itself is the fuel undergoing combustion, the temperature is much higher than that of the puddling furnace, in which coal is the fuel, for a given quantity of oxygen, in the act of burning iron, produces above one-third more heat than in the act of burning carbon. The temperature produced in the converter is able to effect the complete fusion of the purified iron, which remains liquid throughout the operation instead of separating in a pasty form as in the process of puddling. The manifestation of energy during the conversion is very striking: the roaring of the blast in passing through the molten iron, the long flame of the carbonic oxide, variegated by the combustion of small quantities of metals, the brilliant scintillations from the iron, and the white hot flakes of slag whirled upward by the blast combine to produce a volcanic effect which is not easily forgotten. The operation usually lasts for only twenty minutes, its termination being indicated by the almost total disappearance of the flame of carbonic oxide, but a far more exact method of ascertaining when the requisite amount of carbon has been removed, consists in viewing the flame through an optical instrument known as the *spectroscope*, which enables the observer to detect certain lines in the spectrum or image of the flame, the disappearance of which lines marks, to within a few seconds, the conclusion of the process. If Bessemer iron were acquired, the contents of the converter would now be discharged into a ladle (Fig. 9) and thence into moulds having the form of the required bars, but it has been already explained that the necessity for employing a high-priced pig iron prevents the economical application of this otherwise excellent process to the production of malleable iron in this country.

SPIEGEL-EISEN.

In order to convert the decarbonised metal into steel, the requisite proportion of carbon is added in the form of *Spiegeleisen* or *specular iron* (which must not be confused with the specular *ore*). This may be defined as a special variety of white cast iron containing a large quantity of carbon in chemical combination, together with much manganese. It is obtained by smelting, in a blast-furnace with charcoal, a spathic iron ore containing a large proportion of manganese, such as that from the Brendon Hills. The result of the analysis of a sample of this material is here given.

exhibits a foliated crystalline appearance of great beauty. The presence of manganese is probably of importance with regard to the use of Spiegel-eisen as an ingredient of Bessemer steel. It is introduced in a melted state, in the proportion of about 1 part to 30 parts of the pig iron employed, into the converter, which is tilted into a horizontal position to receive it, the blast being interrupted during the addition, and afterwards turned on again, for a few seconds, when the converter has resumed its former position, in order to diffuse the Spiegel-eisen through the liquid iron, after which the steel is transferred to the moulds, being poured, for that purpose, into a large iron ladle lined with loam (H. Fig. 10) which is swung under the converter by a crane (G.), and, after receiving the metal, is swung back over the wrought iron ingot moulds (K), the steel being run out by raising a fire-clay plug in the bottom of the ladle. In making a large casting the ingot mould employed is so massive as to be equal in weight to the metal required to be cast in it, so that it may cool the ingot quickly, and prevent the formation of large crystals in the metal. Another and more recent form of converter suggested by Bessemer, shown in Figs. 11, 12, has a globular form and seven feet in diameter, the air-blast being introduced through a single tuyère passed through the top of the converter, and made of circular fire-bricks (D, Fig. 12) strengthened by a stout iron rod passing down the centre and terminating in a kind of rosette with numerous apertures, through which the air is projected into the liquid iron. When the conversion is finished, the tuyère is lifted out by an ingenious hydraulic crane (E), and the converter tipped by the action of a hydraulic ram, in order to discharge

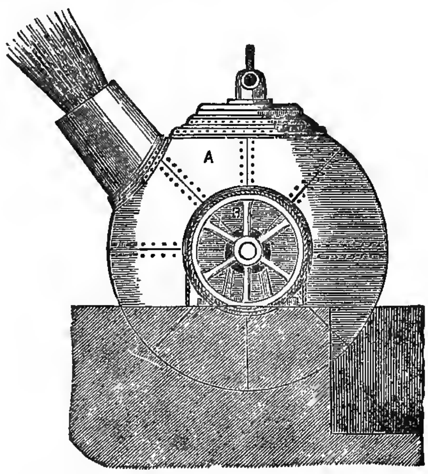

Fig. 11.—Bessemer's Globular Converting Vessel.

its contents into the casting-ladle. It is said that two such converters are capable of producing 200 tons of cast-steel weekly, which would require, by the old process of melting blistered steel, 4,750 crucibles, and 760 melting furnaces.

In order to secure perfect uniformity in the composition and therefore in the quality of the Bessemer steel, the practice has been introduced of actually weighing the casting-ladle, running the fused malleable iron from the converter into it, and then weighing it a second time to ascertain precisely the quantity of metal introduced, the calculated proportion of Spiegel-eisen being then added in a melted state, and mixed with the iron by a mechanical agitator made of iron coated with loam, which is made to rotate rapidly in reverse directions for three or four minutes, before tipping the steel into the ingot-moulds. To obtain a sufficient quantity of Spiegel-eisen of uniform composition, the melted metal is run from the blast-furnace on to a revolving table which divides it into drops and scatters them into a cistern of water, so that they become converted into granules like shot. By mixing well together, say 500 tons of granulated Spiegel-eisen, so as to obtain a perfectly uniform mixture, it is ensured that each charge added to the iron in the converter will contain the same proportion of maganese, silicon and carbon. The granulated metal is not melted, which would cause an alteration in its composition by the oxidizing action of the air, but is merely heated to redness, out of contact with the air, in a kind of crucible, whence it is allowed to drop, through a pipe, into the liquid wrought iron which has been weighed in the casting-ladle. The extensive manufacture of cast-steel rails by the Bessemer process has led to a very perfect organization of the works. The cast iron is run direct from the blast-furnace, into a 12-ton ladle mounted on wheels, and taken to the converting-house, where there are six vessels, each capable of converting 5 tons. The 5 tons of steel are run from the casting-ladle into twenty ingot moulds, so that each ingot weighs 5 cwt. These ingots, when removed from the mould, are reheated in a reverberatory furnace, the hearth of which is fixed on a spindle by which it is made to revolve slowly (once in two minutes) so that the flame of the coal fire may act equally upon all the ingots standing separately, on end, and bring them to the proper temperature for the rolling mill. The railway lines of cast steel are far more durable than those laid with puddled bars. These old wrought-iron rails are capable of being converted into steel, by cutting them up, heating them to redness with a little fuel, in the converter itself, and running the melted cast iron in upon them; when the blast is turned on they soon dissolve, and are converted into steel like the rest of the metal. 100 tons of pig iron, treated by the puddling process, yield 75 tons of railway bars, whilst 85 tons of steel bars are obtained by Bessemer's process. The very large steel

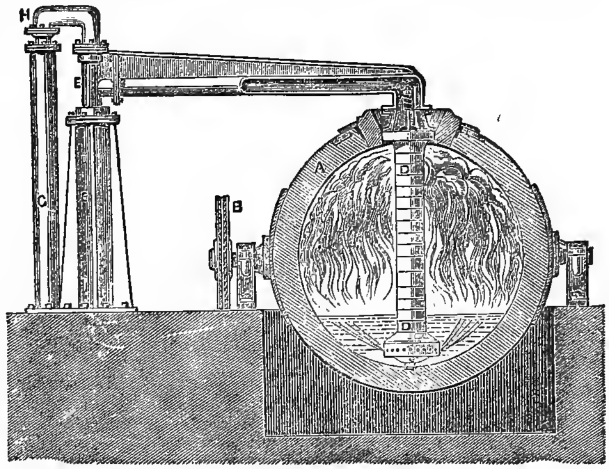

Fig. 12.—Section of Bessemer's globular Converting Vessels. A, The converter. B, Pulley wheel for tipping the converter, connected by a wire rope with a hydraulic ram. C, Pipe conveying the blast. E, Elbow-pipe with telescopic joint.

ingots, sometimes 8 feet long and 3 feet square, and weighing 15 tons, obtainable by this process, cannot be properly forged under the steam-hammer, so that a most ingenious combination of hammer and press worked by hydraulic power has been devised for the purpose. Cast-steel shot, weighing 300 lbs. each, are made by cutting off pieces from a solid cylinder of steel softened by heat, moulding them by pressure between curved surfaces, and rolling them between two iron tables with corresponding grooves of hemispherical section. The lower table is forced with immense pressure against the upper one by the hydraulic ram, and is at the same time slowly turned on its axis. Three balls are made at once in little more than as many minutes.

The effect of hammering or rolling in augmenting the tensile strength of the cast steel obtained by Bessemer's process is much greater than in the case of malleable iron, for the ingots of Bessemer steel which gave a mean tensile strength of 27¼ tons per square inch, had it increased to 68½ tons by hammering or rolling. It is alleged by those who are well acquainted with the art of steel-making, that the presence of a minute proportion of silicon in steel is essential to the production of sound ingots, since when this element is entirely absent, the steel disengages gas as it cools in the mould, and boils up with great violence, an effect which is prevented by the addition of ½ part of silicon to 1,000 parts of steel. The silicon present in the Spiegel-eisen employed in Bessemer's process is therefore regarded as of great importance. A great number of most complete analyses of steel are required to settle this and many other important points in the chemistry of this material, which is daily growing in importance, and with respect to which new theories are continually propounded; at one time *nitrogen* being regarded as an all-important element, at another *titanium*, every theory being apparently supported by a number of chemical analyses and determinations of tensile strength, too often undertaken in the interest of the theory rather than in the unprejudiced search after the truth.

Siemens devised a process for the production of steel by allowing masses of malleable iron, directly they are reduced from the ore, to dissolve in a bath of melted pig iron heated

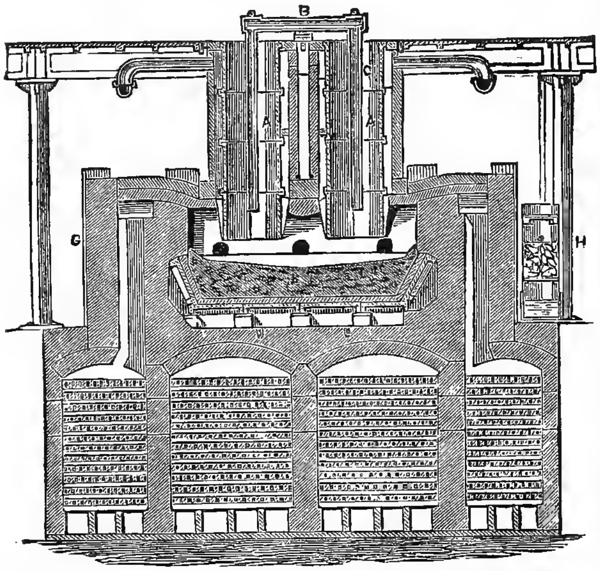

Fig. 13.—Furnace proposed by Siemens, for making cast steel in his Regenerative Furnace. Beneath are shown the chambers containing fire-brick for accumulating the heat of the products of combustion before they pass into the chimney. B. Blast-pipe, from which pipes descend at right angles into the small blast-furnaces A.

in hearth or combustion-chamber of the regenerative gas-furnace. For this purpose, a small blast-furnace (A. Fig. 13) is constructed above the combustion-chamber, so that its lower opening may rest in the cast iron melted in the latter; this blast furnace being fed with hæmatite ore and small coke, produces spongy masses of malleable iron, which do not combine with the carbon to form cast iron as in the ordinary blast-furnace, because the temperature is much lower on account of the limited dimensions of the furnace. These spongy masses of iron are speedily dissolved by the cast iron, and the proportion of iron to carbon becomes raised by degrees to that necessary to constitute steel, which is retained in the liquid state by the very high temperature which the regenerative or accumulative principle of the Siemens' furnace renders easy of attainment.

Puddled steel is an inferior description, employed by boiler-makers and ship-builders, and obtained, as its name implies, by arresting the puddling process when there is still enough carbon (from five to ten parts in a thousand) left to constitute a low steel, when the damper is shut, and the puddled balls treated as in the case of iron. To produce this material small charges, sometimes only 2 cwt., are puddled, and in bringing the iron *to nature*, the flame of the fire is supplied with less air than when fibrous bar iron is being manufactured, so that less of the carbon may be extracted. The presence of manganese in the iron to be puddled is decidedly favorable to the production of puddled steel, perhaps because the slags containing this metal are more thinly liquid, and cover the surface of the iron more effectually, thus hindering the complete removal of the carbon. By refining a white cast iron containing manganese in a forge constructed on the same principleas the English refinery hearth *natural steel* or *German steel* is obtained. The spathic ores containing manganese yield an iron especially adopted for conversion into natural steel, for which reason such ores are sometimes designated "steel ores."

There is as much difference of opinion respecting the effect of the presence of foreign matters upon steel as in the case of bar iron, and for similar reasons, namely, that the quality of steel is so much affected by variations in the mechanical treatment to which it is subjected, that it is difficult to ascertain whether a particular defect in the steel is due to these variations or to the presence of such substances as silicon, sulphur and phosphorus, which are seldom exactly estimated in the analysis of steel by persons whom practical experience has enabled to decide upon the quality of the metal. It is generally allowed that these three elements are injurious to steel, but it is undecided what proportion of each may be present without serious deterioration. There appears to be little question that steel containing five parts of *silicon* in a thousand does not admit of being forged.

Sulphur confers red-shortness upon steel as it does upon bar iron, but the former appears to suffer less injury than the latter from the presence of a given proportion of sulphur. Steel containing more than two parts of sulphur in a thousand is decidedly brittle at a red heat, so that it is useless for forging and can only be employed for castings, for which purpose it is adapted by its increased fluidity when melted. Red-short steel, like iron having the same defect, appears tougher than other qualities of steel, except at an elevated temperature. Manganese is believed to counteract, to a great extent, the red-shortness caused by the presence of sulphur in steel. How much *phosphorus* can be tolerated in steel has been made the subject of much discussion. It is said that steel manufacturers object to bar iron as a material for converting into steel when it contains even one part of phosphorus in a thousand. It is alleged by some that steel made from ores containing titanium is superior in quality, but no conclusive evidence has yet been adduced to show that titanium is really beneficial in its effect upon steel. A ready test for distinguishing between steel and wrought iron consists in placing a drop of diluted nitric acid (*aqua fortis*) upon a clean surface of the metal, when a greenish-grey stain appears upon the iron, whilst the steel exhibits a black spot due to the separation of carbon.

Extract of malleable Iron directly from the ore. —The modern method of smelting iron ores in the blast-furnace, so as to obtain cast iron, which is converted by subsequent process into malleable iron, owes its origin to the necessity created by the great demand for that metal, of extracting it from the poorer ores, such as clay ironstone, which could not be made to yield their iron by a more direct process. In the early history of the metallurgy of iron, there is no mention of cast iron, the intermediate product of the modern iron smelting, the metal being obtained at once in a malleable condition by a process which is still practised, under various modifications, in districts where ores composed of nearly pure oxide or carbonate of iron can be obtained, together with a sufficient supply of the charcoal which is necessary for the operation. The direct process of extracting malleable iron is commonly spoken of as the *Catalan process*, since it has been practised from a very remote period in the Spanish province of Catalonia, where the magnetic iron ore and hæmatite of the Pyrenees are smelted with the charcoal supplied by the surrounding forests. The smelting works comprise a forge, blowing machine, and a hammer, but the first alone will be here described in order to illustrate this method of treating iron ores. The crucible or bath is a nearly rectangular trough (M, Fig. 14) well built around with masonry, about 17 inches deep, 21 inches long, and 18½ inches wide. The bottom of the crucible is composed of a block of granite, which is supported upon small arches to keep it dry.

That side of the hearth at which the blast from the tuyère (T) enters is perpendicular, being built up of massive pieces of iron (*t*), the blast-pipe, or tuyère, of copper, being supported upon the uppermost piece in such a manner that its inclination to the bottom of the crucible can be varied at pleasure, since this appears to exercise much influence upon the success of the operation. The wall opposite to the blast is built up of wedge-shaped pieces of iron (*s*) and presents a curved surface. The working side of the hearth is composed of three thick pieces of iron placed end to end, the side opposite to it being lined with fire-clay, and having a moderate inclination.

To begin the operation of smelting, the hearth is about half filled with burning charcoal, and a shovel is held so as to divide the space above the fuel into two unequal compartments, the larger one, next to the blast-pipe, being filled with charcoal, whilst the other, about half its size, is charged with the ore, previously calcined, broken into small pieces and sifted from the dust; the ore is piled up in a ridge (f) upon the side (g) of the hearth, so that it may be raked into the fire as the charge sinks down. The shovel forming the temporary partition having been withdrawn, the blast is gradually applied so that it may attain its full force after about two hours, the fuel and ore being continually pressed down into the hearth by the laborers. One portion of the oxide of iron is reduced to the metallic state by the carbonic oxide formed from the carbon of the charcoal and the oxygen of the air-blast, but the metallic iron thus produced is not exposed to a sufficiently high temperature to enable it to acquire enough carbon for its conversion into cast iron, and it is obtained in the form of spongy masses of malleable iron or steely iron, according

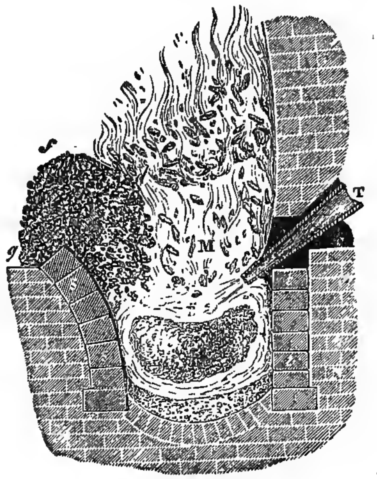

FIG. 14.—Catalan Forge.

to the proportion of carbon taken up by the metal. This depends, to a great extent, upon the manner in which the operation is conducted. If the *siftings* from the broken ore, moistened with water to prevent their dispersion, be added to the charge in large proportion, the iron contains less carbon and is less steely than when these are employed in smaller quantity, probably because the oxidizing action which they exert at a high temperature is unfavorable to the acquisition of carbon by the metal. The iron is also less steely when the blast is directed down to the bottom of the hearth, so that it is less exposed, as it separates from the ore, to the action of unburnt gases very rich in carbon. A large proportion of the oxide of iron escapes reduction, and combines with the silica contained in the ore and fuel, to form a very fusible silicate of iron, the bulk of which is run off through an opening at the bottom of the crucible. In about five or six hours, enough ore is reduced to furnish two or three hundredweight of metal, in lumps which are welded together by pressing them with an iron rod, on the end of which they are transported to the hammer, where they are stamped into a compact state, and afterwards forged into bars. The iron thus obtained is usually of excellent quality, not having become contaminated with foreign matters to the same extent as the melted pig iron from the blast furnace; but the process is a very extravagant one, the ore being made to yield no more than one-third of its weight of metal, with a consumption of more than its own weight of charcoal.

—*Compiled from Metals: their Properties and Treatment.*

COPPER.

THE use of metallic copper dates from an earlier period than that of iron, although the former metal is by no means so plentifully diffused over the earth's surface as the latter. Copper, however, is of much more frequent occurrence in the pure metallic state, and some of the ores of copper can be much more easily made to yield their metal in a malleable condition.

Extraction of Copper from its Ores.—Probably no other metallurgic operation presents such an appearance of complexity as the smelting of copper ores, but this is due to the great variety of the ores to be treated, which necessitates their introduction at different stages of the process. Thus, a smelting process adapted for copper pyrites must contain provisions for the removal of arsenic and sulphur, which are not present in the carbonates and the oxides of copper, so that the processes of smelting are arranged in such a manner that these ores, as well as the slags obtained in some of the operations, can be introduced after the sulphur and arsenic have been expelled.

In a work like the present, it is not advisable to attempt a detailed account of smelting processes which are subject to frequent alterations in order to suit different lots of ore, particularly when such alterations result from the application of practical experience on the part of the smelter, and do not admit of clear explanation upon simple chemical principles. A general outline only of the extraction of copper from its ores will be given here, and before this is entered upon, it may assist the reader to state that it may be summed up under the following heads:

1. *Roasting processes*, intended to expel arsenic and sulphur and to convert the iron into oxide of iron.
2. *Melting processes*, intended to remove the oxide of iron by dissolving it with silica at a high temperature, and to obtain the copper as a pure combination of copper with sulphur (sulphide of copper).
3. Roasting and melting, in a single process, to expel the sulphur and obtain metallic copper.

Before being subjected to the first process, the ores are broken into pieces of the size of a nut, and so assorted that the lot to be smelted may contain about eight or ten parts of metallic copper in the hundred. Moreover, as there is much *gangue* or earthy matter associated with the ores, they are, if possible, so mixed that they may serve as *fluxes* to each other, by producing chemical compounds capable of becoming liquefied by the high temperature of the furnace.

The *fluor*[1] *spar*, which is so commonly associated with copper pyrites, derives its name from its power to effect the liquefaction of earthy substances. Fluor spar is composed

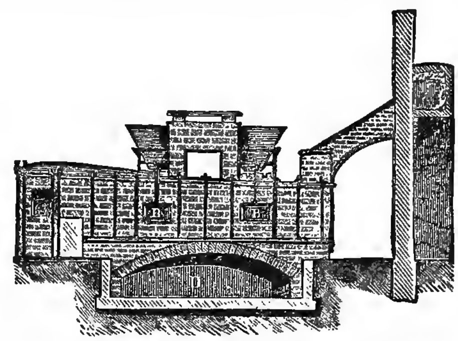

FIG. 15.—Furnace for roasting Copper Ores. BB, Working Doors. D, Vault for receiving the roasted ore.

of calcium and fluorine; if it be strongly heated in contact with silica (quartz) which consists of oxygen combined with silicon, the latter takes up the fluorine to form fluoride of silicon gas, whilst the calcium and oxygen unite to produce lime, which combines with another portion of the silica to form a silicate of lime. The silicate of lime would not easily fuse into a slag by itself, but when clay and oxide of iron are present, as is always the case in the melting furnaces, a slag is readily produced.

First Process in Copper-smelting. Calcining or Roasting to Expel Arsenic and Part of the Sulphur.—The roasting furnace or *calciner* (Figs. 15, 16, 17) is a *reverberatory* furnace, with a hearth (A) of large size (about sixteen feet by fourteen) to allow of the ore being spread out in a thin layer upon it. The hearth is commonly built of fire-bricks set on edge and

[1] From the Latin *fluo*, to flow.

bedded in fire-clay, and the flame is reverberated upon it by an arch of about two feet in average height. At one end of the hearth, near the fire-place, there is an opening or flue (O) through which air may be admitted to the hearth, to furnish the oxygen necessary for the chemical changes effected in the roasting process. On each side of

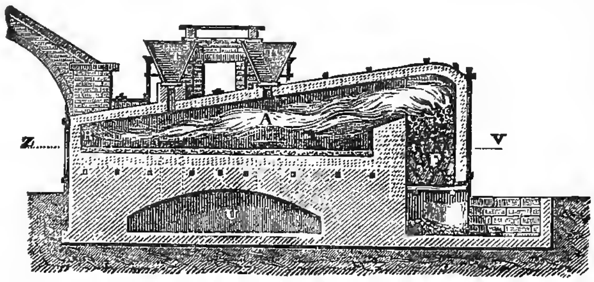

FIG. 16.—Furnace for roasting Copper Ores. Section through the line X Y of the plan (fig. 17).

the hearth there are two openings (r) closed with iron doors, through which the roasted ore is raked out into the arch (U) beneath the furnace. The ore is admitted by opening the hoppers (T) over the arch of the furnace, where it is previously warmed by the waste heat. The fuel employed in the calciners at Swansea is anthracite mixed with one-fourth of bituminous or caking coal, which is necessary to counteract the tendency of anthracite to split up into small pieces and choke the air passages of the fire, the bituminous coal being softened by the heat, and binding the anthracite together. The fire of the calciners requires special management in order that the ore upon the hearth may be brought to the proper temperature. Anthracite coal is not easily made to burn in an ordinary grate, and, when burning, it raises the bars to so high a temperature that they rapidly oxidize and burn away. To avoid this a layer of *clinker* or fused ash from the coal is built up on the bars of the grate (F) so as to preserve them from direct contact with the glowing coal, and air-passages are made through this layer, so that the air becomes heated in passing through them, before it actually reaches the fire, the combustion of the anthracite being thus effected by a current of heated air. The oxygen of the air, passing through the column of heated

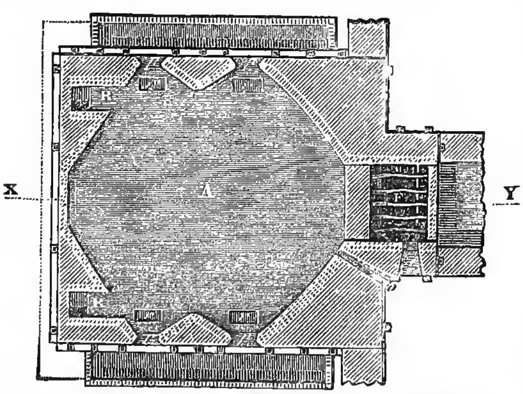

FIG. 17.—Furnace for roasting Copper Ores. Plan at the line of Z Y of the section (fig. 16).

fuel, combines with the carbon to form carbonic oxide, and this gas, being highly heated, takes fire in the air admitted on to the hearth of the furnace, giving a sheet of flame which is drawn through the furnace by the action of the chimney with which the flues (R) communicate, and raises the ore to the temperature necessary for roasting it. Since the air is heavier than the burning gas, a layer of air always exists beneath the latter, separating it from the ore, thus preventing the ore from attaining its melting point, and securing a sufficient supply of oxygen.

Each calciner is charged with three tons of the broken ore, which is spread evenly over the hearth, and roasted for twelve hours, being occasionally raked over through the working-doors (p) in order to expose fresh portions to the action of the air, and to prevent any part of the ore from being melted. At this high temperature, the arsenic present in the copper ore combines with oxygen from the air to form *arsenious acid* (white arsenic) which passes, in the form of vapor, into the flues. About half of the sulphur in the ore also combines with oxygen to form *sulphurous acid* gas which passes up the chimney, a small quantity of *sulphuric acid* being also formed and remaining in the ore as sulphate of copper. Since iron exerts the greater chemical attraction for oxygen, and copper for sulphur, a large proportion of iron acquires oxygen and becomes converted into the *oxide of iron*, while a much smaller proportion of the copper combines with the oxygen from the air to form *suboxide of copper*. When the gases and vapors issuing from the calciners are allowed to escape directly into the air, they form a dense grey cloud of *copper-smoke* which contains the sulphurous acid, mixed with a little vapor of sulphuric acid, the arsenious acid, which condenses in the air to a fine powder, and some hydrofluoric acid gas, produced from the fluor spar. The injurious effect of these products upon the health and vegetation of the neighborhood has induced the copper smelters to devise means for condensing them by passing them into flues and condensing chambers where they are met by showers of water. At some works it has been found profitable to convert the sulphurous acid into oil of vitriol instead of allowing it to escape, but in this case it is necessary to prevent the products of combustion of the fuel from mixing with copper-smoke. *Spence's calciner* employed for this purpose has the fire passing under the hearth instead of over it. This furnace is 50 feet long, and the ore is gradually raked from the cooler to the hotter end as it becomes less fusible. The waste heat of an adjoining smelting furnace is sometimes employed in these calciners, and the calcined ore is raked at once into the smelting furnace. In *Gerstenhöffer's furnace* the ores are crushed between rollers, and allowed to fall over rows of red hot bricks in a vertical furnace, through which a blast of heated air is passed in order to burn the sulphur into sulphurous acid, which is then conducted into the leaden chambers, where it is converted into oil of vitrol.

2nd Process in Copper-smelting. Melting for Coarse Metal, to Dissolve the Oxide of Iron as a Silicate.—It has been seen that the 1st process has had the effect of converting a large proportion of the sulphuret of iron present in the pyrites into oxide of iron, which it is the object of the present process to remove by causing it to combine with Silica, to form a compound capable of being melted and separated from the rest of the ore. At this stage the copper ores containing silica (quartz) can be introduced with advantage, provided that they are free from sulphur. It must not be forgotten that, during the process of calcining, a small proportion of the sulphuret of copper in the pyrites has been converted into an oxide of copper, which resembles the oxide of iron in its property of combining with silica at a high temperature, to form a melted silicate which would pass away in the slag, entailing a considerable loss of copper. This is prevented by the sulphuret of iron which is still present in the calcined ore, and, at the high temperature at which the fusion is effected, exchanges constituents with the oxide of copper, forming oxide of iron and sulphuret of copper. The slag from the 4th process to be presently described, is also appropriately introduced in this fusion, since it contains a considerable quantity of oxide of copper, which exchanges, as above, with the sulphuret of iron in the calcined ore, furnishing more sulphuret of copper to pass into the coarse metal, and oxide of iron to be removed in the slag. The slag from the 4th process (called *metal slag*) also furnishes silica to assist in removing the oxide of iron. In some cases, the smelter adds some fluor spar in order to facilitate the fusion of the charge. The *ore-furnace* (Figs. 18, 19), as it is called, in which the melting for coarse metal is effected, is also a reverberatory furnace, but its hearth (A) is much smaller than that of the calciner (usually about one-third of the size), because the charge has to be made at a much higher temperature; for which reason, also, the fire-grate is larger in proportion; the hearth is also slightly inclined on all sides towards a depression or cavity (B) at one side, which serves as a crucible in which the melted coarse metal collects. The fuel is a mixture of anthracite with one-third of bituminous coal. The charge of this furnace is composed of the following materials, selected for the reasons given above, viz.:—

Calcined or roasted ore, usually about 18 cwt.

Ores containing oxide of copper and silica, 3 cwt.

Metal-slag from process 4, containing oxide of iron, silica, and some oxide of copper, 6 cwt.

Fluor-spar occasionally.

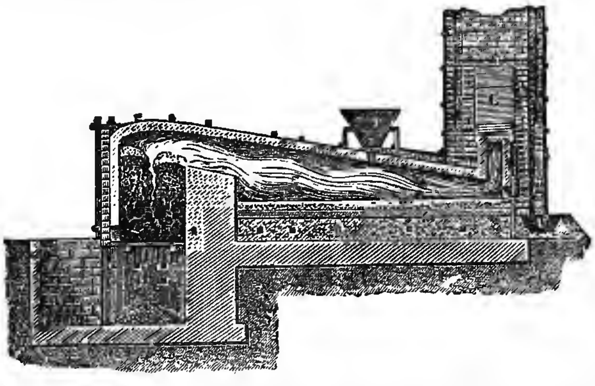

Fig. 18.—Section of Ore-furnace for smelting Copper Ores. T, Hopper for introducing the charge. *p*, Tap-hole for discharging the slag into the slag-moulds U. C, Flue leading to the chimney.

The slag is the first to fuse, in about half-an-hour after the charge has been introduced, and by degrees the whole of the materials become liquid, and enter into violent ebullition, caused by disengagement of sulphurous acid gas, produced by a secondary decomposition of no importance from a metallurgic point of view, save that the ebullition favors the intimate mixture of the melted matters on the hearth.

After three or four hours, the furnace man mixes up the melted matters with a rake, and raises the temperature very considerably, to favor the separation of the coarse metal from the slag. In about half an hour the tap-hole (*b*, Fig. 19), which communicates with the cavity in the hearth is opened, and the *matt** or *regulus* of coarse metal is run out, through an iron gutter (*a*) into an iron box, perforated at the bottom, and standing in a cistern through which water is constantly running; the coarse metal is thus *granulated* or divided into small irregular grains, in order to

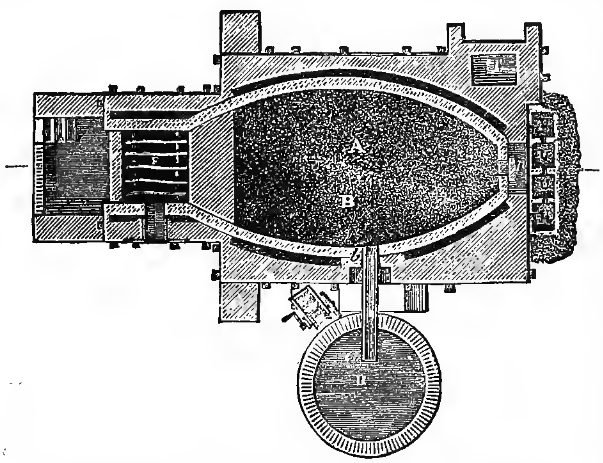

Fig. 19.—Plan of Ore Furnaces for Smelting Copper Ores. F, the Grate. E, Tank for Granulating the Coarse Metal.

fit it for undergoing the next operation. Sometimes the regulus from two or three operations is allowed to accumulate in the furnace before tapping, the slag alone being raked out before the introduction of a fresh charge.

* From the French *mat*, heavy.

The iron box containing the regulus is raised from out of the cistern by a winch (W), and its contents are carried to the calcining furnace.

This coarse metal contains copper, iron, and sulphur in about the same proportion in which they are present in pure copper pyrites, so that the copper amounts to about 33 parts in the hundred, or nearly four times the proportion contained in the raw ore at the commencement of the process. The slag (*ore-furnace slag*) is raked out into sand-moulds (U. Fig. 19), connected with each other by openings in their sides, where it solidifies into blocks of a black, somewhat glassy, appearance, interspersed with white fragments of quartz. It is used for rough building purposes in the neighborhood of the copper works. The ore-furnace slag is composed essentially of oxide of iron (ferrous oxide) and silica combined in about equal proportions, and would be spoken of, in chemical language, as a *silicate of iron* or *ferrous silicate.* It contains also a little copper, usually amounting to one part in 140 parts, representing a loss to the smelter which appears unavoidable. Occasionally, a small quantity of regulus is found at the bottom of the blocks of slag, from which it is separated by hand-picking.

3d. Process in Copper-smelting. Calcination of the Coarse Metal to convert more of the Sulphuret of Iron into Oxide.—Now that the earthy matter has been removed in the slag, it is far easier to oxidize the sulphuret of iron than it was in the first calcining process. To effect this three tons of the granulated coarse metal are roasted in the calcining furnace (Fig. 19) for 24 hours, the temperature being moderated at the commencement, to avoid fusion, and gradually raised in proportion as the removal of the sulphur diminishes the fusibility of the charge, which is raked over every two hours. About one half of the sulphur is converted by the oxygen of the air into sulphurous and sulphuric acids, which escape in vapor, another portion of oxygen combining with the iron from which the sulphur has been removed, to form oxide of iron, so that the roasted coarse metal consists essentially of sulphuret of copper, oxide of iron, and some unchanged sulphuret of iron.

4th. Process in Copper-smelting. Fusion of the Calcined Coarse Metal to Remove all the Iron and to Obtain Fine Metal.—The principles involved in this process are the same as in the second process, viz., the conversion of unaltered sulphuret of iron into oxide of iron by exchange with oxide of copper added for that purpose, and the removal of the oxide of iron in the slag, in combination with silica.

The fusion is effected in a furnace which does not differ materially from that employed in the second process, expect that there is no cavity in the hearth, which is made to slope from all parts towards the tap-hole (Fig. 19). The charge consists of—

Calcined coarse metal (about one ton).

Roaster-slag from the 5th process	About 12 cwt.
Refinery-slag from the 6th process	
Ores containing oxide and carbonate of copper	

(The roaster and refinery slags contain silica in combination with the oxides of iron and copper.) These materials are fused together for about six hours, when they divide, as before, into regulus or matt, and a slag which remains above it. The regulus is sometimes run out into water (like the coarse metal process), when it is called *fine metal*, and sometimes cast into pig-moulds of sand, when it constitutes *blue-metal*, its surface exhibiting a bluish color, due to its still containing a considerable proportion of sulphuret of iron, in consequence of a deficiency of oxide of copper in the charge. This regulus is composed essentially of copper and sulphur, and contains about 77 parts copper in the hundred. The presence of a little sulphuret of iron in this regulus gives rise to considerable differences in its color and appearance, so that it is called by several different names, which do not really imply any important difference in chemical composition.

In some cases, when the charge has contained an excess of oxide of copper, the fine metal has a red brown color, due to the presence of much red oxide of copper and metallic copper, and a pimply appearance caused by the escape of sulphurous acid gas it is then called *pimple metal.* When it is intended to manufacture *best selected copper* for making brass, gun-metal, &c., the blue metal is run into a series of sand-moulds. Since the various impurities which are present tend to collect in a small quantity of metallic copper which is deposited at the bottom of the melted mass, the pigs which are cast first will be the most impure, whilst the others yield the best selected copper in the subsequent operations of smelting. The first pigs yield *bottoms* or *tile-copper* (so called from the shape of the ingots) when smelted. The composition of a sample of these bottoms is here given, in 100 parts: Copper 74, Tin 14, Antimony 4½, Lead 1, Iron 2½, Sulphur 4. It is evident that the metallic copper which has separated, has decomposed the sulphurets of tin, antimony, &c, contained in the blue metal, and has combined with those metals to form an alloy, which is heavier than the blue metal and sinks to the bottom. In some smelting-works, where the fine metal is not obtained in so pure a condition, and contains only 60 parts of copper in the hundred, it is again submitted to the two processes of calcining and melting exactly as in processes 3 and 4, when it yields *black copper or coarse copper*, which contains from 70 to 80 parts of copper in the hundred. The *metal-slag*, as the slag from the 4th process is termed, presents an appearance very different from that of the ore-furnace slag; it is very crystalline and lustrous, and consists chiefly of oxide of iron combined with silica, but it contains a considerable proportion of copper, partly in the form of an oxide in combination with silica, and partly as small particles of metallic copper disseminated through the mass. In some specimens of the metal-slag, the copper appears in very fine brilliant filaments forming *copper-moss.* This slag is usually employed as a part of the charge in the 2nd process (melting for coarse metal), but it is sometimes fused in a separate furnace with powdered coal, when a brittle matt is obtained which contains a very large proportion of copper, and is called *white metal,* a name which is also occasionally applied to fine metal.

5th Process in Copper-Smelting. Calcining or Roasting the Fine Metal to remove Sulphur and obtain Blistered Copper.—The manner in which this process is carried out is varied according to the degree of purity of the fine metal, but the chemical principles which it involves are the following: When a compound of copper with sulphur is heated in air, the sulphur combines with the oxygen of the air, and is thus gradually removed in the form of sulphurous acid gas, the copper also combining with oxygen, and being left as oxide of copper. Further, when an oxide of copper (or compound of copper with oxygen) is melted in contact with a sulphuret of copper (or compound of copper with sulphur), the oxygen of the former combines with the sulphur of the latter to form sulphurous acid gas, and the copper is separated in the metallic state. The pigs of blue metal are introduced, to the amount of 1½ tons, into a reverberatory furnace, where they are roasted, at a gradually increasing temperature, so as to avoid fusion, for about four hours, in order that a part of the sulphuret of copper may be converted into oxide of copper. When it is judged that this has been effected to a proper extent, the temperature is further raised so as to fuse the materials upon the hearth, the doors of the furnace being closed in order to avoid access of air. As soon as the mass is fairly liquefied, the temperature is somewhat reduced, being again raised towards the close. During this fusion, a violent effervescence is observed in the liquid mass, due to the escape of sulphurous acid gas formed by the union of the sulphur from the sulphuret, with the oxygen from the oxide of copper, whilst metallic copper subsides, in a fused state, and is run out in sand-moulds, where it solidifies into ingots which preserve a blistered appearance caused by the escape of sulphurous acid during solidification. The duration of the process depends upon the degree of purity of the blue metal under treatment, but it varies between 12 and 24 hours. A small quantity of slag (called *roaster-slag*) is formed during the fusion, which resembles pumice in its porous texture, but has a dark red-brown color, and consists of the oxides of iron and copper combined with derived silica partly from the hearth of the furnace, and partly from the sand-moulds in which the ingots of blue metal are cast. This slag contains about 16 parts of copper in a hundred, and is used as a portion of the charge in the 4th process. The roasting furnace employed in this process is often constructed with an air-channel (Fig. 20) traversing the whole length of the fire-bridge, open to the air at both ends, and communicating with the hearth of the furnace through two openings (*b b*) in the brickwork. This permits the introduction of heated air into the hearth, by which the roasting is much facilitated.

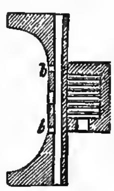

Fig. 20.

6th Process of Copper-smelting. Refining and Toughening, to purify the Copper.—The pigs of blistered copper are far from pure; it contains considerable proportions of sulphur, arsenic, iron, tin, lead and other foreign substances, varying according to the descriptions of ore employed. In order to remove these impurities, the oxygen of atmospheric air is brought into use. The furnace employed does not differ from the melting furnace used in the 2nd process (Fig. 18), and the blistered copper to be refined is piled, in charges of 6 or 8 tons, upon the hearth, in such a manner as to allow air to circulate freely among the ingots. A moderate heat is applied at first, to allow the oxygen of the air to act upon the blistered copper, an action which is facilitated by the porous structure of the metal. The sulphur then becomes converted into sulphurous acid gas, and the arsenic into arsenious acid which passes off in vapor, whilst the iron, tin, lead and other foreign metals are converted into oxides, as well as a portion of the copper. After being roasted for about six hours, the metal is melted, when a thin layer of slag is formed upon its surface; after raking this off, a small sample of the copper is withdrawn and examined by the refiner, who can judge from the appearance of its fracture how long the subsequent process of toughening will probably occupy. In order to toughen the metal, its surface is covered with wood-charcoal or anthracite, which is renewed from time to time, so as to shield the copper from further oxidation, and the melted metal is stirred with a pole of young wood (usually birch) until a small sample half cut through with a chisel and then broken, exhibits a fine close grain, a silky fracture, and a light red color; and a small ingot cast for the purpose and hammered when red hot, is found to be soft and free from cracks at the edges. The copper is then said to be at *tough-pitch,* and is taken out in iron ladles lined with clay, and cast into ingots of *tough-cake* copper. The effect of this process of *poling,* as it is termed, in toughening the copper, depends upon the removal of oxygen from the metal. When the blistered copper has been refined, as above described, by being very slowly melted in contact with air, it is found to have taken up a small proportion of oxygen, which is probably contained in the metal as an oxide (*suboxide*) of copper. The presence of the oxygen, though it does not amount to more than two or three parts in a thousand of copper, has the effect of rendering the copper brittle or *dry,* so that a small ingot of it cracks at the edges when hammered, and its fracture exhibits a deep red color and a coarse-grained, somewhat crystalline structure. When the melted metal is stirred with the pole, the combustible gases, generated from the wood by the heat, effect the removal of the oxygen from the metal, and bring it by degrees to tough-pitch. If, during the operation of casting the ingots, the surface of the metal on the hearth be not well covered with charcoal or anthracite, the copper will *go back* or become brittle again, in consequence of the absorption of oxygen from the air.

If the process of poling be continued after the copper has been brought to tough-pitch, it becomes even more brittle than before it was poled, an effect which was formerly ascribed to the combination of the copper with a little carbon from the wood; but since analysis has failed to prove the presence of the carbon, the following less simple explanation, based upon experiment, is now generally received. Perfectly pure copper exhibits the malleability and ductility of the metal in the highest perfection, but these qualities are deteriorated by the presence of small proportions of the various foreign matters, such as sulphur, tin, antimony, &c., which cannot be entirely removed in the refining process. The injurious effect of these impurities, however, is counteracted in some measnre by the presence of a small proportion of oxygen (not exceeding two parts in a thousand), so that if this element be entirely removed, the copper will be *overpoled*, exhibiting a brittle character due to some of the above named impurities. On the other hand, if too much oxygen has been left in the metal, the copper is dry or *underpoled*. The effect of overpoling upon the metal may be remedied by allowing air to act for a short time upon the melted copper, that a small quantity of oxygen may be absorbed by it. When the copper is intended for rolling into sheets, it is usual to add lead, in the proportion of about five parts to a thousand of copper, just before skimming the surface in order to ladle out the copper. The metal is well stirred after the addition of lead, in order that the action of the air may produce an oxide of lead which combines with the oxides of tin, antimony, and other foreign metals, to form a liquid slag which rises to the surface of the metal and is skimmed off before casting. It is necessary that the removal of the lead from the copper by oxidation should be as complete as possible, since its presence would prevent the scale of oxide of copper from being easily detached from the sheet during the process of rolling an even $\frac{1}{10}$th part of lead in 100 parts of copper suffices to injure its quality. This treatment of the metal with lead is called *scorification*, from the *scoria* or slag which forms upon the surface. The *refinery slag*, skimmed from the surface of the melted copper before commencing the process of poling, has a dull brown-red colour, with a purple shade, and consists almost entirely of an oxide of copper (suboxide) combined with silica derived from the hearth and from the sand-moulds employed to cast the blistered copper. It is employed in the 4th process (fusion for fine metal). The hearths of the copper-furnaces become strongly impregnated with copper in course of time, and are broken out in order that the metal may be removed from them.

Effect of the presence of Foreign Matters upon the quality of Copper.—From the circumstance that the refiner tests the quality of copper by forging a *hot* sample, it will be inferred that the effect of impurities upon its malleability and tenacity is more perceptible at a high than at a low temperature. The foreign matters which commercial copper is liable to contain are arsenic, sulphur, antimony, tin, bismuth, lead, silver, iron, and nickel. Of these, sulphur and antimony are generally considered the most injurious in diminishing the malleability and tenacity of the metal. Arsenic is very commonly found in copper, amounting in some of the Spanish coppers, to as much as one part in a thousand, and was formerly supposed to be as injurious to the quality of the copper as antimony is, but modern experience has shown that copper may be easily rolled and drawn into wire even when it contains a considerable proportion of arsenic. A small proportion of tin is believed to increase the toughness of copper, but bismuth and nickel have the opposite effect.

The conducting power of copper for electricity is reduced in a most striking manner by the presence of foreign matters, so that, in the construction of telegraphic apparatus, it is important that the purest attainable copper wire should be employed. Pure copper is scarcely inferior to silver in its conducting power, and the conducting power of the native copper from Lake Superior, which is almost pure, stands to that of pure copper in the proportion of 93 to 100, whilst the Australian (Burra Burra) copper, also very pure, has a conducting power of 89, and the Spanish copper, which contains much arsenic, has a conducting power only one-seventh of that of pure copper, or in the proportion of 14 to 100. The addition of a small proportion of phosphorus (about five parts in a thousand) to copper is found to harden it and somewhat to increase its tenacity; it is also said to render it less liable to corrosion when exposed to the action of seawater. By adding arsenic to copper, in about the proportion of one to ten, a white somewhat malleable metal is obtained, which is not easily tarnished by air, and is much harder than copper. This compound, which is employed for clock dials and for thermometer and barometer scales, is made by heating five parts of copper clippings with two parts of white arsenic (arsenious acid) arranged in alternate layers and covered with common salt, in a covered earthen crucible.

—*Compiled from "Metals, their Properties and Treatment."*

METALLURGY OF THE PRECIOUS OR NOBLE METALS.

THE process in actual use for the extraction of metals generally from their natural sources are so numerous and vary so much in details, according to circumstances, that only a brief outline of some of the more important methods in use in the case of the chief metals can be attempted here.

Gold.—For the most part this element is found native, and generally in a state of considerable freedom from other metals, the nature of the accompanying metals, when present, varying with the locality. Silver is very frequently associated with native gold; that from Australia and California often containing five to ten, or even more per cent. of this metal, with small quantities of copper and iron in addition. Brazillian gold often contains palladium, and that from Russia platinum. In Hungary gold is found associated with tellurion, whilst the Huelva and Tharsis pyrites and many other minerals contain small quantities of this precious metal interspersed throughout masses of other metallic sulphides. As a rule, the metal occurs in quartzose and granitic rocks, but large quantities have been obtained from time immemorial from the sands of river-beds and from alluvial deposits of the matters washed down by streams from mountainous districts where these rocks occur. Occasionally in these deposits the gold is found in smaller or larger masses known as *nuggets*, some of which have been found of considerable magnitude, weighing upwards of one, and even of two cwt., and worth several thousand pounds sterling; generally, however, the gold occurs in minute grains or "dust." From alluvial soils the gold is separated by simple mechanical means, the earthy mass being agitated with water in a wide shallow

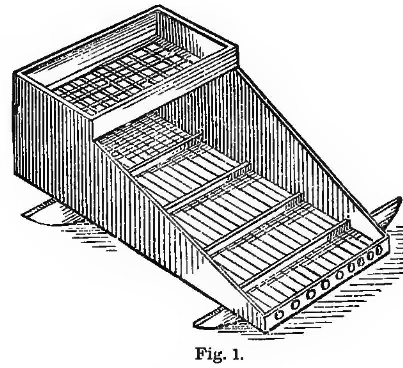

Fig. 1.

basin, technically termed a "pan," a peculiar motion being communicated by the hand so as to scoop out of the pan the muddy water whilst the heavier particles of metal are retained. When necessary, stones and hardened masses are previously roughly pulverized, or they are mechanically picked out by the hand during washing. For systematic working a washing-machine, known as a "cradle," is employed (Fig. 1), consisting of a kind of wooden box, some six or seven feet long and about two feet wide, mounted on rockers so that the bottom has a gentle slope from end to the other; across the bottom are nailed wooden bars (riffle bars, so as to make a series of small shallow weirs in the cradle; at the top end is fixed a sieve, on to which the earth is shovelled, a constant stream of water being kept running on to the mass; the larger stones are thus left on the sieve, whilst the clayey portion, the small gravel, and the gold dust are washed through and deposited in the shallow pools formed by the riffle-bars. Every now and then the deposited particles are removed and dried in the sun, and the lighter earthy particles blown away by the breath, and the small pebbles picked out. Where the soil is a stiff clay, the mass is stirred up with water in a tub with paddles of revolving arms before cradling; and occasionally, instead of carrying the washing so far as to separate all the earthy matters (which often entails loss by the washing away of the finest particles of gold), the cradling is only carried on to a certain point, the gold being extracted from the partially washed mass by amalgamation; this operation, however, is more commonly employed in the case of the powder obtained by stamping or grinding quartzose auriferous rocks, and the washing is then more frequently effected by making the water and suspended matters pass over a series of blankets stretched tightly on frames so as to make a series of very slightly inclined planes; the woolen surfaces arrest the particles of gold with more or less earthy matter. From time to time the deposit is removed, and the gold extracted by means of mercury. Occasionally a kind of magnified cradle is used, consisting of a series of slightly inclined wooden troughs or sluices, ten to twelve feet long, so that the stream from one is delivered on to the next, and so on. Riffle bars are placed in these troughs either directly across or at an angle. When the washing has gone on for a short time mercury is allowed to flow into the upper trough; this runs down, being retained by the riffle-bars, so that the mercury dissolves the accumulated particles of gold. In order to retain the finest particles of gold which sometimes escape through being washed down too rapidly to be absorbed by the little pools of mercury in the sluices, amalgamated plates are placed at the end of the lowest trough; so that the effluent "slimes" must pass over them; the amalgam of gold and copper thus formed is from time to time removed and worked up with the fluid mercury amalgam.

In the extraction of gold from gold quartz, the stamped rock (washed by blankets or sluices when requisite) is placed in an iron pan with a certain quantity of mercury; a stream of water flows into the pan, the overflow passing into another pan at a lower level also containing mercury. Several pans are generally connected in series, each being provided with an agitator worked by steam or water power after the fashion of a mortar mill; the gold is then dissolved out, the agitator continually bringing the auriferous particles and the mercury in contact. Fresh quantities of stamped quartz are continually introduced until the mercury has taken up so much gold as partially to lose its fluidity; the amalgam is then squeezed through chamois leather, whereby a fluid amalgam, containing only a small quantity of gold, is separated, and a nearly solid rich amalgam retained. The fluid amalgam is used over again in the pans, the solid mass being carefully distilled so as to separate the mercury and leave the gold and other metals dissolved out. Certain auriferous minerals, when treated with mercury, do not allow the gold to be wholly dissolved out, the gold becoming sulphurized or otherwise changed on the surface so as to prevent contact between the gold and the mercury. This is especially the case with ores containing sulphur, arsenic or tellurion. To avoid this it has been proposed by Crookes, and also by Wurtz (of New York), to add small quantities of sodium to the mercury. The sodium amalgam thus obtained causes the mercury to wet the metallic particles (probably by destroying the film of gold sulphide, or by preventing its formation). An additional advantage in this process is that the loss by "flouring" of the mercury (reduction to fine particles which do not again coalesce and are consequently washed away) is to a large extent prevented; the mercury being always clean and bright, any small particles mechanically dislodged are readily reabsorbed into the rest of the mass of mercury.

When obtained from certain ores, the gold thus extracted is apt to contain small qantities of foreign metals which destroy its tenacity and other valuable properties; in many cases these metals, if present in the mass left on distilling off the mercury, can be removed by simply melting the residue in crucibles with an oxidizing flux, such as a mixture of nitre and borax; the foreign impurities are thus removed, being oxidized by the nitre, the oxides thus produced being taken up by the melted borax. Another method of purifying gold, especially suited for gold rendered brittle by the presence of tin and antimony, was introduced a few years ago by Mr. F. B. Miller of the Sydney mint; this consists of passing a stream of chlorine gas through the molten metal, when silver and baser metals are converted into chloride, the latter being expelled if volatile, whilst the gold remains unchanged; in this way perfectly pure gold is readily prepared, whilst the silver chloride formed can be readily reduced to the metallic state, and the silver thus obtained separate from the gold. When the silver, in an alloy of gold and silver, largely preponderates, as is the case when silver containing small quantities of gold is extracted from such sources as Spanish pyrites, &c., a more convenient mode of separating the gold is to treat the alloy with nitric or sulphuric acid, when the silver dissolves and the gold is left undissolved (§ 24). In the assaying of coinage alloys, this mode of separation is largely used.

A mode of extracting gold by purely chemical means from gold quartz and other similar sources has been proposed by Calvert: the crushed quartz is subjected to the action of cold chlorine gas so as to convert the gold and other metals present into chlorides which are subsequently washed out by water; from the solution thus obtained metallic gold in a pure state is separated by adding solution of ferrous sulphate, or better, by blowing sulphur dioxide through the liquid;[1] the gold thus separates as a fine powder which is allowed to subside, washed, collected, and fused into an ingot. If silver be also present the metal may be extracted by treating the chlorinated mass with brine, which dissolves the silver chloride, and subsequently separates the silver from the solution thus obtained. Another process, patented by Longmaid, for separating gold from substances containing it consists in fusing the ore in a reverberatory furnace with roasted pyrites, lime, and fluor spar; some gold subsides to the bottom, whilst some remains suspended and is separated by placing iron plates in the fused mass; the gold adheres to these and is then dissolved off from them by immersing them in a bath of melted lead. In this way there is ultimately obtained a gold-lead alloy, from which the gold is separated by cupellation. Neither this process nor Calvert's seems to have come into any considerable practical use, although a process much the same in principle as the latter has been worked in Silesia; this method, described by Plattner in the Jurors' Report of the 1851 Exhibition, consisted in roasting the ore (an arsenical pyrites containing gold to the extent of somewhat less than ½ oz. per ton) so as to drive off arsenic and sulphur, treating the residue with chlorine gas, and then dissolving out by water the chlorides of iron and gold and separating the latter by a reducing agent such as sulphuretted hydrogen.

SILVER.

BESIDES occurring native in Mexico, Chili, and Peru, and in smaller quantities in many other places, this metal occurs in combination with sulphur, forming several kinds of ores according to the quantity and character of the other associated substances; also as chloride (horn silver), iodide, arsenide, bromide, and as antimony and mercury alloys. Considerable quantities are now extracted, the lead smelted from lead sulphide containing small quantities of silver; whilst the Spanish pyrites largely used for the production of sulphuric yields a residue on burning off the sulphur from which silver and copper are obtained in some quantity. From these sources the silver is extracted by methods which naturally fall under one or other of the three classes known as *lead processes, wet methods, amalgamation processes*, the distinctive feature of the first class being that from a suitable mixture of ores a silver-lead alloy is smelted, from which the precious metal is subsequently separated; whilst in the second class the silver is obtained in aqueous solution by treatment with appropriate reagents, and is thence precipitated by chemical agency; and in the third class the silver is extracted by means of mercury somewhat after the fashion of gold, but usually by processes involving more complex chemical actions.

Lead Processes.—When silver exists in the metallic state disseminated through a rocky matrix, a silver-lead alloy is readily formed by merely fusing together the ore and a sufficient quantity of metallic lead, whereby the silver is, as it were, dissolved out of the matrix by the molten lead, much as gold is out of gold quartz by mercury. When the silver

[1] The chemical changes thus taking place may be written:

$$2AuCl_3 + 6FeSO_4 = 2Au + Fe_2Cl_6 + 2Fe_2(SO_4)_3,$$
$$2AuCl_3 + 3SO_2 + 6H_2O = 2Au + 6HCl + 3SO_4H_2.$$

is not present in the metallic state, a silver-lead alloy can be obtained by mixing with the silver ores, galena (lead sulphide), or other lead ores and then smelting the whole together so as to reduce both lead and silver to the metallic state. From the argentiferous lead thus obtained the silver is then extracted by processes the exact character of which depends upon circumstances; if the silver-lead alloys be sufficiently rich in silver and tolerably free from copper, the lead and other foreign base metals present in greater or less quantity are removed by a process termed "cupellation," which consists in fusing the alloy in a shallow dish (*cupel*) made of porous material, such as compressed bone-ash, clay, or marl, moistened with wood-ash liquor, whilst a stream of air plays over its surface; the lead and foreign base metals oxidize and the oxides fuse and are partially absorbed by the cupel and partially blown away by the current of air or drawn off in the liquid state forming the lead oxides commercially known as *litharge* and *massecot.* Finally, when all the foreign metals are oxidized a mass of fused silver is left containing in addition any gold or platinum which may happen to have been originally present; the clearing away of the last traces of oxide produces a rather singular appearance on the surface of fused metal, technically termed the "brightening." The fused silver, especially at high temperatures, absorbs oxygen from the air and on cooling is apt to give it out again, forming peculiar miniature volcanic cones where the escape of gas forces the yet liquid metal in the interior up through the newly-formed thin solid crust; this phenomenon is spoken of as "vegetation," or "spitting," and with large masses of silver (one cwt. or so) is often extremely well defined, the cones being an inch or two in height.

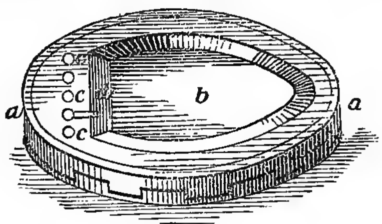

Fig. 2.

Fig. 2 represents the form of cupel usually employed in this country; an egg-shaped ring of half-inch boiler plate, *a, a,* strengthened by cross-bars at the bottom, constitutes a sieve-like frame into which is rammed by mallets, a mixture of bone-ashes and a little wood-ash moistened with weak potash solution; the upper surface of the mass thus formed is worked into a concave form

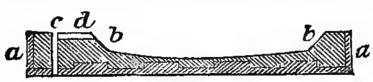

Fig. 3.

b, b, exhibited in section in Fig. 3, the concavity being bordered by a ledge of two or three inches in width all

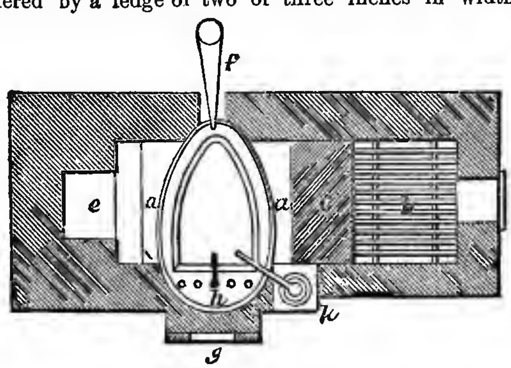

Fig. 4.

round save at the base of the oval, where it is much wider. In this wide part of the ledge or *breast* are bored holes, *c, c, c,* for the purpose of drawing off the fused litharge by means of a temporary channel, termed a "gate," *d,* scooped in the substance of the cupel as occasion requires. According to the amount of silver lead alloy to be worked at a time, the metal ring is from two to four feet long and eighteen to thirty-six inches wide, by four to six inches deep, the thickness of bone-ash in the thinnest part being an inch or a little more. The cupel is set in brick work under the arch of a small reverberatory furnace represented in plan in Fig. 4, and in section in Fig. 5, *a–a,* cupel; *b,* fireplace; *c,* bridge over which the flame from the fire passes, being reflected downwards, as it were, by the arch *d,* and passing to the chimney by the flue *e–e,* running finally underground. The oxidation of the lead is greatly quickened by blowing a stream of air over the fused metal, from the nozzle *f,* whilst the operation may be watched from time to time through the door-hole opposite to the nozzle *g.* As the lead oxidizes and the fused litharge are removed by the gate *h,* (running through the perforations in the cupel and being received underneath in an irod truck or "bogie" *i*), the level of the metal in the cupel is kept approximately

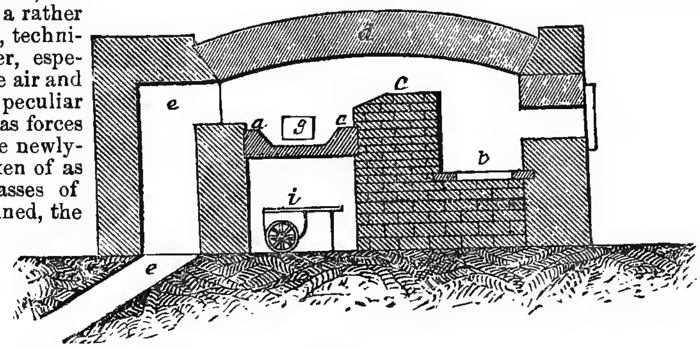

Fig. 5.

constant by running into the cupel through a shute or gutter fused argentiferous lead from the subsidiary pot *k,* in which is a supply of metal, kept molten by a small fire. In this way many cwts. of argentiferous lead are gradually worked up in the same cupel, and ultimately a mass of molten silver of several hundred ounces in weight is obtained. This is drawn off when the operation is finished through a hole bored in the bottom of the cupel; this hole is then stopped up with a plug of ash, and the operation is conducted over again. Usually the finishing of the refining is conducted in a separate cupel, the concentration of the silver by removal of lead, &c., being only carried on up to a certain point in the first cupelling furnace, a somewhat higher temperature being required towards the close of the operation; moreover, the litharge separated at the close of the process is apt to contain a little silver, wherefore it is collected apart and reduced to the metallic state and worked over again as argentiferous lead.

When silver is associated with considerable quantities of copper, the separation of the precious metal is often effected by a combination of processes consisting of three stages; first, a ternary copper silver lead alloy is prepared by adding to the argentiferous copper ore galena (if not naturally admixed therewith), and smelting the whole, or by adding argentiferous lead to a poor silver copper alloy already smelted or otherwise extracted. This ternary alloy is cast into thin cakes weighing three or four cwt. each. Secondly, these cakes are submitted to the process of liquation or "sweating," whereby a rich argentiferous lead runs away in the fluid state whilst the copper remains as a spongy skeleton, which retains a little silver; to extract this, the spongy copper is again fused with lead and the alloy sweated a second time. Thirdly, the argentiferous lead containing a little copper, is either used again for the alloy employed in another first sweating so as to concentrate silver therein, and is then treated by the cupellation process, or is directly cupelled without further concentration, if rich enough. In the case of ores in which copper is absent, or only present in small quantities, but which are very rich in lead (*e. g.* ordinary galena) some ingenious devices are in use for concentrating the small portions of silver present in the lead smelted from such ores, so as to extract it without being obliged to re-oxidize all the metallic lead by cupellation. The best-known process of this kind was invented by H. L. Pattinson, and is hence termed "Pattinsonage." It is based on the fact that if an alloy of lead and silver in which the former metal preponderates be allowed to solidify slowly, crystals form consisting of lead retaining much less silver than the original alloy, whilst the fluid portion is proportionately richer in silver; or in other words, that an alloy of silver and lead melts at a lower temperature than another similar alloy containing less silver, whilst such alloys do not remain permanently commingled but have a tendency to separate one from the other, just as oil and water do after shaking up into an emulsion. In practice the operation is carried out by melting the argentiferous lead in one of the central members of a series of from eight to twelve hemispherical iron melting-pots, each mounted in a separate furnace, but all arranged side by side. When melted, the fire is withdrawn or dampered down and the lead allowed to cool, the formation of crystals being facilitated by sprinkling water on the top and well stirring in the crusts thus produced. By means of a perforated ladle the crystals are fished out and drained, the ladle being supported by chains from a crane overhead, so that its contents can be readily transferred to the next pot on the right-hand side. When about two-thirds of the lead has thus been fished out, the yet fluid portion is transferred to the next pot on the left, and there worked up in a similar fashion along with the "bottoms," or fluid residues of previous operations, or what comes to the same thing, with pigs of argentiferous lead of the same degree of richness. The poorest first crystals in every pot in the series are thus continually passed into the next adjacent pot on the right to be worked over again, whilst the richer bottoms continually travel to the left. Finally, in the two end pots there are formed respectively crystals of lead so poor in silver that it will not pay to work them any further, and bottoms so rich in silver that they are more conveniently cupelled than Pattinsonized. These end limits are usually reached when the lead retains no more than about 300 grains of silver to the ton (⅝ oz.) and when it contains about two per cent. of silver (some 600 oz.) per ton.

Parkes' process for desilverizing lead consists in fusing the argentiferous lead with zinc. From the mixture of metals thus produced, the zinc separates on standing, floating up to the top, whilst the lead remains at the bottom; or rather an alloy of lead and zinc containing about 1¼ per cent. of lead floats up to the top, whilst an alloy of the same metals but containing only about 1½ per cent. of zinc subsides; the lighter zinc alloy is found to contain almost the whole of the silver present. Zinc being a volatile metal, is recovered by distillation from the ternary alloy thus gained, whilst the residual silver lead alloy is cupelled, more lead being added if necessary for the operation. One objection to this process is that the desilverized lead retains zinc, which must be removed by a refining process before the lead is marketable; this is accomplished in various ways, one of the most successful of which is blowing superheated steam through the fused metal, whereby the zinc is oxidized and removed (more or less lead being also oxidized).

Wet Processes.—Among the numerous methods of this kind that have been proposed and worked may be mentioned the process of Augustin for the extraction of silver from copper pyrites; this consists in roasting the ore so as to form oxide of iron and oxide or sulphate of copper with sulphate of silver; the roasted ore is then mixed with common salt and again roasted so that silver chloride[1] is formed (*vide* § 43); the resulting mass is then powdered and treated with warm brine so as to dissolve out the silver chloride, and from the solution thus obtained the silver is precipitated by metallic copper. A modification of this process was proposed by Percy, consisting mainly in the use of sodium with sulphate as a solvent for the silver chloride in lieu of common salt, and precipitation of the silver as sulphide by means of sodium sulphide. With some kinds of ores, carefully roasting suffices to convert silver sulphide present into sulphate, which is dissolved out (along with more or less of the sulphates of other metals) by means of water, and then treated with copper, etc., so as to throw down metallic silver. In Henderson's process for the extraction of copper from cupriferous pyrites containing but little copper (really a modification of Augustin's process), a liquid is obtained containing the chlorides of sodium, iron, and copper, with minute quantities of silver chloride, and much sodium sulphate, etc. To isolate the silver from this solution Claudet employs a soluble iodide, whereby silver iodide is precipitated, the copper being then extracted from the mother liquors by precipitation with iron. The silver iodide is then treated with zinc, whereby metallic silver is formed together with zinc iodide, the aqueous solution of which is used to precipitate the silver from a fresh quantity of liquor; the metallic silver thus obtained contains an appreciable quantity of gold. Another process for treating the same liquid has been recently described by Mr. J. Gibb,[1] as worked successfully on the large scale; this consists in treating the liquors with sulphuretted hydrogen (prepared from alkali waste by hydrochloric acid) so as to precipitate about one-sixteenth of the copper present as sulphide. This precipitate is found to contain practically the whole of the silver; it is separated from the rest of the liquor and dried without draining or washing, so that a certain amount of soluble chlorides still adhere to it. By calcining this precipitate at a low temperature the copper sulphide is oxodized to copper sulphate, which is removed by washing with water, and silver chloride is left in an impure state. From the copper sulphate solution thus obtained the copper is precipitated by means of iron, as is that from the liquor separated from the sulphuretted hydrogen precipitated.

Amalgamation Processes.—The amalgamation processes in use for the extraction of silver from its ores differ from the method employed in the case of gold as described above (§ 46), in that the silver usually occurs mineralized by combination with non-metals, and hence has to be set free from its compounds before it can be dissolved by the mercury, whilst the gold being already in the metallic state usually requires no such treatment. With certain classes of ores the decomposition of the silver compound is effected by the mercury itself, so that a much greater loss of this latter metal is brought about than that due to imperfect condensation during distillation, flouring, and the like. In others the natural silver compound is previously transformed by roasting or other treatment into some other compound more readily attacked by the mercury; whilst in others the separation of metallic silver is effected by means of cheaper reagents, either employed before treatment with the mercury or simultaneously therewith. One of the rudest and most wasteful of these processes, so far as mercury is concerned, is that still largely employed in Mexico, and known as the "Patio" process, being partly carried on in a *patio* or paved space. The ore containing the silver as sulphide, with more or less chloride, is first stamped and then ground with water to a fine powder in a rude but effective mill known as an *arrastre*. The thin mud thus formed is run into a reservoir where most of the water evaporates. The thick paste thus produced is then laid on the patio forming a circular mass of about a foot in depth and forty to fifty feet diameter, weighing some sixty or seventy tons. Salt is then added to the extent of one-fortieth to one-twentieth of the weight and the whole mass well intermixed by treading by mules. After some twenty-four hours from one to two per cent. of "magistral" is added, and the whole again well trodden in and intermixed. The magistral is an impure mixture of iron and copper sulphates, prepared by partially "weathering" copper pyrites by exposure to the air in a wet state, and then completing the oxidation by gentle calcination with a little salt. Mercury is now squirted on to the mixture in a shower by squeezing it through bags or running in from a sheet, and the whole well intermixed by treading; about six parts of mercury are used for every one part of silver present. A chemical action is thus set up and facilitated by turning over and stirring the heap daily for about four weeks. The ultimate effect of this is to form sulphate of soda from the partial oxidation of the sulphur

[1] By virtue of the Reactions—

$$Ag_2S+2O_2=Ag_2SO_4.$$
$$Ag_2SO_4+2NaCl=2AgCl+Na_2SO_4.$$

If unoxidized silver sulphide be present during the roasting with salt, it also becomes converted into chloride, thus:—

$$Ag_2S+2NaCl=2O_2=2AgCl+Na_2SO_4.$$

[1] *Chemical News*, xxxi. p. 165.

in the silver sulphide and its reaction on the salt, together with that produced by the mutual decomposition of the iron and copper sulphates with the salt, forming in addition iron and copper chlorides. Much mercury is lost by conversion into chloride and also by "flouring," the residual mercury dissolves the liberated silver, and is finally separated from the mud and metallic salts by a stream of water. The progress of the oxidation is tested daily, and more magistral added to increase the action if necessary, or lime added to decompose the metallic salts and retard the action if the mass heats too much, as in that case the loss of mercury becomes greater. Finally, the amalgam is placed in large canvas bags holding nearly a ton; much fluid amalgam is thus forced out by weight alone; the residual mass is then squeezed and moulded into wedge-shaped solid masses, which are then piled on an iron plate with a hole in it so as to form a circular kind of dome; over this an iron bell ("capellina") is dropped and its edges luted to the iron plats; burning charcoal is then placed in a temorary cylindrical brick furnace built round the bell, so that the mercury is distilled off from the amalgam, the vapor passing through the hole in the bottom plate into a tube dipping into water in a suitable receiver.

In what is termed the "Saxon," or Freiberg process, the silver ores are mixed with pyrites containiug a little copper (if not already containing such a mixture naturally), and with common salt, and then generally roasted so as to form silver chloride and sodium sulphate, with iron and copper chlorides. The silver chloride thus formed is reduced to the metallic state by placing the roasted mass in a stout barrel with water and lumps of metallic iron, the barrel being rotated for some hours; mercury is then put in and the whole again rotated slowly for nearly a day. Ultimately an amalgam of silver is produced, from which the earthy matters are washed away, and the fluid mercury separated by squeezing; the solid mercurial alloy is then distilled.[1] Various modifications of both the Saxon and patio processes are introduced in certain localities according to the special character of the ores used. At Halsbrücke, where the Saxon process is chiefly employed, silver ores are used containing several metals, notably antimony, bismuth, arsenic, copper, iron, lead, zinc, and sometimes nickel, and cobalt; consequently the crude silver left on distilling the amalgam is very impure. On the other hand the "plata pina," from the Mexican capellina distilling process, is frequently almost fine silver, the impurities averaging about six parts in the 1000 (Makins) whilst the silver from other sources is of intermediate character according to the ore employed.

In order to obtain pure, or, as it is usually termed, "fine" silver, from the impure crude product, refining by cupellation is usually adopted. The metal to be refined is melted along with lead and the whole cupelled; as the lead oxidizes the other metals are also oxidized and removed, so that finally almost chemically pure silver is obtained. If, however, gold or platinum were present originally these metals are contained in the refined silver. Should gold be present, the high value of this metal makes it worth while to extract it by the wet process, consisting of boiling the auriferous silver with nitric or sulphuric acid which dissolves the silver.

PLATINUM.

THIS metal has been known for nearly a century and a half, being originally found in South America and named after silver (*plata*) of which it was supposed to be an impure ore. As experience soon taught this ore was quite unworkable by ordinary metallurgical processes, it was disregarded until the researches of Wood, Berzelius, and Vauquelain, and more especially of Wollaston, and subsequently of Deville and Debray, demonstrated its peculiar properties and their value for numerous purposes, and showed how the metal could be practically worked. Besides occurring in South America platinum is found native but associated with small quantities of somewhat analogous but less used metals, in the Oural mountains and valleys, and in California, Mexico, San Domingo, and Australia. It occurs either as nuggets sometimes weighing upwards of 20 lbs. or as small grains somewhat after the fashion of gold, and is generally found in the alluvial deposits. The accompanying metals, palladium, iridium, osmium, rhodium, and ruthenium, are more or less completely separated from the platinum by processes essentially of one or other of the following three kinds: either the ore is fused by the aid of an oxyhydrogen flame on a bed of lime, by which means palladium and osmium are volatilized, and a fused alloy of the other metals left in which platinum largely predominates, iridium being present only in small quantities, and rhodium and ruthenium only to a yet lesser extent; or the platinum is separated by a wet process due to Wollaston; or an alloy of lead, platinum, and small quantities of palladium, is formed by fusing the platinum ore with galena, litharge, and a flux of pounded glass, the other metals being undissolved by the newly reduced lead (Deville and Debray); from this alloy the lead is removed by oxidation in hot air, after the manner of cupellation, an oxyhydrogen flame being used, the palladium present being thus also expelled.

Of these three processes, the first yields an alloy which is well adapted to the manufacture of crucibles and other vessels intended to resist high temperatures and the action of chemicals, as it is less fusible than platinum and more resistant as to corrosion; but it is not so well suited for the manufacture of large vessels such as sulphuric acid concentrators, in which the junctions are fused together by a skillful application of an oxyhydrogen blowpipe (autogenous soldering). Deville and Debray's process also is apt to yield a less pure metal than Wollaston's, owing to the difficulty in completely removing by subsidence the particles of the other metals undissolved by the molten lead. Hence for certain special purposes (such as the resistance coils of Siemen's pyrometer, § 84), platinum thus prepared cannot be employed even though it have been freed from palladium and osmium by means of the oxyhydrogen blowpipe.

Wollaston's process, by which absolutely pure platinum can, with due care, be obtained, essentially consists in treating the platinum ore with nitric acid, after washing with hydrochloric acid for the purpose of removing any baser metals, magnetic iron ore, &c., present; the latter can to a large extent be separated by a magnet. A mixture of nitric and hydrochloric acids, *aqua regia*, is then allowed to act on the purified ore for some hours or days, certain proportions and strengths being usually chosen, so as to prevent as much as possible the solution of iridium, which mostly remains undissolved in combination with osmium and a little rhodium and ruthenium, forming white metallic scales termed *osmiridium:* about three parts of hydrochloric acid of sp. gr. 1·20, and one of nitric acid of sp. gr. 1·36, will answer well, or analogous mixtures containing about the same percentages of anhydrous hydrochloric and nitric acids. The acid solution of platinum is then treated with sal-ammoniac, whereby platino-chloride of ammonium is precipitated, iridium, rhodium, and palladium being retained in solution. To avoid the possible contamination of the precipitate with iridiochloride of ammonium, it is well washed with water and pressed; the latter salt being much more soluble than platino-chloride of ammonium is thus removed. Finally the precipitate is strongly heated, whereby a spongy mass of platinum is left;[1] this is made into a

[1] By virtue of the following actions; the metallic iron converts the copper chloride present into spongy metallic copper—

$$Fe + CuCl_2 = FeCl_2 + Cu;$$

this reacts on the silver chloride setting free silver and reproducing a copper chloride (cuprous chloride for the most part.)

$$2AgCl + 2Cu = 2Ag + Cu_2Cl_2.$$

If the mercury be added before the silver has been reduced to the metallic state by the first rotating of the barrel and contents, much mercury is lost owing to its conversion into chloride by taking the place of the metallic copper in this second reaction.

[1] The following equations represent the production of ammonium platino-chloride and its decomposition by heat. By the action of the chlorine set free from the aqua regia, platinum chloride is formed—

$$Pt + 2\,Cl_2 = Pt\,Cl_4.$$

On adding sal-ammoniac to this, combination occurs and ammonium platino-chloride results—

$$PtCl_4 + 2\,NH_4Cl = Pt.\,(NH_4)_2\,Cl_6.$$

paste with water and pressed into moulds, which are slowly dried and gradually heated to whiteness and then forged into compact masses; or the spongy platinum is pressed into cakes and fused in a lime crucible by the oxyhydrogen flame. From the mother liquors of the platino-chloride of ammonium more of that salt can be obtained by precipitating all metals by a plate of zinc, redissolving in aqua regia and adding sal-ammoniac; this precipitate is apt to contain iridium. From the final mother liquor palladium is separated by neutralizing with sodium carbonate and adding mercury cyanide solution, whereby palladium cyanide is thrown down from which metallic palladium in a spongy state is obtained by simply heating. The mother liquors of this precipitate contain rhodium: from the osmiridium left undissolved by the aqua regia in the first instance, the metals osmium and iridium with smaller quantities of rhodium and ruthenium are separated by special processes.

Fig. 1 represents one simple form of Deville and Debray's oxyhydrogen furnace from the fusion of platinum, &c.;

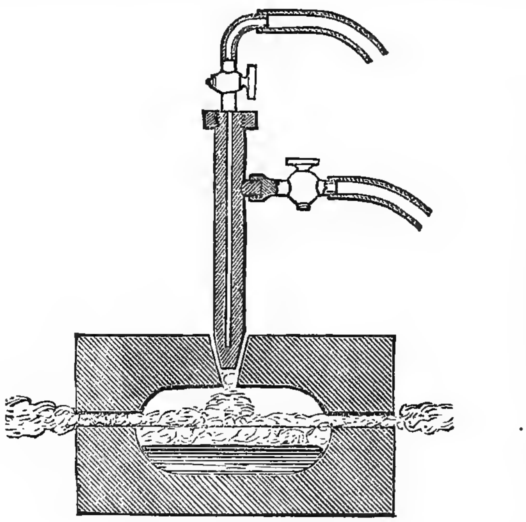

FIG. 1.

the receptacle for the metal to be fused is a compact mass of lime or marble (which immediately becomes converted into quicklime on the inner surface by the heat) hollowed out into a dish shape; this is covered by a similar block in the crown of which is a perforation by means of which the oxyhydrogen flame is made to play

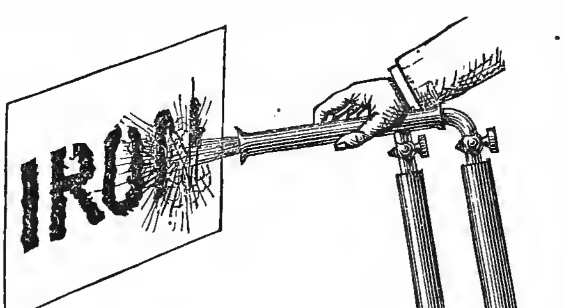

FIG. 2.

inside the crucible furnace; for large masses several distinct flames may be employed. The most convenient form of oxyhydrogen burner for this purpose is simply an ordinary blowing lamp, *i.e.* two tubes arranged concentrically, the combustible gas passing into the annular space outside, and the blast of air or oxygen being passed through the interior tube, the supply of each gas being regulated by cocks. A large flame of this kind supplied with oxygen and hydrogen (best from cylinders of the compressed gases) enables many effective combustion experiments to be made: a steel carving-knife burns with great brilliancy in the flame, and if a large plate of thin sheet iron be held in a vertical position, and the flame cautiously moved over its flat surface, writing may be roughly traced by the perforation of the plate thus brought about (Fig. 2). With even a small flame, such as that used for the lime light, thin platinum foil may be similarly perforated; for this purpose it is not necessary to use hydrogen gas, as ordinary coal gas will often produce the same result; carbon, oxide and oxygen, also, will suffice, the heat evolved in the oxidation of carbon oxide being superior to that produced during the combustion of hydrogen, a given quantity of oxygen being employed.

Compiled from "Metals and their Industrial Applications."

Finally, this compound breaks up on heating, forming sal-ammoniac, chlorine, and platinum—

$$Pt(NH_4)_2Cl_6 = Pt + 2Cl_2 + 2NH_4Cl,$$

the sal ammoniac being to some extent further decomposed by the chlorine in virtue of a secondary reaction.

ZINC.

THE peculiar properties of the alloy of this metal with copper, termed *brass*, have been known from a very early period, many of the so-called antique bronzes containing so much more zinc than tin as to approach much more nearly to brasses than to bronzes in character and composition: these alloys were probably obtained by smelting together a natural or artificial mixture of minerals containing copper and zinc, the processes for the isolation of the latter metal being of comparatively modern origin, depending on the volatility of the metal at a red-heat, *i. e.* being processes of distillation. The chief ores of zinc worked for metallurgical purposes come from New Jersey and the United States, Belgium, Silesia, and Spain, considerable deposits being also found in various parts of Great Britain. They consist mainly of oxide, sulphide, carbonate and silicate, the former being found in New Jersey: *zinc blende* (the sulphide) usually accompanies galena and sometimes pyrites, whilst *calamine* (the carbonate) is found in Derbyshire without intermixture with lead ores, though often it occurs in the vicinity of galena: the silicate (*electric calamine*) is chiefly imported into this country. When blende (known as "black jack" from its color when tolerably pure save a little iron sulphide) is employed as a source of zinc it is subjected to a prolonged roasting for the purpose of burning off the sulphur and forming an oxide of zinc;[1] if lead be contained this roasting must be carried on for a longer period than if the blende be free from this metal: from the oxide thus produced the metallic zinc is reduced by mixing with small coal (anthracite) and heating in a distilling arrangement, in principle not unlike the "capellina" apparatus used for silver amalgam, or in fireclay retorts like those used in the gasworks. Calamine is usually roasted before being submitted to the distillation process, for the purpose of expelling moisture and carbon dioxide and of opening the pores of the mass and rendering it easy to pulverize and mix with the powdered anthracite; frequently a mixture of calcined blende and calamine, or of red zinc ore (oxide of zinc) and calamine is employed instead of one kind of ore only.

The character of the distilling arrangement employed varies considerably in different localities; one of the oldest forms (Fig. 1) consist of a number of large crucibles filled with the mixture of zinc ore and small coal and heated by a reverberatory furnace; each crucible is closed with a cover luted on air-tight: the vapor of zinc and the carbon oxide formed by the heating are conducted out of the crucible through a hole in the bottom, into which is cemented a fireclay pipe passing down through the floor of the reverberatory furnace into a vault below; iron tubes are affixed to the lower ends of these fireclay pipes, dipping downwards into vessels containing water, so that the zinc condenses in the tubes and runs down into the vessels underneath. To

[1] $2ZnS + 3O_2 = 2ZnO + 2SO_2$.

prevent the mass in the crucibles falling down the tubes blocks of wood are inserted into the fireclay pipes; these become carbonized by the heat, and are then sufficiently porous to allow of the vapors passing downwards through them, whilst retaining sufficient strength to prevent the superincumbent solid matter from breaking through them. The iron tubes are cleared out by a rod from time to time lest the condensed zinc and the "fume," or oxide, carried over should block them up.

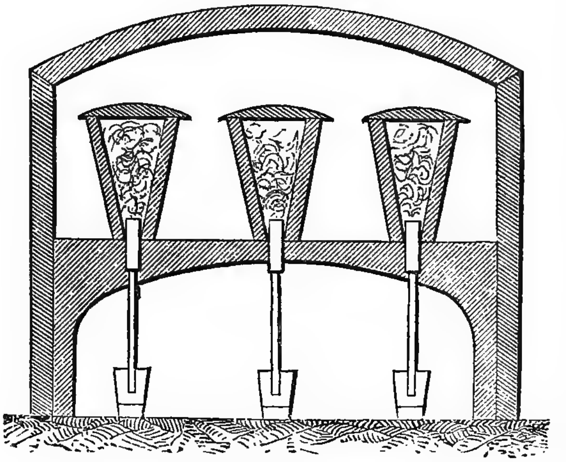

FIG. 1.

In Silesia retorts are used shaped like small gas retorts or large muffles; the vapors are led away into a rectangular downward condensing tube, luted on to the mouth of the retort; several of these retorts, sometimes twenty, are mounted in a "bench" and heated by the same furnace. In what is termed the Belgian process, a large number of retorts are employed mounted in a kind of kiln, each retort being placed at an angle of about 30° with the horizon, the mouths being lowest: short clay condensing pipes are luted into the mouths of the retorts: to these are affixed conical wrought-iron pipes with a narrow terminal orifice some ¾ inch in diameter: the metallic zinc collects in the clay pipes, whilst the iron conical terminals retain a considerable amount of zinc oxide which is collected and used over again with a fresh charge. As many as eighty retorts are sometimes mounted in the same bench, to equalize the rate of working off; those at the top are usually made smaller and are charged with more easily reducible ores, so that the lesser heat communicated to them may not interfere with the process, as a whole, by causing delay through great differences in the time required to work off the charge in each retort. The waste heat from the bench of retorts is employed to roast and calcine ores for a new operation, and to dry and season the fire clay retorts and tubes kept in stock for renewals in case of breakages, &c.

When the zinc ores used contain *cadmium*, this metal is chiefly contained in the first portions of zinc that distil over; the fume which is condensed at the same time is brownish and contains much cadmium oxide; from this fume, or from the cadmiferous zinc, metallic cadmium can be separated, best by a wet process, consisting of solution in acid, precipitation of cadmium sulphide by a current of sulphuretted hydrogen, whereby this metal is completely separated from zinc, conversion of the sulphide into carbonate by solution in acid and precipitation by an alkaline carbonate, and finally distillation of the carbonate, (or of the oxide prepared therefrom by gentle ignition) with lamp-black, whereby metallic cadimum is obtained as a distillate. Metallic cadmium, however, is but little used, the main industrial application of this element being the use of its sulphide as a brilliant yellow pigment; certain of its salts (iodide and bromide) are also employed in medicine and for photography.

THE PHYSICAL PROPERTIES OF METALS.

ONE of the most characteristic properties of metals is the power possessed by them when in more or less compact masses of acquiring (by polishing, pressure, or other mechanical treatment) such a condition of surface that light incident thereon is for the most part again reflected, whereby a peculiar glistening appearance is presented, known as the *metallic lustre.* When fused, lumps are cut with a sharp instrument, or when the metals form crystalline masses which are broken across, the severed surfaces exhibit this peculiar feature; and in many cases when the metal is obtained by chemical action from certain of its compounds, so as to form a deposit on a glass surface (*e. g.* silver), or if the vapor of the metal be condensed on such a surface (*e. g.* arsenic), the glass presents the well-known appearance of a *mirror* of more or less brilliancy according to the nature of the metal, and the way in which it is precipitated on the surface. When prepared by certain chemical processes, the metals often present the appearance of lustreless minute particles, generally black when very small. Metals in this "spongy" condition, however, can often be made to exhibit a considerable amount of brilliancy by strongly compressing a portion of the dry powder against a polished steel or agate surface, when the powder more or less agglutinates into cakes exhibiting lustre on the sides that were next to the polished surfaces; or by simply rubbing in a smooth mortar with a pestle a little of the powder, brilliant streaks are produced by the pressure. Gold, platinum, and silver in particular exhibit this property, the ordinary metals having a strong tendency, when in a fine state of division, to oxidize or rust on the surface; and this greatly interferes with the coherence of the compressed masses, and with their brilliancy when rubbed or polished. If a little spongy silver (prepared by boiling pure silver chloride with sugar and caustic soda, thoroughly washing, and drying) be placed between a pair of dies and compressed by a coining press, a slightly brittle but still coherent coin will be obtained, exhibiting considerable brilliancy on the surfaces that were in contact with the polished portions of the die-surfaces; and an analogous result is obtained if precipitated gold of a dull brown shade (thrown down by ferrous sulphate from gold chloride solution) be employed instead of silver. The peculiar lustre characteristic of metals is, however, not wholly confined to these substances; certain minerals, *e. g.* galena, and some of the non-metals, *e. g.* graphite, occur in nature in masses exhibiting a metal-like lustre when fractured, whilst selenion, silicon, and other non-metals can be artificially prepared in states where they exhibit a closely similar lustre, as can also various compound substances, *e. g.* mosaic gold (tin disulphide). The effect of pressure in heightening the brilliancy of a metallic surface is well seen in the industrial process of *burnishing;* when a layer of metal, such as gold or silver, is deposited by electrical or chemical means on the surface of an object to be silvered or gilt, it usually happens that the freshly covered surface is more or less deficient in lustre, or, as it is technically termed, "dead"; by the skilled application of pressure with a burnisher of polished steel or stone the dead surface is compressed and made to shine with brilliancy. For the final touches on electro-silvered or gilt articles, and for the gilding on china, &c., a burnisher is preferred made of "bloodstone," a compact variety of hæmatite. The ordinary household processes of cleaning and polishing steel and other metallic articles partly depend on the pressure exerted on the surface, although the main action consists in abrading, by means of a fine crystalline powder (usually prepared chalk, or peroxide of iron prepared by calcination of green vitriol or by levigation of burnt pyrites, &c.), the particles of rusted or tarnished metal, so as to display the underlying pure metallic surface.

Owing to the influence of the air, moisture, vapors arising from putrefaction, &c., metallic surfaces, even when highly polished and brilliant, become more or less rapidly tarnished, so that the power of reflecting light is to a considerable extent lost. Before the invention of glass, polished metallic surfaces were employed as *mirrors;* and for reflecting telescopes such surfaces are still in use. Now, however, it is usual to employ as mirrors glass surfaces, behind which a thin coating of some lustrous metallic mass is placed, so that the smooth surface of the glass at once determines the peculiar reflective power of the metal applied to it, and preserves the metal from mechanical injury, and from the corrosion of the air. For this reason these household appliances are ordinarily termed "looking-glasses," although, strictly speaking, it is not the glass that is the essential part. Three principal methods of applying these metallic substances to glass are in use; the best plate-glass mirrors (perfectly plain surfaces) are prepared by spreading out on a table surrounded by a deep groove or gutter, and capable of being raised on hinges so as to be placed at any angle with the horizon, a sheet of tinfoil, and smoothing it with a soft brush; mercury is then poured on and gently rubbed over the tinfoil with a hare's-foot or a roll of flannel, so as to penetrate and brighten the tin; more mercury is then poured on, and the surface cleansed from dross, &c.; finally, the perfectly clean sheet of glass is dexterously slid fluid by slightly warming it before pouring into the vessel to be silvered. It is noticeable that an alloy of three parts of potassium and one of sodium is fluid at the ordinary temperature, being the only metal or mixture of metals known possessing this character, mercury, solutions of metals in mercury, and the newly-discovered metal gallium (under certain conditions) excepted. This mixture possesses the power of adhering to the inside of a glass bottle, forming a well-defined mirror; fused stereotype metal, plumber's solder, and analogous alloys can also, with careful management, be poured into hot glass bottles and shaken over the surface so as to form mirrors of considerable brilliancy, although this method is never practically used. A method which has of late years come largely into use for silvering mirrors of various kinds, and notably the reflectors of telescopes and lighthouses, is based on the power of certain chemical reagents to throw down silver in the metallic state from certain of its solutions, &c., the reduced silver in many

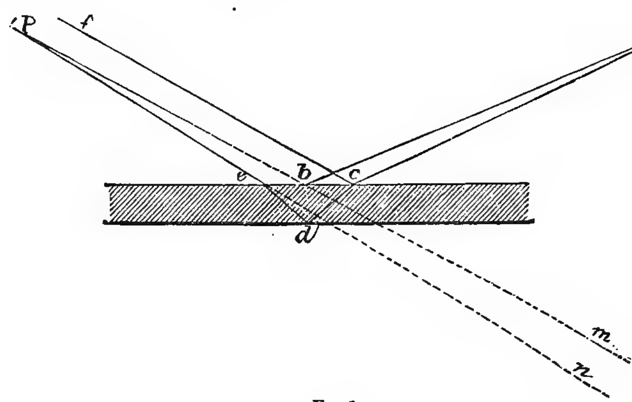

Fig. 1.

over the brilliant mercurial surface in such a way as to avoid enclosing any particles of dust or air-bubbles between the metal and glass. The table is then slightly raised at one end, so that the surplus mercury may gradually run off and be caught in the gutter; and the slope is increased daily, a piece of flannel being placed on the glass with weights on it to facilitate the draining off of the mercury. After two to four weeks, according to the size of the plate, the mirror is complete, the tin amalgam having been completely set, and being tolerably firmly adherent to the glass, although easily rubbed off and scratched on account of its slight tenacity. To preserve the back of the mirror from injury, a suitable wooden frame is provided, in which the whole is fixed, when a finished mirror is the result.

cases adhering firmly to the surface of the vessel in which the action takes place, or to objects immersed in the liquid. Thus, if calcium tartrate in a moist state be placed in a glass vessel with a crystal of silver nitrate and a drop of ammonia solution, and the mixture cautiously heated, and made to flow successively over the whole inner surface of the glass, a fine mirror may be developed. Aldehyde, oil of cloves and other essential oils, grape-sugar, and some other organic substances may also be employed as reducing agents, especially the first substance.

If a "mirror" (*i. e.* a glass surface with a brilliant metallic film behind) be carefully examined, it will be found that in most positions it will give a double image of any object reflected, one image being usually more brilliant than the

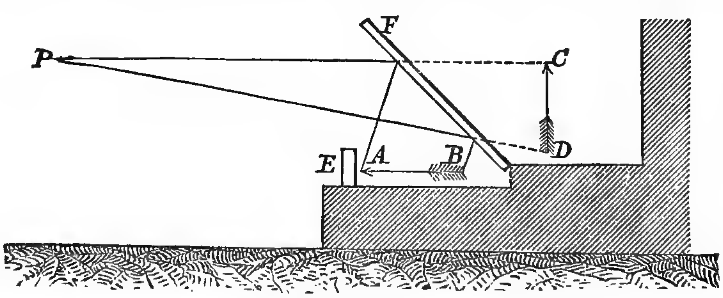

Fig. 2.

For curved surfaces, such as the insides of globes, flasks, &c., for ornamental purposes, a somewhat different plan is employed; a fluid or semi-fluid amalgam capable of adhering to glass is poured into the vessel to be "silvered," and shaken about therein until the inner surface is covered with a film of the composition; the surplus amalgam is then poured out and used for other similar objects. A mixture of one part each of lead, tin, and bismuth, with two parts of mercury, answers well, the mixture being made perfectly

other. Fig. 1 illustrates how this is brought about; a ray of light from an object at *a*, strikes the glass surface at *b*, and is reflected to the eye of the observer at *P*, so that an image is seen situated at *m*. Another ray of light incident on the glass at a point *c*, is partly reflected along *cf*, this portion of the ray consequently never reaching the eye at *P* at all; the rest of the ray enters the glass, being refracted along *cd*; at the junction of the glass and metallic surfaces reflection takes place along *de*, and at *e* the ray is refracted along *e P*, thus also reaching the eye of the observer, but necessarily causing the image formed to be seen apparently situated at *n*, a point different from *m*. The relative quantities of light passing along *e P* and *b P* (that is, the relative brightness of the two images) depend on the degree of obliquity of the incident light *c*; the greater the angle *a b P* (*i. e.* the more obliquely the light falls on the mirror), the brighter is the image at *n*. The power of glass thus to reflect light to a considerable extent without any metallic film behind is utilized in the illusion known popularly as "Pepper's ghost," which consists simply of a large pane of glass sloping forwards from the stage at an angle of about 45° (Fig. 2.) Objects such as *A B*, placed between the footlights *E*, and the pane of glass *F* in a horizontal position, and strongly illuminated, will produce to a spectator in front at *P*, a virtual image or "ghost," apparently situated at *C D*, the illusion being heightened by hiding, by means of screens, all the apparatus in front of the pane from the audience, and darkening that part of the stage behind the pane, the real objects furnishing the ghosts being placed on a dead-black ground. When the lights *E* are extinguished, and other lights illuminating the stage behind the pane turned on, the ghosts disappear, whilst the real actors at *D C* on the stage behind the pane become visible *through* the transparent glass.

Color by Reflection and Transmission.—As a rule, metals reflect visible light of all degrees of refrangibility nearly alike, *i. e.*, most metals appear of a *white* color. Copper, however, possesses the power of reflecting red rays more powerfully than others, and consequently appears red: similarly, gold possesses a bright yellow or orange color, and the alkaline-earthy metals calcium, barium, and strontium, appear slightly yellow. Brass, aluminium bronze, and other alloys of copper possess a rich yellow color, the shade depending on the composition; as a rule, the alloys of a colored and a colorlesss metal exhibit a regular gradation of tint, the color becoming less intense as the percentage of colorless metal increases. Although the light reflected from polished surfaces of most metals is nearly white, yet frequently there is a slight tinge of some color; thus whilst tin, silver, platinum, and others have a nearly pure white color, and hence appear alike when equally burnished, lead and zinc have a bluish shade, and iron and arsenic a greyish hue; these faint tints are best seen by repeatedly reflecting light from the metallic surface, as when a tube polished internally, and open at both ends, is looked into obliquely. The deepening of the yellow tint exhibited when light is once reflected from a gold surface to a red-orange by repeated reflections is readily seen by looking obliquely into an empty metal tankard gilded internally. The pigments and coloring materials largely used in the arts under the name of *bronze powders*, are mainly divers colored alloys stamped and ground to fine powders, and in some cases subjected subsequently to heating and sulphurizing processes so as to develop peculiar shades; *tinsel* is usually paper overlaid with a thin film of silver or other white alloy, and coated over with a transparent colored varnish, or is paper coated with a white or bronze powdered metal, and rolled till the surface is brightly lustrous.

Few metals can be reduced to so fine a degree of tenuity as to allow light to pass through them readily; when this can be done it is usually found that one kind of light is absorbed more readily than others, so that the transmitted light is colored, being deficient in the more absorbed rays. The transmitted light is sometimes complementary to the reflected color, or nearly so, but not invariably; thus gold can be reduced by beating to leaves of thickness not exceeding one two-hundred thousandth inch, and in this condition permits a green light to pass through the color being dependent on the amount of silver added to the gold, the light being more inclined to violet with much silver; by passing electric sparks in vacuo through glass tubes into which metal wires are fused, the glass becomes coated with a continuous film of metallic particles detached from the wires by the sparks; a film of gold thus prepared transmits a fine green light, whilst silver gives a beautiful blue shade. Copper transmits a dull green, and platinum a bluish grey; zinc and cadmium furnish a deep bluish grey, whilst iron films transmit a tint nearly neutral, but slightly brownish.

Density.—Most of the metals used in the arts in the free state are of considerable density, aluminium being by far the lightest, a circumstance which, together with its considerable strength and power of resisting the tarnishing effects of the air, renders it peculiarly suitable for numerous purposes: the draw-tubes of telescopes, opera glasses, &c., and the graduated circles of surveying instruments, &c., are often made of this metal for these reasons. According to the way in which a piece of metal has been obtained, its density will vary somewhat, being increased by hammering or any mechanical action which forces the particles together, *e. g.* wire drawing or sheet-rolling. The following table gives the numerical values of the average densities of most

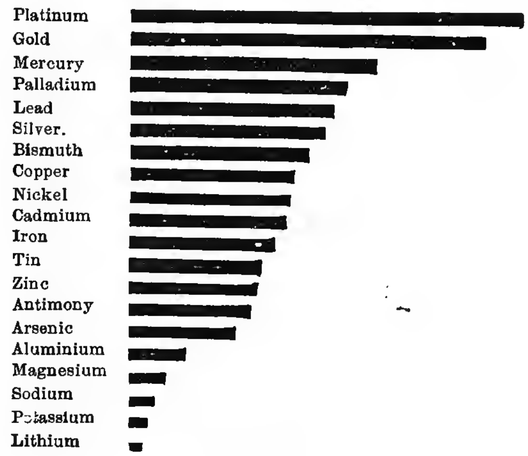

FIG. 3.

of the more important metals, whilst Fig. 3 exhibits the same numbers graphically, the lengths of the lines applied to each metal being the ratios of these numbers.

Specific Gravity of Metals (Water=1.)

Platinum	21.5	Iron	7.8
Gold	19.3	Tin	7.3
Mercury	13.6	Zinc	7.1
Palladium	11.8	Antimony	6.7
Lead	11.3	Arsenic	5.6
Silver	10.6	Aluminium	2.6
Bismuth	9.8	Magnesium	1.8
Copper	8.9	Sodium	0.97
Nickel	8.8	Potassium	0.86
Cadmium	8.7	Lithium	0.59

These numbers necessarily represent the numbers of grammes weighed by one cubic centimetre of each metal; when multiplied by 1,000 they represent approximately the number of ounces per cubic foot. Independently of the changes in density produced by differences in the state of physical aggregation of metals, alterations of temperature of course affect this property, since expansion is caused by increase of temperature, and consequently a given bulk of metal will weigh less at a high temperature than at a lower one.

It is noticeable that the specific gravity of an alloy always approximates more or less closely to that calculated on the assumption that the constituent metals hang together side by side without interference: *i.e. the bulk of an alloy approximates to the united bulks of the constituents.* Thus an alloy of equal *volumes* of platinum and aluminium would, on this assumption, have a specific gravity of 12.05, the calculation running thus:—

		Grammes.
100 cubic centimetres of platinum	weigh	2,150
100 " " " aluminium	"	260
200 " " " the alloy	"	2,410

$$\text{or, 1 cubic centimetre of the alloy weighs } \frac{2410\cdot}{200\cdot} \text{ grammes} = 12\cdot05.$$

On the other hand an alloy of equal *weights* of these two metals would have a specific gravity of 4.64.

$$\begin{array}{llll} 100 \text{ grammes of platinum occupy} & \dfrac{100}{21{\cdot}5} & = 4{\cdot}65 & \text{cubic cents.} \\ \quad 100 \quad \text{"} \quad \text{aluminium "} & \dfrac{100}{2{\cdot}6} & = 38{\cdot}46 & \text{"} \quad \text{"} \\ \hline \quad 200 \quad \text{"} \quad \text{the alloy "} & & \ 43{\cdot}11 & \text{"} \quad \text{"} \end{array}$$

whence 1 cubic cent. weighs $\dfrac{200}{43{\cdot}11} = 4{\cdot}64$ grammes.

In the case of most alloys this proposition is not exactly true, there being generally more or less expansion or contraction during the mixture of the constituents, so that the specific gravity of the alloy becomes either raised above or lowered below that thus calculated: sometimes this difference is somewhat marked, but usually it is not great enough materially to vitiate the generality of the above rule.

Crystallizability.—Some few metals readily assume the crystalline condition on slow cooling after fusion; notably this is the case with bismuth; others do not readily become crystalline, and on this property depends much of their usefulness, as a crystalline texture denotes comparative brittleness. Wrought iron occasionally passes from its normal *fibrous* texture to a crystalline state; this effect appears to be brought about by long continued vibration and subjection to blows, and has been accordingly the cause of various accidents, *e. g.* when a railway axle having become crystalline through long use, breaks owing to the diminished strength thereby caused. Many metals can be obtained crystalline when deposited from a solution by galvanic action; thus lead and silver when slowly precipitated by other metals occur in finely developed crystalline arborescences the formation of which constitutes the familiar experiments of the "lead-tree" and "silver-tree" or *Arbor Dianæ.* Many "native" metals (*e. g,* copper) occur crystallized, being presumably produced by actions of this kind. Frequently the presence of a minute quantity of a foreign metal greatly promotes the crystallization of a metal which becomes crystalline only with difficulty when perfectly pure.

Malleability and Brittleness.—Many metals are sufficiently devoid of the character known as *brittleness,* or tendency to fly to pieces when struck or pressed, to be hammered out into thin leaves, or rolled out into thin sheets; some metals are readily "malleable" at one temperature but brittle at another: in all cases the presence of minute amounts of other metals or non-metallic impurities exerts a marked influence on the degree in which this quality is possessed. Zinc is crystalline and brittle at ordinary temperatures, but can readily be rolled into thin sheets at 100°—150°, whilst at about 200° and upwards it again becomes brittle, and can be powdered in a mortar; sheet zinc for gutters, &c., is therefore rolled hot. Gold is rendered brittle by the presence of traces of antimony; and similar effects on the malleability of many metals are produced by small admixtures with certain other metals, &c. The ten chief metals all possess the power of being extended into thin sheets under the rolling press, and into leaves of greater or less tenuity under the hammer, but to very different extents; lead and zinc falling short of the others, the former on account of its extreme softness and consequent want of tenacity when reduced to thin leaves, the latter on account of the difficulty of working very thin sheets of the metal at the temperature at which its malleability is most marked. They may be thus arranged in order of malleability, the first two being nearly equal:—

Gold, Silver, Copper, Platinum, Iron, Aluminium, Tin, Zinc, Lead, Mercury (solid). It is very probable that mercury (in a frozen state) should be ranged higher up in the series; palladium, like platinum, is highly malleable, though less so than gold or silver, which possess the property to an extraordinary extent; in the ordinary process of gold-beating leaves are obtained so thin that one grain of finished leaves covers at least thirty-five square inches, whilst the extension of this metal can be pushed much further, so that coherent leaves of $\frac{1}{370{,}000}$ inch in thickness have been obtained, one grain of gold covering about seventy-five square inches: the usual thickness of English gold leaf is about double this, or $\frac{1}{200{,}000}$ inch. Silver can similarly be beaten until a given weight of metal is even more extended, one grain covering ninety-eight square inches. The leaves however are not quite so thin as gold leaves, on account of the lower specific gravity of silver. Iron has been beaten into leaves of $\frac{1}{2500}$ inch in thickness.

The manufacturer of thin leaf gold (*gold-beating*) is carried out in the following way. Gold is alloyed with small quantities of other metals according to the color required in the finished leaf; thus there were exhibited in the 1851 Exhibition, by Messrs. Marshall leaves of twelve colors grading from red to nearly white, and designated as—red: pale red: extra deep: deep: orange: lemon: deep pale: pale: pale-pale: deep party: party: and fine gold. The deeper colors are obtained with gold alloyed with from twelve to sixteen grains of copper per ounce and no silver; the middle ones with six to eight grains of copper and twelve to twenty of silver; and the paler ones with from two to twenty grains of silver, copper being omitted. As a curious fact, if silver be added to alloy containing more than eight or ten grains of copper the malleability is sensibly diminished, although no marked ill result is brought about by the addition of silver to fine gold or to gold containing only small quantities of copper. Ordinary gold leaf, such as is used for decorative purposes, contains about twelve grains of silver and nine of copper per ounce. The alloy is heated in crucibles to somewhat above melting-point, cast into ingots, and rolled into ribbons about one and a half inch wide and of such thinness that an ounce extends to a length of about ten feet: no marked difference in malleability is noticeable whether the cast ingot be cooled quickly or slowly. The ribbon is then cut into pieces weighing about six grains each, which are piled between sheets of vellum or parchment paper to the number of about 160 or 170: the *cutch* thus produced is beaten with a seventeen-pound hammer for about twenty minutes, at the end of which time the metal has become extended nearly to the size of the parchments (some three inches square). The rough squares thus formed are quartered and piled again between sheets of prepared gut (*goldbeater's skin*) forming a *shoder* (or *sholder*) consisting of some 700 pieces of metal, the contents of a cutch after quartering being all placed in the same shoder. The beating is then carried on for about two hours with a nine-pound hammer: when the leaves have become extended to the dimensions of the shoder (some four-and-a-half inches square) they are again quartered by a tool made of bamboo sharpened to a cutting edge. These quarters are again piled between fine skin five inches square forming a *mould,* the contents of one shoder filling three moulds (about 900 leaves to the mould). Finally, the mould is beaten for about two hours more till the metal extends to the edges of the skins and here and there flows over: from the finished leaf thus produced squares of three inches and three-eighths are cut from the central portions by a bamboo tool, and piled in a "book" made of soft paper rubbed over with red ochre or red chalk. During the earlier part of the beating the blows are directed mainly towards the center, which causes cracks and rents towards the edges of the leaves; these cracks, however, become perfectly closed up again subsequently as the blows fall on the other portions, the edges of the cracks *welding* together perfectly, so that the finished leaf exhibits no trace of them. The leaves first begin to show light through when the thickness is about $\frac{1}{150000}$ inch, the color being green with gold containing little or no silver, but verging towards pale violet when much of the latter metal is present. The beating is rarely continued until the leaves are less than $\frac{1}{200000}$ inch in thickness, as the saving of the precious metal hardly compensates for the extra labor and the greater waste (through spoiled leaves, and the "pouring over," at the edges of the mould); moreover the thinnest possible leaf does not "cover" so well, being more translucent. Fine gold beats as well as, but not better than that containing small quantities of alloy, whilst it is superior in welding power, so that the leaves are more apt to stick together when one part touches another, and so on. The "mould" skins when old are generally employed for the "shoder," in which the excellence of the skin surface is not of such moment.

Ductility.—Although the property of being drawn into wire is closely allied to that of being rolled or hammered into foil and leaves, yet the two are not necessarily possessed to equal extents by the same metal; gold, silver, and platinum are pre-eminently "ductile," whilst copper and iron are but little inferior to them in this respect. Aluminium and zinc can be obtained in tolerably thin wire, whilst lead and tin have so little cohesion that they cannot be drawn beyond a very limited degree of fineness. On the small scale, wires are readily obtained by casting the metals into thin pencils,[1] slightly pointing the ends of these and passing them into a funnel-shaped hole in a steel plate (*draw-plate*) of suitable size, gripping with pliers the protruding pointed part, and forcibly pulling the whole bar through the hole, the process being then repeated with a slightly smaller hole. Fig. 5

Fig. 5

represents the section of the draw-plate through the holes; a series of holes are generally worked in the same plate, gradually diminishing in diameter from one end of the plate to the other, the complete perforated plate being often termed a "jigger." To obtain greater steadiness in the pull, the pliers should be attached to a band or cord which is gradually wound up on an axle by a handle, the pliers being so constructed that the greater the force required to draw the wire through, the more firmly they grip the end of it: this is easily effected by turning up the handle ends (the panel in which the jaws open being horizontal) and passing over them a triangle of iron to the base of which the band is attached (Fig. 6): the greater the strain on the band, the more firmly is the wire held: the draw-plate is kept in position by being pressed against two vertical projections or "chucks." It is generally necessary to "anneal" the wire from time to time, otherwise it becomes hard or more or less liable to crack or break after having passed through a certain number of holes: "hard-drawn" (or unannealed) wires, however, are usually considerably more capable of resisting tensile strains than the same wires after annealing.

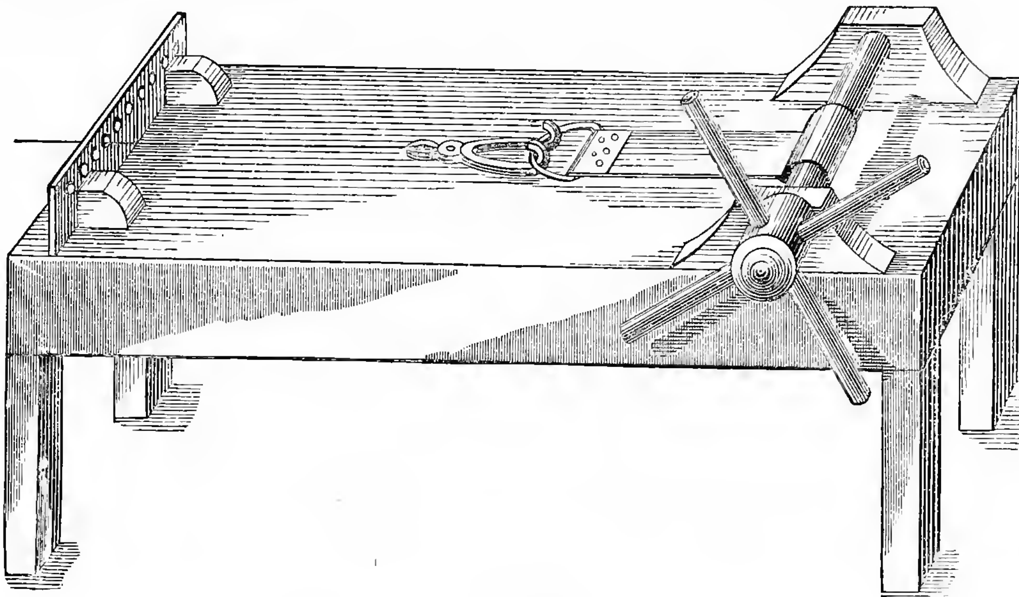

Fig. 6.

In drawing wire on a manufacturing scale, the process is just the same in principle, only, instead of drawing the wire through the draw-plate by hand by means of a wheel and axle, &c., the wire is pulled through by hand with pliers for a foot or two, and this portion then fastened to a revolving drum which then pulls the rest of the wire through, coiling up the drawn out portion on the drum; the wire is then passed through the next smaller hole, being uncoiled from the first drum, and coiled again on a second in so doing, and so on until drawn to the required degree of fineness. In this way the great lengths of wire are drawn at one operation.

Wollaston succeeded in obtaining wires of platinum, gold, and iron of excessive tenuity by first drawing the metals into fine wire, and then casting round this wire a cylinder of another metal, and drawing the compound cylinder again to the utmost possible extent; both the outside metal and the internal wire were thus elongated together; finally, the outside metal was dissolved off by some appropriate solvent, and thus the internal wire was left. To prepare the platinum and gold wires silver was used for the external cylinder, the silver being finally dissolved off by nitric acid. To make the iron wire, silver was also used for the cylinder, but was ultimately dissolved off by means of mercury. In this way a platinum wire was obtained less than $\frac{1}{30000}$ inch in diameter. Some metals require to be heated in order to acquire sufficient softness to enable them to be readily drawn into wire; thus with aluminium. Others are in practice often used in a heated state to facilitate the operation, although the heating is not essential to the ductility of the body. Thus with steel and iron wires or rods of considerable thickness, the "drawing" operation being modified into a kind of rolling, the hot metal being passed between grooved rollers of successfully smaller and smaller grooves. Those alloys which are brittle are necessarily non-ductile, but alloys which are malleable are usually more or less ductile. Brass, a particularly malleable alloy, is also excessively ductile, wires of this alloy having been drawn so fine by means of an ordinary drawbench that seven feet of wire only weighed one grain. It is noticeable that "virgin" brass (made by mixing fresh copper and zinc together, not by remelting old alloy, &c.) is much more ductile than other kinds of brass, even though apparently of the same chemical composition. Many metals which are only drawn into wire with difficulty, can be obtained in a wire-like form by an ingenious process called "squirting." The metal is melted and allowed to cool, and when close upon the solidifying point is forced by mechanical means (hydraulic pressure, &c.) through an orifice of the requisite diameter; the metal, coming in contact with the air, is quickly chilled, and solidified to a wire or rod, which is wound on a drum as fast as it is prepared. By an appropriately formed jet or orifice a long continuous *tube* may be squirted instead of a rod. In this way the ordinary tin, lead, and "compo" tubing used for gas, water, spirits, &c., is manufactured, as is also magnesium wire. Rifle bullets are made by squirting lead into rods half an inch thick

1 For metals of moderately-low melting-points the fused substance may be drawn up into a hot thin glass tube or pipe-stem by suction, and allowed to solidify therein. By fusing the metal in the bowl of a tobacco-pipe and tilting this so that the stem is inclined downwards, the molten metal can often be made to form a rough wire or thin rod in the stem, readily obtainable by breaking away the pipe-clay after cooling.

or so, from which portions are cut off and squeezed into shape by machinery.

Tenacity.—The more crystalline a metal or alloy is the less its power of resisting strains and stresses of various kinds; the more fibrous in structure the better it will resist strain, especially in the direction of fibres.

By forming metals into wires of equal dimensions, and then determining the weight requisite to break these wires, the differences in tenacity exhibited by metals and alloys may be readily demonstrated. A convenient apparatus for this purpose is made of an iron tripod six or seven feet high (Fig. 6), the legs of which are stayed together at the bottom and in the middle; from the top of the tripod is suspended by a stout hook a dynamometer or spring balance furnished with a hook at the bottom, whilst about half way up the tripod is affixed a horizontal axle, supported by the stay in such a position that the centre of the axle is perpendicularly beneath the hook of the dynamometer. This axle is provided with a winch, and round it is coiled a stout rope or leather band with a hook at the end. The wire to be tested is formed into a ring about three or four inches in diameter, the ends being intertwisted and soldered together; the hooks attached to the bottom of the dynamometer and to the rope are then inserted in this ring, and the handle turned so as to wind up the rope and stretch the ring until its form becomes a narrow oblong. The tension is then increased by winding the rope until the wire breaks; the reading of the dynamometer is noted by an assistant at the moment of rupture.

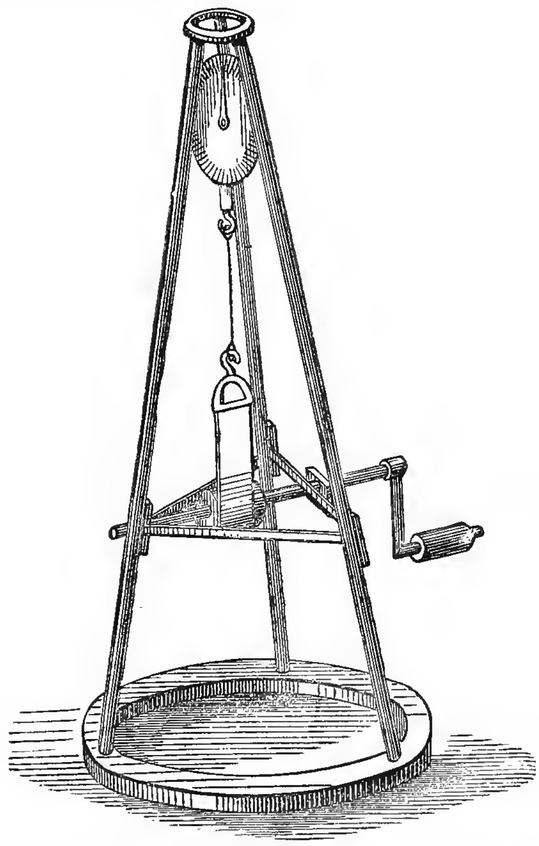

Fig. 6.

In this kind of way the order of tenacity of the metals is found to be as follows:

25 Iron.
16 Copper.
14 Platinum.
12 Aluminium.
10 Silver.
8 Gold.
7 Zinc.
1.5 Tin.
1 Lead

These numbers represent the relative average breaking strains of wires of the same dimensions. The actual value obtained with any particular wire, however, is largely influenced by the purity of the metal, by the character of the strain (whether applied suddenly, or slowly and gradually), and by the physical condition of the wire (whether hard drawn or annealed). Thus, Wertheim [1] obtained the following values representing the weights in kilogrammes required to break wires one square millimetre in section:—

	Gradual strain.	*Strain suddenly applied.*
Cast Steel, hard drawn	—	83·8
" annealed	65·7	—
Piano wire (steel)	70·0	99·1
" annealed	40·0	53·9
Iron wire, hard drawn	61·1	65·1
" annealed	46·9	50·3
Copper wire, hard drawn	40·3	41·0
" annealed	30·5	31·7
Platinum wire, hard drawn	34·1	35·0
" annealed	23·5	27·7
Palladium wire, hard drawn	—	27·2
" annealed	27·4	—
Silver wire, hard drawn	29·0	29.6
" annealed	16·0	16·5
Commercial zinc, drawn	12·8	15·8
" annealed	—	14·4
Pure zinc, cast	4·5	—
Gold wire, hard drawn	27·0	28.4
" annealed	10·1	11·1
Cadmium, drawn	2 24	—
" annealed	—	4·8
Lead, cast	1·25	2·21
" drawn	2·07	2·36
" annealed	1·80	2 04
Tin wire, hard drawn	3·45	3·00
" annealed	1·70	3·62

Somewhat different values have been obtained by other experimenters, the difference being probably mainly due to the presence of minute traces of impurity in the metals examined, etc. Thus Matthiessen gives the following values, somewhat different from the above. The numbers represent the number of pounds weight required to break hard-drawn double wires, No. 23 gauge.

Steel	above	200
Iron		80—90
Platinum		45—50
Silver		45—50
Copper		25—30
Gold		20—25
Tin	under	7
Lead	"	7

Wires sometimes vary very much in tenacity at different temperatures; as might be anticipated *a priori*, those metals which melt most easily become most weakened on heating. Thus Wertheim (*loc. cit.*) found the following values for various annealed wires (as before in kilogrammes per wire of one square millimeter section.

	At 15°.	*At* 100°.	*At* 200°.
Iron	46 9	51·1	46·9
Copper	30·0	22·1	—
Platinum	23.5	22·6	19·7
Silver	16·0	14·0	14·0
Zinc	14·4	12·2	7·3
Gold	10·1	12·6	12·1
Cadmium	4·8	2·6	—
Lead	1·8	0·5	—
Tin	1·7	0·85	—

Thus lead, tin, cadmium and zinc, which melt the lowest of the above, are from only one-half to one-third as strong at 200° as at 15°; copper, silver, and platinum are much less weakened on heating; whilst iron and gold are actually stronger at 100° than at 15°, and are but little weaker at 200° than at 100°.

Certain alloys possess much greater strength than their constituents, and on this property depends much of their practical use; thus gun-metal, standard gold (gold copper alloy), a silver platinum alloy used for electrical purposes, steel, and phosphor bronze (which last two may be regarded as analogous to alloys) are much more tenacious than either of their constituents severally: thus Matthiessen found the following values (as before in pounds per double wire, hard drawn, No. 23 gauge).

[1] *Annales de Chimie,* [iii.] xxii. 440.

Metals Separately.		*Alloys.*	
Copper	25–30	Gun-metal containing 12 per cent. tin	80–90
Tin	under 7		
Copper	25-30	Standard gold: gold copper alloy, (22 carat gold)	70–75
Gold	20–25		
Silver	45–50	Silver platinum alloy (⅔ silver, 3 platinum)	75–80
Platinum	45–50		
Iron	80–90	Steel	above 200

As a general rule, however, the effect of alloying metals together is to impair their tenacity; thus gold is rendered brittle by the presence of a trace of antimony, and an alloy of two parts tin and one of platinum is quite brittle. As already stated, the union of non metals with metals usually wholly destroys the metallic characters, and in particular this chemical union usually gives rise to a product possessing but little toughness and tenacity, such as is requisite for manufacturing purposes, (such products as glass, earthenware, bricks, and various minerals, etc., excepted). Steel and phosphor bronze, however, as above stated, form notable exceptions to this rule, the presence of one per cent. or less of carbon in the first, and of a like quantity of phosphorus in the second, communicating to the substances iron and bronze a considerably greater power of resisting wear and tear and other special qualities. The accurate determination of the tensile strength of wire ropes, bars, etc., of their power of resisting crushing and transverse strains, bending and twisting agencies, etc., is of very great importance to the architect and engineer. Ingenious and powerful machinery for this purpose has been constructed by Mr. David Kirkaldy,[1] whose machines will measure any kind of strain or stress from ten to one million pounds, applied not only to metals but to wood and building materials generally. Modifications of this testing machinery are employed in some iron works, etc., for the purpose of continually examining the strength and value of certain of the products, (*e. g.* Bessemer rails and the like).

Other Physical Properties.—Closely connected with the physical structure which enables metals to exhibit the phenomena of crystallization, malleability, and ductility is the power which some possess of returning to their original shape when deflected therefrom by some external force not too great (*elasticity*); a property possessed to an extreme degree by good steel. The operations of wire-drawing, rolling, hammering, and the like generally increase the elasticity of metals, whilst annealing and fusing usually diminish it. Some metals are almost wholly devoid of elasticity; thus lead scarcely exhibits a trace of this property, being so soft that it is readily abraded by the nail. Some metals and alloys, when worked into appropriate shapes and struck, continue vibrating for some time, and hence are powerfully *sonorous*, (*e. g.* aluminium, bell-metal, steel, standard gold, etc).

The chief value of many metals and alloys for industrial purposes lies in their possession to a greater or less extent of a combination of properties of somewhat opposite kinds; whilst they possess sufficient rigidity to keep their shape even with moderately hard usage and to bear "wear and tear," when once fashioned into articles of domestic and everyday use, they have power of yielding to pressure, &c. to a sufficient extent to enable them to be readily worked into these forms. In some cases the requisite softness for this latter purpose is hardly attained until the temperature is considerably raised; thus most articles of wrought iron are made when the metal is softened by heat so as to yield readily to percussion (*forging*) and other shaping processes. Closely connected with this softening or incipient conversion into a pliable mass of heat, is the phenomena of *welding*, or the adherence together of two separate metallic masses when united by pressure in such a way as to form a joint as strong as the other parts. Iron and plantium possess this power at a high temperature; sodium and some of the rarer metals at the ordinary temperature; gold also can be welded cold, under certain conditions, as in gold-beating. On the possession of these properties depend most of the metal-fashioned crafts, those where the metals are fused and cast being the main exceptions.

Thus in the manufacture of steel pens, as carried out by Messrs. Gillott & Sons, there are no less than eighteen stages between the conditions of bar steel and finished pen; and most of the stages are different applications of these properties of metals in reference to the shaping of the material into the required form. The bar steel is first converted into thin sheets, which are again rolled to the requisite degree of thinness; from the rolled steel "blanks" are punched out by a machine, leaving a kind of skeleton or network of "scrap steel" (Fig. 7), which is melted up or welded together and used over again. Two "side slits"

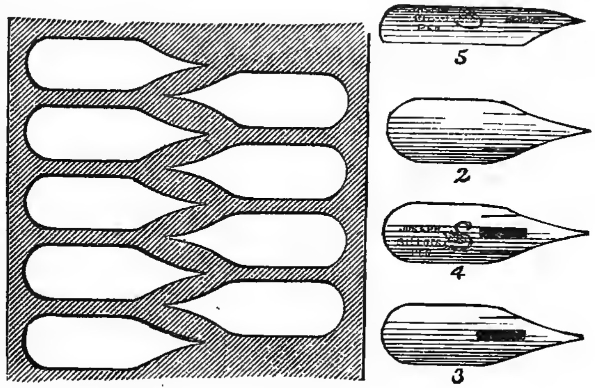

Fig. 7.

are then made in the blank (No. 2), and a somewhat wider centre slit (No. 3) pierced, a portion of metal being punched out in making the orifice; the metal is then annealed and marked with the maker's name; a device or trade mark is raised by embossing (No. 4), and then the hitherto flat pen is converted into a portion of a cylinder, or curved (technically, "raised") by a suitable machine No. 5); after which it is hardened, tempered, and cleaned by scouring with emery, &c.; the tip is then "straight-ground," *i. e.* the metal is thinned at the writing end by grinding in the direction of the length of the pen, after which it is "cross-ground," in the transverse direction. Finally the slit from the nib to the punched-out central part is cut, and the pen is colored and varnished for sale. Similarly the production of an ordinary pin necessitates a number of stages in the shaping process, which is thus carried out by Messrs. Taylor of Birmingham. Virgin brass having been cast into thin elongated bars, is drawn into wire of the required diameter, which is supplied to the pin-making machine from a drum on which it is coiled. The end of the wire is adjusted to the machine, which gradually draws it through a series of pegs so arranged as to straighten the wire and take the curve from the drum out of it; the wire next passes into a kind of die, when a rapidly acting hammer strikes the slightly projected end in such a fashion as to flatten it out and fit it into an expansion in the end of the die groove forming the "solid head" (formerly the head was made of a coil of thinner wire slipped over the pin wire, and hammered into shape; such heads were liable to come off). The head being completed, a knife cuts off the proper length from the wire, and the partially made pin is detached from the die and falls into a groove in which it is suspended by the head whilst the other end is abraded to a point by a kind of revolving cylindrical file. All these operations are performed automatically by the machine, and so rapidly that 200 complete pins are turned out of the machine per minute. Finally the pins are cleansed by agitation in barrels with fuller's earth and water, washed, and coated with tin by boiling with granulated tin and cream of tartar, &c.

Again the manufacture of table-spoons and forks, many kinds of brass-work, cutlery, percussion-caps, copper pans and kettles, medals and coins, and a thousand-and-one articles of every-day use, all depend upon the possibility of forcing the metal into various shapes without fracturing it, by mechanical processes, such as forging, punching, pressing, embossing, and the like. One of the prettiest illustrations

[1] Testing and Experimental Works, 99 Southwark Street, S. E. The specimens in Mr. Kirkaldy's museum, illustrating the results arrived at with many years' employment of his testing machinery on all sorts of material, are of a most interesting and instructive character.

of the application of pressing and shaping force as afforded by the processes in use for "tea-pot spinning," *i. e.* the production of Britannia-metal teapot by a process technically termed *spinning*.

The alloy being rolled into sheets of convenient thickness, a circular disc is cut out and placed in a kind of lathe as represented in Fig. 8, the metal disc being pressed against a

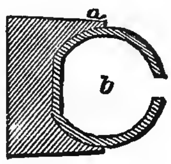

Fig. 8.

nearly hemispherical wooden chuck *a*. The lathe being set in motion the workman presses against the off-side of the disc with a peculiarly shaped tool *b*, held steadily by means tools held one in each hand and applied, the one within and other without the rim of the bowl, the metal is gradually bent inwards as it revolves, so as finally to take an almost globnlar shape; Fig. 10 indicates the closing state of this operation, the nearly globular bowl thus formed being shown in section in Fig 9 *b*. Finally the lid, spout, handle, &c, are attached, and the whole brightened and polished for the market. During the spinning the edge of the disc, some forty or fifty inches in circumference, becomes diminished to almost half that in the bowl, and to about one quarter in the globular pot, the metal being thus as it were pressed in upon itself, as well as somewhat extended, the superficial area of the outside of the globular pot being somewhat greater than that of one side of the circular disc used in the first instance. In a similar fashion jugs and analogous vessels are "spun up," out of plates, the lips for pouring being subsequently shaped by carefully hammering or pressing out the metal on a wooden or metal mould. Silver articles, *e. g.* bowls, teapots, &c., are frequently curved by an analogous operation; the second stage, however, cannot so well be ap-

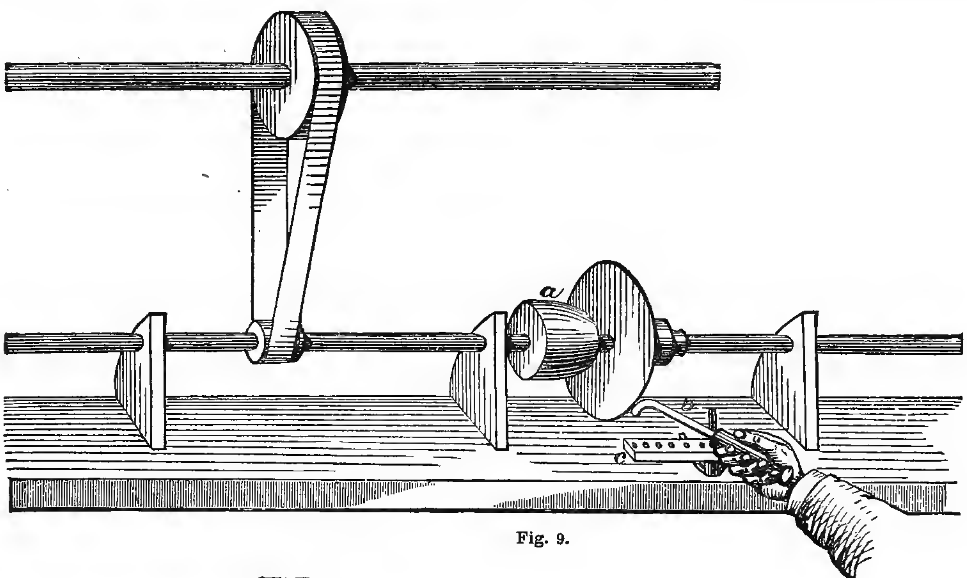

Fig. 9.

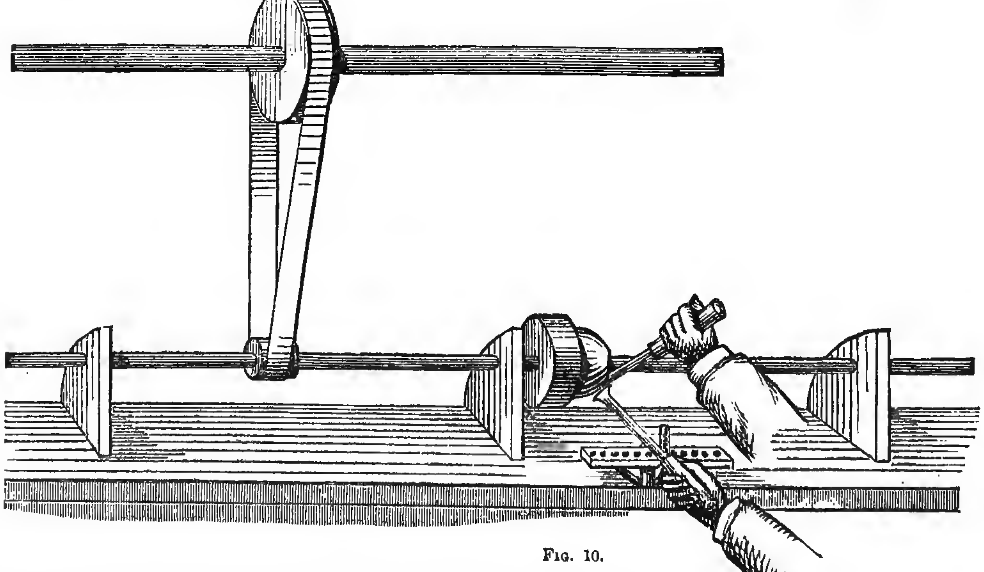

Fig. 10.

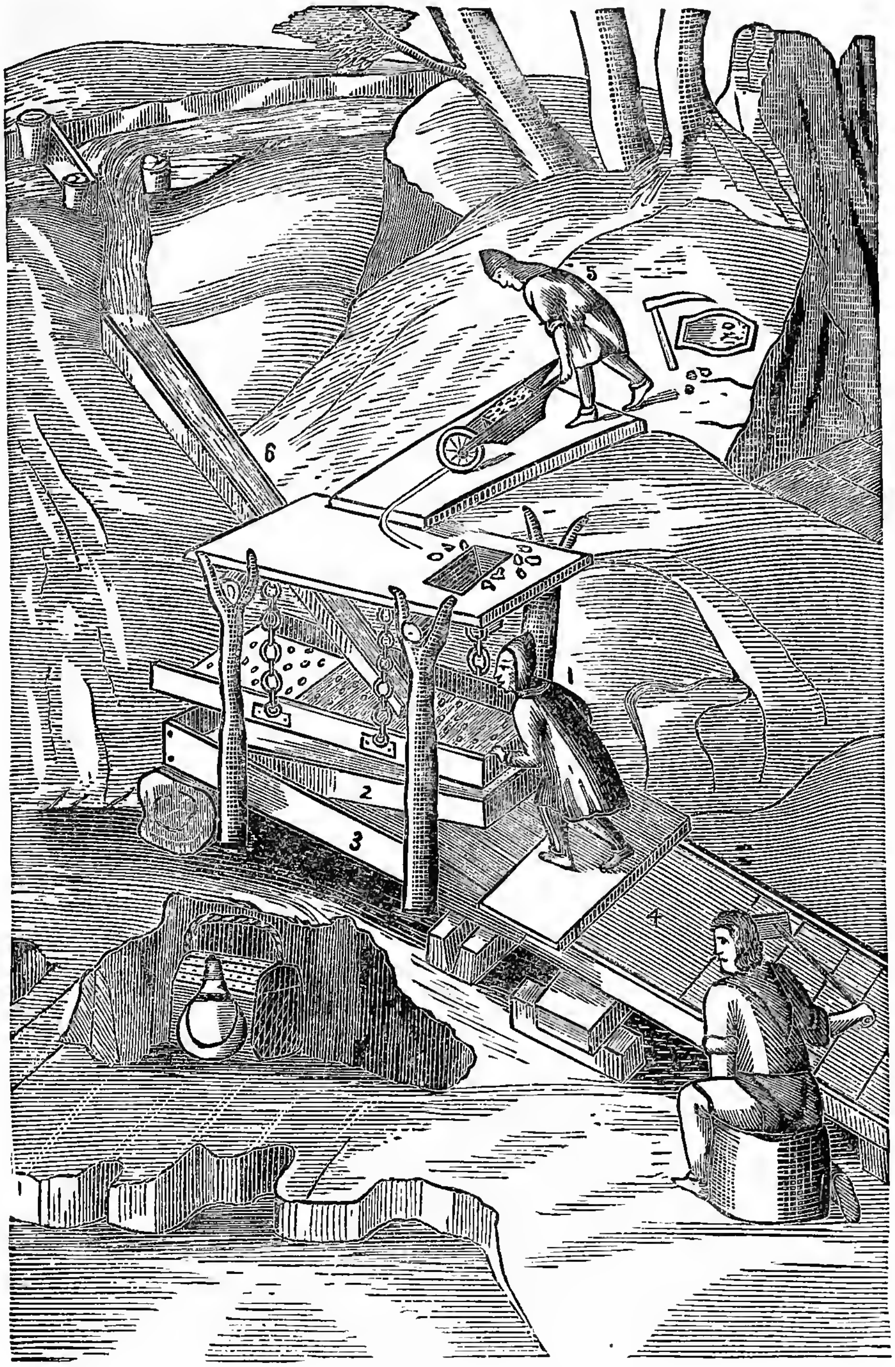
of the rest, *c*, so as gradually to bend the disc over the mould, *a*, and so to convert the disc into a bowl. The bowl thus formed is taken off the lathe and set with the convex part fixed into the concavity of a hollowed-out chuck (shown in section *a* Fig. 9); by the aid of two diffierently shaped plied to silver, so that if a closed-in vessel is required like a teapot, it is usually made in two halves, neatly soldered together.

—*Compiled from "Metals and their Chief Industrial Applications.*

WASHING GOLD ALLUVIA 200 YEARS AGO.

DURING the spring of 1881 Mr. Melville Attwood F. G. S. read before the California State Geological Society a paper "On the Milling of Gold Quartz" which contained the following interesting statement:



MACHINE FOR WASHING GOLD ALLUVIA 200 YEARS AGO.

"If we search the records of past times, we shall find that a great deal has been done years ago, which might be applied with great advantage even at the present time, in proof of which examine the drawings which I have brought for your inspection. The engraving I copied from Sir John Pettus' book on the "Laws of Metals, &c.," published in 1683, nearly 200 years ago. You will see how much better it is calculated to wash gold alluvia than our modern rocker.

An explanation of the engraving, taken from the book referred to, is as follows:

1. The man that worketh with the rattar.

2. The middle floor whereon that which goeth through the rattar doth fall.

3. The lower floor whereon that which cometh from the middle floor doth fall.

4. The plain receiver of that which falls upon both.

5. The person that stands on a board and out of a wheelbarrow throws the matter or ore, into the tunnel which guides it into the ratter.

6. The channel in which water doth run into the rattar.

"Then some of the gold washers use upon their hearths the strong timode black and russet woolen cloth, over which they drive their works, because the woolen cloth is rough and hairy, so that the small and round grains of gold will remain, and not run forth (as it will from the timode), whereby the gold upon the black cloth may apparently be known, though it be small and little. Others use instead of the timode or black woolen cloths, linsey-woolsey (half linen and half woolen; wrought in the manner as the timode is), upon which the gold doth stick better, and such cloths do last longer, because of the linen that is among the woolen, which doth strengthen it; therefore it is better for this work."

HYDRAULIC MINING IN CALIFORNIA.

IN crossing ravines, flumes or wrought iron pipes are used. Many miners object to flumes on account of their continual cost and danger of destruction by fire. Where used, and practicable, they are set on heavier grades than ditches, 30 to 35 feet per mile, and, consequently, are proportionately of smaller area than the ditches. In their construction a straight line is the most desirable. Curves, when required, should be carefully set, so that the flume may discharge its maximum quantity. Many ditches in California have miles of fluming. The annexed sketch will show the ordinary style of construction.

The planking ordinarily used is of heart sugar pine 1½ to 2 inches thick, and 12 to 18 inches wide. Where the boards join, pine battens 3 inches wide 1½ thick cover the seam. Sills, post and caps support and strengthen the flume every four feet. The posts are mortised into the caps. The sills extend about 20 inches beyond the posts, and to them side braces[1] are nailed to strengthen the structure. This extension of the sill timbers affords a place for the accumulation of snow and ice, and in the mountains such accumulations frequently break them off, and occasionally destroy a flume. To avoid damages from slides, snow and wind storms, the flumes are set in as close as possible to the bank, and rest, wholly or partially, as the general topography and cost will admit. Stringers running the

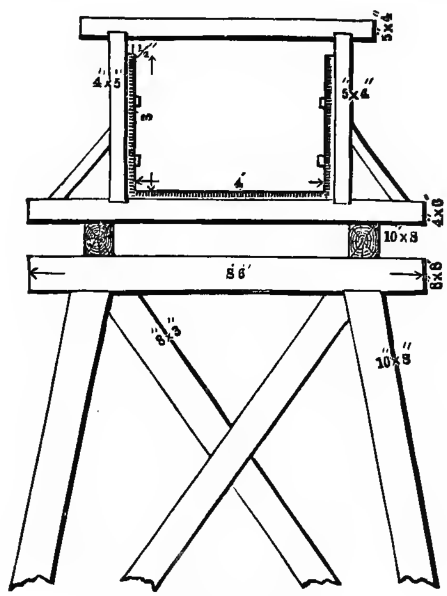
Pipe 30 in dia. Circular Seams single riveted, longitudinal seams double riveted. Manufactured by the Risdon Iron and Locomotive Works, S. F. Cal.

entire length of the flume are placed beneath the sills just outside the post. They are not absolutely necessary, but in point of economy are most valuable, as they preserve the timbers. As occasion may demand the flume is trestled, the main supports being placed every eight feet. The scantling and struts used are in accordance with the requirements of the work.

[1] Side braces and extra extension of the sill are in many cases only an unnecessary expenditure of money.

Wrought Iron Pipes.—The use of sheet iron pipes for conveying water in large quantities originated with the hydraulic miner. The insignificant weight, coupled with their great strength (tensile), admirably adapted them to the service for which they have been employed.

The general sizes of the pipes used in the mines are 40, 30, 22, 15, and 11 inches in diameter, of riveted light sheet iron, No. 16, 14, or 12 iron, Birmingham gauge, made in lengths of about 20 feet, and put together in a stove-pipe fashion, neither rivets nor wire being used to hold the joints in place.



SKETCH OF FLUME.

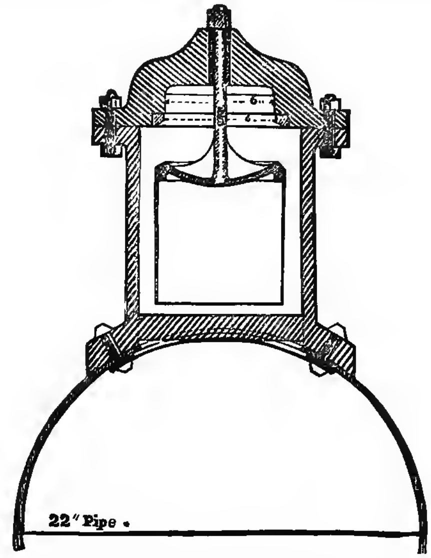
These pipes are light and can be readily and cheaply moved; this in hydraulic mining is of great importance, as it is often requisite to change the position of the lines of pipe. Pipe put together in this rough manner will remain tight when subjected to even as great a pressure as 240 pounds to the square inch. When the pressure requires it, lead joints are used. (See sketch.) *A* represents the pipe; *B* the iron sleeve, between which and the pipe the lead, represented by the dotted lines, is poured. *C* is the flange, bolted to one length of the pipe on the inside for the other pipe to fit over, as shown. Though roughly made and of very light iron, this kind of pipe (connected more like stove pipe than water pipe) is found in practice to be more serviceable, and from its form floating particles of matter readily render it water-tight. Such a pipe, 12 inches in diameter made of No. 18 iron is riveted in the longitudinal seams every 1 to 1¼ inches, whilst in the round seams the rivets may be as much as three inches apart; the rivets small ones, one-eighth or an inch in diameter, showing daylight between the iron, but after water has run through the pipe a short time nearly every leak stops. If necessary, however, 1 or 2 bags of sawdust and a few shovelfuls of earth put in the inlet, will usually make all tight.

This class of pipe is now being replaced by one of better make on which the round seams are made with rivets three-quarters of an inch apart, and the longitudinal seams are double riveted with rivets one inch apart in the row, and with about one-half inch apart from one row to the other. If riveted with care such pipes, after being dipped in an asphaltum bath, are excellent and will last for many years. For the asphaltum bath the following preparations can be used:

Crude asphaltum	28%
Coal tar (free from oily substances)	72%
Or,	
Refined asphaltum	16½%
Coal tar (free from oily substances)	83½%

When the mass has been boiled to a proper consistency, and by test the coating is found to be brittle, it at once indicates that the mixture has been boiled too hot, or that there was too much oil in the tar or asphaltum. After the pipes are dipped they are raised out of the bath and the superfluous asphaltum allowed to drip off, so there is no waste.

Thickness of the Iron, Rivets, Etc.—The thickness of the iron is usually proportionate to the head of water and the diameter of the pipe. Pipes made of the different sizes of iron here mentioned will stand the following strain per sectional inch:



AIR VALVE FOR 22-INCH WATER PIPE.

No. of Iron.	*Made to stand strain per sectional in. Lbs. avd'ps*
12	7,000 to 9.000
12 to 9	9,000 to 12,000
9 to 3-16	12,000 to 14,000
¼ to ⅜	17,000 to 18,000

The head of the water in pounds avoirdupois, multiplied by the diameter of the pipe in inches and divided by the above co-efficients, gives twice the thickness of the iron to be used. Allowance must be made for the security required; that is, if the breakage of the pipe will cause much damage, it is advisable to lower the margin for greater safety.

The diameter of the rivets used are

No. 18	*No.* 16	*Nos.* 14, 12, 11	*Nos.* 10, 8, 7,	¼ in.	5-16 in.	⅜ in.
5-92 in.	6-32 in.	5-16 in.	⅜ in.	½ in.	⅝ in.	¾ in.

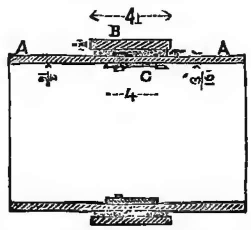
and are usually spaced to make the pipe light, that is, closer than is necessary for the strength of the seam; but this in turn is governed by the pressure on the pipes.

When the pipe is made and put in position, air valves are provided to allow the escape of air from the pipe whilst filling, and especially to prevent any collapse should a break occur. These valves are of many forms, the most usual being a piece of leather loaded and forming a valve opening to the inside of the pipe, and when shut covering a plain hole of from one inch to four inches on the top side of the valve. Where required a better class of valve is used, which sinks and opens when the water leaves it, and floats and shuts when the water rises up to it. (See sketch.) An important point is the admission of the water in the pipe in such a way as to prevent air from being sucked into and travelling along the pipe, which will happen and in large quantities unless the water is regulated. The best plan is to put a gate in the pipe a little below the level where the water enters it, and regulate the flow by this gate, and by this means a steady pressure without violent oscillation can be obtained. Usually, however, the water first flows through a funnel-shaped pipe, which allows the air to escape as it enters, and with a little care this can be made to answer very well. In some instance an air or stand pipe is put in a distance from the entrance or inlet. This catches the air as it travels along the top of the pipe and allows its escape.

The following table shows the usual distances of rivets for corresponding thickness of iron; items relate to 22-inch wrought-iron pipe:

Thickness of the Iron used.	*Diameter of the Rivets.*	*Length of the Rivets.*	*Pitch of the circle seams.*	*No. of Rivets in each circle seam.*	*Pitch of the rivets in the longitudinal seams or double row.*	*Width between the centers of the rivets in the double row.*
No. 12	5-16 in.	⅜	1 in.	69	1⅜	⅝ in.
No 11	5-16 in.	⅝	1 in.	59	1⅝	⅝ in.
No. 9	⅜	1 3-16 in.	1 3-16 in.	59	1 7-16 in. full	⅝ in.
3-16 in.	½	1¼ in.	1 7-16 in.	33	1 11-16 in. full	1 1-10 in.
¼ in.	½	1½ in.	1 7-16 in.	39	1 1 -16 in. full	1 1-10 in.

The accompanying figures[1] given in tabular form show the details of construction of wrought iron pipe 18 inches in



LEAD JOINT FOR PIPE.

diameter, 5,800 feet long, manufactured by the Risdon Iron and Locomotive Works, San Francisco, for the Spring Valley Water Company, which supplies the city of San Francisco. The information here afforded to mechanical engineers is sufficiently explicit for the construction of wrought-iron pipes.

This pipe has a tensile strain of about 5,000 or 6,000 pounds per sectional inch, and has been made with this low coefficient in order to withstand the pulsation caused by a single acting plunger pump, making as high as 36 single strokes (four in length) per minute.

These oscillations are found in practice to run from five to nine pounds per stroke when the air vessel is properly charged, otherwise by carelessness it may exceed 50 pounds per stroke.

At Cherokee there is an inverted siphon of wrought iron. The pipe has an approximate inner diameter of 30 inches, discharging 52 cubic feet of water per second. It has been in continuous use for five years, and now in first-class order. The iron used was ordinary English plate of fair quality. The greatest pressure it sustains is 887 feet, and the thickness of the iron at that point is three-eighths of an inch.

The annexed[2] plan, taken from the original survey on file in the office of the company, shows the line of the pipe and different sizes of iron used in construction of the siphon. The maximum strains on the several sizes of iron used are given in the following table.

Size of Iron.		*Greatest Pressure.*		*Maximum tensile strain on iron per square inch in pounds.*
No.	*Thickness in decimals of an inch.*	*Feet.*	*Pounds.*	
14	.083	170	74	13.374
12	.109	288	125	17,202
11	.012	293	127	15,875
10	.134	355	154	17.240
3-16	.187	435	188	15,080
½	.250	594	257	15,420
5-16	.312	842	365	17,594
¾	.375	887	384	15,360

The Virginia Water Company, Nevada, have constructed a similar wrought iron siphon, 11½ inches in diameter. The maximum pressure in its greatest depression is 1,720 feet, equal to 750 pounds per square inch. The thickness of the iron at the lowest point of depression is No. 0. The pipe was hot-riveted, ⅝ inch rivets, double row on straight seam and single row on round seam. This pipe, when tested, is said to have stood a pressure of 1,400 per square inch.[1]

A paper by Augustus J. Bowie, Jr., A. B. Transaction American Institute of Mining Engineers.

[1] The data were obtained from Joseph Moore, M. E., Supt. of the Risdon Iron and Locomotive Works, under whose immediate direction the pipe was constructed.

[2] The *Mining and Scientific Press*, of January 7, 1871, contains a detailed account of the construction of this pipe, and also gives a diagram of the line.

[1] The Virginia City Water Company has constructed a second siphon, made of lap-welded pipe, 10 inches inner diameter, ¼-inch iron, and placed it alongside the siphon already built.

MECHANICAL AND LEGAL HISTORY OF HYDRAULIC NOZZLES.

A CURIOUS legal contest which has, for a number of years, been waged over a patented machine, has recently been decided by Judge Sawyer, of the United States Circuit Court, District of California. It involved the title and ownership of the famous hydraulic mining machine known as the Little Giant, heretofore made and sold by Richard Hoskin, of Marysville, Cal., but which was formerly made and sold by R. R. & Joseph Craig, of Nevada City. This machine has done more to encourage and develop the hydraulic mining industry of the world than all other causes. It solved the problem of practically handling large streams of water under great pressures, which is a necessity in working our large hydraulic claims on a profitable scale.

Some of our readers may not understand the nature of the work that such a machine is called upon to perform. Some idea may be gathered from a mere statement of the circumstances under which they are used. In some of our large mines the reservoir from which the water is taken is 300 feet above the point where the water is to be used, and the water is conducted from this reservoir to the Little Giant, or hydraulic machine, through large sheet-iron pipes, which in some cases are two feet in diameter. Before the water reaches the Little Giant it is under an enormous pressure, and it issues from the nozzle of the machine with such force that it is projected in a solid stream from 100 to 150 feet against the bank to be washed and literally carries all before it. So compact and solid is the stream near where it issues from the nozzle, that a person could no more strike a heavy crowbar through it than he could through an equal body of iron or steel. Sometimes the banks are very high, in which case the Giant must be kept at a respectful distance from it, otherwise it is in danger of being buried when the bank caves or falls in. The usual method of attacking a bank is to direct the stream at its base and wash out or burrow a tunnel, so as to cut it under the bank until the upper portion falls or caves down in a broken mass. The stream then cleans up the debris which has fallen and washes it into the flume, down which it courses, depositing its articles of gold in the riffles which are distributed over the bottom of the flume.

Hydraulic mining was first carried on by conducting the water through an ordinary two-inch hose and projecting it through an inch nozzle, such as is now used by our fire department for conducting water from fire engines and throwing it upon a fire. This was necesarily slow business, as the stream would do but little execution against a tough cement bank. There was no scarcity of water, but there was no competent machine for handling a large stream. Even with a small hose and nozzle, such as we have described, the labor of holding and directing the nozzle was almost Herculean. The hose had a tendency to fly from side to side, especially when it got a little bent, and the nozzle-man was a lucky one indeed that didn't get thrashed by his pipe and nozzle several times a day. In 1864, J. M. Allenwood, of Timbuctoo, Yuba county, patented what was afterwards known as the "Gooseneck machine." It had two joints; a lower horizontal joint and an upper joint made of a short section of canvas. This machine was one step in the right direction, but the canvas joint was liable to get "kinked," and then the machine would fly around like a whirligig and knocked everything over within its reach. This the miners called "bucking." The machine was, however, used in several mines by using a block and tackle for holding it to its work. In 1867, Jenkin W. Richards, of Michigan Bluff, Placer county, devised a double-jointed machine to take the place of the usual nozzle. It was intended, with this machine, to get the desired range of motion from the two joints, and thus avoid the necessity of bending the hose in order to change the direction of the stream.

This machine never amounted to much, as its joints were found to be almost as unreliable as the hose. It was, therefore, abandoned as a failure, and inventors came to the conclusion that two-jointed machines would never answer. In 1869, the Craigs—R. R. and Joseph—above mentioned, devised and patented a single-joint, ball and socket machine, which it was at first supposed would answer every purpose. Other inventors followed, all with single-jointed machines —except in one or two instances, where some sanguine inventor would bring out a nondescript two-jointed machine to be tested and then taken back to the foundry to be broken up for old iron. Such was the Shaw, the Rice, the Gorman and Hoskin and a number of others. In 1870, Frank H. Fisher, of Nevada City, invented his famous "Hydraulic Chief." This was a two-jointed machine, and the first successful two-jointed machine that any one had produced. Its element of success was in its upper joint. Instead of the canvas or hose section used in the Allenwood machine, he substituted a metallic joint that worked on pivots on both sides, so that the nozzle could only be moved up and down on this joint, while it got its side motions from the horizontal, or lower joint. This machine was a success, and became quite popular for the short time it had been in the field. In the meantime the Craigs commenced suit against several of the machines, Hoskin amongst the rest, and threatened Fisher with a suit, alleging that all of the machines were infringements upon their Globe, or ball and socket single-jointed machine.

Instead of contesting the case with the Craigs, Hoskin compromised his suit with them and entered into a compact with them by which Hoskin was to be the manufacturer and seller and the combination was to drive out competition and control the market. Hoskin then got up the present Little Giant, which was simply a duplication of Fisher's Hydraulic Chief, with slight changes. They also purchased from the inventors, Macy & Martin, a patent which covered the use of riffles in a hydraulic discharge pipe. This "riffle" patent was the key to the situation. Without the riffles none of the machines could be successfully used, and all of their machines were using them. Craig then commenced suit against Fisher in the United States Circuit Court to prevent him from using the riffles and served a preliminary injunction on him *pendente lite.* Fisher was contumacious, and persisted in using the riffles, even after the injunction was served, and as a consequence he was brought before the court on an order to show cause why he should not be punished for contempt of court. Judge Sawyer, after due consideration of the case, fined Fisher $100 and gave him a severe lecture on the danger and possible consequences of violating an order of the court, and warned him to desist in the future from committing any further contempt. Fisher was not altogether subdued by this fine and lecture, but returned to his home in Nevada City, determined to get around the Craigs and the order of the court in some way; but, nevertheless, he did not act without the advice of his counsel. His business was in jeopardy unless he could use riffles in some way in his discharge pipe, because, without the riffles the water which issued from the nozzle would scatter and be ineffectual. He therefore purchased a number of old, worn-out pipes in which riffles had been placed by Macy & Martin, the inventors, and taking out the riffles, placed them in new discharge pipes of his Hydraulic Chief. Again he was brought before the court for contempt, and Judge Sawyer, after considering the case, rendered the decision which has ever since been recognized as authority in like cases, viz: "In a combination of two elements it is an infringement to manufacture one of these elements and combine it with one of the other elements, although the other element is purchased from the patentee himself." Fisher was therefore found guilty of a contempt of court. This being the second offense, Fisher was fined $500 and ordered to be confined in the San Jose jail for 30 days. Fisher says his confinement was not irksome and not altogether without enjoyment. He spent most of his time in a steeple, with a spy-glass in his hand, from whence he became quite familiar with the landmarks around the bucolic city of San Jose. The balance of his time he spent on parole, wandering through the streets and taking needed exercise. After his release he one day happened in the *Mining and Scientific Press* Patent Agency in this city where he was informed by Mr. Jno. L. Boone, who was at that time connected with the agency, that his patent could be reissued so as to cover the upper joint of the Little Giant machine. Munn and Co., of New York, had taken out the original patent, but had only patented the lever attachment by which the machine was handled. A reissue of his patent was then applied for, through the *Mining and Scientific Press* Patent Agency, and in due time the new patent was issued with a claim for the upper joint. Fisher then employed the law firm of Morgan & Heydenfeldt, and a suit was commenced against the Craigs for injuring the reissued patent.

Meanwhile the Craigs had not been idle. They had purchased the old Allenwood patent of 1864, and immediately they reissued it so as to cover broadly a two jointed machine. With this patent they went into court, and defeated Fisher's suit by anticipating his invention with the Allenwood machine. This put a quietus on Fisher. He had become deeply involved financially in his several battles with the Craigs, and it now became necessary to seek other means to afford him a livelihood. He obtained employment in the San Francisco Mint, where he has remained ever since. About two years ago, he again reissued his patent with good success, and he then employed our friend, Jno. L. Boone, Esq., who had meanwhile commenced the practice of law, to commence another suit against Hoskin and the Craigs. This suit was contested on the part of the Craigs by the same attorneys who had successfully defeated the former suit, and the case was prosecuted before the same Judge. This time, however, Fisher was successful, and a decision was rendered in his favor in the early part of the present term, and as the Macy & Martin patent on the riffles has expired, Fisher now succeeds to his legitimate rights, and will hereafter furnish hydraulic mining machines.

—*Mining and Scientific Press.*

THE DRAINAGE OF MINES.

THERE are few situations where workings can be carried to any considerable depth below the surface of the ground without interruption from the accumulation of the water. The surrounding rocks always contain more or less of water, which occupies their joints, fissures, or cavities, and this water rapidly accumulates wherever the excavations are deepest, and must be removed in order that the works may be carried on.

Adit Levels are driven in many cases to draw off this water as fast as it gathers, wherever the formation of the ground is favorable. In some instances very extensive districts have been drained by adits to depths of many fathoms. Thus the great Gwennap adit in Cornwall, which was constructed about a century ago, drains nearly 30 square miles of country by means of branches to a depth varying from 30 to 90 fathoms. The total length of this adit, with its branches, is about 40 miles. Another great adit, known as the Ernst August adit, was finished a few years ago in Saxony, and drains a large series of mines in the Hartz Mountains, some of them to a depth of 214 fathoms. This adit, with its branches, is 14 miles in length; part of it is navigable by boats; and it occupied nearly 13 years in construction—costing £85,500. Sometimes, however, an adit is inadmissible or insufficient, thus—if the mine is situated in a very low place, if it occupies an isolated portion of country, if the water be required at the surface for ore-dressing operations, or if the ground be so little uneven that a very long level would be required in order to drain any considerable depth of workings, some different mode of drainage is necessary.

Pumps and Pitwork.—In trial shafts for workings of small extent, or in a country already partially drained by surrounding mines, water buckets may be used, the water being raised by means of a tackle. As the water increases, however, this mode is found quite inadequate, and some form of pump is necessary. The common suction pump, shown in fig. 1, is rarely used in mining operations, as it will only raise water to a height of about 30 feet, but occasionally, and for temporary purposes, such pumps are used in successive lifts. The mode of action is as follows.

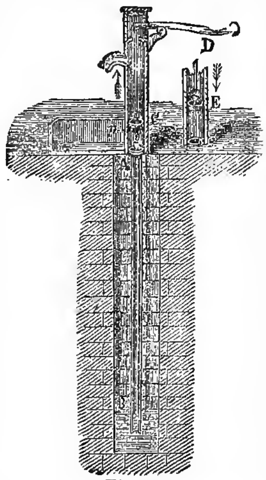


Fig. 1.

The long pipe A B is called the suction pipe, and it must be long enough to reach into the water in the well. The upper end of the suction pipe is furnished with a valve E opening upwards. Above the suction pipe is the working barrel C, containing a well-fitting piston *p*, which is worked up and down by the lever or brake-staff D. This piston or "bucket" contains a valve *v′* opening upwards. When the working begins the water in the suction pipe A B stands at the same level as that in the well. On raising the piston as indicated by the arrow, the valve *v* rises, and the air between it and the water in the suction pipe is rarefied, and the pressure of air on the water in the well causes it to rise in the pipe. When the piston is depressed as at E the valve *v* at the top of the suction pipe closes, that in the piston *v′* opens, and the excess of air is between *v* and *v′* passes out into the general atmosphere. The piston is now again drawn up, the water rises again in the suction pipe, and at length— if the suction pipe is not more than 30 feet long—passes through the valve *v* into the working barrel. The piston now again descends, and the water passes through this valve *v′*, and when it is again drawn up this valve closes, the piston serves as a bucket to raise the water as far as the spout, from which it flows in an intermittent stream. The water thus rises because the pressure of the air upon its surface in the well is greater than the pressure in the suction pipe. If all the air in the pipe were to be withdrawn it would rise until the weight or pressure of water AB was the same as that of the air on the water in the well, or about 15 lbs. to the square inch, varying a little from time to time. This pressure is given by a column of water about 34 feet high. Owing to the difficulty of making all the fittings air tight, about 30 feet is all that can be ordinarily reckoned upon.

Practically, it is found that if the distance A B is 30 feet or under, water may be raised by means of this pump, but if more than 30 feet, the pump will fail. For greater depths, therefore, the pump is modified slightly, as shown in fig. 2. The suction pipe *a*, now called the "windbore" or "snore," is reduced to about 10 or 12 feet, and pieces of pipe, called "pumps," are added above the working barrel to the required or most convenient height—often more than 100 ft. The whole arrangement is now shown in fig. 2, and is called a "bucket" or "drawing lift; *a* is the windbore, *b* is the "door-piece" containing the valve or "clack" *c*; *o* is the door, *d* is the bucket with its clack, *e* is the working barrel, which is bored truly cylindrical, *f* is the first of the "pumps," all of which are about 1 inch greater in diameter than the working barrel. The different pieces are made with flanged joints as shown for convenience of fixing; *g* is the "collar-launder," from which the stream of water is delivered.

This kind of drawing lift is well suited for use in a shaft which is being continually deepened, as additional pumps may be added at the top from time to time. If, however, the depth is more than about 30 fathoms, the water is usually raised in two or more distinct lifts—the drawing lift delivering its water from the collar-launder *r*, fig. 3, into a cistern A, from which it is forced to the surface by the "plunger" or ram *a*, shown in the figure. By the ascent of the plunger "pole" *a* in the "case" *b*, the water which fills the cistern A is made to rise through the wind-bore *h* and clack *c* into the H. piece H. When the pole descends, the clack *c* closes, the water raises the clack *e*, and passes upwards into the pumps above. As the pole again rises, the clack *e* is closed, *c* opens, and a fresh portion of water passes into the H piece. The cistern is kept full by the delivery of water from the top of the drawing lift by the collar-launder *r*, and also, in many cases, by the water from the upper portion of the mine, which is led into it instead of being allowed to fall to the bottom of the mine; *f* is the top pump of the drawing lift, and *f′* the bottom pump of the plunger lift. The plunger pole *a* works in the case *b* through a stuffing box at *i*. The mode of attaching the plunger pole *a′* and the bucket-rod *k* to the main rod *l l*, by means of the "glands" *m m*, and the "set-offs" *n*, is clear from the figure.

The pumps are made of cast iron, generally in lengths of 9 feet, but with a few shorter "matching pieces" in 3 and 6 feet lengths. They are cast about $\frac{3}{8}$ths to $\frac{5}{8}$ths of an inch thick, according to size, intended height of lift, etc., with several projecting ribs for strength. The flanges are about 1 in. thick. The valves or "clacks" are usually of leather strengthened with iron, and it is here that the wear is greatest. The chief peculiarity is, that the hinges or centres of the valves work within guides instead of upon centres, so that the whole valve has liberty to rise a few inches, thus giving a greater water space in the early part of the stroke. Sometimes valves of metal, variously constructed, are used, and occasionally the valves are partly or entirely made of india-rubber. For convenience of access to the valves they are placed in "door pieces," as shown in side view in fig. 2, where *o* is a movable door giving access to the valve *c*.

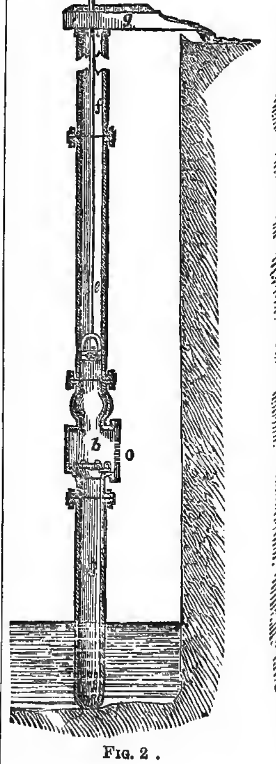

Fig. 2.

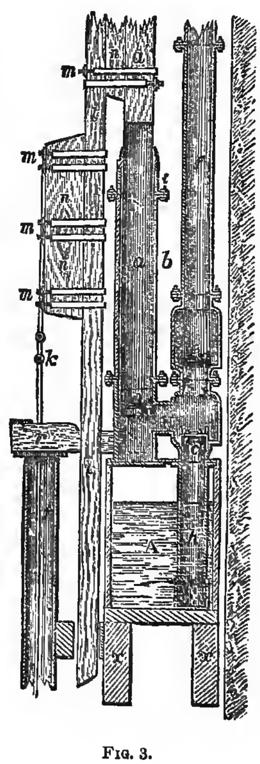

Fig. 3.

The cisterns for the successive lifts are made of wood 3 inches or more in thickness, strongly bound with iron strapping plates, and supported on strong "bearers," *xx*, Fig. 2, which are let into the sides of the shaft.

Sometimes the water to be raised is of a highly corrosive nature, especially that from copper and lead mines. In such cases it is good economy to make the valve seats, working barrel, and other important parts, of gun-metal, and to line the pumps with thin staves of oak or other hard wood. The "pumps" are fastened together with bolts and nuts,

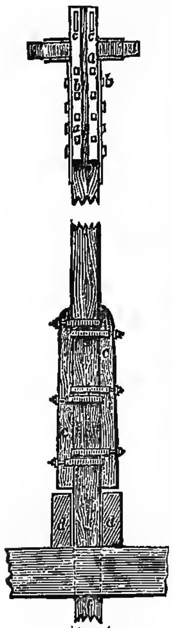

Fig. 4.

"flange-pins," as they are called in Cornwall, where it is customary to place between the flanges rings of thin iron bound round with "bal-shag," a coarse kind of flannel. This, when tightly screwed up, makes the joint air-tight, while it does not interfere with the ready separation of the pumps in case of need.

The "main rod," part of which is shown at *ll*, Fig. 3, is in deep mines made of the longest and straightest balks of Norway pine which can be obtained. The secondary rods are attached to this by "set-offs," as shown at *nn* in the same figure. The different lengths of the main rod are halved together, bolted through, and secured with strong strapping plates.

The upper end is attached to the outer end of the engine "beam" or "bob" by wrought-iron straps, secured by bolts *b* and cottars *c*, as shown in Fig. 4.

At intervals down the shaft catch-pieces *cc* are secured, and bearers fixed across *dd*, in order to take up the weight of the rods in case of a breakage, to prevent the whole mass of many tons weight from falling to the bottom of the shaft. They also prevent the engine from making too long a stroke, or going too far out, and so breaking off the cylinder cover.

The water is raised in the lower or drawing lift by the up or "in-door" stroke of the engine, but the remaining, or plunger lifts, are worked by the down or out-door stroke; the weight of the rods forcing the water up the column of pumps.

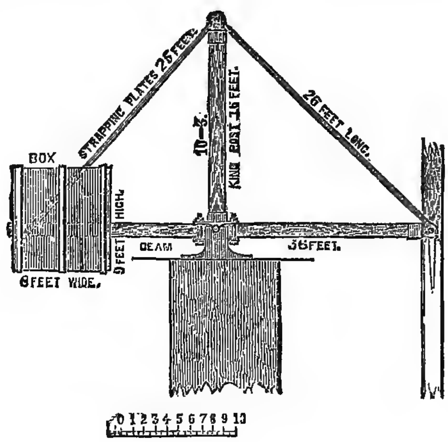

Fig. 5.

Balance Bobs.—When the mine is deep the weight of the rods is more than sufficient for the purpose, and the surplus is generally counterbalanced by "balance-bobs," placed either at surface or in chambers excavated by the side of the shaft underground. Thus at Davey's engine at the consolidated copper mines in Gwennap, Cornwall, the main rod was one-third of a mile long, and weighed 95 tons. The other rods weighed 40 tons, or together 135 tons. 39 tons were required to balance the column of water in the pumps, and the remaining 96 tons were balanced—partly by counter-weights, partly by special hydraulic machinery. One of these balance-bobs is shown at Fig. 5. For raising the heavy portions of "pit-work," as this pumping machinery is called, a powerful "capstan" is fixed just outside the engine-house. Very few of the shafts in the Cornish mines are vertical, and many are of varying inclination, so that it is necessary not only to provide friction rollers, but also to connect the different sections of the main rods by anglo-bobs. One mode of doing this is shown in Fig. 6, where a portion of the ground at the side of the shaft is cut away for the reception of the "balance-bob" *v*, the arms of which are pivoted to sections of the rod *aaa*. Other modes of effecting change of motion by friction-wheels and guide-rails are used where from the hardness of the ground or other reasons, this mode is inadmissible.

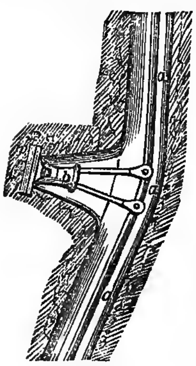

Fig. 6.

—From Principles of Metal Mining.

BLASTING.

In this age of improvement I know of no important industry, in which so much hard labor and money are lost for want of intelligent study and use of modern improvements, as in the simple operation of blasting. When you bear in mind the fact that blasting of minerals lies at the very foundation of all that distinguishes civilized from barbarous life, you will at once admit that its importance makes it well worthy of our attention. You are all aware that the houses of civilized men are very much superior to those of the barbarous races. The first point of difference is in the foundation, and almost the first things needed for the foundation of a house for civilized man are powder and blasting to get stone for the foundation. Another point of superiority of civilized life is the abundance of manufactured iron and glass, yet I think that not one pound of all the immense quantities of these articles manufactured around Pittsburg is obtained without drilling and blasting to prepare either the coal, iron ore, limestone, or sand used in its manufacture. But the very nature of the work of quarrying seems to draw to it many men of one idea who work hard and think little; who having made holes in rocks for many years, insist, therefore, that they know all about blasting and persistently oppose all modern improvements. Many farmers are living yet who have cut many harvests with a sickle before the days of cradles, mowing and reaping machines, etc. These might with the same propriety resist the use of mowing and reaping machines because they know all about farming. Another reason why improvements are not introduced in blasting is because the owners of mines seldom give any personal attention to blasting, but leave it all to the others, who seldom take any interest in improvements, and are often prejudiced against them and condemn them without a trial. The subject of blasting may be divided into three divisions:

1st. The hole and how to make it. 2d. The explosive used. 3d. The manner of firing the charge.

1st. The Hole and How to Make It.—The common way of making the hole is by either churn or jumper hand-drills. Three men usually form a gang, and the gang make from eight to twelve lineal feet of hole per day in hard rock. By either of these modes it is practically impossible to make a round hole—generally a three-cornered hole being made, which is very objectionable—because, if the hole is perfectly round it will present a uniform circular surface to the pressure, and retain the blast until its force is fully developed. But with a three-cornered hole the pressure on the long sides of the hole is concentrated at the corners, which, being required to resist more than their share of the pressure, give way and permit the explosive gases to escape before their force is fully developed, and only a large amount of smoke is produced. A much better plan is to have the holes made by machinery; this secures a cheaper and better hole, being perfectly round, and thus retains the explosive gases until their power is perfectly developed, and do more execution on the rock and with less smoke. In close or underground work, where the air is bad, this is found to be of great advantage. With the latest improved steam drills a gang of three men often make from seventy-five to one hundred feet of hole in one day.

2nd. The Explosive Used.—Explosives may be divided into chemical and mechanical combinations. Chemical explosives embrace what are known as nitro-glycerine, gun-cotton, dynamite, dualin, hercules, Ditmore-powder, rendrock, mica-powder, etc. These are produced mainly by the combination of nitric acid, sulphuric acid, and fatty matter or glycerine, with cotton, tan bark, paper pulp, saw dust, soda, mica scales, pulverized charcoal, etc., as absorbents. These will explode under water, which makes an excellent tamping. Most of them are unfit for sporting or military use; because their explosion is so instantaneous, it ruptures the gun before the ball can start. Their force is more like the blow of a large sledge, whose force is spent in an instant, while the explosion of black powder is more like the action of a powerful spring, which starts the projectile more slowly and continues to propel it until it escapes at the muzzle of the gun. The manufacture of chemical explosives is of comparatively recent date, and in many cases is as yet imperfectly understood. Many alarming accidents have occurred in the handling of some of them, which has given a bad name to the whole family. But enough is now known about some of them to prove them to be perfectly safe when properly understood and handled, and very profitable in certain kinds of blasting.

Mechanically combined explosives are common black powder, carbo-azoteen, and mahoning powder. These are composed mainly of saltpeter or nitrate of soda, sulphur, and charcoal, or tan bark. All of these ingredients are first finely pulverized separately, and then mixed in certain proportions, and incorporated by being run under heavy wheels or rollers for from two to six hours, so as to mix uniformly and bring a certain proportion of each ingredient in immediate contact with the other ingredients. The mass is then generally submitted to strong hydraulic or screw pressure, and then is called pressed cake. Then it is crushed by corrugated rollers and by means of sieves separated into the different sized grains of blasting, sporting, or military powder, each of which has its peculiar mark or name. Carbo-azoteen is made by boiling these ingredients together, and has never been a success. Mechanically combined explosives must be kept perfectly dry; even a slight degree of dampness injures them. As a rule, the finer the grain the quicker the explosion and the smaller the charge; while for large blasts in rock, powder is now used to good advantage in grains as large as grains of corn, and in large artillery charges still larger grains are used, called pebble powder. We now come to the

3d. Mode of Firing the charge.—Three modes are used—squib, fuse, and electricity. Squibs are made of about six inches of rye straw, filled with fine powder, and are used principally in coal blasting. The hole being drilled horizontally three to five feet into the coal, a charge of eight to twelve inches of F F blasting powder is generally put in, then an iron rod five-sixteenths of an inch in diameter, called, a needle, is inserted in the hole back to the powder, then the hole is tamped full by having dry clay or clay pounded solid into it, and the needle is withdrawn, leaving an open passage like a pipe through the tamping to the powder. The squib is inserted in the mouth of this hole and a slow match applied to the outside end; the recoil of the powder burning in the straw throws the burning squib back along the needle hole or pipe to the powder chamber, and the explosion takes place. This mode of firing can only be used in horizontal holes. Fuse consists of a thread of black powder incased in a wrapping of tarred hemp, and called hemp fuse—or in a wrapping of cotton, and called cotton fuse; then, to make it waterproof, a tarred tape is wrapped spirally around it, and then it is called single tape fuse, and will resist dampness a long time; or a double wrapping of tarred tape is wrapped around it, and called double tape fuse, which will burn and fire a charge of powder under twenty feet of water. In all of these fuses there is a central cotton thread, which has been saturated with saltpeter, which makes it continue to burn when it would otherwise go out. Every precaution is taken to make the fuse continue to burn until the fire reaches the powder, and the explosion is produced. But, from some cause or another, holes sometimes hang fire, and are a source of great danger to the miner or quarryman. Holes thus charged, which ordinarily should explode in from one to three minutes, have been known to hang fire for twenty-four hours and then explode. The third mode of firing is by electricity. When using it, the hole, the charge, and the tamping are the same as in firing with a fuse, but, instead of inserting the common fuse already described, an electric exploder is used, which is made thus: A copper cap, one-quarter of an inch diameter and about one inch long, is filled one-third full of fulminate of mercury, into which is inserted the ends of two insulated copper wires connected by a small thread of platinum wire, and the end of the cap is then closed by means of melted sulphur, making it waterproof. Electric fuses are made four, six, ten, and fifteen feet long, with about two inches of the outer end stripped of the insulation and tinned. In using them the blaster selects an electric fuse long enough to reach the bottom of the hole and leave a few inches of wire out of the hole, then puts in enough powder to cover the bottom of the hole one-half inch deep, then his exploder, then one-fourth less powder than if fired with a fuse, and tamps the hole the same as with ordinary fuse; any number of holes may be thus prepared of equal or unequal depth or distances apart.

Directions for Firing.—One wire of the first hole is now connected to one wire of the second hole, and the remaining wire of the second to one wire of the third hole, and so on until all are connected; there will then be one wire of the last hole and one wire of the first hole left unconnected. These wires are then connected by means of long conducting wires to the battery at a place of safety, and, when everything is ready, the circuit is closed, and the small thread of platinum wire in the bottom of each hole becomes red hot, and each cap is exploded with great force at the same instant, and each hole assists its neighbor. And thus by simultaneous explosion, with only three-quarters of the powder used in ordinary fuse blasting, more than double the rock is moved with the same drilling. In quarries where fuse is used it is not uncommon to find six inches or a foot, or even two feet, of the bottom of the holes remaining unruptured after the blast has been fired and cleared away—the drilling of the unexploded piece of hole was so much hard labor lost, and the powder it contained was lost, for if the powder had done what was intended no part of the hole would have been left unexploded. No part of the hole is thus left unexploded where electricity is used, because in firing by electricity the first point ruptured is at the bottom of the hole, and the full force of all the explosive is spent in enlarging the rupture.

For profitable blasting by either mode of firing, the bottom of the hole in open work should be at least one-tenth less from the open front of the rock than the depth of the hole; thus, if the hole is ten feet deep, the bottom of the hole should be not more than nine feet from the face of the rock, and in some rock not more than eight feet, so as to make the bottom of the hole the weakest part of the blast. But if the hole is ten feet deep and filled up four feet with powder, and fired with a fuse at the top of the powder, there will only be six feet of rock on the top of the first point of rupture, and there being nine feet in front of the hole, makes the top the weakest part, and the result is a great discharge of projectiles through the air, to the great danger of all around, and much of the material is lost; but if the same single hole had been fired by electricity at the bottom of the hole, the bottom rock would have been forced out, and the top rocks would tumble down and do no damage, and all be in place to be handled.

The contrast between firing with a squib and by electricity is still greater, because a fuse may sometimes burn to the bottom of the hole before firing the blast, but a squib must always fire at the top of the powder, and as the needle hole is a full quarter inch in diameter, the first blast is a jet of orange flame from the needle hole, which is partly consumed powder, and cools into dense smoke, to the great annoyance of the miner; in light work, only the top is blown off the hole, the first point of rupture taking place at the top of the powder. In conclusion, to show this is not idle theory, but actual fact, I may point to the shaft sunk this summer for the Chicago and Connellsville Coke Company, near Uniontown, under the superintendence of Mr. James Harrison. Mr. Harrison has had great experience in everything connected with modern mining improvements, and on commencing work on the shaft, procured the latest and best improved steam rock drill, an electro-magneto battery, and safe chemical explosives, and, with the assistance of Mr. Thomas, an experienced Welsh shaft sinker, he broke ground about the 15th of last March, and two weeks ago he had sunk the shaft three hundred and twenty-five feet to the coal; has got his ovens and all his buildings up, and, I presume, is now making coke, which, under the old plan of sinking, he could not have done before next April. I can also point to the shaft now being sunk by Mr. J. K. Taggart for E. K. Hyndman, near Connellsville, and to another near the same place, now being sunk by Mr. Hopkins for Mr. Wickham, of Connellsville, both of whom are using electricity and chemical explosives to good advantage. I may further add that theoretically blasting by electricity has been known to engineers for thirty or forty years, for large blasts such as Hell Gate. But it has only been within the last few years that the apparatus has been made so simple and portable as to be of any practical benefit in quarry work. It has now become so simple, and is so easily handled, that a youth can take the apparatus out of the tool-box, lay down the cable to a safe place, charge five or six holes, tamp and fire them, and take up the cable and replace apparatus in tool-box, all inside of ten minutes.

—A paper by Arthur Kirk, transactions Engineers' Society of Western Penna.

ROCK-BORING MACHINERY.

AN admirable sketch of the history and characteristics of rock-boring machinery is given in an interesting pamphlet by Mr. Richard Schram.[1] whose own invention for a rock drill was referred to in the *Mining Journal* a few weeks since. He remarked that during recent years the success attending the introduction of rock-boring machines for accomplishing various engineering works had induced many to decide upon substituting machine work for hand-labor in drilling for the purpose of blasting in mining and excavating operations. Some difficulties have been encountered in selecting a machine precisely suited for the particular work in hand, and thus a certain prejudice against the use of these machines in general has not unnaturally been created.

Referring to the causes which have led to rock-boring machines not having proved wholly successful, Mr. Schram is of opinion that it will be found upon inquiry that it is because their practical working has not been properly understood. Experience teaches us, he remarks, that in the employment of rock-boring machines it is as essential that the whole system of operations be sound and well-planned as that the machines themselves be effective and simple, so as not to require much or frequent repairing. Upon the first introduction of rock-boring machines old experienced miners were employed, and it was quite natural that they should endeavor to give the holes such directions, and proceed generally as nearly as possible in the same manner as they had been accustomed to do in hand-boring. If, however, we glance at the progress of any other branch of industry, we shall find that a more systematic method of working has invariably been the consequence of the introduction of machinery, and that to the improved organization and regularity thus accruing must be attributed no inconsiderable part of the great and manifold advantages of all machine work over hand-labor. Rock-boring by machinery forms no exception to the industries obeying this general law of progress, and upon its introduction rational systematic methods of working must be adopted. At the present time there is scarcely any branch of industry in which machinery does not play an important part. In some branches the mechanical appliances are so perfect that it would be impossible now to dispense with them; in others, on the contrary, the machines may be said to be in their infancy. To this last category rock-boring has hitherto belonged. The idea of using machinery in rock drilling was, Mr. Schram tells us, entertained long ago. In 1844, Burton, an Englishman, suggested the idea of employing compressed air to work a hammer striking upon a drill, but no practical support was given to the suggestion; and it was in the year 1854, that Bartlett, also an Englishman, and in 1855 that Schumann, of Freiberg, first appeared before the public with practical experiments. From these dates down to the present time improvements and developments in rock-boring machinery have succeeded one another with great rapidity.

[1] "The Application of Machine Power in Rock Drilling." By Richard Schram. London: G. Hill, Westminster Bridge-road.

Mr. Schram ranges the existing rock-boring machines into five classes—the ram system, embracing the Schwarzkopff and Warsop drills; the lever system, embracing Schumann's, Burleigh's, Sach's, McKean's, Warrington's, Ingersoll's, Dunn's, Roanhead, Cranston, Barrow, and many other machines; the duplex system, embracing the machines of Sommeiller and Ferroux; the rotary system, embracing the diamond drill, Brandt's, etc.; and the direct acting system, including Darlington's, Schram's, and Reynolds', without slide, and Osterkamp's, Schrams, Cederblom's and others, with slide.

Discussing the merits of the several systems, Mr. Schram remarks that the ram system as applied to rock-boring machines must prove impracticable, and must be so apparent to every one who has seen a worn-out hammer and hand-drill that it is unnecessary to give it any consideration. This lever system has, he says, long kept its place, and several machines constructed upon this system have done very good service, but he considers the disadvantages of the system are the great wear and tear to which the machines must be exposed, and the unpreventable loss of power, results which he regards as inseparable from a mode in which levers or tappets are actuated by the piston. The duplex system has, Mr. Schram states, only been employed in places where compressed air has been cheap and plentiful, as in the Mont Cenis and Gothard tunnels, but in either of these places machines of a later invention would have been found to work both better and more economically. By employing a separate engine to work the slide, the piston which carries the cutting tool runs perfectly free, and as those pistons are made of a large diameter and have a long stroke, the machines are consequently very powerful. But in proportion to their great consumption of compressed air (first in the subsidiary engine and again in the main cylinder) they prove very expensive in working. Moreover, in consequence of the great length of the machines, the holes must all be bored in a nearly horizontal position, thereby necessitating the use of a greater amount of explosive for blasting than would otherwise be necessary. The rotary system, as carried out for blasting operations, has likewise met with very limited approval.

It is true that Lisbeth's rotary hand-drill, as improved by Macdermott, works admirably in coal and soft slate, and no doubt the employment of these machines in coal mines is already extensive, and is rapidly spreading, but they are by no means adapted for the harder varieties of rock. Mr. Schram admits that for prospecting purposes the diamond drill is no doubt extremely valuable. One of the advantages held out in favor of rotary rock drills is that they are incessantly working into the stone, a condition evidently incompatible with any percussive action; but, on the other hand, the force of each blow of a percussion machine is very much greater than the force which in a rotary machine is constantly exerted. Moreover, the constant resistance to which the tool of a rotary drill is subjected necessitates a greater motive power, and after all, the actual work done is less than that of a percussion machine. An interesting trial of a rotary rock-boring machine invented by Brandt was made in 1877 in the Sonenwendstein Tunnel, on the Ebensee, in Austria. On the shore of the lake Ebensee an engine-house was built in which was erected a steam-engine with two steam cylinders, each 24 centimeters in diameter. Water under a very high pressure (stated to be 70 atmospheres) was carried in strong wrought-iron tubes into the tunnel, where it worked the rock-boring machines. These consisted of two auxiliary cylinders acting upon a crank-shaft laid at right angles across the drill, and a worm cut in the middle of this shaft caused the drill to rotate. The central part of the machinery formed a cylinder, in which was fitted a plunger piston attached to a joint, by means of which the machine was connected with a very strong stretcher or standard. Water being admitted to this cylinder, and exerting its force against the plunger, pressed the whole machine forward toward the rock, and thus maintained an enormous pressure on the cutting tool as it rotated. In the extreme end of the drill, which was hollow, there was a steel crown furnished with teeth which, through the rotary motion and the great force with which the apparatus was pressed against the rock, cut the stone in a similar manner to the diamond drill. Water was employed to clear out the debris from the holes.

The drill made 30 revolutions per minute, and, boring holes 7.5 centimeters diameter, it progressed at the rate of 3 centimeters per minute. This rock was dolomite. As great difficulty was experienced in commencing the holes, they were bored double their required depth—that is to say, double the depth at which the explosive proved to be effective, and before being charged and fired were filled up for half their depth with sand. After the first charges were fired the sand was removed from the remainder of the holes, which were then charged and fired again. The heavy expenses of working proved too great for the general adoption of this machine in other places. As belonging to the direct acting system without slides, Mr. Schram has mentioned the Darlington, Reynolds, and Schram machines. Simple as this system is, it is, he says, nevertheless unpractical, because the piston being propelled by expansion, the pressure is consequently least when it ought to be greatest—*i. e.*, at the end of each stroke. Another defect is that pressure is exerted on the lower side of the piston during the forward stroke, thereby counteracting the force of each blow to a most injurious degree. The Darlington machine especially requires twice the quantity of compressed air necessary for most other machines of the same size, notwithstanding which the effect in boring horizontal holes is over 100 per cent. less than in the case of machines of more modern construction. He describes one of his own machines of this class, but remarks that this system, simple as it is, is by no means practicable, as, though the machine will run at an extraordinary high speed, the boring results, as compared with the direct acting machines with slide, are not satisfactory. In the class of direct acting machines with slides are those by Osterkamp, Dœring, Schram, Cederblom, and others; and he here describes his own arrangement, which has certainly much to recommend it. The only moving parts of the machine are the main piston, the side piston and slide, and the rotating movement with its piston. It is an important feature in this machine that the slide rod is made in the form of a double spindle valve; by this method of construction it remains in position without any recoil until the piston has made the greater part of its stroke. As in some varieties of rock it happens that the drill often sticks fast, there is a reversing rod to suddenly reverse the slide, and thus pull the drill out of the hole. With careless workmen it would frequently happen that the piston would strike against the lower cylinder cover, therefore there is an air cushion at the lower end of the cylinder. In addition to this there are an iron ring and an India-rubber washer (exchanged for one of wrought iron when steam is used), with the object of moderating the violence of the shock such blows, inadvertently permitted, would cause. In order that the hole drilled be perfectly round, it is necessary that the cutting tool should partially rotate at each backward stroke so that its cutting edge shall every time strike the rock in a fresh place, but in order not to lose any power it must always make its forward stroke without rotating. For this purpose a twisted bar is employed, connected with a grooved disk, and a brake acted upon by a small piston. Communicating from the slide box with the cylinder is a small port, by means of which the compressed air exerts a constant pressure upon the upper end of the small piston. When the main piston makes its backward stroke the back end of the cylinder is in communication with the outlet, and consequently there is no pressure on the lower end of the small piston. The constant pressure on the upper end of this piston, therefore, now presses it upon the brake which presses upon the disk, preventing it from turning, and thus the main piston is forced to partially rotate round the twisted bar secured to the disk. But when the main piston makes its forward stroke, and steam or compressed air fills the back end of the cylinder, the motive fluid enters through small ports and presses on the lower end of the small piston, thus counterbalancing the constant pressure on the upper end. There being now no pressure on the brake the disk is free to rotate, and the main piston makes its forward stroke without rotating, partially turning the disk as it proceeds by means of the twisted bar. This machine is sometimes made with an automatic feed motion actuated directly by means of a piston, instead of, as in other rock-boring machines, through levers, but the inventor nevertheless recommends in all cases a manual feed, as, notwithstanding all the assertions to the contrary of eager rock-boring machine dealers, practical miners know that in some faulty rock the drill will and must occasionally stick fast. When this happens it takes much longer time to clear the cutting tool, if an automatic feed is in use than in simply giving the handle of a manual feed a turn or two, which is all that is necessary to loosen the drill and permit of the boring being proceeded with. Moreover the workmen are never so attentive to their work when they have nothing to do but to look on as they are when they have the machine constantly under hand. Thus, apart from the increased complication and greater wear and tear to which even the best automatic feed motion renders any machine liable, such a feed has always been found objectionable in actual practice.

Through the perfectly free action of the main piston, and because the motive fluid is admitted to the whole surface of its upper end, each blow is extremely powerful: moreover this free action, combined with that of the slide piston allows the machine to be run at a very high speed, and enables it to be worked with a very low pressure. Its principal feature, however, is its remarkably small consumption of compressed air, as an air compressor which would only be able to drive one machine constructed on the lever system will easily drive two of Schram's, the diameter of cylinder being the same in both cases. There being no parts exposed to blows, and the principal parts being directly actuated by the motive fluid, this machine is less liable to wear and tear than those of other systems. It should also be observed that the working parts are all inside the cylinders, so that rough-handed miners, unaccustomed to use more fragile instruments than sledge hammers and picks, may be safely intrusted with the handling of these rock drills.

Reverting for one moment to the slide action, it may be mentioned that this machine was at first constructed with a cylindrical slide, but considering the leakage of motive fluid caused by wear and tear which has always been found to result from the employment of this form of slide in steam engines, the inventor has considered it most practical to adopt the old form of D slide, which has this great advantage, that even after years of work it always fits perfectly tight on to the slide face. The supports and various other details connected with machine drilling are referred to at equal length, but as these will constantly vary with the work in hand, an abstract of Mr. Schram's remarks would be of little value; the book itself, which is really worthy of careful reading by all practical men, must be referred to for further information on the subject.

—*Mining Journal.*

ROCK-DRILLING MACHINERY.

TOOLS.—The method of fixing the tool to the end of the piston-rod has received a large amount of attention from inventors. In 1866, Jordan and Darlington introduced a loop clip. Later a binding ring came into use. Improvements on these methods are in progress, the object being to retain the tool on the axial line of the piston-rod, without resorting to rings, clips, or set screws. The form of the boring bit has also undergone radical changes, in some instances rendered necessary, not for the purpose of drilling a round hole, but for neutralizing the imperfect action of the turning gear employed. The following figures, which will explain themselves, show "bits" of various forms, the use of which is advocated by inventors of various rock-drills. Another form of tool for running down center or "rupturing" holes is shown in Fig. 2. The bit Z-shape, is the same size as the ordinary drills, but it has also an enlarged part, armed with a Z-shape cutting edge, 4 in. diameter. The length of the boring tools will depend upon the depth of the intended hole. At Ronchamp the longest hole was 9½ ft. At St. Gothard it is about 8 ft., while at Musconetcong Tunnel, New Jersey, the leading holes were usually 10 ft. deep, the longest 14 ft. In ordinary mine headings, and in the employment of comparatively small boring machines, the diameter of the boring steel may vary from ⅞ in to 1¼ in. For rupturing the rock with No. 1 dynamite, or Brain's No. 1 powder, the hole at bottom need not exceed 1 in. in diameter; but if second-class dynamite or compressed powder be employed the hole in that case should be larger. In changing a boring tool care must be taken that the cutting edge of the one to follow it is not wider than the intact cutting edge of the tool withdrawn. In the tool withdrawn it will be often found that the corners have been partly removed; the cutting edge of this tool is, therefore, that portion not rounded, but roughly parallel to the face of the hole. Many instances occurred in the rudimentary stage of boring, when machines were alleged to be useless—the fact having been that the cutting edge of the second tool was wider than that of the tool withdrawn, which, forced into a conical part of the hole, necessarily wedged itself fast, thereby stopping or retarding the working of the machine. As a common rule, the width of the different sets of boring tools at the points should vary from one-sixteenth to one-eighth of an inch from each other; or if the leading sets of tools are $1\frac{1}{4}$ in. wide at the point, the second or "follower" set may be $1\frac{1}{8}$ in., and the third 1 in. wide. No rule can be strictly laid down for determining the time and power requisite to bore holes of varying diameter; but experience seems to show that if a hole 12 in. deep and 1 in. diameter takes 4 minutes, a hole 2 in.

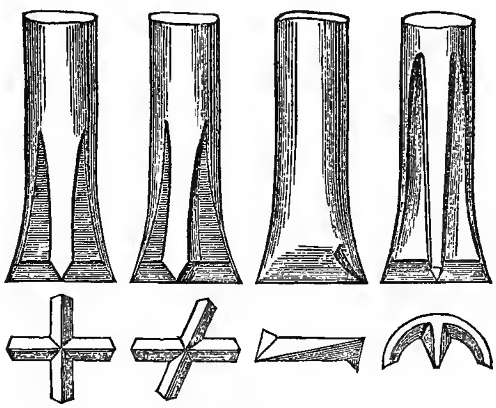

Fig. 1.

diameter and of like depth, bored with the same machine, and under the same conditions as to pressure of air and speed, will take 16 minutes. In other words, the machine and the fluid pressure being the same, the time and power to bore holes to a given depth are as the square of the diameter of the hole. It is, therefore, of considerable importance to keep the diameter of the shot-hole as small as possible, and to supplement mechanical power by employing strong rupturing explosives.

Cut and Sink.—In tunnelling or sinking shafts by means of rock boring machinery, it is necessary to conduct the operations in some special manner. When machines were first introduced into our mines the miner insisted upon employing them as a mere substitute for the borer and the mallet, and boring the holes so as "to take advantage" of the ground. The result showed, however, that such a course was unsatisfactory. Not only was the time required to get a position for the machine, to fix, and to remove it excessive, but the work accomplished was not in proportion to its cost. The engineers of the Mont Cenis Tunnel were the first to recognize the fact that if power machines were to be successfully adopted the hand method of doing the work must be discarded and new conditions established. A given number, ten machines, were accordingly grouped together on a carriage, the natural rupturing lines of the rock disregarded, the holes drilled more or less with the axial line of the heading, the machines and carriage withdrawn, the holes charged, the explosive fired, and the stuff removed.

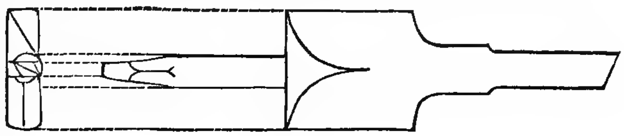

Fig. 2.

These series of operations constituted an "advance," while in America, and in one or two English mines, it is known as a "cut," and in shafts as a "sink.' At the time when the Mont Cenis Tunnel was driven, nitro-glycerine and dynamite had not been largely adopted for blasting purposes. Powder was the explosive used in the execution of that work; this together with the great length of the machines and comparatively narrow width of the heading—9 ft. 10 in.—thereby limiting the angling range of the machines, rendered a considerable number of holes necessary for effecting the removal of the rock. A face of $83\frac{1}{2}$ square ft. was perforated with from 60 to 70 holes, $2\frac{1}{2}$ ft. to 4 ft. deep. The Musconetcong Tunnel, New Jersey, was driven with the aid of dynamite. The advance heading, 8 ft high, was carried the entire width of the tunnel—26 ft. With two boring carriages, and strongly angling the machines on a

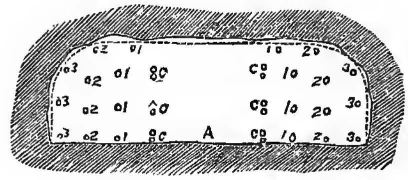

Fig. 3.

line from the top to the bottom of the tunnel towards its axial line, holes 10 ft. deep were made for bringing out the center "cut." The methods of arranging the holes for blasting may be distinguished as—

(*a*).—Mont Cenis and St. Gothard.
(*b*).—Musconetcong and Minera.
(*c*).—Brain's radial system.

(*a*).—The face of the Mont Cenis heading, allowing for contraction towards the top and rounding corners, represented an area of about 80 square feet. This "face" was subjected to the attack of 10 machines, giving 8 square feet of surface per machine, or nearly one hole for each square foot of surface.

The center of the face was perforated with a large hole, and immediately outside of this center 8 other holes were bored, constituting the "center of rupturing holes." Around this set of center holes a series of 3 sets of concentric and 2 sets of semi-concentric holes were drilled. The holes were subsequently fired in volleys and removed the rock—(1) the center, and (2) the portion concentric to the center.

(*b*).—At Musconetcong the tunnel heading, 26 feet wide by 8 feet high, gave a net area of about 175 square feet. This face was perforated with 36 holes by means of 6 powerful boring machines, each cylinder 5 in. diameter. The area of the face apportioned to each machine was 29 square feet. The number and depth of the holes to obtain a cut of 10 feet, or an actual lineal advance of 9 feet, were:

Cut	12	holes, each	$10\frac{1}{2}$	feet deep.
First square up.........	8	"	12	"
Second ditto	8	"	12	"
Third ditto...............	6	"	12	"
Four roof holes.........	2	"	10	"
			8	"
Total	36			

The aggregate depth of the 36 holes was 408 lineal feet; number of square feet of heading to one hole about 4·8. The following is Mr. Drinker's description of driving by the

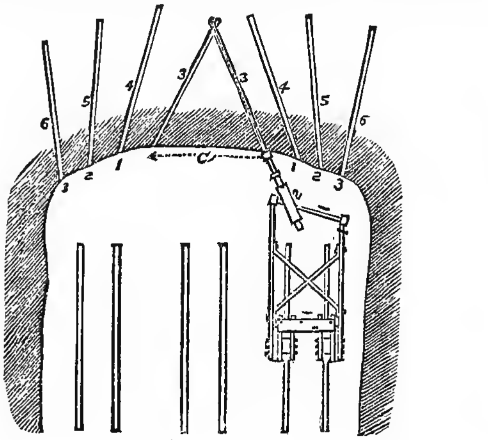

FIG. 4.

cut system: "The method of blasting by cuts is based on the extraordinary force developed by a comparatively small bulk of explosive matter. It consists in first blasting out an entering wedge or core, about 10 feet deep at the center, and subsequently squaring up the sides by several rounds. To do this 12 holes are first drilled by 6 machines, 3 on a side, the holes placed as shown in fig. 3, and marked *C; A* being the floor of the heading. Then 12 holes are drilled, 2 and 2, 6 on a side, with from 1½ to 2¼ in. "bits," the two sets being started about nine feet apart, and at such an angle as to meet or cross at the bottom, the largest bit being put in first. The holes are then charged with about 25 lbs. No. 1 and 50 lbs. No. 2 dynamite, and fired simultaneously by electricity. No. 1 is only used for cuts, inasmuch as in them a quick, strong powder compressed in a small bulk at the bottom of the holes is required where the greater resistance will be found, while the No. 2 added serves in filling up the holes, so starting the sides of the cut as the apex moves—the cut, *a*, being out, a second round of holes is started for the first squaring up, as shown by the numbers 1, 1, 1, 1, Figs. 3 and 4.

In these and subsequent rounds, 2, 2, 2, 2, and 3, 3, 3, the resistance is pretty equally distributed along the whole length of the holes, and as it is not so great as in the cut, No. 2 is used, as in the nitroglycerine being mixed with a larger proportion of absorbent matter, the force is thereby distributed over a greater space. In the first and second squaring up, rounds from 50 to 60 lbs. of No 2 are charged, and in the third, from 80 to 90 lbs., the holes getting stronger as the arch falls at the side. There are generally, also, one or two additional roof-holes in the third round that are not shown in the figure, their position being variable, according to the lay of the rock. The top holes in the first round are also designed to bring down the roof not shaken by the cut, and are, therefore given a strong angle towards the center, and always drilled from 12 to 14 feet deep. The plan, Fig. 4, shows the cut holes, 4, 5, and 6 the squaring up rounds.

"As to the relative depth, the holes of the first squaring up round are always drilled a foot or more deeper than the cut holes, and when blasted they generally bring out a foot additional of shaken rock at the apex of the cut."

(*c*).—**Brain's Radial System.**—This system, devised by Mr. W. Blanch Brain, of St. Annal's Cinderford, was introduced about three years ago at the Drybrook Iron Mines, in the Forest of Dean. The main object of the inventor was to perforate the face of the level without once shifting the stretcher-bar when placed at its proper height. M. André, in his work on Coal Mining, thus notices the radial system: "The fundamental principle which constitutes its distinctive character is to make the holes of a series to radiate from a fixed point. The object of this radiation is twofold—to utilize the face of the heading as an unsupported side, and to reduce to a minimum the time consumed in changing the position of the stretcher-bar. It will be obvious on reflection, that if these ends are attained without

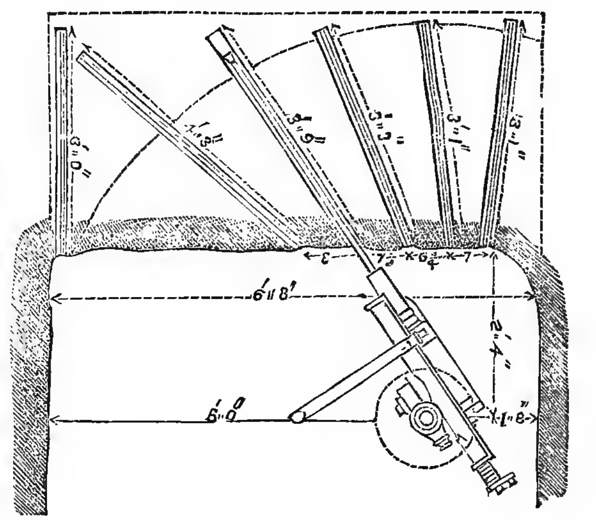

Fig. 5.

incurring a compensating loss, the merits of the system are beyond question, since their attainment leads to rapidity of progress, which is the main purpose of machine labor. It is evident that if the holes are made to radiate from a fixed point, and the horizontal position be avoided, none of them can be perpendicular to the face of the heading, and, consequently, the lines of fracture from each charge tend to reach this face. A consequence of this fact is that no unkeying of the face is necessary since each shot tends to blow outwards. Let it be assumed that the drift to be driven is six feet, eight inches in height. The width in this case is immaterial to the operation of the system. The stretcher-bar, which is to serve as a support to the machine, is fixed at a certain height from the floor, and at a certain distance from the face, as shown in Fig. 5. The height of the bar above the floor, with slight modifications to suit existing conditions, will be the same in all cases; but the distance of the bar from the face will be determined by the length of the machine, or at least by the distance from the centre of the clamp to the end of the piston-rod, into which the bit is fixed. It is obviously desirable to reduce the distance between the face of the heading and the stretcher-bar to the least possible, since the angle of the holes will rapidly increase as the distance is diminished. From the figure it will be observed that the stretcher-bar is fixed 1 ft. 8 in. from the top, 5 ft. from the bottom, and 2 ft. 4 in. from the face. The first and second series of holes are 3 ft. 1 in. deep; the third 3¼ ft. deep; the fourth 3¾ ft.; and the fifth 4¼ ft. deep. The bottom or lifting holes are 3 ft. long.

In a heading 6 ft. 8 in. by 6 ft 8 in., giving an area of 44 square feet, 29 holes were bored, representing a total lineal length of 69 ft. 8 in. As the cut or advance was about 3 ft., it follows that each hole removed nearly 7 cubic feet of rock.—*Mining Journal.*

THE TOOLS USED IN BREAKING ROCK.

THE principal tools used by miners in "breaking ground," as it is termed, are pick-axes or "picks," "pikes," "hacks," "slitters," or "mandrils," as they are variously called, of different kinds; hammers or "sledges," of different forms and weights; shovels; wedges or "gads," and "moyles;" borers or "boryers." Besides these we may mention such miscellaneous tools as "tamping bars," "prickers," "swab-sticks," hatchets or "dags," adzes, saws, and other tools used for blasting, timbering, and other special purposes. All these vary considerably in form, size, and other particulars in different districts, and when used for different purposes. We can only describe here the principal varieties.

Picks.—These are mostly made of iron, with points or "tips" of steel, while the handle, "helve," or "hilt" is formed of ash or hickory. In the metal mines of the West of England the picks are usually of the form shown in fig. 1, which is called the "poll-pick," having its head or "pane" *a* steeled as well as its point. This is the most useful tool the miner has, as it serves as a hammer as well as a pick. It is also very much used as a lever, the curve of the pick serving as a fulcrum, and great leverage being obtained through the handle or "hilt." It is also much used as a hammer to drive the "gad," an instrument presently to be described. A fair length is about 15 inches, the weight is about 4 lbs., but they are made occasionally but little over 2 lbs., and sometimes as much as 7 lbs. or even 10 lbs. The heaviest picks in Cornwall are used in the China clay pits of the centre of the county. Picks of very similar form are used in the lead mines of Derbyshire and Wales. When the pick is much used as a lever, the head is frequently formed as in fig. 2*a*, with a projection wing to afford increased support to the helve. This is called a jackass pick. Similar support is better afforded by making the eye portion of the pick somewhat deeper than usual. Ordinarily, for hard ground, the point is sharpened four-square, but for soft ground it is usually flattened, and for clay ground it is frequently spread out to a width of $1\frac{1}{2}''$ or $2''$, as in fig. 2*b*. Fig. 3 shows a form of pick frequently used in the iron mines of Somerset and Wales, weighing from 4 to 5 lbs. A very similar form, but made somewhat slighter, and weighing only 2 or 3 lbs., is used in the coal mines of South Wales. For sinking purposes they are made much heavier, often 7 lbs., when they are known as "hacks" in some parts. These are often 18 to 22 inches long. Helves of picks vary from 24 inches long in some poll-picks used in confined places, to 36 inches or more. Many other forms of pick are in common use, almost every district having its own special form. The cost of a poll-pick of $4\frac{1}{2}$ lbs. weight, the poll and tip well steeled, is in Cornwall at present about 2s. 6d.; the cost of the helve or "hilt" is 4d.

Hammers.—The chief kinds used in metal mines are mallets or "malls," used for "beating the borer;" "sledges," for breaking up large masses of rock, and for driving the "gad;" and "cobbing" and "spalling hammers" for further reducing the ore; "lath sledges" are used for driving the laths in ground requiring timbering. The head or "pane" is usually steeled, the handle or "hilt is made of ash or hickory. The "eye" is occasionally round, sometimes square, more usually, and much better, oval. Fig. 4 represents the "cat-head" mallet, used for "beating the borer" in many parts of Cornwall. It varies in weight from 4 to 9 lbs.—averaging, perhaps, 6 lbs. or 7 lbs. Fig. 5 is a "bloat-head" hammer used for single-handed boring in the extreme west of England, at St. Just. It weighs from $2\frac{1}{2}$ to 4 lbs. The hilts of these single-handed boring hammers are rarely so much as $18''$ long, but those for double-handed hammers are from 24 inches to 30 inches in length. These boring sledges are sometimes used for driving wedges or "gads," and the pool-pick is also largely used for this purpose. Sometimes a special "gad sledge" is provided for that purpose. It is much like that already figured, but longer in the head and narrower in the pane, and weighs about 7 or 8 lbs. The form shown in Fig. 6 is used for breaking up large rocks, but in this case the weight is often increased to 15 lbs., 20 lbs., or even more. These are sometimes called lump sledges. Fig. 7 represents a "lath-sledge," for driving the "laths" used in timbering tender ground in Cornwall and elsewhere. Fig. 8 shows a "spalling hammer" in common use; the weight will be from 3 to 6 lbs.

Shovels or Spades.—These also vary much in form and size. Fig. 9 represents the long-handled shovel, used almost universally throughout the west of England not only for removing loose material underground, but also for general use at the surface. The "plate" is from 8 inches to 12 inches wide, and 10 to 15 inches long, slightly hollowed and strengthened with a central rib extending about half way down. The point is often, and with great advantage, steeled. The handle or "hilt" is from 4 to 5 feet long in general, slightly curved. The weight of the plate is from 3 to 4 lbs.; the cost, unsteeled, from 2s. to 3s., steeling about 6d. extra. A shovel like Fig. 10 is much used in the iron mines of the north of England. The proper use of the long-handled shovel of the west of England is not very easily acquired; nor is it, perhaps, so well adapted for removing very light and loose material as the shorter handled shovels. For rough and coarse materials, however, its value cannot be over-estimated, as the point makes its way readily beneath or between the masses, and the knee serves as a fulcrum at the same time for the long lever handle. The vanning shovel, used in "vanning" tin and other ores, is somewhat like Fig. 9, but larger, rounded at the ends, and without the strengthening rib. It is made of very thin iron, so as not to exceed 2 or $2\frac{1}{2}$ lbs. in weight. The plate may be about $15''$ long; the handle about 3 feet. Much attention is paid so as to secure a proper curve for both plate and handle, as much of the success of the operation depends upon these particulars.

Wedges.—These are largely used for breaking down portions of rock, being driven by the pool-picks or hammers already mentioned. In Cornwall the wedges most commonly used are known as "gads," "pickers," and "moyles" or mules. The *gads* are usually made of steel, vary from 6 inches to 10 inches in length, and weigh from 1 to 5 or 6 lbs. Fig. 10 shows a very useful form. The *pickers* used in the Western mines are longer and narrower. They are used, as the name implies, to pick out the small fragments of loose rock which wedge in larger portions in some situations. Worn out steel borers make excellent gads and pickers.

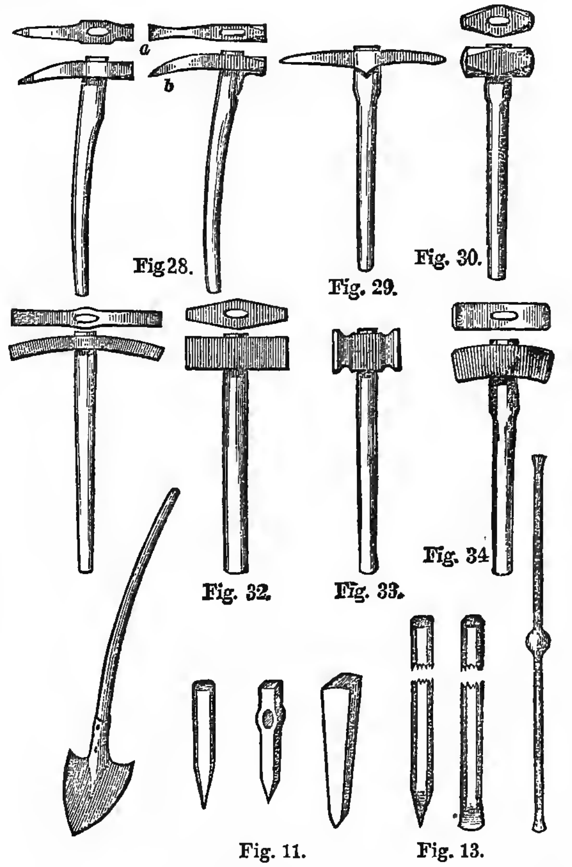

Fig28. Fig. 29. Fig. 30. Fig. 32. Fig. 33. Fig. 34

Fig. 9. Fig. 10. Fig. 11. Fig. 12. Fig. 13. Fig. 14.

In Saxony it is common to make the gads with an eye in the centre, as shown in fig. 11. The miner passes a string through the holes, and so carries a day's supply without inconvenience. The larger kinds of wedges known in Cornwall as "moyles" are used more especially in quarry work. They vary from ten inches to eighteen inches in length, and weigh from seven to twenty pounds. They are sometimes formed of iron throughout, but preferably with a steel tip.

The term gad is sometimes restricted to those which are brought to a point, those having a chisel edge are more properly termed wedges. The cost of steel wedges varies much from time to time, but at the present time is about 8d. per pound. Iron wedges cost rather less than half this amount.

Borers.—These are often called "striking borers," "drills," "bits," and sometimes "augers." Of course they are very different to true augers. Ordinary borers are worked by percussion, borers which revolve under pressure are seldom used in mining operations, except for deep trial borings. The borers used in metal mining are mostly of the form shown in fig. 13, varying in width from one and a half inches down to one inch, and in length from one foot to four feet,—the shorter being wider than the longer ones, in order to afford "clearance" as they succeed each other in boring deep holes. In open quarry work much longer and larger borers are used. In the west of Cornwall, at St. Just, the borers are lighter and smaller than elsewhere, single-handed boring being common as already mentioned. The best borers are made of steel throughout, but sometimes iron borers with steel tips are still used. For boring machines, the form of the cutting edge is very different from that shown in the figure—the chief forms being the "Z" and the "X." The jumper shown in fig. 14 is used in open quarry work, but not often by miners. It is sharpened and steeled at both ends, and is held by the lump in the middle.

Miscellaneous Tools.—The *tamping bar* is a bar of iron tipped with copper, or a rod of hard wood, used for ramming home a "tamping" of clay or earthy material so as to confine the gunpowder or other explosive in a bore-hole to increase its useful effect. The *pricker* was formerly much used to make a hole through the tamping, but since the invention of safety fuse it has gone very generally out of use, the tamping being now rammed around the fuse itself. *Swab-sticks* are rods of wood, with the fibres of the end beaten loose, and used for drawing wet mud or sludge out of a bore hole. Sometimes a kind of syringe known as a gun is used with good effect for this purpose. A hatchet or "dag" is very useful in preparing timber for tender ground, and in Cornwall the miners are expected to be expert in its use, and also in the use of a cross-cut saw, hand saw, adze, and auger.

—*From the "Principles of Metal Mining."*

ON DEAD WORK IN SHAFTS, ETC.

THE shafts for metal mines, besides the actual labour of excavating, require much additional attention before they are ready for daily use. Some shafts are intended for pumping only; some for pumping and raising ore; and many for the use of the miners in proceeding to and from their work in addition to these objects.

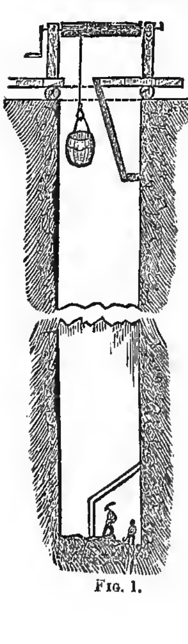

FIG. 1.

Protection from Danger.—As the shaft reaches a depth of 10 to 20 fathoms, it is usual—or at least proper—to protect the men working in the bottom from the danger arising from the occasional fall of stones or materials, since a very small stone falling upwards of 60 feet is sufficient to cause death. A portion of the shaft is covered over by a temporary sloping roof of boards called a "pent-house," as shown in fig. 1, and the men retire beneath this whenever anything is being raised or let down in the shaft.

Striking Deals.—To diminish the risk of accident from the upsetting of the kibbles, what are known as "striking deals" are used in some places. These are pieces of wood placed as shown in fig. 1, which serve to guide the ascending kibble through the opening at the top of the shaft. Fig. 2 is a plan of a shaft divided for pumping and "winding," or "drawing stuff," with a narrow central division for a ladder-way. The winding division a is boarded in entirely from the ladder-way b, but the portico c, containing dd, is only separated at intervals from the ladder-way.

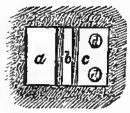

FIG. 2.

Ladders.—The ladders are usually made from 20 to 30 feet long. The "rungs" or "staves"—preferably 10″, but sometimes 12″ apart—are best made of iron bars let into the wooden sides, as shown in fig. 3. At the top and bottom, and at intervals throughout the length, longer bars cc pass quite through the sides, and are secured by a "cotter" as at d, or by a nut as at e. The ladders are placed in the shaft as shown in figs. 4, 5, of which 4 represents the safest mode, as the man-holes bb, in the "solars" aa, are under the ladders. When the ladders are placed as in fig. 5, a careless stepper may step back into the man-hole, and losing his hold on the ladder, may "fall away." Sometimes the man-holes are protected by trap-doors, but this leads to much delay, so that in practice they are seldom kept shut.

Partings.—Partings of the shafts consist of strong beams of wood, which either rest upon the timber "sets" of the shaft, or, in hard ground, are let into the country on either side; longitudinal timbers are nailed to these so as to form the shaft parting, and the same cross timbers serve to support the solars. In the great majority of the Cornish metal mines, and in many of those of South Wales and the North of England, the men go to and from their work by means of the ladder ways just described. The going down is not very hard work, but as the average daily amount of climbing is, perhaps from 400 to 600 feet, and *sometimes* as much as 1500, and as the men have frequently to bring up some of their tools for sharpening, the labor becomes very severe—as much in some instances as the whole of the work underground. In some mines the men are raised in the cages or skips used for raising ore, and this practice is increasing with the increasing use of wire-rope.

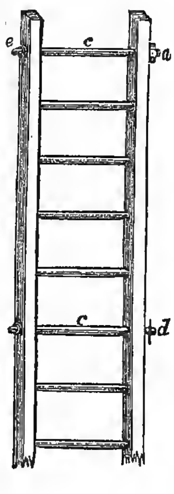

Fig. 3.

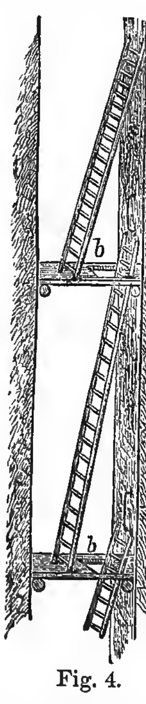

Fig. 4.

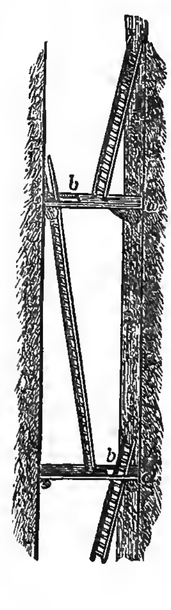

Fig. 5.

Safety Catch.—Sometimes the cages are fitted with safety catches which are intended to prevent the fall of the cage in case of the ropes breaking. One very convenient form of this contrivance consists of a strong spring which serves as the connection between the rope and the cage. The weight of the loaded cage keeps this spring bent, but if the rope should break it is at once relaxed, and, by its recoil, sets free some strong teeth, which immediately force themselves into the shaft railway or guides, and so keep the cage from falling. But all such contrivances are liable to get out of order unless constantly watched; and as it seems difficult to induce men to prepare for a danger which seems very remote, many practical miners prefer to do without all such appliances, and to trust entirely to the perfection of the rope, which is constantly under the inspection of the manager or his appointed agent.

From shallow depths, or while sinking, the men are often raised by means of the rope used for raising the "deads." The writer has been frequently brought up from a depth of between 30 and 40 fathoms standing with one foot in the kibble and holding on to the rope with his left hand; but such a mode cannot be recommended for depths of more than a few fathoms, especially if the rope is at all worn.

The Man-Engine.—In some of the larger Cornish mines the contrivance known as the "man-engine" is used for raising and lowering the men—a special shaft being devoted to this purpose, except that a ladder-way is also placed in the shaft.

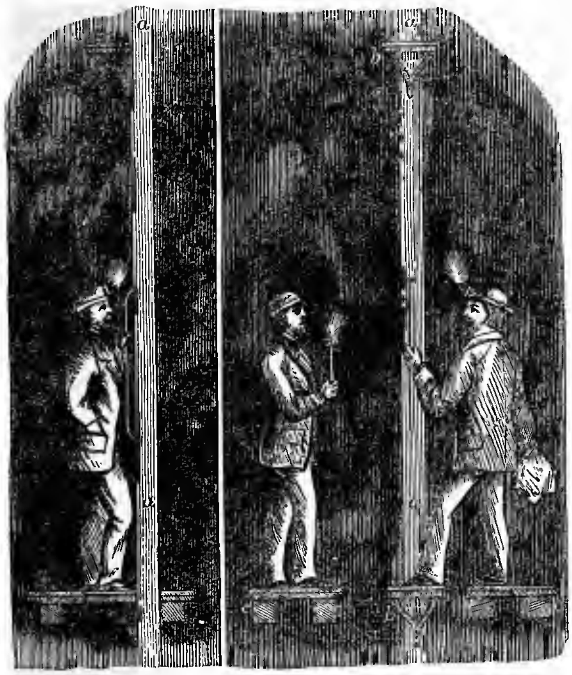

Fig. 6.

The man-engine consists of a beam of wood called the "rod," *a a*. Fig. 6, which is made to move up and down alternately through a space of twelve feet, by means of an engine devoted partially or entirely to that purpose. On the rod at *b b*, steps are fixed twelve feet apart, on which the men stand while it is in motion, holding on by iron handles provided for that purpose. When it stops for an instant before the motion is reversed the steps are level with the "sollars," which are placed in the sides of the shaft. It is evident that if the men who stand on the steps during the upward motion of the rod step on to the sollars during its downward motion, and step back to the rod when it again rises, they will be raised to the surface by successive lifts of twelve feet, without any labor on their part except the stepping off and on. As many men may thus be brought up from their work at one time as there are steps on the rod, and, as the sollars are fixed on both sides of the shaft, an equal number of men may be carried down at the same time, each stepping on the rod as the man leaving work steps off. The weight of the rods, with all connections, averages about 25 cwt. per fathom, or for a depth of 200 fathoms amounts to about 250 tons. The great weight is balanced by several of the "balance-bobs," to be described hereafter. The man-engine is so great an advantage to all concerned, both workmen and employers, that it would soon become generally used in deep mines unprovided with lifting cages but for its great expense. This is very great indeed, since most of the shafts in deep and therefore old mines are too narrow and irregular to allow of its introduction without a good deal of expense in cutting down the irregularities. Still, in large mines, the expense is well repaid by the advantage.

The cost of supplying a man-engine, with driving engine complete to a depth of 200 fathoms—exclusive of the cost of the shaft itself—cannot be taken at less than £2000 to £2500. The interest on the larger sum at 5 per cent., with 10 per cent. added for depreciation of plant and repairs, amounts to £375 per annum. The cost of coal and attendance for driving the engine, for oil and grease, etc., will amount to say £250 per annum in addition.

The labor of climbing from an average depth of 100 fathoms cannot be taken at less than 1 hour daily, or, with 3 shifts of 50 men at an average of 5d., the amount lost by climbing will be each day 62s. 6d., or, for a year of 240 working days, say £801, showing a clear gain of £175. For a depth of 310 fathoms the advantage is many times greater, since the exhaustion of the men from the labor of climbing and the time occupied will increase in a geometrical ratio. However, setting aside all calculations of cost, it is only necessary to look at the men who have just come up by ladders from deep mines to see that some mode of relieving them from such excessive toil is most necessary. The man-engine originated in Germany, where it is called the "fahr-kunst." The idea occurred to some of the German miners, who saw the reciprocating action of the pump rods, to attach steps to it, and this was actually carried into practice. In Cornwall the idea of a man-machine was first carried into effect by Mr. Loam, in 1835, at Tresavean mine in Gwennap, Cornwall, and an award of £500 was made to Mr. Loam for his great boon to the working miners by the Royal Cornwall Polytechnic Society.

—*From the Principles of Metal Mining.*

THE CONVEYANCE AND RAISING OF STUFF.

THE earliest mode of bringing the ore and deads from the "pitch," or the place of work, to the surface, was probably by carrying it in baskets of wicker-work, and this mode is still in use in many foreign mines. For centuries, however, the mode most usually adopted has been to place it in wheel-barrows, and to wheel it along the levels. In many metal mines this mode is still the only one in use, but some form of a tram-wagon is now very generally introduced.

The first improvement was to lay planks along the rough floor of the level, upon which the wheel of the barrow would run more easily. The wheel-barrow used for such purposes in Cornwall is shown in Fig. 1. It has no legs; is nearly parallel lengthwise; and its sides are but little inclined. Its ordinary load is about 1 cwt. to 1¼ cwt. It is usually made on the mine, and its cost varies from 8s. 6d. with a wooden wheel, to 12s. 6d. with an iron wheel. Such a wheel-barrow is admirably adapted for use underground in the old-fashioned narrow levels, and it is far more convenient for tipping sideways than is the ordinary navvy barrow, with side sloping sides and long legs.

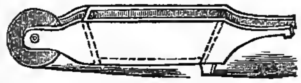

Fig. 1.

Tram-Wagons.—The introduction of a wider system of levels, and their increased length, due to the smaller number of shafts in deep mines, has led to the gradual introduction of tram-wagons, running upon four wheels. These are sometimes made of wood strengthened with iron bands, but are better of iron throughout. Fig. 2 shows a wagon made of boiler-plate. This, when 42 inches long, 30 inches wide, and 18 to 20 inches deep, will hold about a ton of iron ore; will weigh from 3 to 4 cwt.; and cost from £5 to £6.

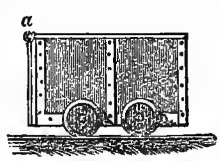

Fig. 2. — TRAM-WAGON, flanged wheels. Door at end, hinged at *a*, made of iron plates riveted.

Sometimes the wagons are made with plain wheels to run between tram-plates, of a form shown in fig. 3, at *a*, but a saving of iron is effected by using flanged wheels running upon wooden rails, 3 inches high and 2 inches wide, faced with thin bar iron, or upon iron rails nailed to wooden sleepers. Three forms of rail are shown in fig. 3, *b c d.* A convenient width between the rails is 36 inches, but the writer has seen gauges in use in Cornwall and South Wales varying from 42 inches downwards to 14 inches, the latter being used for the narrow levels in an old iron mine. The rails used weigh from 10 lbs. to 20 lbs. per yard of length.

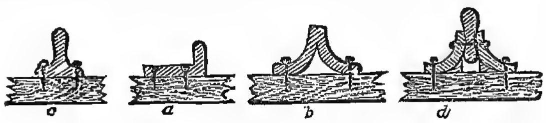

Fig. 2.

The tram-wagons are pushed along by boys or men, sometimes pulled by donkeys or horses, and in a few instances hauled along by wire-ropes or chains, which are coiled around winding-drums worked by stationary engines. Where possible the rails should have a downward inclination of about half an inch per fathom in the direction of the load, as this greatly facilitates the movement of the heavy weight, without materially impeding the return of the empty wagons. In the iron mines of the North of England and South Wales much greater inclinations are rendered necessary by the situation of the ores, and "tail-rope haulage" is exceedingly common.

Methods of Raising Ore.—The stuff having reached the shaft has next to be raised to the surface. From depths not exceeding 15 or 20 fathoms, the "tackle" shown in fig. 7 may be used with advantage. This plan is not to be recommended for greater depths, as the cost may be considerably lessened by the use of other appliances—the "horse-whim," derrick or whipsey-derry, water balance, or steam engine—described in the chapters on machinery for raising ore and pumping. The ore is raised either in "kibbles," "skips," or "cages." The kibble is simply an iron bucket made of boiler plates, riveted together as shown in figs. 1 and 7. They are attached to chains, hempen or wire ropes, and vary in capacity from 1 to 25 cwt. The small kibbles used with the tackle are called "winze-kibbles." They are made about 14 inches high and 12 inches in diameter; holding from 1 cwt. to $1\frac{1}{4}$ cwt. Whim-kibbles are of nearly the same form as winze-kibbles, but they are from 20 to 24 inches high, 14 to 18 inches wide, and made of somewhat thicker plate, with a loop below for greater facility of upsetting in landing. They hold from 4 to 6 cwt. Kibbles of

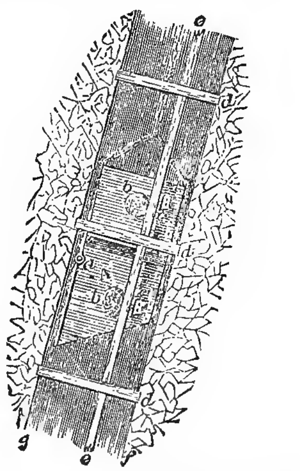

Fig. 4.—A, The Skip, with a hinged door at *a*, wheels at *b*, and guide pieces at *c*, *c*; *d*, *d*, cross timbers let into sides of shaft; *e*, *e*, guides; *f*, foot-wall; *g*, hanging wall of lode.

very large dimensions are occasionally used for deep shafts, and worked by water wheels or steam engines. At Dolcoath mine, in Cornwall, very large kibbles, capable of containing a ton or more of tin stuff, are worked in some of the old irregular shafts. The largest of these are more than 4 feet high, and about three feet 6 inches wide. When kibbles are used in deep shafts it is because they are much inclined and somewhat irregular. The lower side or foot-wall is often partially or entirely lined with "bed-plank" to reduce the friction. The amount of wear, of bed-plank and kibble is very great, the friction is enormous, and the breakages, owing to the strain on the ropes and machinery, are very frequent; so that the use of kibbles for deep or permanent shafts is not to be recommended. A much better plan is to straighten the shaft as much as possible, to put in guides or shaft railways, and to use skips running upon wheels as shown in fig. 4. These skips are now commonly raised by means of wire-rope, but unless the railway be put in very carefully the friction is still considerable, and in Cornwall a speed of 360 feet per minute has rarely been exceeded. For highly inclined shafts, the skips should have wheels as shown in the figure; but when the shaft is nearly vertical, simple guides will suffice. Fig. 5 is a plan of a shaft with double skip-board adapted for wheels, and fig. 6 a similar shaft arranged with "cover and filler" roads for guided skips. The cost of putting in a double skip-board or shaft railway will vary from £1 10s. to £3 10s. per fathom of length.

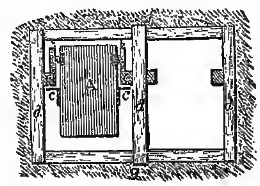

Fig. 5.—Plan of Double Skip-road or Shaft Railway. A, the skip; *b*, the wheels; *c*, *c*, guides; *d*, *d*, shaft timbers; *e*, *e*, the rails.

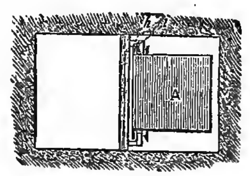

Fig. 6.—Plan of Double "Cover and Filler" Skip Road. A, the skip; *i*, the "cover;" *h*, the "filler."

The skip shown in fig. 4 is filled sometimes at the upper end, but sometimes the rails are bent round so as to allow it to take a horizontal position at the bottom of the shaft, when it is filled by opening the hinged door. This door is then secured with a catch until it reaches the surface, where the "lander" brings it over his wagon and opens the door, so allowing the stuff to slide down the sloping bottom.

Wherever possible, the use of a pair of cages running in a vertical shaft is to be recommended. These are arranged so that the loaded wagon from the "end," "stope," or "face of work" may be run directly into the cage, and raised to the surface with only one loading. In this manner a much greater speed may be attained; and nearly twice the quantity may be raised from the shaft with the same power as in the case of a pair of skips.

Comparative Cost.—From shafts from 10 to 15 fathoms deep, two men will raise on an average, with the tackle, about 12 tons in eight hours. The cost of this in Cornwall is 6s., or say 6d. per ton, or $\frac{1}{2}$d. per "ton-fathom." For depths of more than 15 fathoms a less quantity will be raised, or else a third man will be required, and the cost will be about $\frac{3}{4}$d. per ton fathom. A hempen rope about $1\frac{1}{4}''$ diameter, called a tackle-rope, is generally used with the tackle. With a one-horse whim, one man to receive the stuff and a boy to drive the horse, from 15 to 20 tons per eight hours may be raised from a depth of forty fathoms. The cost will be in Cornwall about 9s., or, say, 6d. per ton as before, but the depth being greater it will only be about 1-6th of a penny per ton-fathom. To raise a greater quantity, or from a greater depth, two horses will be necessary. With the "derrick" or "whipsey-derry" the cost will be a little more than with the horse-whim. Whim kibbles are often raised by means of chains, but the use of chains in shafts is not to be recommended. With large kibbles working in shafts of from 150 to 300 fathoms deep, from 20 to 30 tons per day of eight hours may be raised—the larger quantity, of course, from the shallower shaft. When engine power is used, the cost will be about 10s. to 12s., or, say, 1-30th of a penny per ton-fathom on an average. A water-wheel will save about 2-5ths of this. With a well-arranged skip and shaft railway the cost of raising ore, even where a steam engine is used, will be reduced to about 1-50th of a penny per ton-fathom, or less; and with a pair of cages in a vertical shaft with good arrangements will not exceed 1-100th of a penny per ton fathom.

In metal mines, where ores of a considerable specific gravity have to be dealt with, large cages are seldom needed. A wagon 30″ + 42″ + 20″ will hold about one ton of iron ore, and this is as much as it will be generally necessary or desirable to raise at one time. With good arrangements, a shaft of twelve feet by nine feet will be found large enough to allow of ample pumping space, a good ladderway, and a pair of cages capable of raising twenty tons per hour from a depth of two hundred fathoms. From the foregoing remarks it is evident that kibbles are only suitable for shafts of moderate depth, and preferably for those which are nearly vertical. Cages are only suitable for vertical shafts, but are valuable for all depths. For inclined shafts, skips running upon wheels are most suitable; and it will be worth while in every case to pay great attention to the rails or guides upon which they run. Where the inclination of the shaft from the horizontal does not exceed one in three, as in many ore beds and some few "flat" lodes, the ore may be brought up in the tram-wagons from the levels without using skips or cages, the same tramway being continued up the incline to the surface. In all cases, if at all possible, double roads should be used, or two pits should be put into communication to cause the weight of the descending cage to balance that which is ascending, so that the mineral only shall be lifted. Sometimes where both these modes are for some reason unsuitable, a "dummy" counterpoise may be used.

Ropes.—For shallow pits chain or hemp rope may be used with great propriety, because of the facility with which it may be coiled round small barrels or drums; but for considerable depths, and especially where great weights have to be lifted, the use of wire rope in some form is both safer and much more economical—and is, indeed, now almost universally used. Wire-ropes may be either round or flat, of iron-wire or steel. For round iron-wire ropes, drums of less than twelve feet should never be used; for flat ropes and ropes of steel wire, drums somewhat smaller may be used, but not to be recommended in general.

The following tables of the equivalent working strengths of chain, hemp rope, iron-wire rope, and steel wire rope, will be useful to the young student. They all refer to material of best quality.*

TABLE 1.—WEIGHT AND STRENGTH OF CHAINS.

Diameter of iron	5-16 in.	11-16 in.	15-16 in.
Weight per Fathom	5½ lbs.	28 lbs.	49 lbs.
Working Load	24 cwt.	54 cwt.	120 cwt.

TABLE 2.—WEIGHT AND STRENGTH OF GOOD HEMP ROPE.

Circumference	5½ in.	8 in.	12 in.
Weight per Fathom	7 lbs.	16 lbs.	36 lbs.
Working Load while new	24 cwt.	54 cwt.	120 cwt.
Breaking Strain	8 tons.	18 tons.	40 tons.

TABLE 3.—WEIGHT AND STRENGTH OF IRON-WIRE ROPE.

Circumference	2⅛ in.	3⅜ in.	4⅝ in.
Weight per Fathom	4 lbs.	9 lbs.	20 lbs.
Working Load	24 cwt.	54 cwt.	120 cwt.
Breaking Strain	8 tons.	18 tons.	40 tons.

TABLE 4.—WEIGHT AND STRENGTH OF STEEL-WIRE ROPE.

Circumference	1½ in.	2½ in.	3¾ in.
Weight per Fathom	2½ lbs.	5½ lbs.	12 lbs.
Working Load	24 cwt.	54 cwt.	120 cwt.
Breaking Strain	8 tons.	18 tons.	40 tons.

As shown in the tables, a very large allowance of strength is made for safe working, the working load being taken at less than one-sixth of the ultimate strength. With hemp rope and chains a greater allowance should be made, on account of the imperfection of material and workmanship to which they are especially liable. A large allowance must be made, too, for the strain due to the extra pull in starting. Sometimes this is somewhat relieved by mounting the bearings of the winding pulley or drum upon springs, but even when this is done the extra strain will be very considerable.

* Very complete tables of equivalent strengths are given in Molesworth's "Pocket-book of Engineering Formulæ."

The weight of the chain or rope itself must be taken into account when any considerable length is used, and this too will be much greater with chain or hemp rope than with wire rope. Indeed, for deep pits the use of chain would be forbidden by this consideration alone, as a chain of 300 fathoms long, capable of working with a load of 24 cwt., would itself weigh nearly one ton, while a steel-wire rope of the same strength would weigh only 750 lbs. To relieve the winding engine, and to enable it to overcome the weight of a long length of rope, the size of the drum is made to vary, or the speed of winding at first is reduced. This may be effected either by using a conical winding drum, or by using a flat rope and causing it to wind upon itself.

The Tackle.—The first machine used in mining operations for raising ore or deads is usually the tackle or windlass, shown in fig. 7. This is so simple that it scarcely needs a detailed explanation, but as it is usually made on the spot by the mine carpenter, a few words may not be out of place. The carpenter selects two pieces of "half-timber" *a a* long enough to reach across the shaft, and strong enough to bear the weight. These are called the "bearers," and they are afterwards planked over, except the small space

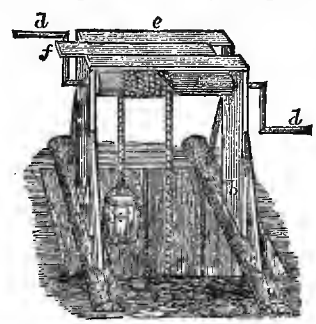

FIG. 7.

required for the kibbles. In the middle of these half-timber bearers the uprights *b b*, made of planks from 10 to 12 inches wide, 4 feet 6 inches long, and 1¼ to 1½ inches thick, are morticed. In the upper end of each upright a slot, about 10 inches long and 1½ inches wide, is cut, and the bottom lined with iron, to receive the iron handles, and to prevent the wood from splitting. The barrel *c* is made of a piece of Norway pine, from 4 to 6 feet long, and 8 or 10 inches thick. The ends of the barrel are strengthened with iron bands to prevent them from splitting when the handles are driven in.

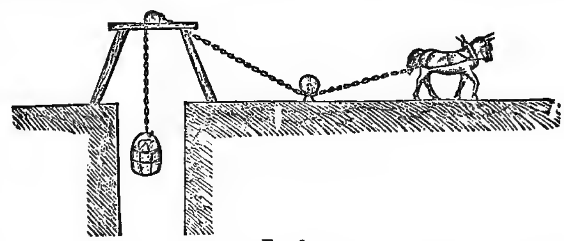

FIG. 8.

The handles *d d* are made of 1″ or 1½″ round iron, bent as shown, and squared and tapered at the ends for driving into the barrel. The handles serve also as an axle for the winding barrel. A piece of wood *e* is then fastened across the top of the tackle, and a groove is made in it to receive

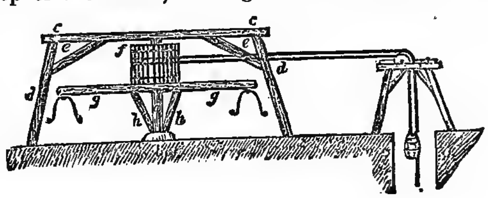

FIG. 9.

a sliding piece *f*, which, being pushed out beyond the bend of the handle, holds it when required, keeping the load from descending. Sometimes stays are fixed extending sideways from the uprights, as shown at *g g*. The cost of preparing and fixing this shaft-tackle should not exceed 25s. or 30s. for timber, iron-work, and labor. The tackle is well adapted for raising material from depths of less than 15 fathoms; for greater depths, up to 50 fathoms, the derrick or "whipsey-derry," fig. 8, is sometimes used, but it is slow in operation, and has little to recommend it except its small first cost, which is from £2, 10s. to £3, 10s.

The Horse-Whim, shown in fig. 9, is a much more efficient machine. This, too, is made on the mine, the mode of construction being as follows:—The axle *a* is of oak, about 12″ diameter, and 12 or 14 feet long. Three sets of arms are morticed into this at distances of 6, 8, and 10 feet from the lower end. Upon these arms wooden segments are nailed, and upon these again the 4-inch planks which form the barrel or cage. Each end of the axle is bound with iron, and each has an iron centre attached. The lower one works in a block of stone, shown at *b*, the upper in an iron socket fixed to the span beam *c c*. This is made of a piece of Norway or Swedish fir, 36 feet long and about 10 inches square, supported by the legs *d d*, which are morticed in the beam, and frequently strengthened with iron strapping plates. Stays are added at *e e*. The barrel *f* is 10 feet diameter; beneath it is placed the driving beam *gg*, 30 feet long, and strengthened by the stays *hh*. At one or both ends of the driving beam a bar of iron is fixed with a yoke to which a horse may be attached. The total cost of such a whim as here described is under £20, and is a very efficient machine.

The Poppet Heads are shown over the shaft to the right of the whim. The construction is as follows:—Two timber "horses" *i i* are first formed. The legs are 12 feet long, and as thick as possible, but not less than 10 or 12 inches. These are partly sunk in the ground, and the upper ends are morticed into the "caps," which are 9 or 10 feet long. The horses are placed one on each side of the shaft, about 5 or 6 feet apart, the centre of the space between being in line with the span-beam of the whim. Carriers are placed across the horses, and the bearings of the pulleys rest upon these. The pulleys are usually of different sizes. Where chain or hemp ropes are used for hauling, one may be about 4 feet and the other about 2 feet, each being 4 inches wide. Wire rope is seldom used with a whim, but should it be used the pulleys must be much larger. The total cost of the poppet heads for whim drawing will not much exceed £6. Very similar poppet heads, but larger, are used in many cases when winding with a steam engine or water wheel. It is not often that water wheels are arranged for hauling purposes, although in some instances, as at Wheal Friendship, near Tavistock, they have been used with excellent effect. The only peculiarity is the application of suitable gear for reversing or stopping the motion. There is no great difficulty in this, but the inconvenience is sufficient to prevent their extended use for such a purpose in shallow mines, and in deep mines a sufficiency of water power is rarely available, and what there is may be often more advantageously used for pumping. We shall therefore reserve our remarks upon water wheels for the chapter on "Pumping Machinery."

An easy and convenient, but not economical mode of using a fall of water for winding purposes is shown in section in fig. 10. The water enters at *a*, and falls upon the

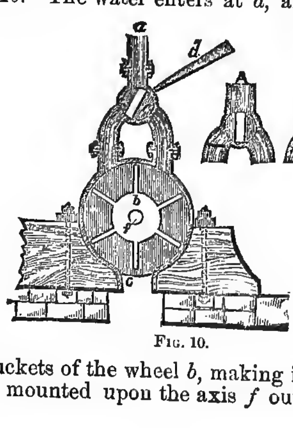

FIG. 10.

leaves or buckets of the wheel *b*, making its escape at *c*. A cogwheel is mounted upon the axis *f* outside the working barrel, which serves to communicate motion to the winding drum *g*, shown in fig. 11. The motion is stopped or reversed by the handle *d*, which moves the valve *e*, bringing the channel successively into the positions shown at A and B. The whole arrangement is shown in fig. 11, where *a* is the inlet for the water, *h* is the case containing the working wheel, *i* is the cogwheel fixed on its axis, and *g* the winding

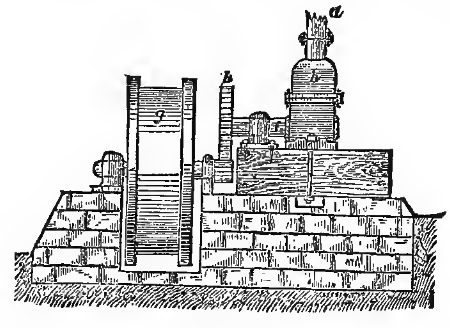

FIG. 11.

drum. This mode of using water power is suggested by a working model which is now in the Museum of Practical Geology in Jermyn Street, London. It is cheap, compact, and easily constructed, and but little likely to get out of repair, but the author is not aware that it is anywhere in use. When the fall of water is great, this simple arrangement will be found very efficient.

The Water-Balance.—In many of the open works on the northern side of the great coal basin of South Wales, water-balance machines are largely used for winding purposes, and for mines of not more than 100 fathoms deep; in a district affording a good supply of water, and free drainage by means of adits, they may be highly recommended. Sometimes they are used where there is no drainage, the water being pumped up from the bottom by an engine, but this is not to be recommended. In some cases the machines are placed at different levels, so that the same water is used five or six times over as many successible lifts. The tram, containing from 12 to 20 cwt., is placed in a cage over an empty water bucket, and the empty tram on a similar bucket at the top. Water is then made to flow into the upper bucket until its weight is great enough to cause it to descend, so raising the filled tram. On the arrival of the full bucket at the bottom of its fall, a self-acting valve opens and the water is discharged, so allowing the process to be repeated. The buckets are made of ½″ boiler-plate, circular in form, and some hold more than 2 tons of water. The landing chain is balanced by a chain which hangs below each bucket, and guide chains are used to keep the buckets from striking each other when the shafts are not divided. A speed of 300 to 400 feet per minute is easily attained by this machine, and the total cost of raising stuff is about 1½d. per ton per 50 fathoms. For great depths the weight of the machinery becomes so great that the economy is reduced or disappears. Somewhat similar machines are used in some of the iron mines of North Lancashire and Cumberland.

The Steam Engine.—For hauling in deep mines a steam engine is generally necessary, and although many forms of steam engine are employed for this purpose, our remarks will apply to two only—the double-acting high-pressure condensing engine, and the double-cylindered horizontal engine. Both these machines work the steam expansively, and both give good duty when in good order and when well attended; but the preference in the future will probably be given to the horizontal engine everywhere at any rate, except in Cornwall. The Cornish winding engine differs but little from the Cornish pumping engine, hereafter to be described, except that it is double acting, *i. e.*, it takes its steam on both sides of the piston instead of only on the upper side. It is, however, supplied with a heavy fly wheel to equalize the motion as much as possible. The driving crank is placed between the fly wheel and the winding drum. Neither a very rapid nor an equal motion is obtained by this form of engine, and the double-cylindered horizontal engine is on the whole much to be preferred. The Cornish double-acting engine is sometimes used for pumping, or for driving, stamping or crushing machinery.

Horizontal Engine.—The cylinder of this engine is fixed in a horizontal position, as show at AB in fig. 12. High-pressure steam is admitted alternately on each side of the piston. The piston-rod is terminated by the crosshead *g*, which works backwards and forwards between the guides *a b*. To this crosshead the connecting rod *g c* is attached, and this turns the drum or fly-wheel by means of the crank C and the main shaft *r*. The whole is fixed on heavy masonry as at C D. To equalize the motion two cylinders are used with their crank at right angles, so that one is exerting its greatest amount of force while the other is at its dead point. A common form of governor is shown at G. To economize steam it is used expansively. The condenser and its connections are not shown in the sketch, but they may be placed in any convenient situation. For winding purposes they are fitted with reversing gear and powerful friction brakes

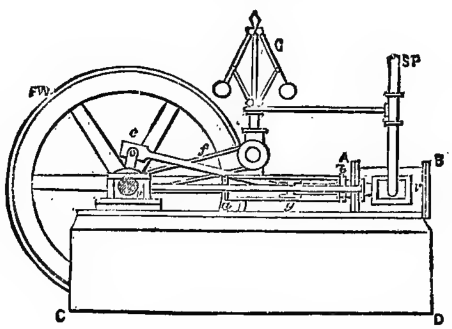

FIG. 12.

The advantage of the horizontal over the beam winding engine is greater compactness and less first cost for equal power, a saving of cost in the necessary buildings, and, if two cylinders be used, a more equable motion. Its only disadvantage is that the cylinders are apt to lose their true form, the lower part becoming more worn than the upper, owing to the weight of the piston. A remedy for this has been found by mounting the piston on the centre of a long piston-rod which passes through stuffing boxes placed at each end of the cylinder. Every winding engine should be fitted with some form of indicator, showing the attendant the exact position of the skip or cage in the shaft at a glance, as in this way many accidents from over-winding may be prevented. To prevent loss of steam by condensation in the steam-pipe, cylinders, etc., these parts, as well as the top of the boilers themselves, are covered with some non-conducting material. The modes of doing this will be explained in a future chapter. The principal forms of boilers will also be there described and illustrated.

—From the "Principles of Metal Mining."

NOTE ON HOEFER'S METHOD OF DETERMINING FAULTS IN MINERAL VEINS.

I DESIRE to call the attention of members of the Institute to a new method of plotting and determining faults in mineral deposits, suggested by Prof. Hans Hoefer, lately of the Mining School of Przibram, and now of the School of Leoben, and one of the editors of the Austrian *Zeitschrift für Berg-und Hüttenwesen*, in the 29th volume of which appears his paper on the subject. I will here give an abstract of its contents, which though partial, will be, I trust, sufficient for my purpose.

In the examination of a fault, we usually follow the rule of Zimmermann, which assumes that the hanging-wall of a faulting-fissure has slid downward in the direction of its dip; but dislocations (coal-seams in particular) show many cases in which one part of the seam has been shoved over the other; that is, the hanging-wall of the faulting-fissure has slid upward instead of downward. For a long time, every dislocation of a mineral deposit upon a cross-fissure was regarded as necessarily belonging to either one or the other of

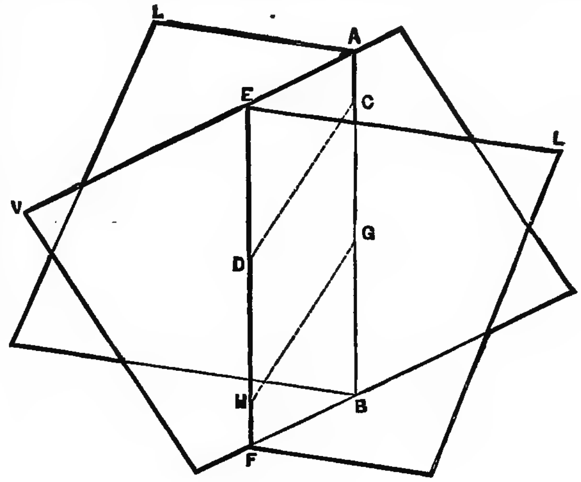

Fig. 1.

these two classes. It was either a slide (*Sprung*) or a heave (*Wechsel*). But it has been proved of one and the same fault that it may appear at one place to be a slide, while at another place, even in the same mine, it appeared to be a heave.

This phenomenon itself suffices to show that the classification of dislocations is not so simple as has been supposed, and the methods pursued by mine surveyors, based upon that classification, may, therefore, need improvement. These methods, as is well known, assume that throughout a given fault the motion of the hanging-wall has been everywhere the same, and consequently that the so-called vertical interval or "throw" determined by exploration of the two dislocated parts of the deposits at any one point is a guide for exploration at all other points. Practice, however, shows that this guide is not unerring. It does not always agree with the indications of actual movement and direction furnished by the striations of the walls of the faulting-fissure. These marks frequently do not follow the dip, but obliquely cross it. The oblique or other motion thus indicated is certainly one of the elements in the geometrical problem presented to the surveyor.

Fig. 1 may illustrate this point. Let *AB* be the line of intersection between the vein *L* and the faulting-fissure *V*, the striations of which indicate that the movement took place in the direction of *CD*. The dislocated continuation *L* of the vein being found at *EF*, the old rule would declare that the case was one of a heave or upward movement of the hanging-wall; and yet it is really an oblique slide. That the distinction is important appears when we consider that, if the vein being worked in the foot-wall of the faulting-fissure had contained an ore-body which was cut off by

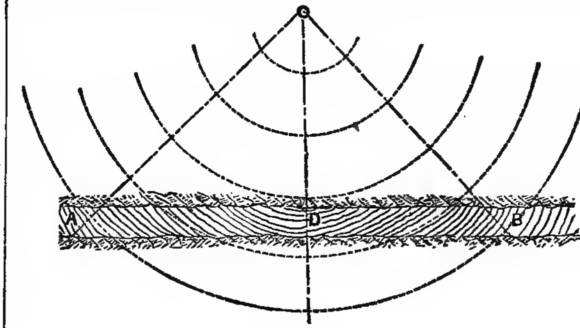

FIG. 2.

the fault at *G*, the old rule would require us to accept the continuation of this ore-body at some higher point in the hanging-wall of the fault; whereas, by the present hypothesis, it is at the lower point H, to which the striations tend. It is apparent that an oblique slide would not, according to the old rule, appear to be a slide at all, unless the striations (that is, the actual movement) were steeper in dip than the lines of intersection. In case L had been horizontally moved, the dislocation would, by the old rule, be a slide, if it had moved in one direction, and a heave, if it had moved in the other; whereas, in reality it would have been neither. But Professor Hoefer goes still further, and declares that the parallel uniform movement of the hanging-wall of a fault is not to be always assumed. The evidence of this statement is drawn especially from coal-seams; not, as I apprehend, because the dislocations of these deposits are different in nature from those of metalliferous veins, but because coal-mining has furnished more extensive excavations, and therefore a greater body of evidence than any other branch of the business. Moreover, we can with greater certainty judge what was the original position of a coal-bed than we can of a fissure-vein. When the latter suddenly changes dip, for instance, beyond a fault, we can not be sure that the change of dip did not exist before the dislocation took place, This phenomenon of a change of dip and also strike is frequent in coal-fields, under such conditions as make it reasonably certain that neither the original position of the coal nor irregularities in the faulting-fissure were the cause; but rather that the relative movement of the two parts of the deposit was not in parallel lines. In many cases where veins show a uniform dip, that is, approach in

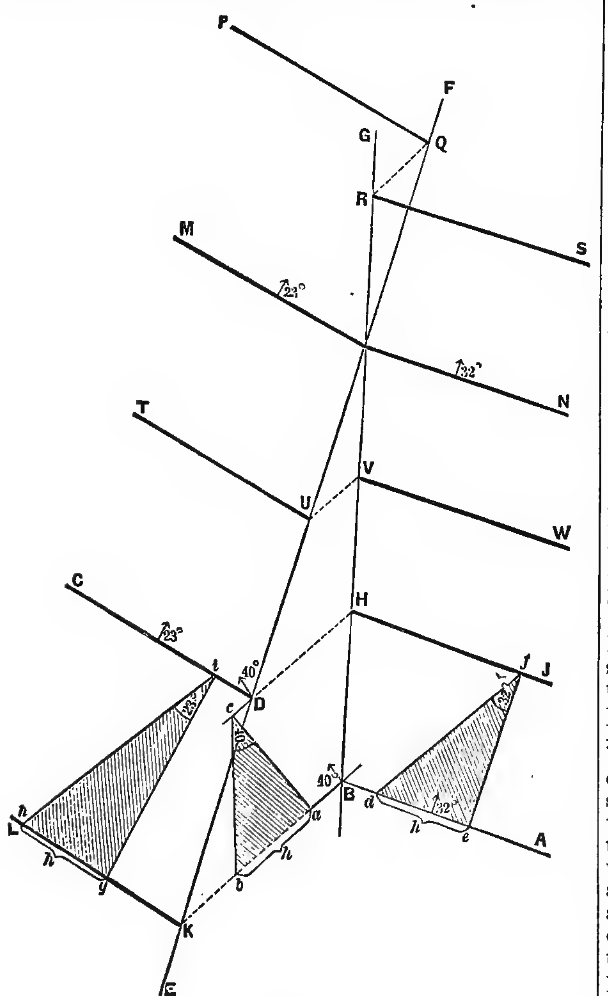

FIG. 3.

form a regular plane, and yet exhibit these changes beyond a fault, it is reasonable to infer, instead of a simple slide or heave, a partial révolution of the mass on the hanging-wall side of the fault around an axis normal to the plane of the faulting-fissure. A simple geometrical construction will show that when one mass of rock has moved in this manner

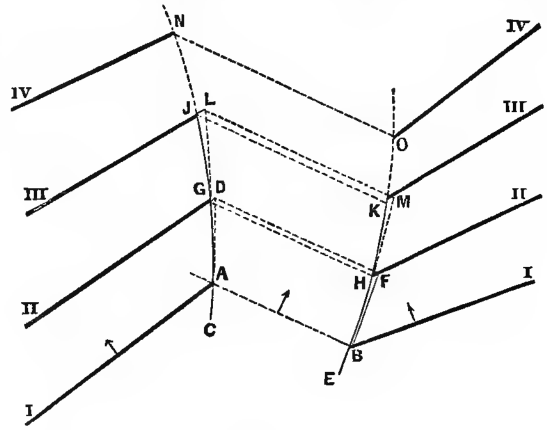

FIG 4.

upon another, the dislocated portion of the mineral deposit common to the two must acquire a different strike and dip from that which has remained unmoved. Professor Hoefer cites as an illustration a very extensive fault in the neighborhood of Aix, which shows to the southeast a greater vertical dislocation than toward the northwest, and can only be explained by a turning movement.

Fig. 2. shows how, in the simplest case, that of a revolution without vertical descent or ascent of the hanging-wall, the striations in the faulting fissure may indicate the axis of the revolution. In this figure, AB is a drift run in the faulting-fissure, and showing striations according to the dotted lines, which pitch in one direction at A, and in the opposite direction at B. In such a case, the center of movement would be found at the intersection of perpendiculars drawn through the line of striations. Thus, if striations were exposed at A, B, and D, the intersection of the perpendiculars would show the center of movement to be at C. In practice, however, it is likely that the several perpendiculars drawn through such striations would not intersect at a given point; and this would show that, besides the turning movement, there had also been a movement of translation of the whole mass, up, down, or along the plane of the fault. The complication of these two movements is, however, not beyond analysis, if the data are sufficiently abundant and exact. Even with the imperfect data usually afforded by the limited exposures in mines, it is much better to work upon a perfect than upon a crude and partial system; and Professor Hoefer thinks that not only the points already mentioned, but also the question of direction of movements (for example, in Fig. 2, whether from B to A, or A to B), can in many cases be satisfactorily determined by the plan he proposes.

This plan may be illustrated for a general case by Fig. 3. Let AB represent the course of a vein dipping 32° (as shown by the arrow), which has been explored on an upper level to where it is cut off by a cross-fissure having the strike BK and the dip of 40° (as shown by the arrow). Let it be assumed that upon a lower level the vein had been opened, with the strike CD and the dip of 23°; that on this level a fault was encountered at D, having the same strike and dip as that at B. By a simple construction, with the help of the triangle abc, in which the angle c is 40, and the side ab is the vertical distance h between the two levels, we find the point c and draw the line cD, which, being parallel to BK and also coinciding with the strike of the fault at D, proves the latter to be identical with the fault at B on the level above. We now determine the two lines of intersection EF and BG made by the fault, with the two portions AB and CD of the faulted vein. This can be done most easily by the aid of the two triangles, def, ghi, in which the base h is taken equal to the vertical distance between the two levels, and the angle opposite h is, in each case, the dip. AB and CD being already given; the corresponding lines, namely, HJ on the level of CD, and KL on the level of AB, are to be found. This is done by drawing HJ parallel to AB through the point f, and prolonging hg parallel to *CD*. The course of the fault at *B* is known; hence the line *BK* drawn on that course intersecting the line *KL* at *K* determines the point *K* for that level, while for the next lower level the point *H* is determined by producing the line *CD* parallel with *BK*; in like manner, the lower levels, *TU*, *VW*, *MON PQ*, *RS*, etc., can be plotted. It is evident that by drawing lines through *KD* and *BH*, the lines of intersection *EF* and *BG* are obtained. It is evident also that on the fourth level *M*, if in working from *M* the fault is encountered at *O*, it will not be necessary to cross-cut, as in the upper levels, to find the continuation of the vein; since at that point, which is the center of revolution, the vein can be found by simply breaking through the cross-fissure. In the next lower level, *PQ*, however, if the fault is encountered at *Q*, it will be necessary to cross-cut for the continuation of the vein in the direction *QR*, a direction opposite to that which would be necessary at *U* or *D*.

checks by graphic construction the errors of observations due to irregularities in the vein and fault. He points out also that this method indicates conclusions as to the nature of the movement which has taken place; since, if the two lines of intersection are parallel, the movement must have been parallel; while if they converge, the movement must have involved a revolution, and the points where they intersect must be the intersection of the axis of revolution with the plane of the fault.

This statement of Professor Hoefer's method suggests the following observations:

Evidently the graphic methods shown in Fig. 3 will not indicate, in case of a compound movement, involving both a revolution and a slide, either the existence, the direction, or the amount of the latter. The relative position of the two parts of the faulted vein, shown in Fig. 3, may have been reached by a simple revolution around an axis normal to

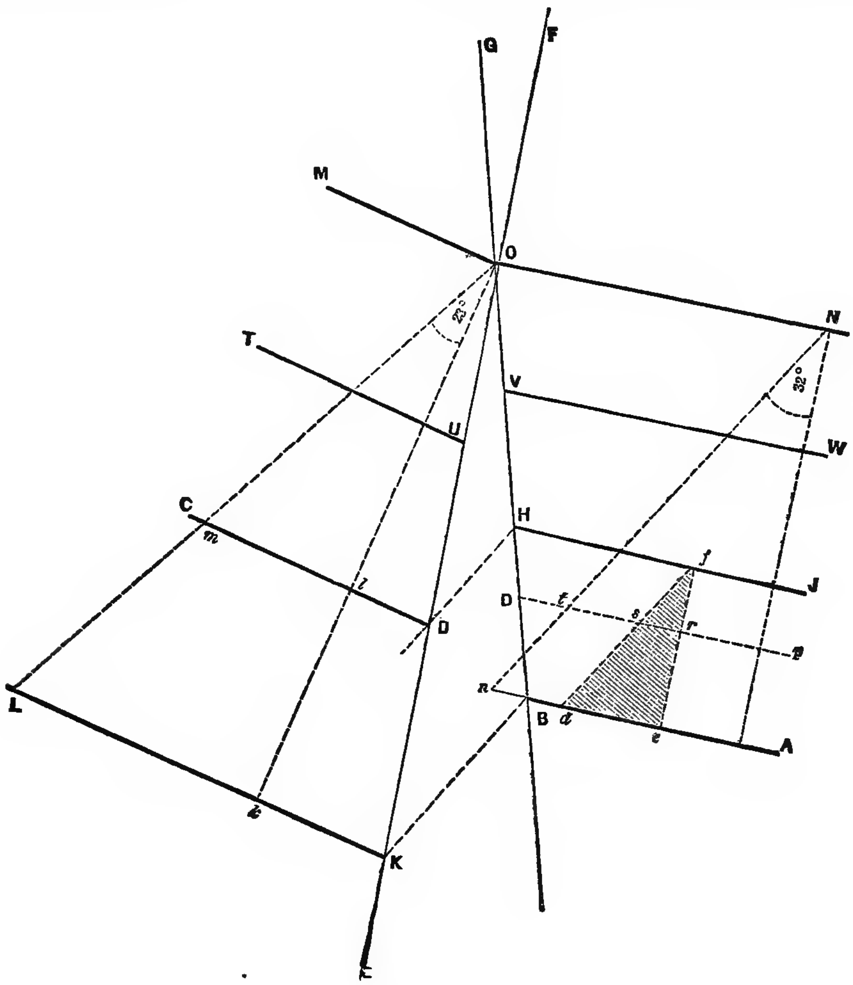

Fig. 5

It will be seen that in this case a revolution has been demonstrated without the help of the indications afforded by the striations.

Professor Hoefer indicates also how this graphic method may be applied to lines of intersection which are not straight, but curved; and to the still more complicated case of a varying strike at different levels in the faulting-fissure itself; that is, for instance, when *BK*, *HD*, *VU*, and *QR* are not parallel. Fig. 4 is the diagram he employs for this purpose. I will not, however, pause to explain it in detail.

Professor Hoefer recommends in practice the general method above described, on the ground that it involves no generic assumption or hypothesis, but makes the work of the surveyor in the first place purely descriptive, and also

the fault at *O*, or by a revolution around some other axis, normal to the fault, coupled with a slide along the fault. For instance, the axis of the revolution may have been at *U*, and the slide may have carried it *apparently* to *O*.

Yet this is precisely the case which may be expected to be most frequently encountered in practice. Simple revolutions must be rare, if, indeed, they ever occur. My own impression on this point is confirmed by the reply of Professor Hoefer to an inquiry which I addressed to him after perusing his paper. He says: "Circular movements combined with movements in straight lines are very frequent in our faults; in fact, I do not doubt at all that a continued careful study will show them to be the rule. Whether simple revolutions often occur, is very difficult to decide, from observations thus far available. You know how one-sided and incomplete the inquiry has heretofore been in this direction. In the southernmost district of Przibram, the Clementi vein shows in its selvages striations, the varying directions of which indicate a circular movement; and my studies (unfortunately interrupted by my departure) led me in this case to the belief that the movement had been circular only. But I did not consider the question definitely settled."

But to return to the illustration of Professor Hoefer's method given in Fig. 3, it is evident that although the method, applied as in that case, to a fault which has been determined in two places, at different levels, will not from these data alone, reveal the exact components of the movement which has taken place, it will nevertheless indicate for any level where the continuation of the vein is to be sought, beyond the fault. It is, however, often important to find the continuation, not merely of the vein, but also of an ore-body in the vein. Thus, in Fig. 3, the miner working from *C* to *D*, and finding the vein cut off by the fault, might know that by drifting into the faulting-fissure to *H*, on the same level, the vein would again be struck; but the point *H* would not in any case (except that of a simple and perfectly horizontal movement) be the point originally adjacent to *D*, before the faulting took place; and if there were at *D* a valuable ore-body, the question would still remain, in what direction from H the continuation of this ore-body should be sought.

For the case of a simple revolution around *O*, the solution of this question would be easy. It is shown in Fig. 5, which I have made by taking part of Professor Hoefer's Fig. 3, and adding two auxiliary triangles, *OLk* and *NnA*. The construction is as follows: From *O* draw *Ok* perpendicular to *KL*, and *OL*, making the angle $LOk = 23°$. Similarly construct from any point *N* on *ON* triangle *NnA*, making the angle at $N = 32°$. The distances cut off on the hypothenuse *OL* by the lines *LK*, *CD*, and *TU*, represent the hights (inclined measurement) between these levels. The same is true of the sections into which *Nn* is divided. The distance of *D* above the level *MO*, along the dip of the vein, is *Om*; and the point adjacent to *D* before the dislocation must lie at the same distance above *ON*. Taking $Nt = Om$, and drawing *Dp* through *t*, parallel with *HJ*, we have *D*, the point desired, which lies the distance *fr* vertically, or *fs*, inclined measurement, above *HJ*.

But if there has been a rectilinear as well as a circular relative movement of the vein masses on either side of the fault, point D^1 will not be the point formerly adjacent to *D*. The continuation of an ore-body cut off at *D* will lie at a distance and in a direction from D^1 directly dependent upon the extent and direction of the rectilinear movement. (I need hardly say that in all of these cases it is of no consequence whether both walls, or only one, actually moved. The total movement may be assumed to have affected one wall only.) In this case, the study of the striations in the faulting-fissure may give valuable, though perhaps rarely exact indications as to the direction of the movement. If the rectilinear movement followed the circular one, the striations may furnish a clear record of it in straight lines. If the two were (as is more probable) simultaneous, the striations would be strictly epicycloid curves; but for their interpretation it would be sufficiently accurate to consider them as fragments of ellipses, having their major axes inclined in the direction of the rectilinear movement. These indications would doubtless be in most instances of practice merely general guides to exploration. But after, by such exploration, the continuation of a given ore-body (as D, Fig 4) had been found, it is plain that the whole movement of the faulted vein could be analyzed and plotted, and that the continuation of any other ore-body could be sought with confidence. In the case before us it would be only requisite to determine the relations of the point actually found to D_1, its theoretical position on the hypothesis of purely circular motion; and the correction thus applied to D^1, could be applied to any other point similarly determined.

I should remark in conclusion, that all these constructions rested upon the assumption that the dip of each segment of the faulted vein is constant. That is, the vein is treated as a plane. But it would not be difficult to include in the method here shown, changes of dip and strike, as these might be discovered in actual working; and under certain circumstances, a change of dip might serve as a useful landmark in surveying. For instance, if in Fig. 3 there were a change of dip in the left-hand portion of the vein, at the level *CD*, then the corresponding change of dip must be shown on the line *GB*, at the point formerly adjacent to *D*; and the discovery of this point would at once, as has been already shown, permit the analysis of the movement which had taken place, and the deduction of all its resultant relations.

A paper by R. W. Raymond, Ph. D., Transactions American Institute of Mining Engineers.

THE SILVER MILL.

DEDUCTION from Practical Experience.—Iron producers, scientists, and railroad engineers have their societies for mutual benefit. Minute details of facts and forms which they develop conduce to general improvement. But no society of practical, actual workers in mining and metallurgy, as developed in the United States, exists to accumulate, and retain, from their several experiences, those minutiæ so essential to the maximum of economy and success.

From a lack of correct, minor details, the apparently superior mills do not always obtain the best results; and often from an old rattletrap mill most excellent results are obtained.

The causes are generally simple, but not always easily found, even by an experienced and observing millman.

It is often very convenient to lay the blame to the "peculiarities of the ore," when it may not belong there.

For an illustration of how deficiency in details may affect needless expense, mention may be made of a mill of recent manufacture and assumed to be first class in every respect. Although the intention was to grind the ore in the pans, the mullers and drivers were remarkably and unnecessarily heavy.

For the sake of exact figures, we will suppose the mill to be set up at Virginia, and working bonanza ore.

A set of shoes and dies would weigh about 1,400 pounds; at 5¼ cents, the cost would be $73.50. The value of the old iron left, after the set was worn out, would be less than $7.50, leaving a loss of $66.00 With mullers of minimum weight, the best average wear of castings is less than fifteen days; the excessive weight would grind them out three days sooner, a difference of $13.20, or nearly $1.00 per day; and these figures are where castings are the very cheapest.

Owing to the scattered and ever changing mining activities, with their unsettled and uncertain futures, and to the intoxicating effects of stocks, it is pretty certain that no mining society could enthuse a sufficiently interested membership; and the only authority available must continue to be, the men and builders, who chance to be selected to accomplish the desired results, be they better or worse. However, Americans need not be ashamed of their progress or status.

The prospecting miner who can extract good, free milling ore, can provide himself with machinery, of the capacity of 3 or 4 tons per day, with very little outlay, but he must be cautious not to drift into that error which has left so many wrecks, viz: the forfeiture of a success to an experiment.

It is commendable for those who can afford it to carefully experiment for improved methods. It is the life of progress.

But for milling on a more extended scale, for the greatest profits, heavier capital is requisite, and nothing more strongly emphasizes the saying, "the best is always the cheapest."

For the milling of raw ores two methods may be said to exist, which involve little difference in the mills, save the relative proportion of power, stamps, and pans.

The older and more familiar method is to crush coarse in the battery and grind in the pans. This involves greater power, greater wear of castings, and greater loss of quicksilver, and not always, better results.

A more recent, but not so universal method, is to crush fine in the battery and to keep the shoes barely off the dies. It may seem incredible that by the latter means more gold and silver may sometimes be extracted than by the former. Ore will naturally break where there is the most mineral, and from a fine comminution in the battery, the mineral will be nearly all disengaged. Quicksilver has a preference for gold and silver; but in grinding it is forced to take up base, which renders it inactive for the more precious metals. Result, more bullion and less value.

slimes before they have much hardened will cut the cohesion, and it is the cohesiveness in slimes that carries the quicksilver, and that cohesiveness, once established, brings all the difficulty of working them.

Of the two methods, a compromise ground is untenable. It is a fact, well known by the experienced, that when thoroughness of grinding is wanting, returns are also. This has

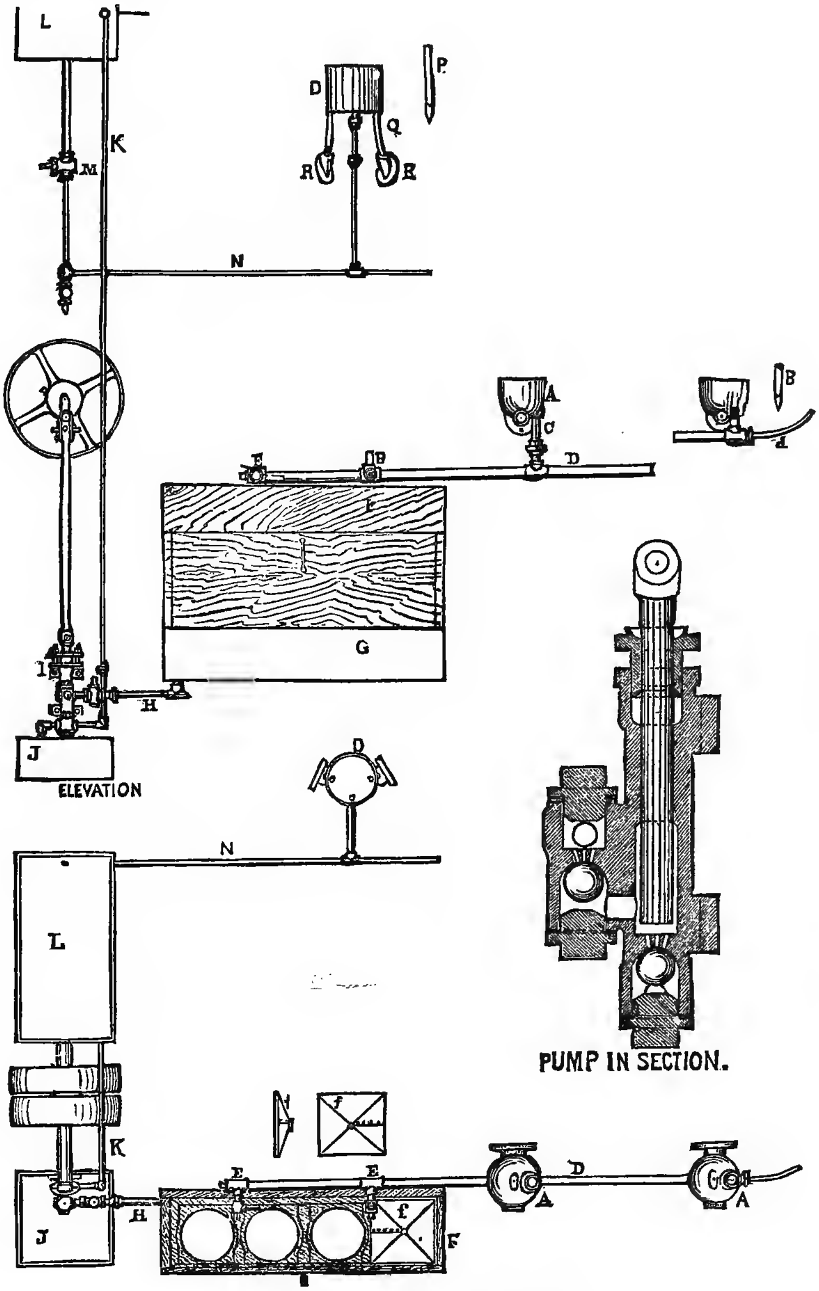

PLATE 1. QUICKSILVER PUMP SYSTEM.

It is a matter of doubt whether, taken all in all, there is an instance where amalgamation without grinding might not equal the more expensive grinding.

Comstock ore is always ground, but they never have exhaustively experimented otherwise. Again, fine crushing increases the percentage of slimes, and the system of working them separate (the sand for the Mine Co. which must not return below a given per cent., and the slimes for the Mill Co.) make it difficult to render the required returns to the mine.

The query might arise, "Would not the slimes exceed the ability to handle them?" Very little sand worked with the been thought a proof against not grinding, but the latter is not to be judged when fine crushing has been compromised.

In a proper conditioned pan pulp once between the shoes and dies would be sufficiently ground, but the amount is so small that it takes a long time for the mass to make the circuit; and to stop when half done would be no better than to alternate grinding one charge and not another.

Crushing.—Countless have been the devices for crushing ore, but that primary crushing device used by all aborigines, the stone mortar and pestle, as developed into the modern ponderous stamp battery, stands as prominently in the van as ever.

As a preparatory for the stamps the rockbreaker is generally a necessity. Of the various styles, so far as introduced, the Blake is so much the best that none other is to be considered in comparison with it.

Self-feeders, in their present perfection, not only make their advantage a saving felt on the pay roll, but increase the efficiency of the battery, and are a saving in the wear of castings. Three kinds are at present prominent in the market, all of which are now under the same control, and the buyer's choice is unbiased by rival owners.

Of these the Hendy feeder has been the most ably introduced, having passed other "jerky contrivances" in the lead. This feeder has generally given good satisfaction, but with it much more work is accomplished. It is important, for economic wear, that a stamp should commence to rise as soon as its force is expended; furthermore, that its rise should be with accelerated velocity; in other words, the cam should be so formed that the first degree of revolution after contact should raise the stamp less than the last degree before dropping, and the curvature of the cam should be as great as possible, and admit of the drop. Of course this can be only at the maximum drop.

Amalgamation.—In amalgamation, as in crushing, the popular process is one of many.

The modern amalgamating pan is a growth from the old arastra, and though quite simple in construction, has been the subject of a variety of forms. A better knowledge of what they can and should do, has narrowed these down to

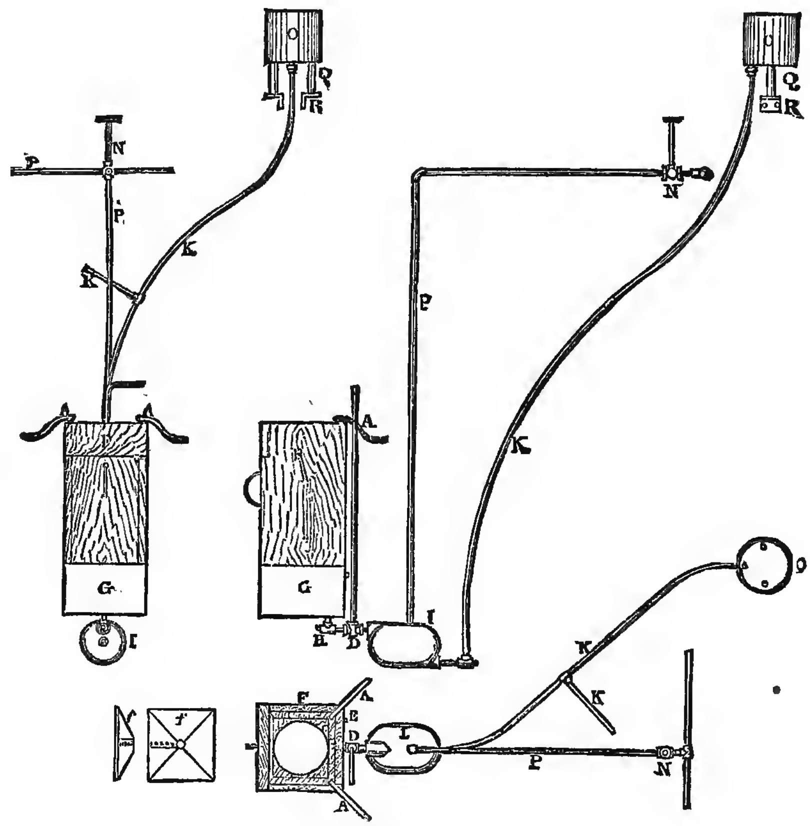

FIG. 2.

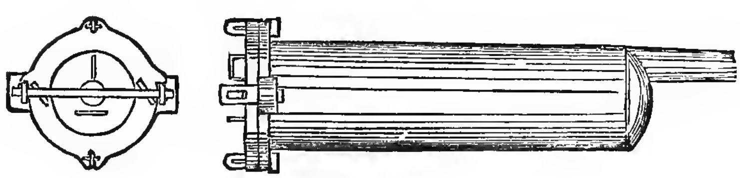

FIG. 3.

especially in wet sticky ores. Some fine dry ores, however, have a tendency to jar off, a circumstance that precludes precision.

The Tullock has for years fed the wet ores of the Comstock with satisfaction, and possibly a case of their failure anywhere might reflect as much on the mill man as on the machine.

The Standard as now improved is the simplest of feeders, and in dry ore probably unsurpassed.

Stamps are now made heavier, and are run faster than formerly; a modern stamp rarely weighs less than 800 lbs., and a stamp that makes no more than 90 drops per minute is counted slow. (The California Mill, Virginia, makes 102.) The wear and tear of a high speed battery of course is more, common generalities. The pan holds from one and one-half to two tons of pulp; the gearing underneath is open and plain; the muller is raised by a left hand screw on top, the handwheels of which should be large; the jam wheel being no smaller than the screw wheel from the fact that at times it is the subject of even greater application of muscle than the latter. Again, when in fast motion it is decidedly inconvenient to adjust a small wheel under a larger one.

As the muller and driver are held to position by but one bearing, it is strange that the inclination has been to make this short. Eighteen inches are none too long for the bore of a driver, and the shaft should pass entirely through it when the castings are new, provision being made in the cap for the end of the shaft when the castings are worn.

Much time and labor are saved in Babbitting the shaft, if it is made with a taper downward through the Babbitt; in which case, instead of withdrawing the shaft and cutting the old Babbitt, the new Babbitt is poured with the old, the taper preventing displacement even if the new Babbitt becomes broken.

But the most important feature of a pan—one which may involve many dollars per day, but which often receives but little attention, and, though simple in principle, is very often not understood because not studied—is the pulp currents.

These currents must needs be uniform and regular to insure uniform work, and they must be strong enough at the bottom of the pan to carry the quicksilver. The motion of the muller makes a current by throwing the pulp to the outside as it advances, which then rolls up at the side and over to the center to be thrown out again. This, so far, cannot be improved upon, and the only service left for the wings is to add to the pan capacity by preventing the pulp from running too high up the sides, to accomplish which the best shape is of an inverted plowshare. Having very naturally a good current above the muller, we have only to work in unison with this underneath.

With the grooves between the shoes leading straight out, the current is impelled only by centrifugal force, which is insufficient to carry the quicksilver; but if the point of a shoe touches the diameter, its outer end being a very few inches either forward or back, a current is forced proportionate to the angle of departure from the given diameter. If the dovetails in the muller and pan bottom are relatively similar, to admit of the shoe and die being one and the same pattern, the currents of the two will be similar and in unison. When the currents are outward they coincide with that above the muller, inward currents, being the reverse. A confusion of the two—unless one strongly overbalances the other—effects stagnation. It does not follow that because an inward current works contrariwise to the one above the muller, it cannot do good work; if it is strong they will compromise.

Definite rules for the angle of drought for shoes and dies cannot be laid down, because the speed of pan, the character and thickness of pulp, and, if grinding, the weight of muller, have each their influence.

It must rest with the millman to determine if the mechanical part of his amalgamation is perfect, or if his quicksilver is churned, or his castings cut out too quickly. A remedy is at hand, if systematically sought.

The speed of pans, a few years ago, was generally sixty or sixty-five revolutions per minute; eighty-five or ninety is more common now. With the slow motion the pulp should be thick, with the fast motion much thinner, and the charges of the latter are worked much sooner. A modern mill with fast batteries and fast pans accomplishes much more than the slow one of old.

The screw on the settler driver should, unlike the pans, be right handed, for besides being more convenient in case of a slipping belt, the power applied to turn the screw helps the muller along.

Settlers are of two classes, one having mullers with wooden shoes, and the other having arms with either wooden or iron shoes or stirrers.

For heavy, underground sand, the muller is easier to start and less liable to clog, and is more commonly used in such cases; but for well ground sand the other style is superior.

A settler should never be allowed to foul by an accumulation of heavy matter at the bottom; it is a positive preventive of good work. It may seem easier to advocate this than always to follow it.

A seeming natural remedy for such conditions is really an aggravation of it, namely, a liberal use of water. There is a point in the thinning when the quicksilver will be precipitated, but the heavy sand held in suspension.

If, after the charge is run out, which should leave about eight inches in the settler, a pan is drawn and no water added for a half hour, the warm charge will gather and carry the heavy sand; now enough water only is added to reduce it to an appearance of still some thickness, and this is all the water that is used in the charge. A horn spoon will show its success in advance of results.

Concentrators for a silver mill must necessarily be simple and capacious. Good agitators, shoveled out often, are profitable.

In some ores "sand sluices" are very effectual. A "sand sluice" for concentrating is a broad sluice twenty or twenty-four inches wide, and in it, at intervals of eight or ten feet, are vertical strips at the sides to hold unfastened riffles. Thin riffles are laid in and the sand runs over them for a time, say one or more hours, when another course of riffles one half inch, or less, thick, is laid on top of the others. This is repeated until the sluice is full, when it is shoveled out; meantime the sand should run through a duplicate sluice. These sluices should have a grade of about three and one half inches to the rod, it is then under control; for by starting with a thin riffle at the bottom, a strong current may be had, whereas a thick riffle will give a deadened current.

These sluices are an advantage where blankets are profitable, and if followed by blankets relieve the latter from much coarse, heavy material.

A blanket sluice should have a grade of about three inches in seven feet.

Quicksilver.—Quicksilver is lost both mechanically and chemically, and eternal vigilance is required in both directions.

The handling of quicksilver, when it is not in direct intercourse with the pulp, has its importance on the score of economy. Consequent upon continued lifting and carrying heavy quantities by the old method of hand labor, was a not insignificant loss.

Partly in proof of this is the bonanza of quicksilver an old mill is known to be.

To save this, and the heavy lugging by hand labor—which if the amount was expended upon water would seem immense—was attempted years ago by way of mechanical substitutes. To contend with was the heavy weight of the liquid and its close connection and relation with air, water, dirt, and amalgam, each of different gravities.

It has been well proved that a poor device for haudling quicksilver is even more extravagant than hand labor.

At one of the Raymond & Ely mills an elevator was put in, but after much bother and trouble was discarded. Later a quicksilver pump with downward working valves was tried. Illustrative of its success was its rapid introduction into other mills.

Yet as a complete system it still had some drawbacks, and the study from time and experience was required to develop its perfection—for it must continue to do its work without any special attention, and for unskilled hands.

Plate I. shows the arbitrary generalities which must be observed to obtain superiority.

Plate II. shows another system, perfected later, which is especially good for a small mill, as the expense is very light even for only two pans. At the Con. Va. & Cala. Mills the pump system is mainly employed; but for the single agitator pans the pressure system does the work.

Quicksilver Pump System.—The setter bowls, A, have a vertical discharge at one side; said discharge is four inches above the inlet, and one inch above the bottom of settler (inside), and is fitted for a wooden plug, B.

A one inch pipe C, connects the discharge to a one and one half inch pipe, D. This pipe D, has an incline of one inch in four feet, and at the upper end a small pipe (d) connects with a steam pipe for an occasional clearing out.

At the lower end of this pipe the strainers are situated. Short one inch pipes, E, may be turned to either of two strainers, and discharge on sheet iron covers (f). These covers may be locked by passing a rod over them.

Strainer box F, is of wood and contains four strainers. It is fitted to the top of a cast iron tank, G. Tank G is five feet long and one and a half wide, and one foot deep. Through the bottom of G a short one inch pipe connects to the pump, I.

The pump has a stroke of five inches, and makes forty per minute. The plunger is of steel, and the packing is ⅜ inch round rubber, to prepare which it should be dropped into melted tallow and wiped dry before cooling; this dispenses with oil on the plunger.

Around the plunger, below the stuffing box, is a recess into which water rises, making a hydraulic packing below the rubber. Rubber gasket ⅛ inch thick is used on the plugs.

A tank, J, stands under the pump to catch leakage. The pump should run only when throwing. The valves being of rubber and seating easily, and the plunger running in hydraulic packing, leaves no possibility for any grinding effect on the quicksilver.

The pump discharges through a ¾ inch pipe, K (this pipe should be well supported near the pump), into an upper reservoir, L. This reservoir stands on a frame work, twenty inches above the pans. The vertical discharge is one inch pipe for eighteen or twenty inches, down to a quicksilver cock (cast iron, with a stuffing box), M. From this cock the distributing pipe, N, is ¾ inch, leads in front of the pans, and may conveniently be on the floor (being protected by wooden strips on each side). At the lowest place in this pipe provision must be made to allow drainage into a settler, or to the reservoir below.

Between each of two pans a branch of pipe, N, enters the bottom of charging bowl, O.

Before entering the bowl the pipe is enlarged to one inch to accommodate a better size of wooden plug, P.

Charger, O, is of cast iron, stands seven inches above the top of the pans, and is supported by two stand pipes, Q (one inch), which connect to the pans by flanges, R. These flanges, for iron side pans, are bolted to the outside and stand at an angle of 60 degrees or more.

Flanges for wooden pans are shown in plate I.

A belt shifter for starting or stopping the pump should be operated from near the upper reservoir.

Quicksilver Pressure System.—A A are one inch pipes from the settlers (no bowls are used). The discharge is 3½ inches, or more, higher than the connected end, and one inch higher than the top of settler bottom. Strainer tank, G, is of cast iron, 1½ feet square by one foot deep.

Pipe E, near the top, is an overflow for water. H is a one inch pipe connecting through bottom of tank, G, to pressure chamber, I. Quicksilver cock, D, is operated by a lever, extending above the strainer for convenience of access.

Pressure chamber, I, has a capacity of a full charge of quicksilver.

P is a half inch pipe connecting to steam mud drum of boiler, or to natural water pressure, or to compressed air. Valve, N, should be convenient to charging bowls.

At the bottom of I a three quarter inch pipe, K, branches and enters through the bottom of two charging bowls, O, thus supplying four pans.

For wooden sided pans, flanges, R, bring the stand pipes, Q, on the top end of the staves.

In action cock, D, being open, the quicksilver will flow naturally into chamber, I, then by closing D and opening pressure valve, N, the quicksilver will be forced through pipe, K, into bowl, O. Six pounds pressure will raise quicksilver one foot. In case of a watermill, where the pressure may not be sufficient, an extra chamber, I, may be introduced half way to bowl, O, which will be self-acting.

After the piping is well put together it should be first tested with water.

The burr, from cutting the pipes, should be reamed off.

Amalgam.—A pan for scouring amalgam resembles a small settler, but should have attached to its arms a shoe extending from rim to cone, the outer end being five or six inches ahead.

Diameter of pan, 5 feet; depth, 1½ foot; speed, 25 per minute. Before retorting, the amalgam should be dried by a hydraulic press or by piling the amalgam some two feet high on a strainer, and allowed to drain for a couple of hours.

The choice of retorts is not of vital importance to success, but as a question of convenience and economy it is to be considered. The hooded central discharge retort, which admits of turning, was extensively introduced and is still largely used outside of the Comstock, where they are almost if not entirely discarded.

As a center discharge does not admit of being filled, a much smaller retort with top discharge will do equal work, for which due compensation is not given, by the turning of the former. In other words, the consumption of iron for a given amount of amalgam retorted is greatest with the center discharge. These are deductions from personal observations, where individual weights and number of charges were recorded, and were extended to several working side by side. The average life of a center discharge retort 14 inches by 5 feet, by 1½ inch thick, was under 35 charges.

The hood and the head with revolving bar attached to its center is doubtless the cheapest form of construction, but for large retorts decidedly inconvenient, and invite a bad job in adjusting the head.

A decided and unprecedented success was made, two years ago, by casting retorts on end, face up, rendering the metal dense and uniform.

Eight retorts cast in this way, of a plan similar to plate III., were made for the Brunswick Mill. They were 5½ feet long, 14 inches inside diameter, and 2 inches thick.

With charges varying from nineteen hundred to twenty-four hundred pounds, they endured upward of eighty-five fires. Compared with the previous average, the advantage is emphatic, the extra thickness of one half inch requiring no appreciable increase of fuel.

To avoid the hard labor of cutting the bullion of a large retorting, use paper to make divisions in the amalgam instead of sheet iron.

Quicksilver melts at—39°, evaporates slightly at ordinary temperatures, and boils at 662°. Its specific gravity is 13·6 at 32°.

2·038 cubic inches weigh 1 pound.

One cubic foot weighs 847·89 pounds.

In a column of quicksilver every foot in height gives a pressure of 5,888 pounds per square inch. That quicksilver will pass through a smaller aperture than water is a popular fallacy, naturally deduced from the fact that the former will often leak from a vessel that will hold the latter. An explanation for this seeming paradox is that quicksilver, being so much heavier, gives far greater pressure, and in wooden vessels, water, having the finer penetration, enters the fiber of the wood and swells it, thereby closing small openings, whereas quicksilver, entering only the open grain, has no expanding effect.

Gold melts at	2,016°,	its specific gravity is	10.3
Silver "	1,873°,	" " " "	10.5
Copper "	1,996°,	" " " "	8.9
Cast iron "	2,786°,	" " " "	7.8
Lead "	612°,	" " " "	11.3

1 oz. Troy of silver is worth	$ 1.2929
1 lb. " " "	18.854
1 ton " " "	37,709.50
1 cubic foot " "	12,355.20

1 oz. Troy of gold is worth	$ 20.6717
1 lb. " " "	301.46
1 ton " " "	602,927.36
1 cubic foot " "	361,808 64

3.89 cubic inches cast iron weigh 1 lb.

To compute the weight of an article of

Cast iron, multiply its cubic inches by	0.2607 lb.
Wrought iron, multiply its cubic inches by	0.2816 lb
Copper, multiply its cubic inches by	0.3212 lb.
Lead, multiply its cubic inches by	0.4102 lb.

Under a column of water 26·5 inches high there is a pressure of 1 pound per square inch.

A circumference equals the diameter multiplied by 3·1416.

The area of a circle equals one half of the diameter multiplied by one half of the circumference, or square of the diameter, multiplied by 0·7854.

The surface of a sphere is the circumference multiplied by the diameter.

The volume of a sphere is the cubic of the diameter multiplied by 0·5236.

Tensile strength of Rods per square inch.

Cast steel,	breaking load,	50 tons;	safety load,	12.5 tons
Swedish iron,	" "	36 "	" "	9.0 "
Common iron,	" "	28 "	" "	7.0 "

Strength of Ropes.

Let C represent the circumference:

New hemp will safely sustain . . . $\frac{0.4\,C^2}{6}$ tons.

Iron wire will safely sustain . . . $\frac{2.6\,C^2}{6}$ tons.

Steel wire will safely sustain . . . $\frac{3.75\,C^2}{6}$ tons.

Rust Joint Cement (Quick-Setting).—1 lb. sal ammoniac, 2 lbs. sulphur, 80 lbs. iron filings. Mix to a paste with water.

Slow-setting—2 lbs. sal-ammoniac, 1 lb. sulphur, 200 lbs. iron filings.

For holes in castings, take 1 part gum arabic, 1 part plaster Paris, and 1 part iron filings. Mix with a little water.

Babbitt metal, 3·7 copper, 0·89 tin, 7·3 antimony.

Metal that expands in cooling—Lead, 75 parts; antimony, 16·7; bismuth, 8·3.

Taper for keys for shafting—One-sixteenth inch to four inches.

—*A paper by M. P. Boss in the Scientific American.*

THE ORIGIN AND CLASSIFICATION OF ORE DEPOSITS.

THE mineral matters which have proved useful to man form three categories; first, the earthy: as gypsum, clay, marble; second, carbonaceous: as coal, lignite, petroleum; third, metallic: as iron, gold, silver.

The metals occur rarely native, oftener as ores, that is, combined with sulphur, silica, carbonic acid, etc. These form a series of deposits, of which the physical and chemical characters and history differ widely. They may be grouped into three classes, as follows:

1. Superficial deposits.
2. Stratified deposits.
3. Unstratified deposits.

Superficial Deposits.—These include the accumulations of gold, stream tin, platinum, gems, etc., which are obtained from the surface material, gravel, sand, and clay, derived from the mechanical decomposition of rock masses, through which metals or ores were sparsely distributed. Thus, gold usually occurs in small quantity in the quartz veins of metamorphic rocks. By the erosion of these rocks, having been freed from its matrix, and that more or less perfectly removed, this gold is concentrated by a natural washing process similar to that employed by man, but on a grander scale. In the same manner the oxide of tin, which is hard, heavy, and very resistant to chemical agents, is distributed sparsely through granitic rocks, or vein-stones; and where these have been eroded the cassiterite remains in the alluvial deposits of streams, where it can be cheaply and easily collected.

Superficial deposits have probably furnished nine-tenths of all the gold that has been obtained by man, the greater part of the tin, all the platinum and its associated metals—iridium, osmium, etc., and all the gems except the emerald, which in South America is obtained by mining. Thus it will be seen that the surface deposits are scarcely less important, economically, than the others. The superficial deposits of gold are for the most part confined to the foothills of mountain ranges, and are the products of the erosion effected by ages of frost, sun, rain, and ice, which are continually wearing down all the more elevated portions of the earth's surface. Shore waves also, in some instances, have worn away the rocks against which they have beaten, and have produced accumulations of *débris* that contain gold, platinum, gems, etc., in sufficient quantity to be economically worked. When a beach deposit of this kind has been raised above the sea level, it sometimes becomes convenient and profitable mining ground. On the coast of Oregon, at and above Port Orford, the beaches now yield gold, iridium, and osmium in sufficient quantity to afford profitable employment to quite a mining population, and in the Black Hills the old Potsdam sandstone beach, formed by the beating of the Silurian sea upon the cliffs of Laurentian and Huronian rocks, traversed by auriferous quartz veins, now constitute what are there known as the "cement deposits," from which a considerable portion of the gold of this region is obtained. As has been mentioned, however, the chief supply of gold in all ages has come from the *débris* that has accumulated at the foot of mountain slopes. All mountain *chains* are composed of metamorphic rocks, and nearly all the mountain ranges of the globe are traversed by quartz veins, in which are concentrated much of the gold that was originally finely disseminated through the sedimentary strata—conglomerates, sandstones, shales, etc.—now granites, schists, and slates.

By the lateral pressure that has metamorphosed the sedimentary rocks, and produced the segregation of the quartz veins, great folds and ridges were formed, which rising high above the general surface, act as condensers of moisture, and receive the most copious precipitation from the clouds. Hence on these mountain sides an enormous system of water power is developed, which is spent in grinding up the rocks and transporting the *débris* to the bottom of the slope. Here it is further washed, sorted, and the gold locally concentrated to form the rich "placer" diggings. As no great skill or expensive mining machinery is required to work the placer deposits, every man with good health, a pick, shovel, pan, and stock of provisions, may go into the business. Gold washing is the simplest, as it was probably the earliest of all mining enterprises, and has at different times employed nearly the entire population of a district or country; it is not surprising therefore, that it has resulted in the production of an enormous quantity of gold. It is evident, however, that most of the placers of the world have been already exhausted, and while the little known continent of Africa promises to furnish a large amount of metal from its "golden sands," we can hardly expect that the production of California, Australia, and New Zealand will ever be repeated in the world's history.

Stratified Deposits.—These may be subdivided into several groups, such as

1. Ore forming entire strata; *e. g.*, beds of iron ore.
2. Ore disseminated through strata; as copper in the schists of Mansfeldt, and in the sandstones of Lake Superior.
3. Segregated masses in strata; as sheets of copper in the Lake Superior sandstones; balls, kidneys, and sheets of clay ironstone in the shales of the coal measures, etc.

Unstratified Deposits.—These have been divided into

1. Eruptive masses.
2. Disseminated through eruptive rocks.
3. Contact deposits.
4. Stockworks.
5. Fahlbands.
6. Impregnations.
7. Chambers.
8. Mineral veins.

Of *eruptive masses* of metalliferous matter I must confess myself incredulous. Examples of these are cited in the crystalline iron ores of the Island of Elba, those of Nijni Tagilsk in Russia, and in Sweden, and even the iron ore beds of Lake Superior and Missouri. As late as 1854 this was the view taken of our crystalline iron ores by Whitney, in his "Metallic Wealth;" but great advantages have been since made in our knowledge of these deposits, and it is now generally conceded that all our crystalline iron ores are simply metamorphosed sedimentary beds. The evidence is accumulating that those of the Old World have the same character. Professor Otto Torell, the Director of the Geological Survey of Sweden, recently told me that he had visited all but one of the iron districts of Sweden, had found that in all these the iron ores were metamorphic, and he had no doubt that those yet unexamined were of similar nature. When metamorphic action has been peculiarly violent, the beds of iron ore have been more or less dismembered, and perhaps in some instances have been actually fused; but that any bed of iron ore is the result of an eruption from the interior of the earth is scarcely to be credited.

The examples of the occurrence of metalliferous matter *disseminated through eruptive rocks* are by no means uncommon, and the amygdaloid traps of Lake Superior, in which the cavities formed by gases have been more or less perfectly filled with copper, suggest themselves at once. Pyrites, magnetic iron, and platinum are found sparsely diffused through trap rocks, and are sometimes concentrated in such a way as to form valuable deposits when the trap decomposes. *Contact deposits* are usually understood to be accumulations of metal or ore along the planes of contact between two strata; and the sheets and strings of copper which are concentrated at the junction of the trap and sandstone in some parts of the south shore of Lake Superior, constitute illustrative examples of this class of mineral deposits. There is, however, considerable diversity in character among the deposits grouped under this head, the chief distinction being that in some cases the ore or metal has been segregated from one or the other of the strata at the time of their deposition, and in others it has come from a foreign source, and has been deposited in a more or less continuous sheet in cavities formed between the surfaces of the adjacent rock beds. To the second of these classes would seem to belong the argentiferous ores of Leadville, Colorado. These are deposited along the plane of junction between an underlying limestone and overlying porphyry, and undoubtedly accumulated in vacant spaces formed by the solution of the limestone. These ore bodies have apparently much in common with the pockets and chambers excavated in certain limestone beds, and subsequently filled with ore, to be described further on. The true structure of these Leadville ore bodies can, however, only be accurately learned when they shall be penetrated below the zone of unchanged sulphurets into which they will undoubtedly merge in depth. The term *Stockwork* is applied in the Old World to a mass of rock or veinstone penetrated in all directions by small intersecting sheets or veins in such a way that the whole mass is mined out. Some examples of this kind of deposit may be found in most of our mining districts, but the most important which have come under my observation are in the Oquirrh Mountains, in Utah, and at Silver Cliff, Colorado. In the first of these localities beds of quartzite, in the second, of porphyry, have been shattered, and the crevices between the fragments have been filled with ore deposited from solution. The name *Fahlband*, or rotten layer, originated in the silver mines of Konigsberg, in Norway, where there are parallel beds of rock impregnated with the sulphides of iron, copper, zinc, etc., and which, by their decomposition, have rendered these beds so soft as easily to be removed. We occasionally meet with pyritous rock in this country, which decomposes in the same way, but none yet known to me have any considerable importance as metalliferous deposits. *Impregnations* may be defined to be saturations of porous rock with a mineral solution or vapor from which ore has been deposited. The cinnabar which is sometimes found impregnating unchanged or metamorphosed sand stone, is generally cited as affording typical examples of impregnations. In such cases, which occur in California and South America, the deposit of ore has been ascribed by some writers to vapors, by others to solution, and it would seem that the latter is the more credible theory, although the vaporization of mercury is easily effected, and, like other metals, it may be transported by steam, as we have proof at the geysers in California. More familiar and satisfactory exhibitions of impregnation are, however, afforded by the copperbearing sandstones of Lake Superior, New Jersey, and New Mexico, and the silverbearing sandstones of Silver Reef, in Southern Utah. In all these cases it is evident that a porous rock was once saturated with a metalliferous solution, from which, in the Lake Superior region, metallic copper was precipitated; in New Jersey and New Mexico, sulphides of copper and iron; at Silver Reef, sulphide of silver. As such repositories of the metals are easily penetrated by surface-water and air, we usually find the sulphides decomposed to a considerable depth; the copper ores converted into carbonate and silicate, the sulphide of silver into the chloride.

Chambers or *pockets* in limestone form the receptacles of ore in many countries, but nowhere else are such striking examples of this class of deposit as those found in our western mining districts. From a study of these I have been led to add them to the catalogue of forms of ore deposit as a distinct and important addition to those given by other writers. The distinctive characters of those accumulations of ore in chambers and galleries has not been heretofore generally recognized, and a want of information in regard to their true nature has led to much litigation and heavy losses in mining. The best examples of chamber mines are the Eureka Consolidated, Richmond, etc., of Eureka, Nevada; the Emma, Flagstaff, Kessler, etc., in little Cottonwood district, and the Cave Mine, near Frisco, Utah. All these mines are alike in this, that the ore is found more or less completely filling irregular chambers in limestone. Some of these ore bodies are of great size, and the aggregate product of these chamber mines is so great as to make it necessary to record this as one of the most important forms of metalliferous deposit. From the Potts chamber in the Eureka Consolidated mine, it is said that ore of the value of a million dollars was taken, while a still larger amount was produced from the great chamber of the Emma. The origin of these chamber deposits is, in my judgment, simply this: A stratum of limestone, more than usually soluble in atmospheric water, carrying carbonic acid—which dissolves all limestones—has at some time been honeycombed by chambers and galleries such as those which traverse the limestone plateau of central Kentucky, of which the Mammoth Cave is an example. Subsequently this rock has been broken through and upheaved by the subterranean forces which have disturbed all our important mining districts, and through the fissures then formed mineral solutions ascend, flowing into any receptacle opened to them. Where these fissures cut an insoluble rock they become, when filled, simply fissure veins; but where a cavernous limestone was broken into, such caverns and galleries as were opened were more or less filled with ore. It has been suggested that the caves now holding ore were excavated by the metalliferous solution, but we find some of them entirely empty, with their sides encrusted with spar, and having all the characters of ordinary limestone caves, and even where the ore occurs, the walls of the cavity have the same character, are hard and unimpregnated with ore. Hence we must conclude that the chambers were formed, like modern caves, by surface water, and when the country was upheaved and the rock shattered only part of them were opened, and that these received the solution and ore, while the unopened ones remained empty. The character of the ore contained in the chambers varies much, as it does in the fissure veins of our mining districts; and the solutions from which they were filled must have been different in the different localities where they occur. Argentiferous galena was evidently the most abundant ore deposited in the chambers, as it is elsewhere; but in some cases this is associated with a large amount of iron sulphide, in others very little; while the ratio of gold to silver is inconstant, and the aggregate of both varies from nothing to several hundred dollars to the ton. The ores of Eureka run high in lead, contain much iron, and about seventy dollars in the precious metals, half gold, half silver. The ores of the Emma mine carried less iron, more lead, much more, silver, less gold, and a little copper; while those of the Cave mine at Frisco contain no lead, much iron, a little copper, and are sometimes exceedingly rich in both silver and gold. In all the chamber mines yet worked in this country the ore taken out is thoroughly oxidized, but in the deeper workings of some neighboring fissure veins the soft, ochery ores of the chambers are found changed below into compact masses of galena and iron pyrites; the galena carrying the silver, the pyrites the gold. Hence we may conclude that the ore origiually deposited in the caves consisted of sulphides, and that whenever these mines shall be worked below the water level ore of this character will be found. It should be said, however, that if the theory I have suggested of the formation of the limestone galleries is true, they will not be found to extend to so great a depth as the ore bodies of fissure veins, since the excavation of the limestone, if produced by atmospheric water, must be confined to the zone traversed by surface drainage. In a very dry and broken country the line of permanent water level may be very deep, as at Eureka, where the ore bodies extend and are oxidized to a depth of at least 1,400 feet. Such a condition of things could only exist in a very dry climate; but we have evidence that there have been great climatic changes in our western mining districts, according to King and Gilbert, two wet periods having been succeeded by two dry ones, the last prevailing now. We may therefore find chambers wrought in the limestone in a dry period below the present or normal water level. The enormous production of gold and silver from the chamber mines already worked proves the great importance and value of this class of deposits; and while we may predict that they will be fouud to be more superficial than true fissure veins, still no limit can be fixed to the future yield of mines of this character, even though they should not be profitably worked below 1,500 feet from the surface.

Mineral Veins.—Some writers on economic geology—Werner, Von Cotta, and Von Groddeck, for example—enumerate very different kinds of mineral veins, but disregarding the local characters which all ore deposits exhibit, and the hybrids which are formed by the blending of two distinct forms—not of uncommon occurrence, I agree with Whitney in recognizing but three distinct classes, viz.:

1. Gash veins.
2. Segregated veins.
3. Fissure veins.

Gash veins may be defined to be those which occur only in limestone, are confined to a single stratum or formation, and hence are limited in extent, both laterally and vertically. Typical examples of gash veins are furnished by our lead deposits of the Mississippi Valley. These occur at three horizons, viz.: about Galena, in the Galena limestone, belonging to the Trenton Group; in southeastern Missouri, where the mine La Motte is located, in the equivalent of the Calciferous sand rock; and in southwestern Missouri, where the mines of lead and zinc occur in the Lower Carboniferous limestone. The origin of deposits of this character is apparently quite simple. The cavities which form the repositories of the ore are generally the cleavage planes or joints of a soluble limestone rock, that become channels through which surface water charged with carbonic acid flows in a system of subterranean drainage. We usually find two sets of joints approximately at right angles to each other, and vertical if the rocks are horizontal. To form gash veins, one or both of these sets of vertical joints are locally enlarged into lenticular cavities or "gashes," whence the name; but sometimes caves of considerable size, irregular pockets, and vertical or horizontal galleries are formed. These are subsequently lined or filled with ore, sulphides of lead, zinc, and iron, originally disseminated through the limestone, and leached out of it by water which saturates and traverses all rocks in a humid climate. The solution thus formed reaching a cavity, has by evaporation deposited the ore as a lining to that cavity; narrow fissures being, perhaps, filled, walls of larger cavities coated with stalactites depending from the roof, etc. Subsequent solution has sometimes widened a fissure once filled with ore, leaving the ore body as a central partition, a curtain more or less complete hanging from the roof, or a mass of fragments mingled with infiltrated sand and clay in the floor of the cave. In southwestern Missouri the carboniferous limestone contains layers of chert, which are insoluble, and which sometimes form horizontal floors or ceilings of caverns. These, breaking down by their own weight, have formed masses of *débris*, cemented together by the ore, which has thus acquired its peculiar brecciated character.

From the description of gash veins given above, it will be seen that they have much in common with the pockets and chambers previously described; but there is this important difference, that the ore filling the gashes and irregular chambers of the leadbearing limestone is indigenous, having been derived from the leaching of the adjacent rock, while in the chamber mines of the West the ore is exotic, having been brought up through fissures from a remote source below; so that, while in physical characters the Western gold and silver bearing ore chambers resemble gash veins, they are really but appendages to true fissure veins, and only occur in a country that has been much broken by subterranean forces.

Segregated veins are confined to metamorphic rocks, are conformable with their bedding, and are limited in extent both laterally and vertically. Their ore bodies form lenticular masses of greater or less dimensions, of which the material is chiefly quartz, which has segregated *i. e.*, separated from the surrounding rock. The quartz veins so abundant in the gneisses and schists of Canada, New England, and the Alleghany Belt, are all examples of this class of ore deposits. The most important constituent of segregated veins is gold, which here seems to have been mechanically dispersed throughout sedimentary rocks, and to have been concentrated with the quartz in the process of metamorphism to which they have been subjected. With the gold we always find iron pyrites, sometimes chalcopyrite, and the latter occasionally in sufficient quantity to be worth working. From these remarks it may be inferred that segregated veins have no deep-seated origin, are less continuous in depth and laterally than fissure veins, and therefore constitute a less permanent foundation for mining enterprises. It may be said, however, that some of them are of enormous dimensions, and that they not unfrequently occur in succession, or so approximate that they are equivalent to a continuous mineral deposit.

Fissure veins occupy crevices which have been formed by subterranean forces and have been filled from a foreign source. They traverse indiscriminately all kinds of rock, and are without definite limits laterally or vertically. They have as characteristic features, smooth, striated, sometimes polished walls, slickensides, clay gouges or selvedges on one or both sides, and a banded or ribboned structure throughout. The vein-stone is usually quartz, and the constituents include the ores of all the metals. The mode of formation of fissure veins is apparently this: In the regions where the earth's crust is broken up in the adjustment of the cold and hard exterior to the cooling and shrinking nucleus, cracks are formed, often miles in extent, along which the rocks suffer displacement, sliding on each other to form what are known as "faults." As the planes of these faults are more or less undulated, with displacement, the bearing is upon the projecting bosses of each side. Between these, open fissures are left of greater or less dimensions. These reach down to a heated zone, and form the conduits through which thermal waters flow to the surface. Such waters coming in different localities from different depths, and reaching rocks of various composition under great pressure and high temperature, having great solvent power become loaded with various mineral matters. As they rise to the surface the pressure and temperature are reduced, and the materials held in solution are deposited to line and perhaps ultimately fill the channels through which they flow. This theory of the filling of mineral veins, *i. e.*, by precipitation from heated chemical solutions coming from below, is supported by such an array of facts that it must be accepted by all who will make a careful and unprejudiced study of the subject. It is true, however, that various other theories have been, at one time or another, put forth for the explanation of the phenomena. Among these a few deserve a passing notice. They are:

1. **The theory of igneous injection.**—According to which the matter filling mineral veins has been erupted like that of trap dikes, and such veins as those of Lake Superior, containing metallic copper, have been suggested as affording good examples. But here we find metallic copper and silver associated, and each chemically pure; whereas, if they had ever been fused, they certainly would have formed an alloy. The copper is also found in crystals of calc spar and other minerals, where it must have been deposited with the other constituents of the crystal, and that crystal formed from solution. Other opposing facts might be cited, but it will be sufficient to say that not one sound argument can be advanced in favor of this theory.

2. **Aqueous deposition from above.**—This theory, first advanced by Warner, but since generally abandoned, supposes the contents of mineral veins to have been deposited from a solution which flowed into the fissures from above; but in that case the vein matter should be horizontally stratified, limited in extent downward, and spread over the surface adjacent to the fissure; whereas no one has yet reached the limits in depth of the ore in a true fissure vein, and the characteristic banded structure can only have resulted from successive depositions of a long-continued flow of a hot solution. This theory has been recently advocated in this city by Prof. Stewart of Nevada; but it is not only not sustained, but really disproved by all the facts observed by the writer some years devoted to the study of our Western ore deposits.

3. **Lateral secretion.**—According to this theory, the material filling all mineral veins has leached into the cavity from the wall rocks. While this is true of gash veins, it can have played but a very subordinate part in the deposition of ore in fissure veins. This is proved by the facts that different sets of fissures which cut the same formation frequently contain very different ores; and where the rocks of totally different character are, by faulting, brought to form opposite walls of fissure, the ore may be symmetrically deposited in corresponding layers. It may also be said that the same fissure frequently traverses several formations, and yet its character may be essentially the same throughout.

4. **Sublimation.**—The facility with which certain metals are volatilized, and the fact that various minerals

have been deposited from vapor, have formed the basis of this theory; yet it is difficult to see how any one can ascribe more than a local and insignificant effect to this cause. It is true that the action of water, as steam, is much the same as when fluid and highly heated, in the solution and transport of minerals; and the deposit of mercury, sulphide of iron, and even gold, from the mingled water and steam of the California geysers proves this. So we may concede that steam has been an agent in the chemical solution and precipitation of ores; but this is a very different thing from the sublimation of the metals represented by these ores, and all knowledge and analogy indicate that the silica which forms so large a part of vein stones, and is so often seen in combs of interlocking crystals, has been deposited from an aqueous solution. But argument is really wasted in a discussion of the filling of fissure veins, since we have examples that seem to settle the question in favor of chemical precipitation from ascending hot water and steam. In the Steamboat Springs of Western Nevada, for example, we in fact catch mineral veins in the process of formation. These springs issue from extensive fissures which have been or are being filled with silicious veinstone that carries, according to M. Laur, oxide of iron, oxide of maganese, sulphide of iron, sulphide of copper and metallic gold, and exhibits the banded structure so frequently observed in mineral veins.

In regard to the precise chemical reactions which take place in the deposition of ores in veins, there is much yet to be learned, and this constitutes an interesting subject for original investigation, which I earnestly commend to those who are so situated that they cannot pursue it.

It may be noticed, however, that the thermal springs which are now forming deposits like those in fissure veins, contain alkaline carbonates and sulphides, and we have every reason to believe that highly carbonate alkaline waters containing sulphuretted hydrogen under varying conditions of temperature and pressure, are capable of taking into solution and depositing all the metals and minerals with which we meet in mineral veins.

To these necessarily brief notes on the filling of mineral veins should be added some interesting examples of the mechanical filling of fissures which have been recently brought to light in Western mining. These are furnished by the remarkable deposits of gold and silver ore, the Bassick and Bull-Domingo near Rosita, Colorado, and the Carbonate Mine at Frisco, Utah. All these are apparently true fissure veins, filled to as great a depth as they have yet been penetrated by well rounded pebbles and bowlders which have fallen or been washed in from above. The porous mass thus formed has been subsequently saturated with a hot ascending mineral solution, which has cemented the pebbles and bowlders together into a conglomerate ore. In the Bassick this ore consists of rich telluride of silver and gold, free gold, and the argentiferous sulphides of lead, zinc, copper, and iron. In the Bull-Domingo and Carbonate mines the cementing matrix is argentiferous galena. That the pebbles and bowlders have come from above is distinctly shown by the variety in their composition and organic matters associated with them. In the Bull-Domingo and the Bassick the pebbles consist of various kinds of igneous rock, mingled with which in the latter are masses of silicified wood and charcoal, while in the Carbonate mines the pebbles are mainly trachyte, but with these are others of limestone and quartzite.

Fossils and other foreign bodies have before this been found in mineral veins, and Von Cotta mentions the occurrence of quartz pebbles extending to the depth of 155 fathoms in the Grüner Lode at Schemnitz, Saxony, but no conglomerate veins like those mentioned above are known to exist elsewhere, and they constitute another of the many new forms of ore deposit which the exploration of the rich and varied mineral resources of the United States have brought to light. To enumerate and classify these has been the chief object of this article.

In regard to the ultimate source of the metallic matters which give value to our ore deposits but little can be said with certainty. The oldest rocks of which we have any knowledge, the Laurentian, contain gold and copper, which are indigenous; hence, as old as the rocks that contain them, and have been simply concentrated, and made conspicuous in the process of their metamorphism. The rocks are all sediments, and the ruins of pre-existing continents. By their erosion they have in turn furnished gold, copper, iron, etc., to later sediments by mechanical dispersion and chemical solution. We now find gold everywhere in the drift from the Canadian Highlands, and we have every reason to believe that all the sedimentary strata more recent than the Laurentian have acquired a slight impregnation of several metals from them in addition to what they have obtained from other sources, and we may conclude that the distribution of many of the metals is almost universal. Sea water has been proved to contain gold, silver, copper, lead, zinc, cobalt, nickel, iron, manganese, and arsenic; and there is little doubt that all the other metals would be found there if the search were sufficiently thorough. Hence, sedimentary rocks of every age must have received from the ocean in which they were deposited some portion of all the metals, and for the formation of metalliferous deposits some method of concentrating these would alone be required. A pretty theory to explain such concentration through the agency of marine plants and animals has been suggested by some German mineralogists, and amplified by Profs. Pumpelly and T. S. Hunt. Plants have been credited with the most active agency in this concentration, but evidence is still wanting that other animals or plants have played any important part in the formation of our mineral deposits. The remains of seaweeds are found in the greatest abundance in a number of our Palæozoic rocks, and it is almost certain that the carbonaceous ingredient in our great beds of bituminous shale has been derived from this source, and yet we find there no unusual concentration of metallic matter, and none of the precious metals have ever been detected in them.

The metallic solutions which have formed our ore deposits have been ascribed to two sources. One theory supposes that they have drained highly metalliferous zones deep in the interior of the earth; the other, that they have leached diffused metals from rocks of different kinds comparatively near the surface. The latter view is the one that commends itself to the judgment of the writer. However probable such a thing might seem, no evidence of the existence of distinct metallic or metalliferous zones in the interior of the earth has been gathered. On the contrary, volcanic emissions, which may be supposed to draw from a lower level than water could reach, are not specially rich in metallic matters, and the thermal waters which have by their deposit filled our mineral veins, must have derived their metallic salts from a zone not many thousand feet from the surface. The mineral springs, which are now doing a similar work, are but part of a round of circulation of surface water, which, falling from the clouds, penetrates the earth to a point where the temperature is such as to drive it back in steam. This, with fluid water under pressure and highly heated, possessing great solvent power, may be forced through vast beds of rock and these be effectually leached by the process. Should such rocks contain the minutest imaginary quantity of the metals, these must inevitably be taken into solution, and thus flow toward or to the surface to be deposited, when, by diminished temperature and pressure, the solvent power of the menstruum is diminished. It is evident from these facts that we cannot trace the history of the metals back beyond the Laurentian age. And since we find them diffused in greater or less quantity through the sedimentary rocks of all ages, and also find processes in action which are removing and redepositing them in the form of the ore deposits we mine, it is not necessary to look farther than this for a sufficient theory of their formation.

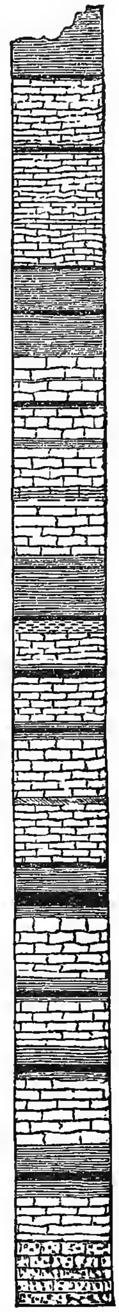
—*A paper by J. S. Newberry, School of Mines Quarterly.*

THE ANTHRACITE COAL FIELDS OF PENNSYLVANIA AND THEIR EXHAUSTION.

COAL is monarch of the modern industrial world, with its wonderfully diversified interests, and their ever-expanding development. But supreme as is this more than kingly power at the present time, comparatively brief as has been the period of its supremacy, and unlimited, in the popular apprehension, as are its apparent resources, yet already can we calculate its approximate duration and predict the end of its all-powerful but beneficent reign. This is especially the case with our limited Anthracite; the more widely diffused Bituminous having in reserve a much longer term of service—short indeed as a segment of the world's history, but so long compared with an average human life, as to be of slight practical concern to the present generation. The territory occupied by the Anthracite coal fields of Pennsylvania is but a diminutive spot compared with the area of Bituminous coal in Pennsylvania alone, to say nothing of its vast extent in other portions of the United States, Great Britain, France and Belgium. The area of the Anthracite of the United States is but 470 square miles, not one-twentieth the size of Lake Erie, while the wide-spread Bituminous coal fields cover twice the area of our four great lakes; the Anthracite making but an insignificant showing on the map of the continent. But the comparison with the Bituminous area is deceptive, unless the relative thickness of the two is taken into consideration. If the Anthracite beds were spread out as thinly as those of the Bituminous region, they would cover eight times their present area, or 3,780 square miles. And again, if the denuded spaces within the borders of the Anthracite coal fields were covered with a deposit of coal as thick as we may justly suppose they once were, and as the remaining still are, the available area would be increased to about 2,000 square miles, or 1,280,000 acres; equal to a coal deposit of 92,840,960,000 tons. Contemplating the number and extent of the coal beds shown in the accompanying cross-section, a total thickness of 107 feet, distributed in fifteen workable beds, interstratified with a full mile in thickness of rock and shale, we are lost in wonder at the luxuriant growth of tropical plants required to produce this vast amount of compressed fuel, and the mighty processes of nature by which it was placed in its present position. The ingenuity of scientists is taxed to account for this wonderful accumulation of fuel, once vegetable, now mineral; once waving in fresh green beauty on the surface of the earth, now buried under hundreds of feet of solid rock; once growing in a level deposit of mud so plastic that the lightest leaflet dropping on its surface left its impress, now the mud hardened into slate, and the rank vegetation changed to hard and glittering coal, rising and falling in geologic hills and valleys, surpassing in number, depth, extent, sharpness of flexure and acuteness of angle, anything visible in the light of upper day.

Some slight idea of the growth of these ancient forests may be gained from the computation, that to form only one of these large beds of coal required a deposit of vegetable matter perhaps one hundred feet in thickness. What shall we say then to the amount of vegetation stored away in the Mammoth bed, which extends through all three of the Anthracite coal fields, covering an area of 300 square miles, with an average thickness of twenty feet, and containing, it is estimated, 6,000,000,000 tons of coal! Not less wonderful and interesting than the coal deposits is the grand floor of conglomerate which underlies them; a vast sheet of rock, infinitely old, composed of fragments of other rocks infinitely older, bound together by an almost imperceptible cement which holds them so firmly that gunpowder will scarcely separate them. Whence came this great sea of pebbles, water-rounded and water-born, to their present resting-place? We find them now as the current has dropped them—masses of silex as large as ten-pound cannon balls, and almost as round, so shapely have they been worn by the actinn of some ancient current. These were deposited first, and then, in regular order, trending to the southwest, came sizes graduated down to those of a pea and grains of sand. This more than marble floor bears few saurian foot-prints; scarcely an impress of bird, or beast, or fish, or sign of animal life. Nothing but a bed of almost pure silica; a solid foundation on which to build up the mass of rock and the fossil fuel that we call Anthracite, older than the hills and predestined for the use of coming man. The pebble-laden flood ceased, and was followed by placid waters and gentle currents, bringing fine mud and silt to cover the rocky bed. Then the waters drained away, or the land rose, until fit for vegetable life, it was covered with the mighty flora of the carboniferous period. Again it sank, carrying with it its store of decayed and decaying vegetation, and another flood of pebbles rolled over it. How many ages were consumed in the process so briefly described, who can tell? Nature's operations are on too vast a scale, and her working time too long to admit of hasty activity in the production of results. It may well be said that all the years since the creation of man would he too short a time to produce a bed of coal. However long the process just described, it was of frequent repetition during the coal period; and thus we find pebble-beds, slate and coal in often recurring series, as in the following cross-section made at Treverton, the western terminus of the middle anthracite coal basis.

CROSS SECTION IN THE SOUTHERN ANTHRACITE COAL FIELD OF PA.



Red Ash Coal, 3 ft.	Sandrock.
" " 7 ft.	Gate.
" " 3 ft.	Little Tracy.
" " 6 ft.	Tracy.
" " 6 ft.	Diamond.
" " 3 ft.	Little Orchard.
" " 6 ft.	Orchard.
Grey Ash Coal, 10 ft.	Primrose.
White Ash Coal 5 ft.	Holmes.
" " 7 ft.	Seven Feet.
" " 25 ft.	Mammoth.
" " 6 ft.	Skidmore.
" " 9 ft.	Buck Mountain.
Red Ash Coal, 8 ft.	Lykens Valley, upper.
" " 3 ft.	Lykens Valley, lower.
Total Coal, 107 ft.	

But through all the changes of time and scene, the upheavals and depressions, the submergence and emergence of the land, we find a remarkable uniformity in the growth of plants, continuing almost without change throughout; sigillaria, lepidodendra, ferns, &c., following their kind, unvaried through successive series of strata, in each leaving their characteristic impress of stems and foliage on the enduring tables of the rocks. The coal flora is rich in variety and of great beauty, as Professor Lesquereux's careful research abundantly testifies. Their exact forms show a quiet condition of the waters, at least during the deposit of the slate covering of the coal beds; and the intervening rocks show the same facts. When impressions of the flora are found in the solid coal itself, we have the same evidence; but this is of rare occurrence. The best impressions usually occur in the smooth top slate covering the coal beds. When we examine the arrangement of the Pennsylvania Anthracite beds we wonder at their complexity. Without evidence of volcanic disruption, not even a protruded trap-dyke, or extensive up or down-throw, we often find contortions and disturbances of the strata. The beds are rarely horizontal, but lie at every angle, and sometimes even pass the perpendicular and fold back upon themselves. In places they occupy our mountain summits, nearly 2,000 feet above the level of the sea, and again depressed more than 3,000 feet below it, making a variation of a mile in altitude. Yet the coal, which is the frailest material in this rocky mass, is not destroyed, but generally in good workable condition—solid, almost crystallized, almost pure carbon, and frequently in beds too thick for economical working.

Faults in the Anthracite beds usually have a northwest and southeast direction, and show the beds compressed, and again correspondingly enlarged, but no sudden dislocations or breaking off of the strata. Soft coal or dirt faults, are of common occurrence in the red ash or softer coals in the western end of the Anthracite fields. The colored ash of burned coal is due, doubtless, to the presence of iron; but why this coloring matter is confined to the upper series of coals in the eastern portion of the range, and to the lower beds in the western district: and why there is a gradation in the middle district, from white ash in the lower, to grey in the middle, and red in the upper beds, are problems yet to be solved. How shall we account for the great disturbance of the strata from their original horizontal position? Was it caused by volcanic force—of which there are no indications—or by contraction of the earth's crust? And if the latter, why is it confined to the Anthracite region, and not extended to the Bituminous also? And how shall we explain the isolation of the smaller coal fields, like those of Rhode Island, Richmond, Va., or Deep River, in North Carolina; or the disproportion in the quantity between the limited area of Anthracite and the wide-spread fields of Bituminous? Why do we find an abundance of shells and remains of animal life in the latter, and rarely any in the former? A few saurian foot-prints recently found at the Ellangowan colliery, in Schuylkill county, and a few shells found in Glendower pit, in the Wyoming valley, are signal exceptions to an almost universal rule. After an exploration, covering the period from 1835 to 1850, Prof. H. D. Rogers and his corps of assistants failed to find any other specimens. Neither has Prof. Lesley in his new geological survey of Pennsylvania, nor the writer in his thirty years' residence and active service, underground and in surface explorations, been any more fortunate. Nor in all this area do we find a single workable bed of iron or limestone, and scarcely a covering of fertile soil. The coal once exhausted, nothing is left but the worthless shell, desolate and deserted. The Anthracite region, mainly confined to one-sixth the area of the four mountainous counties of Luzerne, Schuylkill, Carbon, and Northumberland, in Pennsylvania, is crowded with an industrious population, which increased fifty-one per cent. in ten years; that is from 229,700 in 1860, to 344,771 in 1870; whilst the four adjacent agricultural counties of similar area increased in the same time from 319,542 to 339,942, only six per cent. It is located on the parallel of 40° 30′, one hundred miles from any seashore, no part of it is less than 500 feet above tide—near the head waters of the large rivers that drain it, the Susquehanna, Schuylkill, Lehigh, and Delaware. The noisy trains crossing the valleys and climbing the mountains all merge, day and night, to these hives of industry, where multitudinous steam engines are hoisting and pumping, and breakers crushing. Thousands of miles of railroad thread the surface and dive into the interior, to roll out the black diamond flood in millions of tons of fuel to warm and employ the nation. The *fearful loss* of good material involved in mining and preparing Anthracite, as shown in the accompanying tables, though greatly to be deplored, seems to be almost inevitable. The disposition of the coal in large solid beds, and its highly inclined positions, involves strong supports to keep the superincumbent mass from crushing and closing the avenues to the mines; and these supports must consist of massive pillars of the solid coal itself. Wooden props, however ponderous and strong, can only be used for the minor supports. Some of this pillar coal is ultimately removed, but much of it is inevitably lost, especially in the larger beds which frequently range from 20 to 40 feet in thickness and are often inclined at an angle of from 40 to 70 degrees. It is estimated that not more than 66 per cent. of the coal is ever taken out of the mines. That which is brought to the surface is run through a huge structure from 80 to 100 feet high, very appropriately called a "breaker," ingeniously contrived for the destruction of coal. There are over 300 of these immense buildings in the Anthracite region, costing on an average $50,000 each, or an aggregate of $15,000,000. To the top of these the coal is hoisted, and then descends through a succession of rolls and screens, emerging at the bottom in a series of assorted sizes, from huge blocks of lump coal to unmerchantable dust, which forms a grievously large proportion of the whole. This process involves a loss of good coal, equal to 20 or 25 per cent., of the entire quantity mined. For the coal wasted in mining, say 40 per cent., and in preparing, 25 per cent., no one is paid; it is a total loss to landowner and shipper.

Plans for utilizing the waste coal dirt, or culm of Anthracite collieries, have been frequently suggested, but none have come into general use. The Anthracite Fuel Company, at Fort Ewen, on the Hudson, in 1877, used 90 per cent. coal dust and 10 per cent. fuel pitch, and made 300 tons of fuel per day, consuming over 50,000 tons of culm. The Delaware and Hudson Company also used at their mines 60,000 tons per annum. They now ship all their coal down to pea sizes, and consume the culm in generating steam. If all our coal companies would follow this examples it would enable them to sell half a million tons more coal, and burn the same amount of refuse, thus earning or saving a half million dollars per annnum, to add to their revenues. The Philadelphia and Reading Railroad Company has recently introduced a method of burning coal dust in the furnaces of its engines, and the plan appears to meet with success. The amount of water which drains into a mine from a mile or more of surface is enormous, for the average amount of rain and snow-fall is 58,840 cubic inches per square yard annually, and the miners are liable to absorb not only the rain fall on the surface immediately over them, but all that which, by contour of the surface or by converging strata, tends toward them. On an average possibility five tons of water are hoisted for every ton of coal raised—another loss chargeable to mining. The preponderance of waste coal, illustrated, by the accompanying tables, seems excessive; but the writer's experience in surveys of certain tracts of land, and in preparing maps which show the area exhausted, compared with the amount marketed from ten or more collieries, in a period of twenty years, proves that the loss is not over estimated, especially in the Mammoth bed, whose average thickness is 25 feet. An eight-foot bed of coal yields much better in proportion. When they exceed six or eight feet in thickness, especially if steeply inclined, they are not only expensive to mine, but a large proportion of the coal must be left to support the rocky roof. The Bituminous coals, particularly those of the United States, are not subject to those serious losses, and are quite cheaply mined and prepared. No breakers are required, as the only division is into coarse and fine coal, which are easily separated by screens; and the fine coal can be readily converted into coke, making a better condensed fuel than the coal in its natural shape. The bituminous beds are nearly horizontal and rarely more than six feet thick, so that it is necessary to have extensive pillars; and as the coal is above water level, or in shallow basins, it is not necessary to put up extensive hoisting and pumping machinery. The simple, natural ventilation of American Bituminous mines also does away with the extensive and costly appliances for this purpose of Anthracite mines, in spite of which so many miners annually fall victims to the noxious gases.

And Now as to the Harvesting.—The total amount still to be mined, according to the accompanying tables, is 26,361,076,000 tons. The total waste, as experience has shown, is equal to two-thirds of the coal deposit, and reaches the appalling amount of 17,574,000,666 tons, leaving thus only 8,782,075,333 tons to send to market. In all our calculation of Anthracite, we have counted the area as if in a level plain, and made no allowance for the undulations which must necessarily increase the amount of coal. But as many of the flexures are abrupt and broken, making much faulty and refuse coal, it will cover any over-estimate of area or thickness we have made in our calculations. Our tables show that 360,017,-817 tons have been sent to market in the fifty-eight years from 1820 to 1878, inclusive. Our consumption now amounts to 20,000,000 tons annually. The increase of production for the past ten years has been 187,112,857 tons. At this rate we shall reach our probable maximum output of 50,000,000 tons in the year 1900, and will finally exhaust the supply in one hundred and eighty-six years. The present product of the anthracite coal fields is (1878) as follows:

Southern	40 collieries	1,229,081 tons.
Middle	180 "	9,529,525 "
Northern	128 "	7,680,990 "
Total	348 "	18,439,596 "

At this rate the eastern end of the northern field is being rapidly exhausted. The middle field, too, which contains the lower productive coals, is likely to cease extensive mining about the year 1900; while the western portion of the northern field, extending from Pittston to the western end, and the southern field from Tamaqua to Tremont, comprising about 100 square miles, which contain more coal beds and deeper basins, must furnish the supply for the coming years. Partially successful experiments have been made to use petroleum as a substitute for coal to some extent. But is it not already evident, under the reckless prodigality of production, that this occult and mysterious supply of light, heat and color will be exhausted before the Anthracite, and can, at best, only temporarily retard the consumption of the latter? As already intimated, the question of the exhaustion of our coal supply is scarcely more at the present time than a curious and interesting calculation. It has not yet become so grave and portentous as in Great Britain, where a commission, with the Duke of Argyle, Sir Roderick Murchison and Sir W. G. Armstrong at its head, was recently appointed by Parliament to ascertain the probable duration of the coal supplies of the kingdom. There it is serious, indeed; for when Britain's coal fields are exhausted, her inherent vitality is gone, and her world-wide supremacy is on the wane. When her coal mines are abandoned as unproductive, her other industries will shrink to minimum, and her people become familiar with the sight of idle mills, silent factories, and deserted iron works, as cold and spectral as the ruined castles that remain from feudal times.

The modern growth and ultimate decadence of this great empire may be calculated from the statistics of her coal mines. In 1800 her coal product was about 10,000,000 tons; in 1854 it was 64,661,401 tons; and in 1877 it was swelled to 136,179,968 tons. This period was a time of continued prosperity, when England ruled the world, financially and commercially. In the twenty-three years from 1854 to 1876, inclusive, she produced the enormous quantity of 2,210,710,091 tons of coal; and, more wonderful still, exported only 222,196,109 tons—say ten per cent.—consuming the rest within her own borders. The average increase of her annual output has been 3½ per cent. Will it so continue or has she reached the summit of her industrial greatness and commercial supremacy, and will they now decline, and with it, her naval and military power, the subservient agent, and, to a large extent, the creature and result of those great interests? Her coal product in 1878 was less by 1,587,905 tons than that of 1877. Is this the beginning of the inevitable decline? There is reason to believe further on account of the great depression in business, that the production of 1879 will be less than that of 1878. Our anthracite product, compared with the coal product of Great Britain, is so small as to really seem insignificant. The English commission counts as available all coal beds over one foot thick—we count nothing under two and a half feet thick, nor below 4,000 feet in depth—showing a net amount in the explored coal fields of 90,207,285,898 tons; estimated amount in concealed areas, 56,273,000,000 tons; total, 146,480,285,398 tons, distributed as follows:—

	Explored.	*Unexplored.*	*Total.*
England	45,746,930,555	56,246,000,000	101,992,930,555
Wales	34,461,208,913	......	34,461,208,913
Scotland	9,843,465,930	No estimate.	9,843,465,930
Ireland	155,680,000	27,000,000	182,680,000
Total	90,207,285,398	56,273,000,000	146,480,285,398

The exhaustion of this magnificent mass of coal at this present rate of increase, viz: three and a half per cent. per annum, is estimated by Professor Jevons as follows:

1876, actual output	133,300,000 tons.
1886, estimated annual output	186,600,000 "
1896, " " "	261,200,000 "
1906, " " "	365,700,000 "
1916, " " "	512,000,000 "
1926, " " "	716,800,000 "
1936, " " "	1,003,500,000 "

Thus in sixty years the output would be nearly eight times the present amount, and about one fourth of the total amount to be found in Great Britain. This vast estimate seems too enormous. It does not allow for great loss when cost of labor and much competition will prevent the working of small coal beds under two feet in thickness, or for the cost of mining when from 2,000 to 3,000 feet deep. Nor is it possible that Great Britain's industries and export trade combined will ever require so great a quantity. Modern discoveries and improvements, in applied science, tend to diminish the consumption. The 8,000,000 tons annually required for gas works may be materially reduced by the use of the electric light. The domestic consumption, now equal to one fourth the product, or 33,000,000 tons a year, may increase. But will not the iron manufacturers be on the wane, and her coal exports—now ten per cent. of her coal product—fall off as those of other countries increase? We have about 340 collieries, and produce 20,000,000 tons per annum, or about 60,000 tons each. Great Britain has nearly 4,000 collieries, and mines 132,000,000 tons, or 33,000 tons per colliery. The greater the yield per colliery the less the expense in mining. If we decrease the number of mines and increase their capacity not only to raise the coal, but to exhaust a constant current of foul air and dangerous gases, clouds of powder smoke and millions of gallons of water, we will reduce the cost of mining. Most of the Anthracite mining in the United States is now done at a less depth than 500 feet vertical; but as the coal nearer the surface becomes exhausted, the mines must go deeper and become more expensive. What folly it is to boast of our world's supply of Anthracite, and feverishly endeavor to force it into foreign markets, when we can so readily foresee its end! Would it not be wiser to limit its product, restrict its sale to remunerative prices, and consume it at our own firesides, and in our own manufactures? The monopoly of the Anthracite coal fields by some seven corporations, which, according to the accompanying tables, now control about two-thirds of the whole, and the best coal area, must prove, under economic management, a profitable investment for their stockholders. Mining, selling and transporting their own coal, as they do, individual enterprise cannot hope to compete with them, and must vanish from the ground, and their only rivalry will be with each other, and with the Bituminous trade. Fortunately for the public, this rivalry will always be keen enough to keep the price of coal at a fair low rate of cost and profit. The coal resources of Great Britain are all developed now, and in process of depletion; while in this country, when our 470 square miles of Anthracite are exhausted, we have more than 400 times that area, or 200,000 square miles of Bituminous, from which to supply ourselves and the rest of mankind with fuel. The coal product of the world is about 300,000,000 tons annually. The North American continent could supply it all for 200 years. With an annual production of 50,000,000 tons, it would require twelve centuries to exhaust the supply. But with a uniform product of 100,000,000 tons per annum, the end of the Bituminous supply would be reached in 800 years. What the annual consumption will be when this continent supports a teeming population of 400,000,000 souls, as will be the case some day, must be left to conjecture. But with half that population, as energetic, restless and inventive as our people in this stimulating climate have always been, under the hopes of success, such a country as this constantly holds out to tempt ambition and reward enterprise, it is a very moderate estimate, guided by the actual output already reached in Great Britain, to suppose that there will be ample use for one hundred million tons a year of Bituminous coal for home consumption alone.

If it be true, as Baron Liebig asserts, that civilization is the economy of the poor, we have it in our immense areas of Bituminous coal. There is no known agent that can answer as a substitute for the vast power and almost limitless usefulness of coal in its general adaptation to the wants of man; and that nation will maintain the foremost rank in enlightened modern civilization which controls, to the fullest extent, while it lasts, this wonderful combination of light and heat and force. We are wiser than our fathers; and from the modest but sublime altitude to which we are lifted by physical science, and the far-extended range of mental vision which it opens up to us, we can see further into the plans of Providence than those who went before us, and can conjecture the early, if not the remote future of the human race in our land and in other lands. Happy that people whose legislators study the best mode of developing the natural resources of their country, and whose great men become great by improving the condition and promoting the welfare of the human race. The greatest of England's five Georges was not either of those who wore the crown, but plain George Stephenson, of Manchester; and none of the royal Jameses did half so much for the civilization of his country as James Watt.

Output of Anthracite Coal from the Year 1820 to 1880, inclusive.

A Paper by P. W. Sheafer, E.M., read before American Association for the Advancement of Science.

THE AVAILABLE TONNAGE OF THE BITUMINOUS COAL FIELDS OF PENNSYLVANIA.

THE great outspread of the coal measures over portions of thirty-one of the sixty-seven counties of Pennsylvania, and the large number of workable seams comprising the coal series,—together with some workable seams lately shown to belong to the (so-called) barren measures,—create the impression that these fields contain a practically inexhaustible supply of fuel, and those who have estimated or attempted to estimate their available tonnage have generally promulgated this view. But the *actual total contents* of this coal-field can be of little or no importance to us at present; *calculations including all seams*, whether thick enough to mine or not, whether pure enough to furnish the marketable fuel or not, whether accessible at reasonable depth or not, are of no practical value. As coal producers, we are interested, not in the total contents, but in the total amount of *easily accessible coal of good quality contained in beds thick enough for remunerative mining.* The estimates contained in this paper refer exclusively to workable and accessible coal of commercial value,—we may call it "*available*" *coal.* I am not aware that any one has as yet attempted to estimate in detail the amount of *available* coal in each county and in each bed. Heretofore the data to do this have been lacking, but now, since the completion by the geological survey of the series of county reports, illustrated by geologically colored county maps, it is possible to take up each county separately, and estimate in detail, approximately, at least, the contents of each seam. The general estimate to which I have referred as lacking the elements of detail essential to accuracy, have usually been made by multiplying the total *area* covered by coal measures by an *assumed average* of the united thicknesses of the workable seams. Thus some estimates place this area at between twelve and thirteen thousand square miles, and the average coal thickness at from fifteen to thirty feet or the amount of available coal at from 180,000,000,000 to 300,000,000,000 tons. By reference to the tables accompanying this paper it will be seen that these figures greatly exceed the total of my detailed estimates.

Calculations based on an *assumed* average thickness of coal must necessarily give untrustworthy results, because it is not possible to determine *a priori*, and in advance of detailed estimates, the average coal thickness in a field where every bed is subject to more or less radical variation in its thickness and quality. In counties containing throughout their entire area persistent seams of coal, large deductions are to be made for areas over which some beds thin to an unprofitable thickness or become locally too impure to furnish a marketable fuel. I have not attempted to calculate the several coal areas with any great degree of accuracy; with few exceptions, the areas expressed in acres reduced from measurements based on a unit of five square miles, hence these acreages nearly all appear as multiples of 3,200 acres. The maps from which the calculations were made are drawn on a scale of two miles to one inch, and as these are necessarily only approximately correct both in the ground plan and coloring, a finer differentiation would but lend false pretensions of accuracy to work necessarily involving errors of considerable magnitude. Seams less than two feet thick have been ignored. The areas of beds from two to three feet thick are calculated down to water-level; their areas beneath water-level have been ignored. Seams from three to five feet thick are estimated to a depth of one hundred and fifty feet beneath water-level. The areas of seams more than five feet thick are computed to a depth of four hundred feet beneath water-level when their quality and thickness are known. The areas of beds more than four feet thick lying above water-level, but over-laid by a great thickness of superimposed measures, have been calculated so as to include a distance of from one to two miles from their outcrop lines,—varying with the dip.

The maps from which the areas were computed are colored in five tints to represent the subdivisions of the carboniferous system of rocks, as follows:

Upper Barren Coal Measures.
Upper Productive Coal Measures.
Lower Barren Coal Measures.
Lower Productive Coal-Measures.
Conglomerate series (with coals).

The lower edge of the Upper Productive tint limits the area of the Pittsburgh bed; the Lower Barren tint defines that of the Freeport Upper coal, and the Lower Productive tint the Brookville coal bed; the areas of intermediate or higher seams were estimated from assumed intermediate out-crop lines. After computing the total area of each persistent seam in any county, the percentage of this area over which the bed will probably be found of workable quality and thickness, and its average thickness were arbitrarily assumed after a careful study of the data published in the county reports. It is evident that there is here introduced a large personal error; it is impossible to entirely eliminate such errors, but they can hardly be large enough to seriously impair the value of the conclusions. The mass of facts published in each county report thoroughly demonstrates the character and value of each coal seam and limits this personal error between *comparatively* narrow bounds.

But it matters little how much time and care are spent upon such work, the personal error must always be a factor of some importance. Even in the anthracite regions, which are so thoroughly developed by actual mining as well as by an immense amount of prospecting work, there seems to be some difficulty in estimating the available coal. In his report on the Philadelphia and Reading Coal and Iron Company's property, Mr. Joseph S. Harris estimates the total contents of the anthracite regions at 13,999.8 square miles one foot thick—equivalent to about 15,600,000,000 tons—and the coal area at 433 square miles. In a paper read September 1, 1879, before the American Association for the Advancement of Science, Mr. P. W. Sheafer estimates the total contents at 26,361,076,000 tons, placing the coal area at 470 square miles. It is evident that the discordance between these two estimates is due in part to an unavoidable personal error; Mr. Sheafer estimating the average coal thickness at nearly double that assumed by Mr. Harris—the estimate of coal areas differing very slightly. The coefficient of error is probably greatest in the counties containing very small available areas,—these have been most liberally estimated (Bradford, Cameron, Clinton, Forest, Crawford, Lycoming, McKean, Potter, Sullivan, Tioga, Venango, and Warren); but in the counties containing large available areas the estimates are probably much less than the actual amount, as I have strenuously endeavored to underestimate rather than exaggerate the available tonnage. The actual average coal contents per acre for each foot of bed measurement is somewhat in excess of 1,650 tons of 2240 pounds, but deducting *one-eleventh* for slate, bone and sulphuric partings, I have assumed an average of 1,500 tons of 2240 pounds per acre for each foot of bed measurement.

The total amount of available coal, limited as above to depth, thickness, etc., is 33,547,200,000 tons.[1] Assuming that 75 per cent. of this can be won in mining, we have 25,160,-400,000 tons as the possible product.

There is little doubt but that under good mining management fully 75 per cent. of this coal can be recovered. Under favorable circumstances, more than 90 per cent. should be won at mines worked on the long-wall plan or on a modification of the long-wall and panel systems.

The total available tonnage may be divided thus:

Beds over 6 feet thick,	10,957,200,000
Beds from 3 to 6 feet thick,	19,586,800,000
Beds from 2 to 3 feet thick,	3,003,200,000
Total,	33,547,200,000

Excluding coals less than three feet in thickness we have an available tonnage of 30,544,000,000 tons, of which 75 per cent. being recovered=22,908,000,000 tons as the possible output from seams three feet or more in thickness. Probably two-thirds of this amount lies favorably situated for mining, and at ordinary prices for labor can be mined and placed on the cars at an average cost not exceeding one dollar per ton; but the remaining third lies beneath water-level or beneath a thick covering of superior-imposed measures, and will probably cost from one dollar and a quarter to one dollar and a half per ton at the present price of labor.

[1] The estimates do not include the Broad Top Coal Field.

This two-thirds=15,272,000,000 tons, accessible above water-level, and contained in beds not less than three feet thick, is sufficient to maintain the present average yearly output from Pennsylvania for about eight hundred years, or to supply the whole world for fifty years. The statistics of production in Pennsylvania show a yearly increase of about 6 per cent. from 1864 to the present time. If this ratio of increase is maintained, the yearly output will reach an enormous figure in thirty or forty years (as shown in the first column of the following table); but as West Virginia, Ohio, Indiana, and several of the Western States are rapidly developing their coal resources and taking their share of the increased demand, it does not seem probable that this percentage of increase can long continue, and I have accordingly calculated another table on a scale of decreasing percentages of increase,—shown in the second column,—estimated on a basis of 16,000,000 tons production in 1880.

Year.	*Yearly Tonnage.*	*Yearly Tonnage.*	*Yearly increase (compounded.)*
1880	16,000,000	16,000,000	
1890	28,640,000	28,640,000	6 per cent.
1900	51,265,600	46,396,800	5 per cent.
1910	91,766,424	68,000,000	4 per cent.
1920	164,270,219	91,120,000	3 per cent.
1930	.....	111,166,450	2 per cent.
1940	.....	122,840,000	1 per cent.

Although the figures of the second column are much smaller than those of the first column, they still are in my opinion much in excess of any output we will ever reach in Pennsylvania. I am inclined to think that the ratio of increase will diminish more rapidly,—say 1 per cent. every five years,—that the maximum output will be reached between 1900 and1920, and will not exceed 50,000,000 tons per annum. At this rate more than five centuries will be required to exhaust the coal. Seams less than three feet in thickness, unless of unusual purity, or located in the counties forming the northern edge of the coal-field, are of little importance at present; nearly all the coal now marketed coming from seams averaging three and a half feet or more. Many of the smaller and more impure coals will never be marketed,—they will answer well to supply the local demand for domestic use and small manufacturing establishments. Probably 10 per cent. of the total available coal will be used to meet this demand, but only a small percentage of this will actually be won in mining, as small mines (*country banks*) worked vicariously from year to year are almost invariably mismanaged, and more than one-half of the coal irrecoverably lost. The possible output from beds above water-level, and more than three feet thick, has already been estimated at 15,272,000,000 tons. It will be safe to assume that one-third of this will be sufficiently good quality to furnish good coke, an amount (5,090,666,666 tons) sufficiently to smelt 2,500,000,000 tons of iron; the remaining ten thousand million tons will furnish excellent gas and steam coals. The average workable thickness and available tonnage of each seam are shown in the following table, which is illustrated by the columnar section drawn on a scale of two hundred feet to an inch.

Upper Barren Measures:			
Washington bed,	3′ to 3½′	787,200,000	
			787,200,000

			1,028,600,000
Total			33,547,200,000

The Upper Barren measures furnish but one workable seam, the Upper Productive measures five beds, the Lower Barren measures three or four coals attaining workable size in parts of three or four counties, the Lower Productive measures eight workable seams, and the Conglomerate series three or four seams, workable over limited areas in the northwestern counties.

Upper Barren Measures.—This series furnishes but one seam of commercial importance, the Washington bed, which attains its best development in Washington and Fayette counties, but is not persistent as a workable seam in any other county. The series of rocks contains (see section) several other seams, but they are usually very thin and of poor quality, although one—the Waynesburg "A" bed—may prove workable over a small area in Fayette county.

Upper Productive Coal Measures.—*Waynesburg Bed.*—This is a seam of great importance in Greene and Washington counties attaining also a good thickness in Fayette and Westmoreland, holding the fifth place among the productive coal seams. Professor Stephenson's admirable maps show its depth beneath the surface at almost every cross-road and town in Greene and Washington counties, (see reports K, K K, K K K.)

Uniontown Bed.—This is locally workable in parts of Fayette and Greene counties. It is of little importance.

Sewickley Bed.—The same remarks apply equally well to this bed, and to the

Redstone Bed, which is also locally workable in Westmoreland and Allegheny counties, with an average thickness of from two to three feet.

Pittsburg Bed.—This is the best and most valuable seam of the bituminous coal area. It ranges from six to twelve feet in thickness, and according to my estimates contains nearly one-third of the available bituminous coal in Pennsylvania. Its most extensive areas are found in Fayette, Washington, Allegheny, Westmoreland, and Greene counties, small areas also occurring in Indiana, Somerset, and Beaver counties. The purity and quality of this coal, and the excellent character of coke made from it.—the famous Connellsville,—render it many times more valuable than any other seam.

In parts of Washington and in Greene county it lies deeply covered beneath a great thickness of overlying measures, but its depth at almost any point can be easily determined from Professor J. J. Stevenson's maps, (Report K and K K).

Lower Barren Measures.—In Indiana, Somerset, and Butler counties this series contains several beds attaining workable size over limited areas, and in Armstrong and Beaver counties there is also a small quantity of minable coal in these measures. It will probably be worked principally to supply the local demand.

Lower Productive Coal Measures.—In Fayette and Westmoreland the coals of this series contain a large amount of available coal; in Allegheny county the Freeport coals will furnish a large supply, but they are always of inferior quality. The tonnage of these three counties available from the Lower Productive measures was estimated *en masse*, the data not being sufficient to warrant a finer differentiation.

Millerstown Bed.—This is locally workable in Butler county. It will be mined to meet the local demand.

Freeport Upper Coal.—This bed is workable in parts of fifteen counties. It furnishes some excellent coal, is often a superior cooking coal, and in the western counties is always a strong steam and often a good gas coal. A small area of this seam in Clarion county is of a "block" character, and the coal has been used raw in a small furnace (10′ x 33′) to smelt the limestone carbonate ores. This bed ranks third among the productive seams.

Freeport Lower Coal.—A bed of great importance in Jefferson, Indiana, Clearfield, Cambria, Amstrong, Centre, and Allegheny counties, and workable in parts of Beaver, Butler, Elk, Blair, Cameron, Westmoreland, and Fayette counties. It ranks fourth among the productive seams, and will furnish a large supply of good steam, cooking, and gas coals, the character varying with the locality.

Kittanning Upper Coal.—Nearly all of the cannel coal in Pennsylvania occurs at this horizon. It is the celebrated "Darlington" Bed. The seam often consists partly of cannel and partly of bituminous coal, but is most frequently a bituminous seam of fair quality, attaining workable thickness in parts of Butler, Armstrong, Somerset, (bed "D,") Beaver, (cannel,) Indiana, Jefferson, Elk, and Lycoming counties. It holds the seventh place among the productive seams.

Kittanning Middle Coal.—This locally becomes workable in Butler, Lawrence, Jefferson, Armstrong, Elk, Cameron, and Clarion counties. It will furnish probably one half as much coal as the Kittanning Upper bed.

Kittanning Lower Coal.—In twenty-two counties this bed attains a workable thickness and lies above water-level, favorably situated for mining. The seam lettered "B" in Clinton, Bradford, Lycoming, Tioga, and Sullivan counties has been considered its eastern equivalent, (see Reports H H H H, H^5 and H^6, showing "B" =Lower Kittanning coal.) Along the Allegheny escarpment it is an excellent cooking coal, and in the western counties often a good gas coal, and always a strong steam coal. In point of production it probably ranks second only to the Pittsburg bed; but the Freeport Upper coal may possibly equal or slightly exceed it in the amount of easily accessible coal. It averages from two to four feet in the western, and from three to six feet in the eastern counties.

Clarion Bed.—This is formed in two sub-divisions in some of the western counties, its upper split being known as the "Scrub-grass" coal, (see Reports V, VV, QQ, QQQ.) Its output will probably be applied almost exclusively to satisfy the local demand It sometimes furnishes coal of excellent quality, but the bed is usually quite thin.

Brookville Bed.—Bed "A" of the Allegheny escarpment counties. It will be about equally productive with the Kittanning Upper seam, but often furnishes a very sulphurous fuel.

Conglomerate Series.—*Mercer Coals.*—The Mercer upper and lower coals are workable over limited areas in Lawrence, Jefferson, McKean, Elk, Mercer, Venango, and Forest (?) counties. Excepting in McKean, where their proximity to market enhances their value, and in Mercer county, where they attain their best development, they are of little importance. In Elk and Jefferson they will yield a considerable tonnage, but in the latter county at least this will be applied almost exclusively to meet the local demand.

Quakertown Coal.—Workable over a small area in Mercer county.

Sharon Coal.—In Mercer county this is a bed of great value, but its available area will be exhausted in the near future. This horizon will furnish a small amount of coal in Crawford and Warren counties, but in the latter county it is thin and of inferior quality. Its available tonnage has been estimated on a most liberal basis.

Area.—The area actually covered by the bituminous coal measures in Pennsylvania is about 9000 square miles. The Upper Productive series extend over but a small fractional portion of this area; the barren measures cover a considerable area, hiding beneath a thick covering large areas of the coals of the Lower Productive measures, otherwise easily accessible. The limits adopted in making these estimates necessarily compel the exclusion of many such areas in computing the available coal.

Estimates in detail for each county are given in the following tables in alphabetical order. It may appear that in many cases very small areas are assigned to persistent seams occurring over large areas. The explanation of this will be found in the impure or variable character of the bed, or its depth beneath water-level or beneath superimposed measures over a portion of the area. The casual observer is apt to form a favorable opinion of the quality, thickness, and regularity of coal seams not warranted by the actual facts. Finding several banks working on the same bed at different localities in a county or township, at all of which the bed is of fair quality and thickness, he is naturally led to infer that the seam will be found of equal value over the area he has examined; but he has perhaps, had no opportunity of examining an equal or greater number of trial openings, at which the bed was found to be *worthless*, for these have all been abandoned, have fallen shut, and the openings are almost obliterated. Unless this fact is kept constantly in view, and the variable nature of most of our bituminous coals (especially the smaller seams), thoroughly appreciated, estimates bascd on bed measurements made at *working banks* will almost invariably be found to exaggerate the true amount of available coal of marketable quality.

The reports already published by the Second Geological Survey of Pennsylvania, descriptive of the bituminous coal area, now number twenty-one octavo volumes, besides two volumes and one atlas on the fossil flora of the coal measures, and a special volume on the coke industry of the Youghiogheny. Nearly all of these reports are illustrated by geologically colored county maps on a scale of two miles to one inch. Besides this series of maps, there is another series now in preparation on a scale of six miles to one inch, which, when completed, will be published in atlas form. At some time in the near future it is my intention to construct from these maps an accurately colored map of the bituminous coal area. I had hoped to illustrate this paper with such a map, drawn and colored to show the relative areas of the principal productive horizons, but as the maps of Cambria, Somerset, Clearfield, and Centre counties are not yet completed, I have thought best to wait until all of these are finished and approved by the State geologist. The estimates of areas and tonnage in these four counties probably contain larger errors than any of the remaining districts, as it is impossible in the absence of the geologically colored maps to accurately limit the productive areas.

The tables showing the county tonnage develop the fact that each county contains an average of but four or five accessible seams of commercial importance.

Two counties contain nine important seams.
Two counties contain eight important seams.
Four counties contain seven important seams.
Two counties contain six important seams.
Two counties contain five important seams.
Seven counties contain four important seams.
Two counties contain three important seams.
Seven counties contain two important seams.
Three counties contain one important seam.

If the counties are tabulated according to their available tonnage we find Fayette standing at the head, followed by Washington, Greene, Allegheny, Westmoreland, Indiana, Jefferson, Armstrong, Somerset, Cambria, Butler, Clearfield, etc., but we must not lose sight of the fact that this may not be the order in which they stand in reference to their present value and importance as coal-producing areas. Mr. Joseph S. Harris, in his able report on the Philadelphia and Reading Coal and Iron Company's property, has clearly shown that the *present money value* of any coal area depends largely upon the time at which development is commenced, the time elapsing before its maximum output is reached, and the time occupied in exhausting the tract, the present money value rapidly decreasing as any one of these variables is increased. The same principle is undoubtedly applicable to the bituminous coal areas. Those areas, so situated that their development can be economically prosecuted at present or in the near future, possess a much greater relative present value than areas not so favorably situated; thus some of the counties forming the northern rim of the bituminous coal area are, because of their proximity to the northern markets, and their present development, of much greater present importance as coal producers than centrally located areas containing many times as much available coal. The amount of coal excluded from these estimates on account of poor quality, depth beneath water-level or beneath overlying rocks is very great. As these estimates prove the existence of an amount of easily accessible coal of good quality sufficient to supply the demand for several centuries, estimates of the tonnage of these impure seams or inaccessible areas would be of no practical value to the present generation.

NOTE.—The coals named after the letters A and B, in Clinton, Lycoming, Tioga, Bradford, and Sullivan counties, have been classed above as Lower Productive coals, binding their equivalents in the Kittanning Lower and Brookville beds. The identification of these latter with beds A and B of the Alleghany mountain escarpment, is shown by Mr. William G. Platt, in Reports H^5, H^6. Prof. I. C. White has more lately suggested that the coals of these northeastern counties may belong to the Conglomerate series (see report on Susquehanna and Wayne.) As I am not convinced that enough is known about these coals to prove the correctness of Prof. White's suggestion, I have adhered to the old classification.

A paper by Dr. H. M. Chance, Proceedings American Institute Mining Engineers.

WINDING GEAR FOR MINES AND WIRE ROPE.

MR. HENRY A. VEZIN, in a paper contributed to the proceedings of the Engineers' Club of Philadelphia, describes the improved methods of haulage in use at the Von der Heydt mine, four miles from Saarbrücken, Rhenish Prussia, where two systems are used. One consists in the use of wire ropes with two engines, one at each end of the road; the other, in an endless chain drawn by one stationary engine. There are two roads with wire rope, one 5709 feet long, with ropes five-eighths of an inch in diameter, and the other 12,368 feet long, with ropes of ¾-inch diameter. When one engine is hauling the train, the one at the other end unwinds by letting its drum run loose, with the brake slightly set, so as to give its rope, which now acts as tail rope, enough tension to prevent its dragging on the intervening ground between the rollers. The tracks have many curves in the adits, levels, and cross-cuts in which they are laid. The wire ropes are of charcoal iron, the rollers of cast-iron, and these latter are set inclined in the curves to prevent the ropes from jumping out. The train, which consists of 100 cars coupled together, each car holding half a ton, is drawn at a velocity of 8 to 11½ feet per second, or 5·5 to 7·8 miles per hour. To each end of a train is coupled an iron guide-car with a device to guide the rope on the rollers, which device is only in use on the car at the rear of the train. If the loaded cars are brought to the end of the track in the mine without delay, and if they are unloaded promptly at the other end, 25 trains, carrying 1250 tons of coal, can be hauled out in 10 working hours on the shorter line, and 15 trains, or 750 tons, on the longer one. A conductor accompanies each train. The levels and adits passed through are provided with a telegraph cable, in which at every 1000 feet an apparatus for breaking the circuit is inserted. By pulling vigorously at the cable, the conductor can transmit signals, even when the train is running at full speed. These roads have been in operation for 20 years. Upon the arrival of a train at the mouth of the adit, the cars are pushed singly under the chains of two chain tramways. The length of each of these is 1738 feet, and each has a curve of 479 feet radius, forming an arc of 168 degrees. Sharper curves can not be passed without releasing the car from the chain, as described below. The cars are placed at intervals of about 50 feet, and serve as supports for the chain rendering rollers between the rails of the tracks unnecessary. The chain rests in forks which are riveted to one end of each car. These roads have been in use since 1872. The iron of the chains was originally ⅞ inch in diameter, and has been worn down to ⅓ inch. The principal chain tramway is in the Burbach adit, and delivers the coal to the same shipping-point as those described above. The cars are hauled by horses to the underground terminus. The length of the road is 5773 feet, consisting of two straight lines connected by a curve of 81·4 feet radius, forming an arc of 103 degrees. To pass this curve, the chain draws the cars up an incline, beyond the summit of which it passes around a guide-pulley placed so high as to release the cars. This point of release is the beginning of the curve, laid on a grade, down which the cars run by gravity to take their places automatically under the chain in the new direction. The cars are about 50 feet apart, as in the former case, so that 80 to 85 loaded ones and the same number of returning empty ones are always under the chain. It rests on the coal or on the edge of the car, its weight being sufficient to prevent slipping, so that forks are unnecessary. Each car holds ½ ton. This tramway, in October, 1880, had been working uninterruptedly since September, 1874, with a capacity of from 400 to 500 tons in ten working hours. It could easily, at its regular speed of 4.1 feet per second, or 2.8 miles per hour, deliver 1250 tons in the same time. The chain is made of iron four-fifths inch in diameter. The inside length of each link, or the pitch of the chain, is 3 inches. The chain is wound 1½ times around the driving-drum, which is covered with wood with a conical hollowed surface, on which the chain slips sideways as it is wound on the one side and off on the other. This wooden lagging cost $25, and lasts over a year before having to be turned off. The original lagging (of oak) was still in use in October, 1880. A cast-iron chain wheel-sleeve would cost $75 to $100, and wear out in four months, and would have the objection that its teeth would not accommodate themselves to the increased length of links or pitch resulting from wear. The grain of the wood is not placed radially, as it would become too smooth, but as nearly as possible with the circumference. The chain showed very slight signs of wear. It sustains a tension of two tons. The driving-engine, placed near the mouth of the adit, is connected with the drum by gearing, and is said to work with seven indicated horse-power. The drum is four to five feet in diameter. The same method of driving is used on the two short tramways. At the Burbach adit tramway, the cars, just before being released, are drawn up a slight incline and then run by gravity down a short curve and over a bridge to the shipping point.

The road with wire rope, as well as those with chains, are horizontal. The chief-engineer assured me that there would be no difficulty in overcoming grades of 14 to 15 degrees (25 feet to 26-8 feet per 100) without the use of forks on the cars, though it might be necessary to have the chain rather heavier than the four-fifth inch one.

Total Cost of Hauling Per Ton per 100 Feet.

By horses, 1-5 cents.

That is to say, hauling with horses would have cost seven times as much in the Burbach adit as it did by chain in 1879.

Improved Winding Gear for Mines, etc.—Important improvements have recently been introduced by Mr. John Craven, of Wakefield, England, in the form and arrangement of winding gear for mines, the improvement consisting mainly in obviating the necessity of coiling ropes round the drums usually employed, and so removing the danger and expense arising from the great wear and frequent injury of the ropes by one coil chafing against the other. In order to effect these objects, the inventor employs a single winding rope, an upper set of grooved headgear pulleys, and a lower set of grooved winding pulleys, each consisting of two pulleys and an intermediate grooved pulley between the two sets. The rope is attached at one end to one of the cages, passes over one of the headgear pulleys, under one of the winding pulleys (to which the motive power is applied), and back over the intermediate pulley, and then under the other winding pulley, and thence over the other headgear to the other cage, to which the end of the rope is attached. This arrangement is designed to give greater durability to the rope, and to obviate all tendency to slipping of the rope, as in proportion as the weight of the load is increased the adhesion of the rope is augmented. The bearings of the intermediate pulley may be carried in a movable frame, either inclined or otherwise, so as to admit of the pulley being adjusted as required, in order to maintain the rope taut. The following specific advantages are claimed for the invention: No chafing of rope as in the ordinary system of drum, so that the ropes last longer; reduction of work for the engine to do in starting; reduction of strain upon the engine, &c., in stopping; speed, instead of being obtained by a large diameter of drum, is got from the engine running quickly; a smaller engine is required than with ordinary gear, owing to the comparative lightness of the winding pulley; the winding pulleys have only one groove each, and are of very small weight, comparatively; saving in first cost, the engine house being much narrower, and only one rope required instead of two; great adhesion, no slip occurring between the rope and the pulleys.

Iron Age.

The Preservation of Mining Steel Wire Ropes.—Complaints are constantly made as to the rapid wear and tear of steel wire ropes used for winding at mines, and this cannot be said to be owing so much to the quality of the material as to the sudden checking of the movements by the use of friction clips when there is a heavy strain upon the ropes. If checked by friction, the rope is liable to heat or tear, or if not allowed to slip at all, to snap off. Now, steel wire ropes are costly things, and should be made to last as long as it is possible for them to do, without giving way or breaking, and how this can be best effected has long been a momentous matter for the consideration of mine owners and mechanical engineers. But no system has been brought forward or adopted until recently by which the full value of a rope can be obtained, and the fraying and breaking of the strands effectually prevented. An invention, however, has recently been patented in London, and is described in the *Mining Journal*, which promises to be of considerable value. The invention is patented by Mr. R. B. Jones, of the firm of Garnock, Bibby & Co., of Liverpool, and James Hughes, an employee of the firm, and relates to improvements to clips, stoppers, or brakes for steel wire and other ropes, being also applicable as winches or for hauling purposes, so that a brief notice of the invention must be of more than ordinary interest to those daily using metallic ropes. The invention is designed to check the rope whilst working, without any of the severe punishment caused by hard compression or attrition, and without sensible wearing friction on the rope. For this purpose a brake is fixed, not the rope itself but on mechanism connected with V-pulleys, round which the rope is twined forming a figure of eight. The friction on the pulleys is so great by reason of the turn round each pulley given to the rope that no appreciable relative motion can take place between the pulleys and the rope. As a brake, however, is applied on the axles of the pulleys, or rather on brake wheels on these or on one of the axles, whatever friction is expended on stopping the rope is spent on the brake-block or the belt and brake-wheel and not on the rope. The apparatus is simple and effectual. Upon the overhanging ends of two shafts having bearings in a stout frame four pulleys are placed, two on each shaft, which are connected by spur gearing. On the other ends of the shafts are placed two brake-wheels with a single brake-strap, so arranged that a man, by means of a lever, can put a sufficiently powerful strain on the brake-strap so as to give the brake the requisite power.

Upon one of the shafts is a worm wheel, or first wheel of other train of gearing, and a clutch, so arranged that the gearing can be thrown into gear with the shaft at a moment's notice and be thrown out again, and the gearing can be worked either by hand or power. In operation the rope is passed from a reel through a guiding eye on to one of the other pulleys; it passes round that, then round the other outer pulley the opposite way, then round the opposite inner pulley, the direction being the same as in the first instance; and, lastly, it goes round the remaining pulley in the same direction as round its companion second pulley. The brake can be applied gradually or suddenly without any more friction or severe compression on the rope. By putting the clutch into gear the apparatus becomes a winch, and, the brake being thrown out of action, the rope hauled in. In lowering heavy weights the brake can be applied, the clutch thrown out of gear, and the descent regulated with the greatest nicety by hand pressure on the brake lever. The apparatus is no more severe on the rope when the brake is applied than at other times, excepting, of course, the increased tensile strain necessarily entailed when the lowering of a heavy weight is checked, and whilst in other winding apparatus there is the riding of one turn over the other to the great injury of the rope, in the Jones and Hughes apparatus the drum can be coiled to any depth but no turn rides on the other under pressure from the strain of the work performed. The apparatus can also be used merely as a stopper or brake, or a winch, as they may be desired; so if the winch be not required the spur wheels and winch need not be added, and it becomes a simple stopper. This simple machinery, so admirably adapted for clipping, stopping, hauling, or braking still wire ropes, and can be so easily arranged as to make a complete winch or stopper, should commend itself to mine owners as well calculated to preserve the ropes for winding, and so obtain from them a much larger amount of work than is now the case.

Testing Wire Ropes.—At the royal colliery of Friederichsthal, near Saarbruecken, a press has been erected for the purpose of testing wire ropes used for mining purposes. The cylinder of the press is supported by cast-iron standards, giving a clear vertical working space of about 1 meter between the fixed and movable clamps by which the test pieces are held. The latter is upon a crosshead parallel to a second one above the ram, the two being connected by side rods. The length of stroke and diameter of the ram are both 300 mm., and its effective surface is 707 square cm., which at the highest pressure of 200 atmospheres corresponds to a pull of 141.4 tons. The sides of the press cylinder are 100 mm., and the bottom 150 mm., thick; the side rods connecting the two crossheads are 90 mm. in diameter. The experiments described were made upon three ropes that had been laid aside after use. The first was a round steel rope of 28 mm. in diameter, with seven strands of seven wires each, and a hempen core of 10 mm. diameter. The total section of the wires was 250 square mm., and the tensile strength when new was guaranteed to be 28.2 tons by the maker, and proved to be 31.8 tons on trial. As it had been exposed to the air for some time, it was considerably and rather unequally rusted. The second rope, also of round steel, was 29 mm. in diameter, with six strands each of eleven wires 1.65 mm., upon a core of seven (one of 1.65 mm. and six of 1.45 mm.); the whole having a hempen core of 12 mm. The total section, apart from the six thicker core wires, was 200 square mm., and the tensile strength 21.89 tons guaranteed, and 26.63 tons actual. This was much better preserved than the preceding one, and the results obtained are considered as more accurate. The third rope was a flat one of cast steel wire, 60 mm. broad and 13 mm. thick, made up of six round ropes, each having strands of six 1.45 mm. wires and a hempen core of 2 mm., the section of the metal being 238 square mm. When new, the tensile strength guaranteed was 25 tons. There being no means of applying the press to the lifting of heavy loads of known weights, the loss due to friction produced by the hydraulic packing leather could not be directly observed, and was therefore calculated by Reuleaux's formula:

$\frac{F}{P} = \frac{1}{D}$ where F is the friction of the ram, D, the diameter of the ram, and P, the load upon it.

Moreover, if p = pressure per square cm. = 1.033 observed gauge pressure in atmospheres; p^1 = weight of ram and attached moving parts; q = section of ram; s = effective strain on the rope;

$$P = q\,p \quad F = \frac{q\,p}{D} - \frac{p^1}{D}$$

$$s = p\,q - p^1 \left\{ \frac{p\,q}{D} - \frac{p^1}{D} \right\} = \frac{D-1}{D} p\,q - \frac{D-1}{D} p^1 = \frac{D-1}{D} p\,q - C,$$

from which the following expression was obtained:

$$s = 727.75\,a - C,$$

Giving the actual strain on the rope from the observed gauge pressure in atmospheres a. C is a constant whose average value varied with the weight of the moving parts from 1375 to 1435 kg. The object of the experiments was to determine the value of different methods in use for attaching ropes to the drawing cages. These were: 1. Baumann's method, in which the end of the rope is fixed in a conical box by three wedges, the train being uniformly distributed by a hard metal packing, whose surface is accurately molded to that of the rope. 2. Similar method, but without protecting casing between the rope and the faces of the wedges, which are rough and hardened. 3. The ends of the wire were untwisted so as to nearly fill the conical box, and secured by an annular wedge. 4. Like No. 3, with the end secured by a conical plug. 5. Similar to 3 and 4, the joints being made by running in lead, zinc or hard composition metal. 6. End turned into a loop and secured by pairs of iron rings, driven home by blows upon an anvil; length of point 700 mm. 7. Loop with ends secured by three clamps with two bolts to each; length of joint, 500 mm. 8. Loop with three clamps, having four bolts to each; length of joint 600 mm.

Fastening.	*Breaking Strain.*		*Flat rope, 60 + 13 mm.*

Plug, No. IV	18.8—24.8	15.0—22.6	. . . .
Lead joint, No. V	12.1—16.1	12.1—18.3	5.2
Zinc joint, No. V	19.3—24.1	20.1—23.0	28.5—29.2
Hd. met. jnt., No. V	24.4—25.9	23.0—23.4	17.5
Loop, No. VI . . .	10.2—11.3	16.8—17.9	. . . .
Loop, No. VII . .	15.3—27.7	13.8—22.9	24.8—29.5
Loop, No. VIII	19.7—27.7	15.3—23.7	29.1—30.2

The variations in the above figure are caused by the rope slipping in the holder before the actual breaking strain was reached. This was especially the case with the lead joint No. 5, where the soft metal was invariably compressed and the rope was pulled out of the joint. Better results were obtained with zinc and hard metal, but the individual differences show that the metal must be cast at a high temperature to make a proper joint, when the wire is likely to be overheated, whereby its tenacity is diminished. Fastening No. 1 gave the best results, the strength of the joint being almost equal to that of the rope. The method of securing an eye with rings driven on proved thoroughly worthless, as the rings invariably slipped at a low strain.

Iron Age.

The Strength of Wire Ropes.—Among the different subjects upon which attention was bestowed by the French commission appointed in 1878 to investigate the causes of accidents in mines, the strength of wire ropes was not the least important. The report of the commission on this subject was recently published under the auspices of the Government, and constitutes an elaborate document, covering not only researches made in France, but giving observations made in England, Belgium and Germany. New iron wire ropes, during the first days of their use, stretch from 1 to 2 per cent., and when nearly worn out they undergo slow and continuous elongation. Many engineers and manufacturers profess to have no doubt that by vibration the iron of ropes becomes hard and breaks easier. Other manufacturers have produced the results of tests, which, according to them, prove that the wire of rope which has been in use shows the same tensile strength per unit of section. They freely acknowledge that the wires of an old rope have not each the same strength; but they claim that this is only the result of a decrease in the section due to abrasion and rusting. The results of some experiments submitted do not entirely bear out this argument. Thus, a rope consisting of six strands of 18 wires each (having a diameter of 0.0788 in.) was used 10 months and twenty days, and during that time had been hoisted and lowered 54,360 times, drawing 90,509 tons from a depth of 361 feet, and had been wound around the hoisting drum 233,235 times. The average result of the tests of the 18 wires of a strand in the new and in the old ropes was as follows:

Iron wire rope.	*Total tensile strength of wire Lbs.*	*Tensile strength per sq. in.—Lbs.*	*Elongation at rupture. Per cent.*	*Elastic limit. Per cent.*	*No. of bends.*
New	494.5	103,437	1.036	0.498	7.0
Old	385.8	86.055	0. 258	0.258	6.4

The diminution of the elasticity in the wire of the old rope shows that the iron has undergone a molecular change. It may be concluded that the tensile strength per square inch is really greater than above given, since rupture generally occurs at the point of smallest section of the wire, and since the sectional area is not uniform throughout its length. The annexed table gives the results of a second set of experiments, in which a number of the wires of the new rope were tested a second time, to determine the effect of the previous rupture; the diameter of the wires was .0709:

Wire rope.	*Tensile strength of each wire.*	*Tensile strength per sq. in. Lbs.*	*Total elongation. Per cent.*	*Elastic elongation Per cent.*	*No. of bends.*
New, first test	434.7	113,792	1.058	0.455	9.0
New, second test	437.6	114,645	0.670	0.520	7.9
Old	292.1	78,232	0.462	0.278	. . .
