TONNAGE LEGISLATION

WHEN it was announced, towards the close of the year 1880, that a Royal Commission had been appointed to consider the operation of the Tonnage Law, the action taken by the Government occasioned no surprise amongst persons interested in shipping. Disputes and differences of opinion, between the officials of the Board of Trade on the one side, and shipbuilders or shipowners on the other, had been growing more and more frequent in recent years; the rapid development of shipbuilding and the introduction of new types of ships or new systems of construction making difficult the application of the Law of 1854. When that Law was passed its language was clear and unmistakable, strictly applying to the ships then built. Wood still held the first place as the material for construction, and the technical terms used by Moorsom bore special reference to wood ships, although they were not inapplicable to the existing iron ships. Ships were then of moderate size and simple construction; ocean steam-navigation was comparatively in its infancy; and the marvellous growth in dimensions, speeds, and diversity of type which has taken place in the last quarter of a century could not have been foreseen —much less provided for in framing the Tonnage Law. It will readily be seen, therefore, that controversies of opinion were unavoidable when the Act of 1854 had to be extended to modern steamships, every clause being subjected to the closest scrutiny, and a strict legal interpretation being given to phrases which were originally clear enough, but of which the modern readings were doubtful or obscure. Shipowners naturally desired to secure the minimum nominal tonnage for their ships, since dues and taxes were assessed thereon; the Board of Trade surveyors, on the other hand, while acting with perfect fairness, might be expected to adopt an interpretation of the law which tended towards a tonnage exceeding that admitted by the owner. In some notable instances of recent occurrence the Board of Trade has either had to yield to these claims for reduced tonnage-measurement, or has been beaten in an appeal to the Law Courts; and it was natural, under these circumstances, that an attempt should be made to secure such an amendment of the Act of 1854 as was needed to prevent further controversy.

Nor was this the only reason for revision. Ever since the present tonnage law has been in force for British ships there has been a tendency on the part of other maritime nations to approximate to our system of measurement. The International arrangements made in connection with the Danube navigation and the Suez Canal have been based on the Moorsom system; and at the present time there is a closer approach to a uniform system of tonnage than has ever been reached before. This desirable result has been produced to a large extent by the action of the Board of Trade, whose successive Acts for the Amendment of the Law of 1854 have been adopted in foreign countries, although they have failed to secure Parliamentary approval at home. Consequently we stand, at present, in the curious position of still having in force the earliest and confessedly imperfect edition of the Moorsom system, whereas English experience and suggestion have given to other countries amended editions. On this ground, therefore, it was desirable to revise the tonnage law, even if the system remained unchanged in principle.

Further reasons for revision of a more thorough and sweeping kind were not wanting. It was admitted that the Law of 1854 was a great improvement upon its predecessors: more scientific in its mode of measurement, and having a sounder basis as applied to the ships built when it was framed, and to the then existing conditions of trade. On the other hand, it was alleged that subsequent changes in trade and shipping rendered the operation of the Tonnage Law injurious, hampering the skill of the shipbuilder, fostering certain inferior types of ships, and favouring heavy loading. In short, it was asserted that a change of system was needed on the grounds of greater safety to life and property, and greater fairness and freedom as between different types of ships.

All these reasons for inquiry are recognised in the Instructions issued to the Royal Commission. No one can fairly complain that the field of investigation is unduly limited; and a perusal of the evidence taken by, or the documents submitted to the Commission, will show that the exponents of every shade of opinion had the greatest freedom allowed them in illustrating their views. If no other purpose had been served, the inquiry would have been justified by the very valuable summary of facts and opinions which it has been the means of putting on record. All that it is necessary to read for the full understanding of the past history of British tonnage laws can be found in the Minutes of Evidence or the Appendices; and much valuable information respecting foreign tonnage laws can also be found therein. Valuable as this feature of the work may be, however, it does not represent the purpose for which the Commission was primarily appointed, and when one turns to that aspect of the subject the results are not nearly so satisfactory.

In NATURE, vol. xxv. pp. 585-7, it was stated that the Commission did not make a unanimous Report. Three of its members dissented from the majority, and each of them produced a separate Report. This is not a matter for surprise; in fact it would not have been surprising had the Commission simply followed the precedent of the Parliamentary Committee of 1874, and submitted the evidence without making a Report. The majority consisted of nine gentlemen whose opinions are entitled to the greatest respect, including shipowners, shipbuilders, dock-proprietors, and representatives of the Board of Trade. As explained in vol. xxv. pp. 585-7, they recommend the retention of the principle of the existing law—viz. measurement of internal capacity—but propose certain amendments in detail. Some of these amendments are reasonable enough, but others are of questionable character; it is, however, of greater importance for our present purpose to consider whether the arguments advanced against a change in the principle of measurement are sufficiently weighty to prevent any change. Of all these arguments the most important are those relating to international obligation and convenience. Bearing in mind what was said above respecting the action of this country in leading up to a system of international tonnage, on the basis of internal measurement, it will be seen that an abandonment of that basis ought not to be lightly undertaken. But this fact need not bar the inquiry as to the advantages to be gained by such a change; for obviously the most thorough and exhaustive investigation would be needed, on other grounds, before the change could be made. And if after due investigation British shipowners were convinced that the change was desirable, the evidence which would convince them could scarcely fail to induce foreign maritime nations to follow our lead. The matter might well form the subject of an International Conference before final action was taken; much as was done in 1873 when the Suez Canal Regulations were framed.

Turning to the other side much more forcible arguments can be urged against a continuance of the present system. Moorsom took great pains to explain his reasons for using internal capacity as the basis of tonnage measurement; these may be summed up in the statement that internal capacity was the fairest measure of the possible earnings of most ships. This was probably the case in 1854; but is no longer true. In most ships the limit of freight-earning is now found in their "dead-weight capability"; that is to say, the prevalent cargoes of commerce do not now fill the whole space, when the weight taken on board has reached the limit of draught which can be accepted with a due regard to the safety of the ships. This is not true of all ships, but of most. Passenger ships, for instance, do not come under this condition; in them space is of the greatest value. Other types of ships, always engaged in carrying light cargoes still come under the condition which in 1854 was thought to be nearly universal. Still these cases are now the minority; and in the majority dead weight capability is the more important condition. This being so it is obviously unfair to assess the tonnage of all ships on the basis of internal capacity. In certain special classes, such as the "awning decked" class, it is alleged that the whole space available can never be filled with cargo; and on these classes the existing law bears heavily, although they are acknowledged to be eminently safe and seaworthy.

On other grounds the retention of internal capacity as the basis for tonnage is to be deprecated. Even with the amendments suggested in the Report of the Majority, there can be no hope that the disputes hitherto so frequent will cease, when a decision has to be arrived at respecting the spaces to be included in or excluded from the gross tonnage; and the deductions to be made therefrom in estimating the register tonnage. The Majority evidently realise this difficulty and attempt to meet it by more precise definitions; but the ingenuity which has been displayed in dealing with the phraseology of the Act of 1854 is not likely to fail in finding loopholes in the barriers now proposed. Nor can it be admitted that some of the proposals of the Majority are fair or foreseeing, having regard to the obvious tendencies and the possibilities of progress in shipbuilding and engineering. Into this discussion, however, it is not possible to enter here.

The three dissentient Reports contain much sharper criticism of the Majority Report than appears in the foregoing remarks. Exception has been taken to the tone of these Reports by some members of the Majority, but apparently not with much justice. Mr. Glover represents the shipowners who desire to be "let alone," and think the present Tonnage Law needs little or no change. Mr. Waymouth, accepting the view that "dead-weight capability" now rules the freight-earning of most ships, proposes to make dead-weight capability the basis of tonnage. Mr. Rothery advocates the "displacement," or total weight of the laden ship, as the fairest basis. Respecting Mr. Glover's views nothing need be said additional to what has already been stated respecting the working of the present system; but it is desirable to glance at the other proposals.

Mr. Waymouth has revived the oldest system of tonnage. "Keels" and other coal vessels were so measured time out of mind; and various empirical rules were framed for the "dead-weight capability" of other classes of ships. Being empirical they were easily evaded; Mr. Waymouth favours a well-known system of measurement, which takes account of the true form of the ship and renders evasion impossible. His system demands a fixed load-line; this is one of its difficulties. In order to overcome this objection to his scheme Mr. Waymouth favours the appointment of some central authority by which the load-line will be fixed. It is known that the Board of Trade is now taking preliminary action and ascertaining the feeling of shipowners on the subject of establishing such a central authority. If it should be formed, then the load-line question might be dealt with more satisfactorily than it has been hitherto, and one difficulty in dead-weight measurement would disappear. But others, and probably fatal ones, would remain ; more particularly in dealing with passenger steamers or vessels built to carry light cargoes. In such cases Mr. Waymouth proposes to fix, for tonnage purposes only, a deep load-line; this is not merely objectionable, but would probably be impracticable in many vessels. The dead-weight system has much to recommend it for consideration on the grounds of simplicity and exactness, as well as freedom from the difficulties incidental to internal measurement. But it is not likely to come into use.

Mr. Waymouth, it will be noted, agrees with the majority in proposing to continue the immemorial practice of basing tonnage measurement upon earnings or earning-power. This principle, although long accepted, has always been held open to question, on the ground that the accommodation provided for a ship in harbours, docks, canals, &c., should regulate the dues paid by her, and not her earnings. The "service rendered," and not the earnings, does appear the fairest basis of assessment, and has a considerable weight of authority to support it ; but to adopt this basis would clearly necessitate a settlement of the mode of appraising service rendered. Mr. Rothery proposes to take the displacement, or volume of water displaced by a ship to a fixed load-line, as the measure of this service. The load-line, he suggests, might be fixed by the owner or some central authority. To this proposal many objections have been raised; but that which seems to have most force is found in the statement that the volume of water displaced does not measure the accommodation required, since various degrees of fineness of form under water might be associated with the same extreme dimensions—length, breadth, and draught. Two ships agreeing in these dimensions and requiring practically the same accommodation might differ in displacement by as much as 50 to 60 per cent. of the smaller.

Mr. Rothery's proposal has, however, done good in recalling attention to the principle of taxation on *service rendered.* In further investigations this is not likely to be overlooked ; and it must be possible to frame some scheme which is not open to the objection to displacement above mentioned. The proposal to take the product of the three extreme dimensions of a ship as a basis for tonnage has been considered, and has much to recommend it, if associated with a fixed load-line. It cannot be said that any of these alternative schemes have received the full consideration they require before being brought forward for adoption. The investigation would necessarily be laborious, and the issues dependent upon it are so important that it should be intrusted only to competent and impartial hands. Certain conclusions are necessarily forced upon every person who makes a study of this subject. First, it is impossible in any revision of tonnage law to ignore the question of the load-line legislation. The majority of the Commission, in their final Report, propose to keep the two questions distinct; but it has been stated publicly by Mr. Waymouth that up to the very last draft Report, the majority made recommendations in the opposite direction ; and if this is the case the less weight attaches to the recommendation which actually appears. Second : in considering future legislation, both for tonnage and for load-line, greater regard must be had to the provision of stability for merchant ships than has been had heretofore. Rough "rules of thumb" for free-board, in relation to depth of hold, are out of date. Third : the work to be done must be largely dependent upon the calculations made by competent naval architects for various types of ships, and various conditions of loading. Such calculations applied to vessels which have been thoroughly tested at sea under known conditions of lading must be the foundation for future rules for load-lines. Lastly, it is much to be desired that the proposed Shipping Council should be constituted, and that it should be a central body, including all classes interested in shipping, and having behind it a staff of skilled naval architects. The Marine Department of the Board of Trade has been much abused, and probably unfairly criticised in many cases. Its action, both as regards tonnage legislation and the load-line of ships, may not have been all that could be desired, yet it must be admitted to have been well intentioned. But it cannot be supposed that the Department as now constituted is capable of dealing with the questions pressing for solution. Neither its nautical, technical, nor adminstrative staff is competent for this task. And it may be supposed that the necessary reinforcement of that staff, the valuable assistance and advice of a Council of Shipping, and the more scientific investigation of matters relating to the safety and good behaviour of merchant ships by naval architects, will be welcomed by the Board of Trade as warmly as by the shipping community. Until these further investigations are completed, amended legislation scarcely seems practicable. It is clearly impossible on the lines laid down in the Report of the majority of the Royal Commission of 1881.

W. H. WHITE

MYTH AND SCIENCE

Myth and Science. An Essay. By Tito Vignoli. International Science Series. (London: Kegan Paul, Trench, and Co., 1882.)

THIS work is devoted to a theory of myths and myth-formation, which is to some extent novel. Looking to the general, if not universal, tendency of all races of mankind to create myths, the author contends that the propensity must point to some feature of human psychology of more than a merely superficial character, and without disputing previous theories as to the origin and growth of myths, he seeks to explain the *raison d'être* of the myth-forming faculty. Thus, for instance, he says :—

> "The worship of the dead is undoubtedly one of the most abundant sources of myth, and Spencer, with his profound knowledge and keen discernment, was able to discuss the hypothesis as it deserves. . . . . Yet even if the truth of his doctrine should be in great measure proved, the question must still be asked how it happens that man vivifies and personifies his own image in duplicate, or else the apparitions of dreams or their reflections, and the echoes of nature, and ultimately the spirits of the dead."

And, speaking of Tylor, he adds :—

"He admits that there are in mankind various normal

> and abnormal sources of myth, but he comes to the ultimate conclusion that they all depend on man's peculiar and spontaneous tendency to *animate* all things, whence his general principle has taken the name of *animism*. . . . . But, while assenting to this general principle, which remains as the sole ultimate source of all mythical representation, I repeat the usual inquiry; what causes man to animate all the objects which surrounds him, and what is the cause of this established and universal fact?"

And elsewhere the author states this problem thus:—

> "To attain our object, it is necessary that the direct personification of natural phenomena, as well as the indirect personification of metaphor; the infusion of life into man's own shadow, into reflex images and dreams; the belief in the reality of normal illusions, as well as of the abnormal hallucinations of delirium, of madness, and of all forms of nervous affections; all these things must be resolved into a single generating act which explains and includes them."

Such being the problem with which the work is mainly concerned, its solution is attempted by the following theory:—Assuming the fundamental identity of human and brute psychology, it is argued *a priori* that, seeing the tendency to personify inanimate objects is so universal among primitive men, we might expect to find a similar tendency in animals, and this, according to the author, we do find:—

> "Animals are accustomed to show such indifference towards numerous objects, that it might be supposed that they have an accurate conception of what is inanimate; but this arises from habit, from long experience, and partly also from the hereditary disposition of the organism towards this habit. But if the object should act in any unusual way, then the animating process which, as we have just said, was rendered static by its habitual exercise, again becomes dynamic, and the special and permanent character of the act is at once revealed."

And he proceeds to describe many experiments of his own, in frightening or surprising animals by making inanimate objects perform unusual movements. From these considerations and experiments he concludes that every object of perception is "implicity assumed" by an animal to be "a living, conscious, and acting subject;" that the animal transfuses into all things, "in proportion to the effects which result from them, his own nature, and modifies them in accordance with intrinsic form of his consciousness, his emotions, and his instincts."

This being taken as true of animals, the theory proceeds to the consideration that if we superimpose on the animal faculties of sensation and perception, the distinctively human faculties of reflection and symbolic thought, we should obtain a full explanation of the psychology of myth-formation.

We have said that this theory is to some extent novel, and it will now be seen that the extent to which it is so consists in its relegating to the domain of animal psychology that tendency to animism which has already been recognised as the feature in human psychology which is largely concerned in the formation of myth. But even thus far the theory is not wholly novel, for Comte supposed that animals possessed some crude ideas of fetishism, and Spencer, in his "Principles of Sociology," says:—

> "Holding, as I have given reasons for doing, that fetishism is not original but derived, I cannot, of course coincide in this view; nevertheless I think the behaviour of intelligent animals elucidates the genesis of it;"

And he proceeds to detail cases which he has himself observed of "the idea of voluntary action being made nascent" in animals upon their seeing or feeling inanimate objects moving in unaccustomed ways. This, we think, is the whole extent to which the observed facts of animal intelligence entitle us to go. Uniformity of experience generates in animals, as in young children, organised knowledge of animate and inanimate objects, so that they are always more or less prepared with some antecedent expectation of the manner in which this or that object will behave. When, therefore, an inanimate object begins to move in some unaccustomed manner, the animal becomes alarmed, and no donbt "the idea of voluntary action becomes nascent."[1] But to argue from this fact that "every object, every phenomenon is for him a deliberating power, a living subject, in which consciousness and will act as they do in himself," and consequently that to animals the whole world "appears to be a vast and confused dramatic company, in which the subjects, with or without organic form, are always active, working in and through themselves, with benign or malignant, pleasing or hurtful influence"—to argue thus is surely to go far beyond anything that the facts either warrant or suggest. The very consideration that an animal shows alarm and horror when an inanimate object begins to behave like an animate one, points to the conclusion that he has made a pretty definite mental classification of objects as animate or inanimate. Therefore, without going further into the matter, it seems to us that the attempt made by this writer to argue for an universal animism as a feature of brute psychology, is a failure.

Of more interest and sounder theory is the part of his work which treats of the connection between Myth and Science. He says:—

> Man, by means of his reduplicative faculty, retains a mental image of the personified subject, which is only transitory in the case of animals, and it thus becomes an inward fetish, by the same law, and consisting of the same elements, as that which is only extrinsic. These phantasms are, moreover, personified by the classifying process of types, they are transformed into human images, and arranged in hierarchy, and to this the various religions and mythologies of the world owe their origin. Since such a process is also the condition and form of knowledge, the source of myth and science is fundamentally the same, for they are generated by the same psychical fact"—*i.e.* that of ideally classifying objects of perception—"the historical source of the two great streams of the intellect, the mythical and the scientific, is found in the primitive act of *entifying* the phenomena presented to the senses"—in the one case with the conception of personality, and in the other with that of natural order.

This idea of myth and science having a common root in the rational faculty of man is not, of course, a profound one, seeing it is obvious that myth, like science, arises from the need or desire of reason to *explain* the facts of nature which are everywhere obtruded upon the observation of "the thinking animal"; but it is perhaps well that this truth should be clearly stated, as it is in the work before us. We think, however, that here, as indeed throughout, the work is needlessly protracted.

GEORGE J. ROMANES

---

[1] See NATURE, vol. xvii. p. 168 *et seq.*, where this subject is treated at more length.

A PRIMER OF ART

A Primer of Art. By John Collier. (London: Macmillan and Co., 1882.)

IN this admirable little work Mr. Collier has succeeded in bringing clearly into view the helpful relation in which science may stand to the Arts of Design—sculpture, drawing, and pre-eminently painting. The aim of the primer is to give the outlines of such knowledge of the artistic field of vision, of the visual powers, and of the means of delineation, as may best aid the student to acquire that power of strict imitation of natural objects which is the artist's first qualification.

The notion hitherto prevailing and perhaps somewhat superciliously held to on the part of art—that because the primary functions of science and of art respectively are widely different, therefore no legitimate help can be rendered by one to the other—is practically discredited in every page of Mr. Collier's little work. Throughout, his object is to pioneer the student to an artistic goal; throughout, the means employed have all the security of clear scientific principle. The theory of the Primer is that by knowing with scientific accuracy how some things *are*, the task of exhibiting artistically how other things *appear* may be greatly simplified.

After devoting a few charming pages to the latest suppositions concerning the origin of sculpture and drawing—pages illustrated by specimens of prehistoric and even palæolithic art—Mr. Collier quits "debateable ground" for that on which surer scientific light can be shed for the guidance of the student in the practice of art.

And here nothing is overlooked. Boundaries, Light and Shade, Texture, Perspective, Colour, and Contrast are the headings of so many terse and luminous little chapters, through each of which comes some word to the learner from the invisible world where science works, warning him how, unless he gives heed to certain hidden actualities within and without him, he may and probably will go many times wrong before he lights on the best way of rendering the natural objects before him.

Accurate seeing is necessary to ensure accurate delineation. The *facts* of simple appearance are what the art student needs to lay hold of. Science, whose constant business is with facts of every order, aids him here with suggestions how to discriminate between sight and inference—between that actual aspect of an object which is due to its present relation to the sight of the observer, and that compound mental view of it which is due to the mixed memory of many previous aspects. A perusal of Mr. Collier's pages on the nature of perspective, on the undulatory theory of light, on the action of a lens, on the structure and nervous mechanism of the eye, and on the physiological rationale of the phenomena of colour show how much scientific information can be given without the use of a single technical phrase.

Having learnt to see, the art student must further learn to delineate. Here again, in discussing the painter's media, it is still with the authority of science the teacher speaks. The chapter on "Turbid Media" clears up the difficulty respecting the varying behaviour of pigments as used on different "grounds." Here, too, as elsewhere, each practical suggestion is accompanied by a scientific reason why the means advocated should be adopted, such reason being always backed by some absolutely lucid explanation of the *nature* of the difficulty to be surmounted, or of the effect to be aimed at.

With the subject of landscape painting comes up the question of aërial perspective; and thereupon follow some admirable pages on the constitution of the atmosphere and the refraction of light. In dealing later with certain necessary discrepancies between natural appearances and their painted imitations, Mr. Collier clears out of the way, by a simple scientific consideration, an insidious problem with which the artistic beginner is apt needlessly to perplex himself—namely, how correctly to represent effects of light and shade within the very limited range of luminosity afforded by his materials. The solution lies within the sphere of optics. The eye takes next to no heed of the degree of total illumination; the *absolute* luminosity of the picture therefore does not signify. All that is needful is to render the *relative* proportions of light and shade in the object or scene depicted; the effect will then be accurate, since sight adapts itself readily and unconsciously to any *scale* of illumination that may be visible at one time.

For the rest, this little work of Mr. Collier possesses all the attributes of a first-rate primer. As we have observed, it is terse, clear, simple, instructive, and alluring. While the student receives aid from various departments of knowledge, calculated at once to forward his progress in painting, and to enrich his ideas of the world in which he works, there is nothing attempted to which the finished artist—aware as he is of the part played by imagination and by an incommunicable sense of harmony in the production of the finest art-work—can yet take any exception. Mr. Collier frankly admits the limitations of science with regard to these points, and leaves untouched all vexed questions concerning harmony of line and colour, on the ground that, important though they are, too little is known about them to make discussion profitable.

Yet that there is no real antagonism between accurate knowledge wherever it can be had, and the loftiest artistic imagination, and further, that science may help to free that imagination by giving it mastery over its means of expression, are truths borne witness to throughout the eighty-eight pages of the primer. The scientific reader will recognise in Mr. Collier's successful endeavour to link the rival sisters (Art and Science) in friendly partnership for the better portrayal of that Nature of which both are students, a welcome sign of the times, and an indication of the direction in which we may look for firmer ground than has hitherto been found for fruitful artistic discussion.

L. S. BEVINGTON

OUR BOOK SHELF

A Treatise on Rivers and Canals. By L. F. Vernon-Harcourt, M.A. Vol. I. Text, 352 pp.; Vol. II. Plates, 21 Pl. (Oxford: Clarendon Press, 1882.)

THIS work was intended (see Preface) to present "in a simple and concise form descriptions of the principal and most recent works on rivers and canals, and the principles on which they are based." It appears to have had its origin in a course of lectures delivered at the School of Military Engineering, Chatham, in 1880, but has been so carefully revised as to be free from the defects of a mere reprint of a lecture course, and may be fairly said to fulfil well the object proposed in the preface. Great pains has evidently been taken to obtain data of actual examples of important works within the above scope; the series of twenty-one well-executed large plates of these is a most valuable feature of the work. The get-up of the work, being issued from the Clarendon Press, is of course excellent; the number of folds in the plates is an inconvenience (few have less than six, and one has ten folds), which might have been obviated by placing fewer diagrams on each plate. A very useful feature is the addition at the end of each chapter of a short summary of its matter, with many good practical remarks.

The work opens with a chapter on the physics of the subject, followed by one on discharge-measurement, then by one on general principles. Then come seven chapters on various appliances and details, viz., dredgers, piling, foundations, locks, inclines, lifts, fixed and movable weirs, dams, and movable bridges. Then follow one chapter on inland canals, one on great ship canals, one on protection from floods, four on improvement of tidal rivers, and lastly, one on the improvement of the mouths of tideless rivers.

From the great variety of subjects treated of in a compass of 322 pages, the treatment is sometimes unequal. The descriptions of the newest forms of the various appliances are, together with their illustrative plates, very interesting and instructive. But perhaps the most valuable part of the whole work is the last five chapters on the difficult and important subject of the improvement of river mouths; the few guiding principles that can be said to be known about so obscure a question are well brought out from the study of grand examples. The subject of discharge-measurement is not adequately treated: a reference to the recently-published (1881) "Roorkee Hydraulic Experiments" would probably have materially influenced this chapter in giving less importance to current-meters, and more to floats (especially tube-rods), and in the entire rejection of the old Chézy formula, $V = C \times \sqrt{RS}$, with a *constant* value of C. The chapter on inland canals is also (perhaps unavoidably) sketchy: thus the description of Indian canals covers only two pages, many of them being simply named.

ALLAN CUNNINGHAM

Galeni Pergamensis de Temperamentis et de Inæquali Intemperie Libri tres, Thoma Linacro Anglo Interprete, 1521. Reproduced in exact Facsimile. With an Introduction by Joseph Frank Payne, M.D. (Cambridge: Macmillan and Bowes.)

THE book before us is one of a series of facsimile reprints of eight books, published in the years 1521–22, by John Siberch, at the first press established at Cambridge; and it would appear, that after the issue of this series, no other works were published there until the year 1585, when a law was passed, limiting the printing of books to London and the Universities.

The revival of classical literature which swept over Europe towards the close of the fifteenth century, effected a complete revolution in the theory of medicine, as well as in philosophy. English scholars of that period were, as a rule, unacquainted with Greek, the few exceptions being men who had studied at the Italian Universities; among these was Thomas Linacre, a Fellow of All Souls, Oxford, who, about the year 1495, visited Italy in the suite of Selling, when the latter was appointed envoy to the Pope, and, after being a fellow student with the sons of Lorenzo de Medici, under Politiano and Chalcondylas, proceeded to his degree of Doctor of Medicine at Padua. On his return to England, he brought with him the reputation of being one of the most elegant and accurate scholars of the day. Shortly afterwards he was appointed tutor to Prince Arthur, and became Court physician on the accession of Henry VIII. to the throne. The physicians of the day were mostly ecclesiastics, but no restriction was placed on the practice of medicine by persons, however ignorant of its principles; and Linacre, with the view of remedying the abuses that prevailed, devoted his fortune, amassed by the sale of the clerical livings to which he had been presented, to the foundation, in the year 1518, of the Royal College of Physicians, which, under its charter, had power to regulate the practice of medicine in the neighbourhood of London. It is interesting to know, that according to Linacre, a physician should be "a grave and learned person, well read in Galen, respecting but not bowing down to the prestige of the Universities; claiming for his own science a dignity apart from, but not conflicting with that of theology; looking upon surgeons and apothecaries with charity, and not without a sense of his own superiority."

The Galenical theories of humours and temperaments formed the groundwork on which the Greeks based their practice of medicine, and Linacre to bring these theories within the reach of all students of medicine translated into Latin six of Galen's works, among which were the "De Temperamentis" and "De Inæquali Intemperie," now before us, thus helping to replace the mysticism and empiricism of the Arabians by the accumulated observations recorded by Hippocrates and Galen. In these works it is assumed that to the four humours, blood, pituite, yellow bile, and black bile, there are the corresponding properties, moist-heat, moist-cold, dry-heat, and dry-cold; and that between health and disease there are four temperaments, characterised by an excess of either one or two of the cardinal qualities, heat, cold, moisture, and dryness. These were the only external influences acting on the body the ancients could recognise, as they were ignorant of the chemical processes of respiration, of the constitution of the atmosphere, and of electricity, of which we now take account. These theories are elaborated, and further, it is indicated that medicines may be classified according to their heating, drying, cooling, or moistening qualities, and should be administered so as to temper the errors of the humours in disease; and though the work has ceased to have a practical value for physicians, it yet remains of interest to the student of humoral pathology, and of the philosophy of the middle ages.

Students are indebted to the enterprise of Messrs. Macmillan and Bowes for the reprint of this scarce work, which was the first book containing Greek characters printed in England, and we are glad to learn that the same publishers propose shortly to issue the remainder of the series. The book is edited by Dr. J. F. Payne, and is prefaced by a portrait and an admirable life of Linacre.

Rhopalocera Malayana: a Description of the Butterflies of the Malay Peninsula. By W. L. Distant. (London: W. L. Distant, care of West, Newman and Co., 54, Hatton Garden, E.C.)

WE have received the first part of this handsome work, in which it is proposed to describe and figure all the species of butterflies which inhabit the Malay Peninsula and the islands of Penang and Singapore. Forty-four coloured figures of butterflies are given in this part, occupying four plates of large quarto size: and they are most admirably executed in chromo-lithography. Some of the figures, indeed, are hardly to be distinguished from good hand colouring. The descriptions are full and careful, and much judgment is shown in using, as far as possible, old and well-established names, and in rejecting needless sub-divisions of the genera. It is expected that the work will be completed in six or seven parts, forming a handsome quarto volume; and we trust that the author may obtain numerous subscribers in our wealthy colonies of Singapore and Penang, as well as at home, to encourage him to complete the work in the same full and careful manner as he has commenced it.

As most of the butterflies of the larger Malay Islands must be studied in comparison with those of the Malay Peninsula for the purposes of his work, we would suggest to Mr. Distant that he would add greatly to its value to all European collectors if he would give, in a supplementary part, a complete synopsis of the known species of butterflies inhabiting the Indo-Malayan region. Having figured all the continental Malayan species, the descriptions of those of the islands might be, in most cases, by comparative characters, aided occasionally, perhaps, by outline woodcuts. We believe that such an extension of the scope of the work would double its value, and add largely to the list of subscribers; while the increased expenditure would be comparatively unimportant.

A. R. W.

Conic Sections Treated Geometrically. By S. H. Haslam, M.A., and J. Edwards, M.A. (London: Longmans, 1881.)

THIS is a neat little treatise on the conic sections, containing—what appears to be a novelty—a method of *plane projection*, to which the authors give the name of *Focal Projection*. The remarkable feature of the book is, that the authors, who are evidently well up in these curves, should not be acquainted with the writings of the present master of St. John's College, on the same subject. No one who has looked into Dr. Taylor's recent works, could be unacquainted with what he has said upon the contributions of Boscovich and G. Walker, and would hardly use the "generating circle" of a conic in the same fashion as Boscovich does, and write, after the definition, "which we have called the *auxiliary circle of a point*."

Schwatka's Search: Sledging in the Arctic in Quest of the Franklin Records. By W. H. Gilder. Maps and Illustrations. (London: Sampson Low and Co.)

THIS is the complete record of the expedition sent out by private subscription, in 1878, under Lieut. Schwatka, to endeavour to find the records of the Franklin expedition, which were reported to be in possession of the Nechelli Eskimo. With the general results of the expedition, our readers have already been made acquainted. The reported records, as might have been expected, were never found. But in and around the Fish River, and in King William Land and neighbourhood, several relics were obtained, and several graves and cairns found. The expedition, indeed, completed the story of the sad disaster of the *Erebus* and *Terror*. During the search, sledge-journeys of upwards of 3000 miles were made, and thus much welcome additional information was obtained concerning the country between Hudson's Bay and King William Sound. The expedition came a good deal into contact with the Eskimo, concerning whom Mr. Gilder has much to tell us. The narrative is interesting, and is welcome as throwing additional light on an Arctic expedition in which Englishmen have always continued to be interested. There are a number of good illustrations.

Chambers's Etymological Dictionary of the English Language. A new and thoroughly revised edition. Edited by Andrew Findlater, M.A., LL.D. (Edinburgh: W. and R. Chambers, 1882.)

THIS little work, since the publication of the first edition, edited by the late Mr. James Donald, has had deservedly a very extensive circulation. It is just the book to have at one's elbow for constant reference, handy, clearly printed, fairly full, and thoroughly trustworthy. This new edition has evidently been so thoroughly revised by Dr. Findlater, as to be virtually a new work. The selection of words has been made with great discrimination, the definitions are clear and comprehensive, and the etymologies up to the latest results of linguistic research. The dictionary contains a large number of scientific terms, though there are one or two others that we think ought to have found a place. The dictionary is the best of its class; the appendix contains much useful information, including a table of the Metric System.

Tunis; The Land and the People. By the Chevalier de Hesse-Wartegg. (London: Chatto and Windus, 1882.)

HERR VON HESSE-WARTEGG spent some months in Tunis last year, and has made a readable book out of his notes. He has also drawn largely on other sources of information, so that those who know little about a country which has been so much before the public recently, will find some useful information in this volume. The author spent a good deal of time about Tunis and its environs, but seems also to have visited several other places in the Regency, including, apparently, Kairwan. He tells us a good deal about the people and their customs, about the government, the Bishas, antiquities, &c. There are several good illustrations, but no map.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Silurian Fossils in the North-west Highlands

ON my return to-day from a geological tour in the North-west Highlands, I read with much interest the letters of Mr. Hudleston and Prof. Bonney on the above subject. The question as to the geological position of the limestone series in West Ross-shire, correlated by Murchison with the Durness limestone, is one to which I devoted special attention during my late visit to the neighbourhoods of Lochs Carron, Doule, Kishorn, and Maree. The general appearance of the limestone in these areas is sufficiently like that of Durness to lead to the supposition that it is of the same age, but this of course can only be proved by fossil evidence. The conclusion at which I have arrived, however, in regard to the geological position of the limestone, and as to its relation to the so-called Upper Gneiss rocks of the central parts of Ross-shire, is in direct opposition to the views of Murchison, and accords in the main with that of Prof. Nicol. The great triangular patch at the head of Loch Kishorn consists of a series of thick beds of grey limestone, with a few bands of sandstone in an unaltered condition, and is undoubtedly dropped by faults amongst much older strata, as maintained by Prof. Nicol. Between Lochs Carron and Doule the same series is seen to rest unconformably upon much higher beds than those which it is supposed by Murchison and others to underlie at Loch Kishorn. As I purpose shortly to give a full account of these researches, I will not venture now to trespass further on your space.

Earthquakes and Mountain Ranges

IN NATURE of the 27th ult., in a note on a recent meeting of the Seismological Society of Japan, it is mentioned that the observations of Prof. Milne "as far as they have at present gone, show in a remarkable manner how a large mountain range absorbs earthquake energy." It may be worth while to mention, as an exception to this, that the Swiss earthquake at 1 p.m. on July 25, 1855, which apparently had its origin among the mountains on the south side of the Valais, between Visp and S. Nicholas, both of which places were seriously damaged, travelled through the Bernese Oberland, across the great valley of Switzerland, and then through the Jura. I was at the time in a small inn, at a place called Belle Rive in the Munster Thal, on the north side of the Jura. The house was severely shaken, so that some plaster fell from the ceiling. This was about seventy-five miles from the place of origin, and the wave in that interval had passed through two mountain ranges. It is probable that this earthquake was caused by a disturbance of a quite different kind from the volcanic disturbances of Japan, and that may account for a difference in the result.

O. FISHER

Vivisection

THE editor of NATURE has no room for proofs; I must, therefore, confine myself to statements of facts which "A Student of Medicine" can verify by consulting the books I shall name.

Prof. Schiff is the author of several works detailing an enormous number of vivisections. Some six years ago the "Gazetta d'Italia" calculated that, of dogs alone, he had used in his laboratory 14,000—supplied to him gratuitously by the municipality of Florence—besides great numbers of other animals otherwise procured. Afterwards he received only about eight dogs a week from the police, and, in consequence, posted up an advertisement offering a franc for every dog brought to him, and a *bonus* upon ten dogs brought by one person. In the "Physiologie de la Digestion" he says: "I am forced to cut the vocal cords of the greater number of my dogs, lest their nightly howlings should compromise my physiological pursuits."

In Prof. Schiff's "Lezioni di Fisiologia Sperimentale" will be found ample justification of my statements with regard to the character of the vivisections performed by him. I regret much that there is no room to quote examples here. It will be observed by the reader of these "Lessons of experimental physiology," that the nature and duration of the majority of the experiments render the administration of chloroform either impossible, or at the best, utterly inadequate to hinder suffering. The animal is either *distinctly sensible* throughout the experiment, or has been already operated on some days previously, being preserved in a mangled and paralysed condition for further experiment.

As regards the "anæsthesia," I have to-day questioned a medical graduate, who resided seven years in Florence while Prof. Schiff lived there, and was constantly in his laboratory. He says that, although chloroform was commonly administered on tying down the animals (he believes. for the convenience of the operator), no pretence was made of keeping them under the influence of the anæsthetic after the preliminary incision, and that—as in fact is conclusively proved in Prof. Schiff's own works—mutilated animals were reserved from day to day, and from week to week, for further investigation.

If since leaving Florence and publishing his "Lessons" Prof. Schiff has mended his ways, I am sincerely glad to hear it. Should such, indeed, prove to be the case, public opinion at Florence—which ran high against him and his doings—must be credited with some share in the reformation.

In conclusion, let me say in regard to the discourteous charges of "error," "ignorance," and disregard of "facts" so freely brought against me by your correspondent, that if in this case any person is amenable to them, it is certainly not one who, being perfectly acquainted with the works both of Prof. Mantegazza and of Prof. Schiff, bases her estimate of their performances on *their own explicit statements*. ANNA KINGSFORD

11, Chapel Street, Park Lane, W., April 14

[MRS. KINGSFORD's letter was forwarded to our correspondent in Geneva, who sends the following reply:—]

In reply to Mrs. Kingsford's letter, I have the following remarks to offer:—

1. If Mrs. Kingsford is "perfectly acquainted" with the works of Prof. Schiff, she must know that there exists a small book in which he has explained in detail his methods of vivisection, &c. The title is: "Sofra il metodo seguito negli esperimenti sugli animali viventi nel laoratorio di fisiologia di Firenze." It first appeared in 1864; the second enlarged edition bears the date 1874. The book is written in a popular style, so as to render it easy even for the uninitiated to understand what vivisection is, and how it is practised by Prof. Schiff; it should be read by every person desirous of forming an unbiased judgment on the subject.

2. My letter was a reply to the accusation brought against Prof. Schiff of perpetrating "horrible tortures," "atrocities," &c. The *number* of dogs used for experiments (which number is erroneously stated), and the price supposed to have been paid for them are evidently irrelevant to the question. Moreover, you will find stated on p. 53 of the above pamphlet, that Prof. Schiff never accepted a dog unless its owner assured him that he would otherwise kill it himself; and I can corroborate from personal recent experience here in Geneva the further statement in the same passage, that if a person likely to be a kind master offers to take one of his dogs, he is always ready to give it away.

3. I regret to find that Mrs. Kingsford allows herself to misquote. The passage in the "Physiologie de la Digestion" referred to is on p. 291 of vol. i.: "Je suis *obligé* de faire subir la section des *nerfs laryngés à beaucoup* de nos chiens." The section of the vocal cords is a dreadful operation, that of the nerves in question so slight, that if performed on dogs whilst at their meals, they do not leave off eating! To this I can testify. Moreover, you will notice that Schiff says, "Je suis *obligé*," and the fact is he was *forced by the police* in Florence to cut the nerves in question; not indeed on most of his dogs, but on those which were not used for vivisection properly so called, but were kept during long periods for other (and perfectly painless) observations, such as those detailed regarding the very dog mentioned in that lecture (see the 13th lesson, p. 325).

4. People not versed in physiology are not competent to draw conclusions from a work such as the "Lezioni di Fisiologia sperimentale." Mrs. Kingsford herself offers an example of how gross the errors are into which they may fall when she declares that in the majority of experiments the administration of anæsthetics is either "impossible or inadequate." On p. 70 of the pamphlet "Sofra il metodo," &c., Schiff says: "Nello stato attuale delle nostre conoscenza non existo *un solo esperimento* praticato nell' animale viventi, al qualo non si possa, e quindi non si debba, togliere il carattere di crudeltà mediante l'uso degli anestetici;" and lower down: "Da 25 anni non mi sono *neppure una volta* veduto nella necessità di escludere l'uso degli anestetici." On p. 52 he writes: "Brediamo dover aspettare finchè ogni traccia di sensibilità, e l'effetto meccanico delle sensazioni sia scomparso."

5. To the medical graduate's statement and insinuations I oppose Prof. Schiff's affirmation and my own knowledge of his character and scientific habits. It is curious that this gentleman, after having spent seven years in Prof Schiff's laboratory, should be ignorant that *chloroform* is *never* used by him (see p. 49).

6. That many animals which have been operated upon are kept alive for ulterior observations is expressly stated in my first letter, and any person, however ignorant of science, can understand that whole branches of physiology can only be studied under the condition of this being so. They are kept not only as Mrs. Kingsford so pathetically exclaims, "from day to day, and from week to week," but sometimes from year to year." The question at issue is whether they suffer or not, a question easy to decide by their appearance, appetite, and demeanour. And the fact is they *do not suffer*, a statement any one can corroborate who chooses to come and look at the dogs in the School of Medicine here. *Why* they do not suffer is explained in detail in the pamphlet referred to above.

7. Prof. Schiff has *not*, alas, "mended his ways in deference to public opinion;" he tells me that never since the year 1847 has he departed from the methods detailed in the book quoted at the beginning of this letter.

Geneva, April 23 B.SC., STUDENT OF MEDICINE

Red Variable Stars—"Variab. Cygni (Birmingham), 1881," &c.

THE above star, so called by Schmidt in the *Astr. Nach.*, No. 2421, is now a striking object of 8 magnitude. On December 21, last year, it was certainly not over 12, and, probably, it was less. This appeared about its minimum, and its maximum seemed to have been attained on June 6, when it was 8 mag., as at present. On May 22, when I first found it, it was about 9. If it is now at maximum, there must be a striking inequality in its periods of decrease and increase, but perhaps it will go on to a greater magnitude this time than before.

U Cygni (No. 553 in my Red Star Catalogue) seemed last night (April 28) to be smaller than I ever saw it previously, and under 11 mag. Its colour was, however, very marked. The blue star near it (Arg. +47° 3078), which I have long considered to be slightly variable (see Catalogue), seems now at a maximum of 8 magnitude, though contrast with its diminished neighbour, may have some effect on its apparent size.

No. 448, in which I have also detected variability, is now about 8·5, and as deeply coloured as when I first found it in April, 1876. J. BIRMINGHAM

Millbrook, Tuam, April 29

Matter and Magneto-electric Action

THE very interesting lecture by Mr. Spottiswoode on the above subject incidentally throws light upon a phenomenon which probably has puzzled some other of your readers besides myself.

When a somewhat weak current is passing between the knobs of a Becker-Voss electro-induction machine, its passage can be altogether stopped by simply blowing across the path of the current. The handle is turned in vain; and even when the blowing has ceased, a short time is required before the current is able to pursue its old path. When the instrument has been warmed, and the current becomes stronger, the blowing, although now unable to stop the current altogether, drives it into irregularly curved paths, which are determined by the force exerted. I do not remember to have seen the experiment mentioned in any book. It is as curious as it is simple.

We now see why the air requires to be at rest for the weak current to force a passage through it, and to keep that passage open for the succeeding sparks to follow; while the stronger current leaps from point to point, as though in pursuit of the warmed and opened passage which has been driven by the wind out of its former position.

HENRY BEDFORD

All Hallow's College, Dublin, April 15

CYCLONES[1]

SINCE it first became known that a considerable proportion of the storms which visit this part of Europe come from the middle and northern parts of North America, the meteorology of that country has been invested with a peculiar and increasing interest for the inhabitants of Western Europe, and though, according to Hoffmeyer, the chance that a depression in the United States will subsequently cause a storm somewhere in our own islands is only one in four, it is a ratio quite substantial enough to make us regard with attention warnings such as those transmitted to us through the medium of the *New York Herald*.

While America is thus from her enormous size and westerly position enabled to act the part of our weather prophetess, she bids fair in addition to leave us far behind in the more theoretical branches of weather-science, and though to admit this may be somewhat wounding to our national *amour propre*, it is nevertheless an idea which is openly entertained by some of our leading meteorologists. For our comfort it may be reasonably ascribed, in part at least, to our small size and unfavourable geographical position having afforded but little encouragement to really able men to devote their attention to a science whose operations are conducted on a scale compared with which our area of observation is indeed microscopic, so that until within quite recent times the succession of fair and foul weather in these islands was regarded merely as a series of irregular, eccentric, and totally unpredictable changes. The work before us, entitled "Methods and Results," by Prof. William Ferrel, of the American Coast Survey, and prepared for the use of the coast pilot, forms the second part of a series of meteorological researches undertaken by the author, which comprise an elaborate theoretical investigation into the general and local mechanics of the atmosphere. In Part I., which appeared in 1877, the general motions of the atmosphere are more particularly dealt with, and conclusions are arrived at which have appeared in part in the *Mathematical Monthly* for 1860 and the *American Journal* for November, 1874.[2]

In both these publications the author lays great stress upon the important part played by the deflecting force to the right of its path, to which a current of air is subjected by virtue of the earth's rotation *in whatever direction it may be blowing*. This deflecting force is measured by the acceleration $2n \cos \psi$, where n represents the angular velocity of terrestrial rotation, and ψ is the co-latitude (see NATURE, vol. v. p. 384).

With the assistance of this element he theoretically deduces in Part I. the general motions of the atmosphere, which agree with what is known from observation. He also makes considerable use of this same principle, which he was the first to enunciate correctly, when dealing with the theory of cyclones in Part II. As we propose just now to confine our attention to Part II., which treats mainly of cyclones, we shall not refer to Part I. except incidentally. Part II. is sub-divided into three chapters, the first of which deals with the mechanical theory of cyclones, and deductions therefrom. In Chapter II. the results of the theory are compared with those of observation, and Chapter III. treats of tornadoes, hailstorms, and waterspouts. The chief elements considered in the theory of cyclones are (1) the earth's rotation, (2) the gyratory velocity round the low centre, (3) the friction, (4) the inertia, and (5) the temperature and humidity of the air.

These elements are all discussed in turn, and many important conclusions drawn from the resulting equations. Some of these conclusions have already been either directly deduced by the employment of analogous methods, or inductively inferred from an examination of data, by Guldberg and Mohn, Colding, Peslin, Sprung,[1] Clement Ley, Hildebrandsson, Meldrum, Loomis, and Toynbee. Some however are quite new, especially those which are derived from a consideration of the temperature term.

The general theory of the cyclone, according to Ferrel, may be briefly stated thus:—

If from any initial cause interchanging motions are set up between the air in a certain district and another surrounding it, the air in the first district tends to gyrate round its centre by virtue of the deflective force of the earth's rotation, and in the same direction as that of the component of terrestrial rotation, which acts in the plane of its horizon. In the northern hemisphere this would mean gyration contrary to watch-hands, and in the southern hemisphere gyration with watch-hands. In the outer district the gyrations of the air, by the principle of the preservation of areas (or moments), are contrary to those of the interior district. These two systems of contrary gyrations tend to draw the air from the centre of the inner district and the exterior limit of the outer district, and heap it up in the place where the gyratory velocity vanishes and changes sign, thus causing a maximum barometric pressure there, with corresponding minima at the centre and outer limit respectively.

In addition to this, when the gyrations have once commenced they give rise to a centrifugal force which tends to drive the air still more from the centre of the inner district, and so increase the barometric depression there; but which in the outer district, partly owing to its distance from the centre, and partly to the small velocity of the gyrations, has but little effect on the distribution of pressure. The gyrations, especially near the centre and exterior limit, would be very rapid, were it not for the friction between the air and the earth's surface, which retards the motion, but does not entirely prevent it, since, as the author very pointedly remarks, "without some such motion frictional resistance would not be brought into action." So far we have only considered the gyratory component of motion, and as in the imaginary case of no friction, this would be the only kind of motion, the gyrations might then be entirely circular. When, however, as actually happens in the atmosphere, friction acts, a radical component becomes necessary, since the deflecting force is now partly employed in counteracting the frictional resistance to the gyrations, and the magnitude of this radial component (on which depends the inclination of the wind to the isobar), varies *cæteris paribus* directly with the amount of friction.[2] As a result of the two

---

[1] "Methods and Results of Meteorological Researches for the use of the Coast Pilot." Part II.—On Cyclones, Waterspouts, and Tornadoes. By William Ferrel. (Washington, 1880.)

[2] "Relation between the Barometric Gradient and the Velocity of the Wind," by W. Ferrel, Assistant U.S. Coast Survey.

[1] "Die Trägheits-curven auf rotirenden Oberflächen," *Zeitschrift für Meteorologie*, Band xv., January Heft, 1880.

[2] This result is best seen in the following expression for the angle of inclination of the wind to the isobar $\tan i = \dfrac{f}{2\left(n \cos \psi + \dfrac{s \cos i}{r}\right)}$, where f is the coefficient of friction, s the velocity of the wind, and r the dis from the low centre.

tendencies—gyration and inflow, or outflow according as the air is in the interior or exterior part—the air near the surface takes a middle course, and flows spirally around and toward the centre from the zone of maximum pressure on the one side, and on the other in a contrary spiral outwards from the centre to the outer limit of the anticyclone.

It is important to observe that the author explains the accumulation of air with its maximum at the dividing line between the interior and exterior districts (cyclone and anticyclone, as they are termed elsewhere throughout this work) as "due at the start mostly to the gyrations in the *upper* part of the atmosphere," which, being less influenced by friction, are in consequence more circular than those below; the pressure from this accumulation tending to force the air near the earth's surface out from beneath it on the one side toward the centre of the cyclone, and on the other toward the outer limit of the anticyclone.

The difference of pressures or gradient between the regions of high and low pressure in a cyclone, is thus shown to be, not so much the *cause* of the wind, as the mechanical result of the deflecting force of the earth's rotation and the centrifugal force engendered by the gyrations.

It should, however, be borne in mind, that the forces just mentioned, are by no means to be regarded as causing the cyclone in the sense of being *independent* sources of energy. They can only arise in consequence of some initial motion of the air, which must itself be due to a small difference of pressure, and unless such primary disturbing cause be continually maintained by external influences, the entire system of motion will shortly come to rest.

The preceding view of cyclone generation has already made some way since Ferrel first enunciated its leading characteristics in his previous writings. It lies midway between what is sometimes called the in-blowing or ascension-current theory of Reye and Espy, which regards the central depression as the main cause of the wind, and that held by Thom, Meldrum, Willson, and Loomis, according to which the central depression is mainly due to the centrifugal force generated by two pre-existing currents passing one another in opposite directions. A third theory, held by Blanford and Eliot, and evolved chiefly from a study of the cyclones in the Bay of Bengal, makes the condensation of vapour the *primary* cause of disturbance, but allows the greater part of the *subsequent* depression of the barometer to be due to the causes adduced by Ferrel. This latter theory, in fact, only differs from that put forward by the author in the part played by condensation of vapour in giving rise to the initial motion of the air, which Ferrel considers to be considerably less than that exercised by a difference of temperature. Among the conclusions arrived at by the author, and which are generally confirmed by the results of observation, may be noticed the following; but these, it must be remarked, are only strictly true for a regular, symmetrical, and stationary cyclone:—

(*a*) "The wind inclines towards the centre from the direction of the tangent, and the amount of inclination is nearly in proportion to the friction (mainly of the air against the earth's surface)."

(*b*) "The inclination diminishes with the altitude, and therefore at some distance from the earth's surface the gyrations are more circular than near it."

(*c*) "Toward the centre of a cyclone, where the gyratory velocity is greater, the inclination is less, and therefore the path more nearly circular."

(*d*) "The inclination increases with decrease of latitude, attaining its greatest value at the equator, where the air should flow directly towards or from the centre, and there should be no gyrations."

(*e*) "As the motion of the air below in cyclones is *toward* the centre, in the upper regions of the atmosphere it must be nearly circular, but inclined to the tangent a little *from* the centre."[1]

Inertia comes into play where a cyclone is increasing or diminishing in violence, and its effect is to increase the inclination in the former case and diminish it in the latter, but in general the amount is found to be insignificant.

It was stated in the above brief sketch of the theory, that outside the annulus of high pressure surrounding a cyclone the air should move outwards anticyclonically. Ferrel subsequently puts the matter thus: "*Every cyclone is accompanied by a corresponding anticyclone, and the former cannot exist without the latter.*"

The words cyclone and anticyclone are here used quite apart from the question of barometric pressure, and simply mean districts in which the motion of the air is spirally in towards the centre, or out from the centre respectively. Guldberg and Mohn likewise adopt this definition, which is obviously far more scientific than the too common habit of referring to them as regions of low and high pressure.

Mr. Ferrel, however, differs from all previous investigators in thus linking together the cyclone and anticyclone as mutually dependent parts of the same phenomenon. They have hitherto been treated separately, at least in practice, and though the author's conclusion sounds like a simplification, because it makes *one* out of *two*, we scarcely think he has proved the converse to his proposition, viz. that every anticyclone is accompanied by a *corresponding* cyclone, and cannot exist without it.

For example, in the case of such an anticyclone as every winter forms over Central Asia it would be difficult to point out exactly its corresponding cyclone or cyclones, though it is possible, as the author says, that it may be partly due to the overlapping of the anticyclones, which should surround the permanent North Atlantic and Pacific cyclones at this season.

The relation between the barometric gradient and the velocity of the wind in a symmetrical cyclone is given by the following equation:—

$$G = \frac{1076{\cdot}4(2n\cos\psi + \nu)s}{\cos i(1 + {\cdot}004\,t)}\,\frac{P}{P'},$$

where $\nu = \frac{s\cos i}{r}$, and G is the gradient in millimetres per sixty geographical miles, s the velocity of the wind in metres per second, n the earth's angular velocity of rotation per second, ψ the co-latitude, i the inclination of the path of the wind to the isobar, $P\,P^1$ the barometric pressure at the given elevation and at the earth's surface respectively, t the temperature in degrees Centigrade, and r the distance from the low centre in kilometres. Where the gradient is given, the velocity of the wind can be conveniently found from the equation

$$S = -\tfrac{1}{2}a \pm \sqrt{\tfrac{1}{4}a^2 + bG},$$

where, if the ordinary English units of space and time are used, viz. a mile and an hour, and the gradient is expressed in inches per sixty geographical miles, we have—

$$\begin{cases} a = \dfrac{0{\cdot}52505\,r\cos\psi}{\cos i} \\ b = \dfrac{r(1 + {\cdot}004\,t)}{{\cdot}005262}\,\dfrac{P}{P'} \end{cases}$$

The equation for the gradient in terms of the wind's velocity is substantially the same as that already given by the author in *Silliman's Journal* for 1874, with the exception of the temperature correction, which was there simply referred to in the text.

As the whole question of the author's formula for the gradient has been thoroughly ventilated in his previous

---

[1] This conclusion only applies to districts within a moderate distance from the centre. At great distances from the centre the radial component predominates, and the air flows nearly directly towards the centre below, and from it above.

works and in the *Zeitschrift für Meteorologie* (Band x.), we need not notice it here except to point out that, assuming the correctness of the formula, the gradient, *cæteris paribus*, should vary (1) directly with the latitude, (2) inversely with the distance from the centre, (3) inversely as the temperature, (4) directly with the amount of inclination.

The foregoing results have all been obtained without considering the term depending on temperature and humidity, and which expresses the effect of the disturbing force necessary to start and maintain the interchanging motions between the interior and exterior portions of the air over a given area. That such a disturbing function is necessary, is evident both from preliminary considerations, and also from the form of the general equations of motion, since they would otherwise be satisfied by the conditions for a state of *rest*. The author enunciates this principle in Part I. Chap. III. where he says: "*There can be no winds then without a disturbance of the static equilibrium by means of a difference of temperature or of aqueous vapour in different parts of the atmosphere.*" And it is important to bear it in mind, if only because we are too often apt to overlook it in the multitude of secondary causes brought to light by a study of atmospheric mechanics. A consideration of this term, in which temperature and humidity are treated jointly, and the former is *assumed* to vary with the distance from the centre, leads to the remarkable conclusion that there are two species of cyclones, one with relatively *warm* centres, the more common case, and the other with relatively *cold* ones.

These cyclones differ specifically from each other chiefly in the way in which the pressure is distributed and the gyrations directed at different altitudes.

In a cyclone with a relatively warm centre the air at the earth's surface moves in a cyclonic spiral round and towards the centre, but as we ascend the gyratory velocity diminishes with the altitude, and the annulus of high pressure approaches the centre, until at a very high elevation the highest pressure of that stratum might even be at the centre, and the air gyrate anticyclonically from it over the whole area at that level. In brief, the cyclonic area becomes smaller, and the anticyclonic larger, as we ascend.

In a cyclone with a cold centre the reverse occurs. At the surface of the earth the initial tendency of the air is to move outwards, and this may be so strong near the surface that there may be only anticyclonic gyrations at this level, with the maximum pressure of the *lowest* stratum at the centre. As we ascend, however, the gyrations round the centre become more and more cyclonic, while the annulus of maximum pressure gradually retreats further and further from it.

There is, besides, according to the theory, an *ascending* motion of the air in the interior part of a warm-centred cyclone, and a descending motion in the exterior part, both generally *small* in comparison with the horizontal motions toward and from the centre. In the case of a cold-centred cyclone these motions are reversed.

Now as a barometer at the earth's surface records simply the integrated effect of what happens in all the strata up to the top of the atmosphere, this might obviously vary in the *same* way for both kinds of cyclones, and so tell us absolutely nothing of such remarkably diverse conditions prevailing at higher altitudes. The behaviour of the air in the warm centred cyclone is what we are accustomed to observe in the case of *most* cyclones, and as they are as often found with relatively *cold* centres as with *warm* ones, the former occurring more frequently in *summer* and the latter in *winter*, it is difficult to understand why the characteristics of the cold-centred cyclone have never yet been found to prevail, at least in moving cyclones. The author indeed offers an explanation of this circumstance, and endeavours also to account for the absence of stationary cold-centred cyclones in regions like Central and Eastern Asia and North America in winter, where the temperature gradient would be remarkably favourable to their production. The fact, however, that in the centres of these regions at this season there is not only no cyclonic tendency of the winds or depression of the barometer, but, on the contrary, a pressure greatly above the normal, seems strangely at variance with what we should expect according to the theory of the cold-centred cyclone, and is hardly satisfactorily explained away as the result of the irregularity and size of the area, combined with the excessive *cold*, which latter is supposed to increase the density and pressure more than the cyclonic tendency diminishes them. The only two cases of cyclones with cold centres which the author seems able to find are the two general wind systems of the northern and southern hemispheres respectively, which "are simply two great cyclonic systems with a cold centre, having the cold poles of the earth for their centres. The motion of the air eastward around and toward the poles in the middle latitudes, giving rise in those latitudes to the normal south-west winds in the northern, and north-west winds in the southern hemisphere, form the cyclones, and the trade-wind region the corresponding anticyclones, with the equatorial calm-belt for the common limit of the two systems. The tropical calm belt and corresponding maxima of barometric pressure near the parallels of 30°, correspond to the similar calm and dividing line between the cyclone and anticyclone in the ordinary and smaller cyclonic systems."

The primary cause of cyclones, according to Ferrel, is a *horizontal temperature gradient*, so that if a portion of the atmosphere is heated or cooled more than the surrounding parts, and the isotherms are approximately circular, we have the initial conditions for a cyclone; but after the disturbances due to such primary causes have set in, secondary causes depending on loss of heat by expansion in ascent, and gain of heat by compression in descent, as well as retardation of cooling where aqueous vapour is being condensed, come into play, which *on the whole* tend to counteract the initial motions.

The condition of the atmosphere *vertically* with respect to temperature and humidity, is thus of great importance in regard to the duration of a cyclone when it has once started.

The author investigates this point at some length, and works out the conditions for cyclone generation in quite a novel manner, from a consideration of both vertical and horizontal temperature gradients. Generally speaking, the condition most favourable to the maintenance of an ordinary cyclone is that the vertical temperature decrement in the interior should be less than in the surrounding regions. This condition is found to be more easily sustained where the air is charged with aqueous vapour, since under these circumstances it cools less rapidly in ascending than when dry. He further points out that where the decrement of temperature in the interior is less than outside, especially when this condition occurs throughout the entire atmosphere, a cyclone may arise without any horizontal temperature gradient (provided only a small instantaneous impulse be given), and that such a state of *unstable equilibrium* more readily occurs when the air is warm and saturated with vapour. While, however, he thus admits the important *rôle* played by vapour in maintaining cyclonic action when once started, he distinctly denies its claim to be considered "*either a primary or principal cause of cyclones.*"

As these islands in all probability seldom, if ever, form the birthplace of a cyclone, but we are rather accustomed to experience them either fully developed or else in the condition of being "filled up," the circumstances which attend their generation do not practically very much concern us. Still it must not be overlooked that conditions which would tend to create and maintain a cyclone in our midst, must of necessity tend to augment the violence of a storm arriving on our coasts, so that if meteorology, or that branch of it termed weather forecasting, is ever to become an exact science, we must endeavour to find out, by captive balloons or otherwise, what can never be determined by registration at the earth's surface alone, viz. the condition of the atmosphere *vertically* as regards temperature and humidity.

The author concludes his theoretical investigation into the mechanics of cyclones by a discussion of the causes of their motion over the earth's surface. He first of all shows that every cyclone possesses an inherent force tending to urge it towards the pole of the hemisphere in which it has been formed. This follows immediately from the fact that the deflecting force due to the earth's rotation varies with the cosine of the colatitude, and is therefore greater on the polar than on the equatorial side of a cyclone, a residual poleward component of force being thus brought to bear upon every portion of the cyclone. In addition to this, a cyclone, as soon as it is generated, must partake of the general motions of the atmosphere, which the author more especially deals with in his "Meteorological Researches," Part I., to which we have already made allusion; and since the general motions of the atmosphere are there considered to form two great cyclonic systems round the poles, all ordinary cyclones are simply cyclones within a cyclone, so that their general motion of translation is partly the result of the actual motion of the air in these large and perpetual, though perpetually changing, cyclones, and partly that of their inherent tendency to *press polewards*.

For example, as the author says, "in the trade-wind latitudes the wind at the earth's surface is westward . . . and hence the cyclones in these latitudes are carried westward, . . . and having a tendency towards the Pole, the resultant of the two is a westward motion, inclined a little towards the poles, or in the northern hemisphere a motion about west-north-west. After having arrived at the parallel of 30° or 35° in the tropical calm-belt, where there is no westward motion, the progressive motion is a Polar one mostly, but after progressing still nearer the Pole, into the middle and higher latitudes, the general eastward motion of the atmosphere here, which is great in the upper regions, carries now the cyclone toward the east, and the direction of the progressive motion, which is usually about east-north-east, is the resultant of this eastward motion and the motion round the Pole. All well-developed cyclones, therefore, having their origin near the equator, have mostly a progressive motion represented by a curve somewhat in the form of a parabola, having its vertex in the tropical calm belt at the parallel of 30° or 35°."

It is moreover shown that the general motions of the atmosphere must not only cause the cyclone to travel more or less with them, but also affect the inclination of the wind to the isobars, decreasing it in the front, and increasing it in the rear part.

With regard to further modifying causes, the author favours the views of Clement Ley regarding the effect of the distribution of aqueous vapour in determining the direction in which a cyclone propagates itself.

He does not indeed attempt to explain how they sometimes wander off on an entirely unlooked-for course, or else remain stationary for some considerable period; otherwise he might claim to have at least attempted a solution of the entire problem on which weather science depends. Clement Ley himself, in his admirable little work,[1] recently published by authority of the Meteorological Council, tells us that the reason why the course of a cyclone cannot be exactly foretold is because "in the first place the causes which determine the course of depressions are not fully known; in the second, place so far as they are known, it is certain that the course of depressions is generally related *to the distribution of pressure over a very large area*." In fine before we know how the *small* cyclones are going to behave, we must in every case know the *form* of the larger cyclones round whose centres they travel.

THE GIZZARD-CONTENTS OF SOME OCEANIC BIRDS

THE following results of the examination of the gizzards of twenty sea-birds, which were caught by the officers of this ship in the South Atlantic and Southern Indian Oceans during the last quarter of 1881, may be of interest to some of the readers of NATURE.

With one exception all the birds belonged to the Petrel family—the Procellaridæ—and fifteen of them were of the well-known species -the Cape-pigeon or Cape-petrel (*Daption capensis*). The most frequent of the gizzard-contents of these twenty birds were the mandibles of a cephalopod, which were found in eighteen instances; the otoliths of some small osseous fishes occurred in five instances; and some curious stony masses, varying in weight from half a grain to five grains, were obtained also in five instances. The other substances, which were observed less frequently, were the vertebræ of a fish, feathers, Velellæ, the horny rings probably of some crustacean, and a small hard seed.

With reference to the seed just mentioned, I should observe that it was taken from the gizzard of a Cape-pigeon, about 550 miles to the east of Tristan d'Acunha, in the South Atlantic. The wide range of this species of petrel is well known; we ourselves first observed this bird rather to the southward of the island of Trinidad, which lies about 600 miles off the coast of Brazil; and thence we traced it as far as the island of Amsterdam, in the southern portion of the Indian Ocean. From our own observation, therefore, it is quite possible that a seed might be transported from Trinidad to Amsterdam, notwithstanding that these islands are from five to six thousand miles apart; and Mr. Mosely's surmise (*vide* a footnote in Mr. Wallace's "Island Life," p. 250) that various species of Procellaria and Puffinus may have played a great part in the distribution of plants, and may to some degree explain the similarity in the mountain floras of widely distant islands, would appear to receive some support from the single instance of this seed. With regard to the kind of plants to which the seed belongs, Mr. Moore, director of the Botanic Gardens, Sydney, kindly informed me that it possessed no character sufficiently distinctive to enable him to decide as to its probable source.

The stony masses found in the gizzards of five of the birds, all of which were caught in the South Atlantic, were of two kinds: one of the masses was of a dark colour and homogeneous texture, and rather porous; when heated it gave off black fumes with a smell of burnt organic matter, and was fusible with soda into a black glass; the other masses had the appearance of greasy quartz, scratching glass with ease; but when heated in a closed tube they blackened and evolved black fumes with a powerful odour of burnt animal matter; after the incineration they became white, and with the blowpipe were fused into a white glass after the addition of soda; no effervescence was exhibited on the application of an acid. The behaviour of these masses under heat is very similar to that described by Mr. Darwin in his "Geological Observations," in the case of a stony incrustation on St. Paul's Rocks, deposited, as he considered, from water draining through birds' dung.

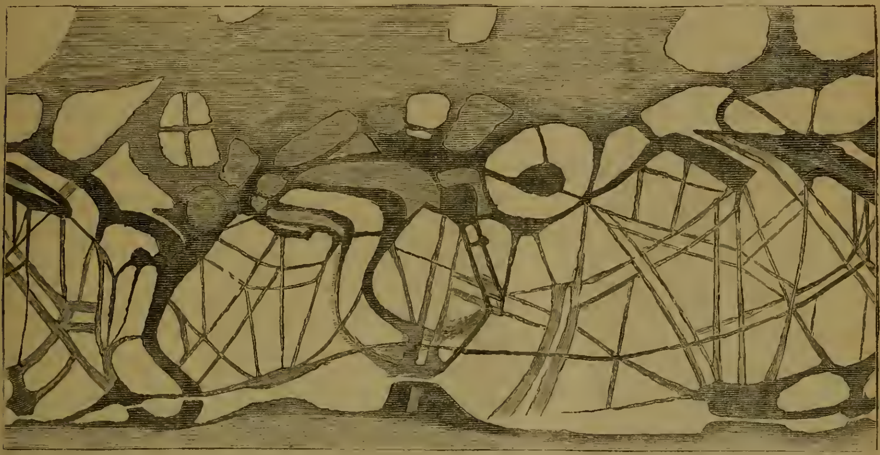
RECENT DISCOVERIES IN THE PLANET MARS

AN intended article, of which an announcement appeared in NATURE a few weeks back, on the topography of Mars as delineated for the second time by Prof. Schiaparelli at Milan during the opposition of 1879-80, has been anticipated and in part superseded by information which has been received relative to the more recent discoveries made by him in the beginning of the present year. Pending the preparation of a fuller and more detailed memoir, he has published a preliminary notice, read before the Academia dei Lincei on March 5, and accompanied by a photographed drawing of the planet's surface. The results are of a very remarkable and unexpected character; and as through the courtesy of this distinguished observer, the notice and photograph have been placed in my hands, I am induced to reproduce the latter, which, though not pretending to minute accuracy (the original, in fact, is only a provisional sketch), will give a sufficient idea of the marvellous duplication of the so-called "canals," which, between January 19 and February 24, in about twenty instances, unfolded itself progressively under the observer's eye. The discussion which took place at the late meeting of the Astronomical Society, so far as my information extends, substantiated strongly by independent evidence the existence of these long, narrow streaks, some of them even in positions where they have not been delineated by Schiaparelli; but their duplication by similar and parallel lines does not seem to have been elsewhere noticed. Some difference of opinion may possibly be expected concerning these strange appearances; and the consequent enfeebling (to say the least of it) of the long-admitted terrestrial analogy may be, to some minds, unacceptable; but the established reputation of the observer demands at any rate a respectful attention to his statements. It may be preferable to suspend a more detailed account till we receive a full elucidation of the subject in the memoir, of which we possess only a preliminary notice; for the present it may suffice to mention that he found the atmosphere of Mars apparently clearer than in 1877, and was thus enabled to recover the markings then detected more satisfactorily even than in 1879-80, and to confirm the general accuracy of his two earlier charts; while the concise, but very clear intimations that he has given, as to the variable brightness of some great regions, the progressive enlargement on one side since 1879 of the "Kaiser Sea" (his Syrtis Magna), the brightening of certain supposed continents or islands towards the limbs, the confirmed existence of oblique white streaks, the unfolding of minute labyrinthine detail, and the continuous development already mentioned, day after day, of the collateral lines which double the so-called "canals," and extend with them ordinarily along great circles of the sphere—all these and similar announcements make us anxiously desire a more extended and detailed communication. For some of these most remarkable appearances parallels may be to a certain extent produced from the results of earlier observers; but, so far as at present appears, the duplication stands alone. The discoverer is disposed to infer a connection between these progressive developments and the seasons of the planet, and on that account hopes that, owing to the position of the axis at the ensuing opposition at the opening of 1884, notwithstanding the diminished diameter (only 12″·9), confirmation of his announcements may be obtained from other observers. We sincerely trust that a report which has reached us may be verified as to the erection of a much larger telescope in the Royal Observatory at Milan, and that the extraordinary talent and diligence of the director may be richly rewarded, not only by the confirmation but the extension of results which must so materially influence our conclusions as to the physical condition of this peculiarly interesting planet.



T. W. WEBB

THE CAUSE OF TUBERCULOSIS

THE first step in the rational treatment of every malady is obviously the recognition of its cause, and it is this recognition which enables medical men to do battle against disease. It is a truism to say that as regards infectious maladies the knowledge of their cause is an essential step in preventing their spread and arresting their ravages. The malady known as tuberculosis, and generally characterised by constitutional disturbance associated with the production of minute nodular new-growths in the various organs, especially the lungs, spleen, lymphatic glands, serous membranes, the membranes of the brain, liver, &c.—[at first greyish and transparent, but afterwards becoming opac and degenerating into a yellowish-looking *débris*, and hereby implicating and destroying the organs in which they are located]—has been shown to be an infectious malady communicable from one human being to another, from man to animal, and from animal to animal.

The successful experiments of inoculating with, feeding on, and causing to inhale human tubercular matter, carried out on the lower animals, such as guinea-pigs, rabbits, dogs, pigs, &c., by Villemin, Dr. Wilson Fox, Mr. John Simon, and Dr. Burdon Sanderson, but especially by Cohnheim and Salomonsen, Tappeiner, and Baumgarten are conclusive in these respects. Similarly it has been shown that the tuberculosis of cattle or Perlsucht is communicable not only within the species but also to other animals. Whether Perlsucht is also communicable to man, especially through meat and milk, as is maintained by some observers (Semmer, Baumgarten, and others), is as yet an open question, and, as must be obvious to every one, one to which fearful importance is attached, considering how great the distribution of this disease is in the bovine species. What the cause of the malady is, has until now been undetermined, although it has been at various times surmised that, like other infectious diseases, it is of a parasitic origin. Thus Schüller, and especially Klebs, have tried to prove that owing to the presence of micrococci in the tubercular deposits, these micrococci were the materies morbi. And indeed Klebs maintains to have succeeded in cultivating outside the body of an animal, *i.e.* artificially the "monas tuberculosum," as he calls the said micrococcus, and to have again produced the tubercular disease by inoculating animals with this purified micrococcus. Klebs' observations and conclusions have not been accepted as reliable, and it has been reserved for Dr. Koch to discover the real cause of the disease, in identifying it with a specific bacillus. In a weighty paper, "The Etiology of Tuberculosis," published in the Berlin *Klin. Wochenschr*, 1882, No. 15, Dr. Koch sets forth the whole course of his investigation, the methods and experiments, all his observations and definite conclusions on this question, and anyone who peruses carefully this paper will come to the conclusion that Koch's results are to be accepted with unconditional faith, and I have no manner of doubt will be considered by all pathologists as of the very highest importance. To those who are familiar with Dr. Koch's previous work, especially that on the etiology of splenic fever or Anthrax, and his observations on pathogenic Bacteria, this last work of his, on the Etiology of Tuberculosis, will be an additional and brilliant testimony to his ingenious and successful method of research.

The first step in the inquiry was to ascertain whether any definite form of microphyte is constantly present in the tubercular deposits. This question could not be solved by the ordinary methods of research, but with new methods; it was decided in the affirmative. For the demonstration of the presence of the specific bacillus—which Koch calls the tubercle-bacillus—the following method proved successful: Tubercular deposit fresh, or after hardening with reagents, is stained for twenty to twenty-four hours—at a temperature of 40 Centigrades, only half to one hour is required—with a half per cent. solution of methylene blue, to which a small quantity of a 10 per cent. solution of caustic potash is added. After this, the tubercular material is stained for a minute or two in a concentrated watery solution of vesuvin. and then washed in distilled water. When examined under the microscope, all elements of the tubercular deposit, such as cells, nuclei, fibres, and granules, appear of a brownish colour, while the tubercle-bacilli alone stand out very conspicuously in a beautiful blue tint.

By this method Koch ascertained the constant presence of the specific bacillus in the tubercular eruption in man and animals, including the Perlsucht of cattle, both in spontaneous tuberculosis, as well as artificially produced, *i.e.* by inoculation. These bacilli differ from all other micro-organisms by characteristic properties.

The next step in the inquiry was one of essential importance in determining the nature of the bacillus as the materies morbi, viz. to isolate by successive cultivations outside the animal body, the tubercle-bacilli, and having thus completely freed them of all parts of tissue of the tubercular deposit to introduce them into the system of suitable animals. If these animals became afflicted with typical tuberculosis, and if at the same time similar animals kept under precisely the same conditions, but not infected with the bacilli, remained perfectly normal, it will be admitted that the exact proof has been given that the bacilli constitute the cause of the tubercular malady.

All these conditions have been fulfilled by Dr. Koch in an eminent degree.

The tubercle-bacilli were successfully cultivated outside the body of an animal. Pure serum of blood of sheep or cattle is sterilised by keeping it exposed in test-tubes plugged with cotton wool, for six days daily for one hour, to a temperature of 58 centigrades. After this the serum is heated for several hours up to a temperature of 65 centigrades; by this it is transformed into a solid perfectly transparent mass, well adapted for the cultivation of the tubercle-bacilli. Such serum inoculated on its surface under special precautions with tubercular matter of any source—tuberculosis of man or animal, spontaneous or artificially produced, and kept at a temperature of 37 or 38 centigrades (*i.e.* about blood-heat) for over a week, becomes gradually covered with peculiar dry scaly masses; these masses are the colonies of the specific tubercle-bacillus.

A minute particle of this crop is used for establishing a second similar cultivation, this again for a third, and so on. Tubercle-bacilli obtained in this manner, after several successive generations, prove as effective in inoculating animals with typical tuberculosis as fresh tubercular matter.

All animals susceptible to the malady that Koch inoculated with these artificially cultivated bacilli, became invariably affected with the disease; not one escaped; while other similar animals kept under precisely the same conditions, except that they did not receive any tubercle-bacilli, remained perfectly healthy.

It is important to notice that the tubercle-bacilli require for their growth and multiplication a temperature of at least 30 centigrades, and, consequently, they are limited to the animal body, unlike the bacillus that produces splenic fever or anthrax, which is capable of multiplication at ordinary temperatures, as low as 20 centigrades, and even less.

The expectorated matter of tubercular patients is generally charged with tubercle-bacilli, and these often contain spores. And it is probably through the presence of such spores that that matter retains for a long time its infective properties. Koch made experiments on guinea-pigs with such sputa after having been kept dry for fourteen days, for four weeks, and for eight weeks, and he found that in all instances the sputa had retained their full virulence. It is therefore just to assume that such sputa, even when dried on linen, clothes, or even distributed with the dust of the room, may be a source of infection.

The practical importance of the discoveries of Koch must be patent to everybody. In the recognition of the tubercle-bacilli as the *fons et origo* of this terrible pest of the human race—according to statistics quoted by Koch one-seventh of all deaths being caused by tuberculosis—in the recognition of the presence of these bacilli in the sputa of tubercular patients, and in the tubercular deposits of cattle afflicted with Perlsucht, we have at once become supplied with the knowledge of the most common manner of how tuberculosis may and probably is spread, as well as with the weapon of combating the most fertile sources of infection. In preventing the distribution—either by proper disinfection, or by destruction—of the expectorations of tubercular persons, and further, in superintending and restricting the use of tubercular animals of the bovine species, we possess the means of preventing the spread of this deadly and terrible plague, and hereby saving a vast amount of human life. These discoveries of Dr. Koch were made entirely through experiments on living animals. E. KLEIN

DEEP-SEA EXPLORATION

IN NATURE, vol. xviii. p. 348, we described Negretti and Zambra's Patent Deep-Sea Standard Thermometer. Some uncertainty as to the accuracy of its indications in deep sea service led to a re-arrangement of the instrument, which now greatly increases its reliability. The improvement is chiefly due to suggestions furnished by Commander Magraghi (see NATURE, vol. xxiv. p. 505) (of the Royal Italian Navy) to Negretti and Zambra. Several of these improved thermometers may now be fastened on one line, and serial temperatures at any required depth obtained with certainty.

FIG. 1.

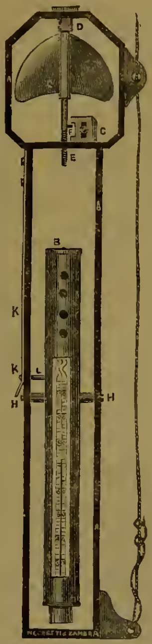


FIG. 2.

FIG. 3.

The woodcuts exhibit the apparatus, Fig. 1, as prepared for lowering down into the Sea, and Fig. 2 after the hauling up has commenced—the thermometer having reversed and registered the temperature at the moment of turning over. Fig. 3 shows the peculiar construction of Negretti and Zambra's inverted thermometer used in their improved deep-sea apparatus. The apparatus will be understood by reference to figures (Nos. 1 and 2). A is a metal frame, in which B, the thermometer, is pivoted upon an axis, H, but not balanced upon it. C is a screw-fan attached to a spindle, one end of which works in a socket, D, and at the other end is a screw, E, about half an inch long, and just above it is a small pin, F. On the spindle G, is a sliding stop-piece, against which the pin, F, impinges when the thermometer is adjusted for use. The screw, E, works into the end of the case, B, the length of play to which it is adjusted. The number of turns of the screw entering the case is regulated by means of the pin, F, and stop-piece, G. The thermometer and its case is held in position by the screw, E, and descends into the sea in this position—as Fig. 1; the fan, C, not acting during the descent, because it is checked by the stop, F. When the ascent commences, the fan revolves, raises the screw, E, and releases the thermometer, which then turns over and registers the temperature at that spot. When the hauling-up has caused the thermometer to turn over, a spring at K forces the pin, L, into a slot in the case B, and clamps it (as seen in Fig. 2) until it is received on board, so that no change of position can occur during the ascent from any cause. The case, B, is cut open to expose the scale of the thermometer, and also perforated to allow free passage of the water.

SOME PRIMITIVE IDEAS ON METEOROLOGY

IN an article published in NATURE (vol. xxv. p. 82) on the opinions of the Chinese Emperor Khang-hi on certain natural phenomena, it will be remembered that the *yang* and *yin*, or the male and female principles of Chinese philosophy, played a conspicuous part. Japan, it is well known, adopted at a very early period in its history the law, polity, science, philosophy, and writing of the Chinese, and with them the *yang* and *yin*; and it may not be uninteresting to our readers to see how the doctrine of these dual forces, mutually repellent as well as attractive, has been employed to explain the facts of meteorology. A recent issue of the *Japan Gazette* newspaper of Yokohama contains the translation of a work written in 1821 by a certain Arai Yoshinari, called the "*Ten-chi-jii*; or, Ideas about Heaven and Earth." The heavens, the writer says, are very high, the earth is very thick; we cannot ascend to the one or go down into the other; consequently man was unable for many generations to comprehend the phenomena of either; but now the opinions of all philosophers on this subject are based on the action and reaction of the male and female, the active and passive principles of nature upon each other. The rain is a changed form of the male, and the vapour under the earth of the female principle. When the male principle sinks into the earth it pursues the female. The earth is the mother of all things and the heaven is the air or wind where the sun, the moon, and the stars hang shining. There are two kinds of air—the heaven-air and the earth-air. The motion of the heavens is contrary to that of running water. The heavens move from east to west, while water runs from west to east. In some districts, indeed, water in the earth runs towards the north, but meets the earth-air which obstructs its flow, causes much agitation, and finally its complete evaporation from the surface of the earth. The vapour thus formed ascends and becomes clouds, which are again turned into rain by the action of the wind. The water has periods of increase and decrease according to the male and female seasons; thus in summer, which is the male season, water increases, while in winter, or the female season, it diminishes. Again, the earth-air is changed into rain when it moves from east to west; and therefore, previous to rain, we see a white vapour in the morning ascending in the east. "This is a clear proof of the earth's growing hot." For the same reason mountains become somewhat darker just before rain.

Thunder is produced by the mingling of the male and female principles. Sounds are often heard in the earth in the neighbourhood of volcanoes. This is due to the irritation of the earth-air, which sometimes sends out flames. It is said that a kind of beast accompanies the thunder, and it moves about in the air. This is nothing strange, because at a certain island called Ampon, which is about 3900 *ri* (1 *ri* = 2½ miles) from Japan, there is a bird called the *Kasubara*, which is covered with fur instead of feathers, and which eats fire. Other birds live on wind. As this world is unlimitedly great and extensive there may have lived strange beasts and birds, like the thunder beast which the Japanese talk about. The volume of sound given out by thunder depends on the number of water-clouds in the air. When the latter is small, the sound of the thunder is not loud and appears far off. On the other hand when the clouds are piled up in the heavens, the sound is loud and is simultaneous with the lightning. The sound is caused by the passage of fire through the water. The ancients regarded thunder as the report of the battle between fire and water—the male and female elements. If this were the case there is no reason for the interval between the flash and the sound. Earthquakes are subterranean thunder; the noise is caused by the rush of water which has long been kept confined by the earth-air. Snow is the vapour which rises from the earth; when it ascends high enough it becomes frozen and falls as snow. Fog is also this vapour. Haze is the vapour mixed with smoke from some volcano. The writer concludes by expressing his intention of making the actions of nature, such as rain, wind, &c.—difficult as they are to explain—quite clear on a future occasion.

These ideas may be taken as representing those of most educated Japanese of half a century ago, with the exception perhaps of a few who had been taught by the Dutch. What the Japanese peasant thought, and still thinks of thunder, earthquakes, storms, and other striking natural phenomena will be found in a deeply interesting chapter of Mr. Griffis's "Mikado's Empire." One of the principal Japanese artists, Hokusai, some of whose works have recently been given to the English public, did not think it beneath his genius to endeavour to picture the extraordinary creatures that form the zoological mythology of Japan. There the astonished student of Japanese pictorial art can behold Futen, the wind demon, Raiden, the creator of thunder, the fish whose movements cause earthquakes, the *kappa*, or demon of the deep, and dragons of sufficient variety of form to satisfy the weirdest imagination.

NOTES

RARELY has so distinguished and representative an assembly been seen in Westminster Abbey as that which met to pay the last honours to Mr. Darwin, on Wednesday last week. The Abbey indeed was crowded. The character of the long line of distinguished men who followed the honoured remains to the grave, may be seen from the list of pall-bearers:—The Duke of Devonshire, the Duke of Argyll, the Earl of Derby, Mr. J. Russell Lowell, the American Minister, Dr. W. Spottiswoode, P.R.S., Sir Joseph Hooker, Mr. A. R. Wallace, Prof. Huxley, Sir John Lubbock, and the Rev. Canon Farrar. Mr. Darwin has been buried close beside the grave of Sir John Herschel, and within two paces of that of Sir Isaac Newton. At the Royal Academy dinner on Saturday, Mr. Spottiswoode, in replying for science, could not but refer to the loss "of our greatest philosopher and noblest spirit." "I know not," he said, "whether, in the presence of statesmen and leaders of thought, of commanders both by sea and land, of artists, of preachers, of poets and men of letters of every kind, it is fitting that I should speak of greatness; but if patience and perseverance in good work, if a firm determination to turn neither to the right hand nor to the left, either for glory or for gain, if a continual overcoming of evil with good in any way constitute elements of greatness, then the man of whom I speak—Charles Darwin—was truly great. He lived, indeed, to a good age; he lived to complete the great work of his life; he lived to witness a revolution in public opinion on matters with which he was concerned such as few had seen before—a revolution from opposition to concurrence, a revolution from antipathy to sympathy, or whatever else may better express a complete change of front. And so having at the beginning been somewhat rudely pushed aside as an intruder and disturber of accepted opinions, he was in the end not only borne on the shoulders of his comrades to his last resting-place, but was welcomed at the threshold by the custodians of an ancient fabric and of an ancient faith as a fitting companion of Newton and of Herschel, and of the other great men who from time to time have been gathered there."

M. JAMIN, president of the Academy of Sciences, having summoned M. Quatrefages to deliver an *éloge* on the late Mr. Charles Darwin on Monday last, the eminent zoologist read a long and eloquent oration, which was received with unanimous plaudits, and will be printed in the next *Comptes Rendus*.

WE take the following from the *Times*:—The Council of the Royal Society have selected the following fifteen from the fifty-two candidates for the Fellowship who have presented themselves during the present session. The election, which rests with the Fellows of the Society, will take place on Thursday, June 8, at 4 p.m. The names are—Prof. V. Ball, Dr. G. S. Brady, Dr. G. Buchanan, C. Baron Clarke, Francis Darwin, Prof. W. Dittmar, Dr. W. H. Gaskell, Mr. R. T. Glazebrook, Mr. F. Ducane Godman, Mr. J. Hutchinson, Prof. A. Liversidge, Prof. I. Malet, Mr. W. D. Niven, Mr. R. H. Inglis Palgrave, and Mr. W. Weldon.

THE fifty-second Annual Meeting of the British Association for the Advancement of Science will commence in Southampton on Wednesday, Aug. 23. The President-Elect is C. W. Siemens, D.C.L., F.R.S. Vice-Presidents-Elect: The Right Hon. the Lord Mount-Temple, Capt. Sir F. J. Evans, K.C.B., F.R.S., Hydrographer to the Admiralty, F. A. Abel, C.B., F.R.S., Prof. de Chaumont, M.D., F.R S., Col. A. C. Cooke, R.E., C.B., Director-General of the Ordnance Survey, Wyndham S. Portal, Prof. Prestwich, M.A., F.R.S., Philip Lutley Sclater, F.R.S. General Treasurer: Prof. A. W. Williamson, F.R.S., University College, London, W.C. General Secretaries: Capt. Douglas Galton, C.B., D.C.L., F.R.S., Francis Maitland Balfour, F.R.S. Secretary, Prof. T. G. Bonney, F.R.S. Local Secretaries: C. W. A. Jellicoe, John E. Le Feuvre, Morris Miles. Local Treasurer, J. Blount Thomas. The Sections are the following: A—Mathematical and Physical Science—President, Right Hon. Prof. Lord Rayleigh, F.R.S. Vice-Presidents: G. H. Darwin, F.R.S., Prof. G. C. Foster, F.R.S. Secretaries: W. M. Hicks, M.A., Prof. O. J. Lodge, D.Sc., D. McAlister, M.A., B.Sc. (Recorder), Rev. G. Richardson. B—Chemical Science—President, Prof. G. D. Liveing, F.R.S. Vice-Presidents: A. G. Vernon Harcourt, F.R.S., Prof. H. E. Roscoe, F.R.S. Secretaries: P. Phillips Bedson, D.Sc. (Recorder) H. B. Dixon, F.C.S., J. L. Notter. C—Geology—President, R. Etheridge, F.R.S. Vice-Presidents: Prof. T. Rupert Jones, F.R.S., Prof. J. Prestwich, F.R.S. Secretaries: T. W. Shore, F.G.S., W. Topley, F.G.S. (Recorder), E. Westlake, F.G.S., W. Whitaker, F.G.S. D—Biology—President, Prof. A. Gamgee, M.D., F.R.S. Vice-Presidents: Prof. W. Boyd Dawkins, F.R.S., G. E. Dobson, F.L.S., Prof. M. A. Lawson, F.L.S., Prof. J. D. Macdonald, F.R.S. Department of Anatomy and Physiology:—Prof. A. Gamgee, M.D., F.R.S. (President), will preside. Secretaries: W. Heape, A. Sedgwick, B.A. (Recorder). Department of Zoology and Botany:—Prof. M. A. Lawson, F.L.S. (Vice-President), will preside. Secretaries: W. A. Forbes, F.Z.S. (Recorder), J. B. Nias. Department of Anthropology :—Prof. W. Boyd Dawkins, M.A., F.R.S., F.S.A., F.G.S. (Vice-President), will preside. Secretaries: G. W. Bloxam, M.A., F.L.S.) (Recorder), T. W. Shore, jun., B.Sc. E—Geography :—President: Sir R. Temple, Bart, G.C.S.I. Vice-Presidents: H. W. Bates, F.R.S., Lieut.-Col. H. H. Godwin-Austen, F.R.S. Secretaries: E. G. Ravenstein, F.R.G.S., E. C. Rye, F.Z.S. (Recorder). B—Economic Science and Statistics :—President: Right Hon. G. Sclater-Booth, M.P., F.R.S. Vice-Presidents: W. E. Darwin, F.G.S., R. H. Inglis Palgrave, F.S.S. Secretaries: G. S. Baden-Powell, F.S.S., Prof. H. S. Foxwell, F.S.S., A. Milnes, M.A., F.S.S., Constantine Molloy (Recorder). G—Mechanical Science :—President: John Fowler, C.E., F.G.S. Vice-Presidents: A. Giles, C.E., W. H. Preece, C.E., F.R.S. Secretaries: A. T. Atchison, M.A., F. Churton, H. T. Wood, B.A. (Recorder). The First General Meeting will be held on Wednesday, August 23, at 8 p.m. precisely, when Sir John Lubbock, Bart., M.P., F.R.S., will resign the Chair, and C. W. Siemens, D.C.L., F.R.S., President elect, will assume the Presidency, and deliver an address. On Thursday evening, August 24, at 8 p.m., a *soirée;* on Friday evening, August 25, at 8.30 p.m., a Discourse on Pelagic Life, by Prof. H. N. Moseley, F.R.S.; on Tuesday evening, August 29, at 8 p.m., a *soirée;* on Wednesday, August 30, the concluding General Meeting will be held at 2.30 p.m.

It may be useful for some of our readers to be informed that the following arrangements have been made by the American Association for the Advancement of Science for reduced fares from Europe to Montreal, for those attending the meeting on August 23 next :—The Allan Line will grant ten tickets at $100 each from Liverpool to Quebec and return; the Dominion Line will grant twenty-five tickets at $80 each from Liverpool to Quebec and return; the Beaver Line will grant tickets from Liverpool to Quebec and return at $80 each.

THE eleventh meeting of the French Association for the Advancement of Science will take place at Rochelle, commencing August 24. The General Secretary is Prof. Gariel, 4, rue Antoine Dubois, Paris.

THE honorary degree of LL.D. has been conferred on Mr. J. R. Hind, F.R.S., by the University of Glasgow.

THE death is announced, at the age of forty-eight, of the well-known physicist Prof. Zöllner, of Leipsic.

LADY THOMSON, widow of Sir Wyville Thomson, is to receive a grant of 400*l.* from the Royal Bounty Fund.

THE French Eclipse Expedition has arrived at Alexandria.

ON April 27 the French Academy received M. Pasteur, who has been nominated to fill the chair vacated by the recent death of M. Littré. The ceremony attracted an immense concourse of people, including the *élite* among French *savans* and politicians. M. Pasteur delivered an eloquent address against the opinions of his predecessor, who was partly defended by M. Renan. The two speeches are among the most interesting and elaborate that have been delivered under such circumstances.

WE have received, as specimens of the seismological literature of Japan, reprints of certain translations which have appeared in the *Japan Gazette* newspaper. The first is the narrative of an earthquake shock at Osaka, accompanied by a high wave, in 1707; the second, a similar narrative of a great earthquake in the province of Echigo in 1829; and the third an earthquake chronology. The editor, Prof. Milne, speaks of the first as little more than a series of anecdotes of various events which took place at the time of the disaster; and although the seismologist may not be able to glean many facts of value, the paper will at least give him a specimen of the kind of literature through which he will have to wade in searching for facts of scientific importance. He adds that he is acquainted with sixty-five Japanese works on the subject, and that in Japan there is a literature on earthquakes comparable with that of any other country, and although much of it may be of interest only to the general reader, much of it has a value scientifically. The second monograph is interesting, on account of the many references it contains to popular beliefs respecting the connection between earthquakes and other natural phenomena. Thus, an unusual warmness in the weather, a change in the colour of the moon, mirage, falling stars, &c., are all referred to as being connected with the approach of an earthquake. The third paper is a translation of an earthquake Calendar, commencing at 295 B.C. and ending with the widespread and destructive earthquakes of 1854. This work shows that, notwithstanding the frequency of these phenomena in Japan, the native chroniclers have always carefully recorded them. Probably nowhere else in the literature of the world can we find so long and complete a record of the recurrence of various natural phenomena—for eclipses, great waves, volcanic eruptions, &c., are also noted—than in this work.

A SERIES of three excursions has been arranged by the Geologists' Association, to afford members an opportunity of becoming acquainted with the physiography and geological character of the Weald. The first excursion, on May 6, will be to Redhill and Crawley; the second, May 30, to Tilgate Forest, Cuckfield, and Hayward's Heath; and the third, May 29 and 30, to the Isle of Purbeck.

THE annual general meeting of the Iron and Steel Institute will take place on May 10, 11, and 12. The papers to be read are :—On certain physical properties of iron and steel, by Mr. Edward Richards, Hematite Steel Works, Barrow-in-Furness; On the use of brown coal in the blast furnace, by Prof. Ritter Peter von Tunner, Leoben, Austria; On the Bilbao iron ore district, by Mr. William Gill, M.I.C.E., Luchana, Bilbao, Spain; On a new method of getting coal, by Mr. Paget Mosley, London; On the compression of fluid steel, by Mr. William Annable, Govan, Glasgow; On the chemical composition and testing of steel rails, by Mr. G. J. Snelus, F.C.S., A.R.S.M., Workington; On the consumption and economy of fuel in iron and steel manufacture, by Mr. J. S. Jeans, London; On the tin plate manufacture, by Mr. Ernest Trubshaw and Mr. E. S. Morris; On the relations of carbon and iron, by Mr. Geo. E. Woodcock, Atlas Works, Sheffield; On a new centre crane for Bessemer plant, by Mr. Thomas Wrightson, M.I.C.E., Stockton-on-Tees.

ON April 30 M. Carlier, one of the most active members of the Académie d'Aérostation Météorologique, made an ascent at the La Villette gasworks, Paris, in order to try if it is possible to steer a balloon by using in the car a large oar composed of a plane fixed perpendicularly to a solid handle worked with two hands. The dimensions of the plane are one metre by two, and the handle is about three metres long. The weight of the sails is counterpoised when worked, and the weight of the whole system is about 10 kilograms. It is the second time that M. Carleer has ascended with this apparatus. Although the air was in a state of great agitation the motions of the balloon were easily seen from the ground. M. Carlier intends to make a series of ascents in order to learn how to make the best of this system, which is to be used only for partial direction, as in the case of Thames barges, which, although they must follow the run of the tides, can be directed to some extent by means of the oars.

THE May number of the *Proceedings* of the Royal Geographical Society contains a paper of much interest by Mr. L. K. Rankin, B.A., on "The Elephant Experiment in Africa." Mr. Rankin accompanied Capt. Carter on his journey with the three Indian elephants in 1879, meant for the use of one of the Belgian expeditions. In his paper Mr. Rankin gives full details of the conduct of the elephants up to Mpwapwa, where their troubles began. Although they were severely attacked by the Tsetse, no permanent evil effect seems to have followed. At Mpwapwa, indeed, a report was sent to the King of the Belgians, in which it was stated that the elephant experiment was a complete success, on account of their immunity against Tsetse, their ability to live on the uncultivated food of the country, and to march over all kinds of ground. A few days after the report, however, the largest elephant suddenly died. Mr. Rankin attributed its death to insufficient food and over-work. In India it had been stall-fed ; in Africa it never seems to have had enough to eat—the back-bones of all these stood six or seven inches from their flanks at Mpwapu. It is clear also that their loads were far beyond what they had been accustomed to. As is known, the other elephants subsequently died. This experiment cannot be considered a fair one, though the lessons it taught will be of service in any future attempt to utilise the animal as a beast of burden in Africa.

A HYDROMOTOR recently invented by Herr Fleischer of Kiel, for propulsion and steering of vessels, acts (we learn from Wiedemann's *Beiblätter*, 3) by pressure of steam on water, in a cylinder, forcing out the water as a jet below. A float on the water in the cylinder works, in a simple way, the opening and closure of the valves for admission and escape of the steam, and the vacuum produced by condensation of steam in a condenser opens valves for readmission of water. The hot water layer, which forms on the liquid surface, and the wooden lining of the cylinder, reduce the condensation during expulsion of the water to a minimum. A comparison of the working of the author's vessel with that of the *Water-witch* and *Rival* (also propelled by hydraulic reaction) showed that while the kinetic energy of the expelled water was in the *Water-witch* 31·5 per cent. of the indicated quantity of steam, and in the *Rival* 26·3 per cent. in the (so-called) "hydromotor" it was 89 per cent. Herr Flischer, in a recent *brochure*, investigates the physics of his motor.

IF those members of the Quekett Microscopical Club who intend to be present on the occasion of the opening of Epping Forest by Her Majesty on Saturday next, the 6th inst., will communicate with the Hon. Sec. of the Quekett Microscopical Club, 7, The Hill, Putney, S.W., he will do his best to find places for their accommodation.

WITH reference to our notice of "Through Siberia" (vol. xxv. p. 582), the Rev. H. Lansdell writes that in the List of Illustrations at the commencement of vol. i. he acknowledges the sources whence they are taken ; and with reference to the photograph of a "Buriat girl" he states that he bought the photograph, in the Buriat country, of the man who took it, that the girl was known even by name to his local friends, and that he has every reason to believe she was a pure Buriat and not a metis.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus erythræus* ♂) from India, presented by Mrs. Lamprey ; a Chinese Tiger (*Felis tigris* ♂) from China, presented by Mr. G. Brown ; two Bauer's Parrakeets (*Platycercus zonarius*) from Australia, presented respectively by Mr. J. Charlton Parr, F.Z.S., and Miss Eva Maitland ; a Mississippi Alligator (*Alligator mississippiensis*) from Florida, U.S.A., presented by Master Bennett ; a Slow-worm (*Anguis fragilis*), British, presented by Mr. Poyer Poyer ; two Axolotls (*Siredon mexicanus*) from Mexico, three European Pond Tortoises (*Emys europæa*), five Carpathian Scorpions (*Scorpio carpathicus*) from Italy, presented by Mr. T. D. G. Carmichael ; a Black-backed Piping Crow (*Gymnorhina tibicen*) from Australia, deposited ; two Common Squirrels (*Sciurus vulgaris*), British, two Green-horned Parrakeets (*Nymphicus uvæensis*) from the Island of Uvea, Loyalty group, purchased ; a Black-backed Kaleege (*Euplocamus melanotis*) from Sikkim, received in exchange ; a Hybrid Paradoxure (between *Paradoxurus larvatus* and *Paradoxurus leucomystax*), two Variegated Sheldrakes (*Tadorna variegata*), bred in the Gardens. The following insects have been exhibited in the Insect House during the past month :—Butterflies : *Papilio podalirius*, *Anthocharis cardamines*, *Araschnia levana*, *Thais polyxena*. Moths : *Deilephila euphorbiæ*, *Chærocampa elpenor*, *Sphinx pinastri*, *Saturnia pyri*, *S. carpini*. Silk Moths : *Attacus roylei*, *Actias selene*, *A. luna*, *Telea polyphemus*. The insects have, with few exceptions, been very good specimens.

OUR ASTRONOMICAL COLUMN

THE PRESENT COMET.—The following orbit of the comet discovered by Mr. Wells on March 17 has been calculated by Mr. Hind from the Harvard College and Albany observations on March 17, and observations by Prof. Tacchini at the Collegio Romano in Rome on April 6 and 21 ; the small corrections were taken into account :—

Perihelion passage, June 10·69852 M.T. at Greenwich.

	°	′	″	
Longitude of perihelion	53	47	46·3	From mean equinox 1882·0.
,, ascending node ...	205	8	2·6	
Inclination	73	57	47·2	
Logarithm of perihelion distance	8·796420			

Motion—direct.

Hence the positions for Greenwich midnight will be—

	R.A.			Decl.		Log. distance from	
	h.	m.	s.	°	′	Earth.	Sun.
May 4	21	19	11	+71	31·3	9·9870	0·0670
5	21	36	12	72	19·0		
6	21	54	57	73	1·5	9·9793	0·0502
7	22	15	27	73	37·7		
8	22	37	35	74	6·4	9·9724	0·0324
9	23	1	9	74	26·4		
10	23	25	49	74	36·9	9·9664	0·0134
11	23	51	6	74	37·1		
12	0	16	22	+74	26·4	9·9612	9·9932

If the intensity of light on March 19 be taken as unity, the intensity on May 12 is 15·6.

The perihelion distance is given by different computers as follows :—

Kreutz—observations to April		7	0·06343
Lamp	,,	,, 9	0·06123
Oppenheim	,,	,, 11	0·06459
Hind	,,	,, 21	0·06258

From the above elements it will be found that at the ascending node the comet makes a close approach to the earth's orbit, the distance being only 0·0048, or, assuming 8″·848 for the solar parallax, 443,500 miles, roughly twice the distance of the moon. The ascending node is passed on July 11, but the earth will be far from that point of her orbit.

THE SO-CALLED *Nova* of 1848.—There does not appear to be any recent notice of the magnitude of this object, though the last published observations by Dr. Julius Schmidt in 1868 showed that it had not sensibly changed for some years. It was slightly over 13m. Its position for 1880·0 is in R.A. 16h. 52m. 46·5s., N.P.D. 102° 42′ 26″. Webb in the last edition of his "Celestial Objects for Common Telescopes," p. 356, says : "colour very fine, 1875," but this note must surely refer to some other object, the *Nova Ophiuchi* of 1848, having been too faint for years past to show striking colour. Perhaps some reader of NATURE may be able to state what is its present degree of brightness. There are two stars having the following positions with reference to *Nova* which may assist its identification.

11m.	Angle	249°·4	Distance	7′ 55″
10·11m.	,,	144°·5	,,	8′ 51″

It follows a 9m. Lalande-star 14·7s., and is 18′ 22″ north of it. In 1874 it was below the twelfth magnitude.

GEOGRAPHICAL NOTES

LIEUT. DANENHAUER and two of the crew of the ill-fated *Jeannette* have arrived at St. Petersburg, where they were met with a hearty reception. Lieut. Danenhauer has little hope that Capt. De Long and those with him can have survived, though Engineer Melville is searching for them. He speaks of the unsatisfactory nature of the charts of the Lena mouths and that part of the Siberian coast, and states that Baron Nordenskjöld has added little to our knowledge in this respect. But the Baron did not profess to do so, and indeed could not, seeing that his aim was to get over the ground as quickly as possible. The Lieutenant also is not sanguine as to the possibility of opening up trade by the mouth of the Siberian rivers, forgetting apparently that the time of his arrival at the Lena mouth was past the time most favourable for navigation, and the conditions of his arrival were certainly unfortunate.

WRITING on Chinese maps, the *North China Herald* says that the present dynasty has made greater efforts at map-making than any former one, and appears to have been the first to introduce into them lines of latitude and longitude. The old maps of China are very vague and inaccurate, and are not ancient in any sense. Ssu-ma-Chien when compiling his history did not judge it needful to illustrate it with maps, but his commentators have supplied this deficiency, and recent editions of his work contain maps poorly done of China at successive periods. The geographical works of the Han dynasty do not contain maps. The first maps that have been retained in modern editions of ancient books are those of the Sung dynasty, and they seem to be connected with the invention of printing, which dates from A.D. 932. It was the influence of foreign countries that caused the Chinese to enter rigorously into the work of map-making at this period. The Buddhists began to compile works with maps of India and the countries through which lay the routes to India. One of their larger works at this time contains a map of China, of Persia and Rome, according to the geography of the Han dynasty, and a map of India as known to the Buddhists. The Mahommedans followed the latter in teaching their notions of map-making to the Chinese. But all through the Sung dynasty till the 13th century, when the Mongols established their Empire, Chinese scholars possessed but imperfect views of geography, and failed to obtain clear ideas either of foreign countries or of their own in regard to topography. During the Mongol domination many Europeans visited China and brought with them a certain portion of geographical knowledge. No steps, however, were taken by the Government to improve maps and common geographical books, which remained as bad as before. The Chinese had junks in the Indian Ocean from the 5th century, yet in the 16th century we find in maps of that time that Cambodia and Siam are islands; that Java lies west of Siam, that the Greek empire (Fulin), Arabia, and Medina are three small islands a little to the west of Java, and that an immense southern continent fringes the map from a little south of Ceylon to a point not far south of Java, and again farther east. Good maps have only existed since the Jesuit missionaries came to China, and they belong only to the present dynasty. The Emperors Khang-hi and Kien-lung encouraged the survey of their dominions and the construction of good maps. Danville's *Atlas Chinois* is the result in French of the surveys made under Khang-hi by Gerbillon and his companions. All European maps of China rest mainly on those surveys. Among the atlases of the empire, that made by a former governor of Honan province deserves special praise. It is on a large scale. Each square of 200 *li* represents a square degree. Two inches and a half represent 200 *li*. This affords ample space for names, which are freely inserted on the most frequented roads. As a specimen of engraving it is rough, and of course being on wood and done by provincial workmen it cannot equal the copperplate maps which were issued last century from the Government workshops in Peking. But it is in comparison with past times a great advantage to the people to have a map on a large scale for four or five dollars, on which both degrees and miles are marked by a system of chess-board squares with quite sufficient accuracy for ordinary use. For this they are indebted to Khang-hi and the Jesuits.

MR. C. R. MARKHAM has presented to the Geographical Society a long and careful report on the instruction at present supplied to this country in practical astronomy, navigation, route-surveying, and mapping. Although much improvement has taken place since nautical astronomy was placed in the South Kensington programme, still Mr. Markham shows that much remains to be done ere practical instruction in these important subjects is on the footing on which it ought to be in a country whose interests are so dependent on good seamanship. The Council, on the basis of Mr. Markham's report, have made a series of recommendations to the Board of Trade and the Lord-President of the Council; the former are recommended to raise their standard, and the latter to place navigation and nautical astronomy among the science subjects in the New Code. The report and the recommendations deserve serious consideration.

THE last two parts of the *Deutsche geographische Blatter* contains detailed accounts, by the Brothers Krause, of their researches in the Chukchi Peninsula, accompanied by maps and illustrations; this forms a valuable addition to the information obtained by the *Vega* Expedition. Nos. 2 and 3 of the *Mittheilungen* of the Vienna Geographical Society contains a paper by Herr Ferd. Blumentrit, on the Ancestor-Worship and Religious beliefs of the Malays of the Philippine Islands.

M. MASCART is delivering daily lectures to the naval officers who are to leave on June 1, on the Antarctic Expedition now fitting out at the expense of the French Government. These lectures are delivered at the Parc St. Maur, where instruments have been established. The lecture will be published by Gauthier Villars, after having been revised.

IN the April number of *Petermann's Mittheilungen* M. Ernest Marno gives an interesting account of the barriers of the Bahr-el-Gazal, and their removal from April to June, 1881. Dr. Fera Loïol of Prag contributes a long paper of great interest, with numerous illustrations, on the formation of terraces in the Alpine valleys. Dr. Oscar Drude writes on the botanical exploration of North Africa from Morocco to Barca.

"A VISIT to Madeira in the Winter 1880 81" is the title of two lectures by Dr. Denis Embleton, of Newcastle-on-Tyne, published by Messrs. Churchill. Dr. Embleton, besides giving his own experience, has brought together much information on the islands in all their aspects.

THE Dutch Polar Expedition, which participates in the great International undertaking, will start for Port Dickson on July 1 next. Half the cost is borne by the Dutch Government, the other half having been raised by public subscription. The expedition will return in 1884 if all is well. At the same time the annual Dutch Polar Expedition to the Novaya Zemlya region—the fifth—will start early in May from Amsterdam, commanded by Lieut. Hoffmann. They hope to return in October.

SOME OF THE DANGEROUS PROPERTIES OF DUSTS[1]

THE lecturer pointed out that the dangerous properties of dust with which he proposed to deal were altogether distinct from the subtle, invidious dangers of microscopic dust-motes which pervade the air—dangers the existence and nature of which had been fully revealed by the classical researches of Pasteur, Tyndall, &c.

Compared to those, the dangers which he would discuss were as palpable as are the comparatively gross dust-particles which give rise to them, and yet, although their existence and, to a great extent at any rate, their causes have been known and demonstrated for many years, those who are most directly interested in them and should be most keenly alive to them appear either to have ignored their serious import or to have undervalued the teachings of practical experience and scientific research regarding their causes and effects.

Seven years ago Mr. Abel, in a lecture on Accidental Explosions, delivered at the Royal Institution, directed attention to the fact that solid combustible and especially inflammable substances, if sufficiently light and finely divided to allow of their remaining for a time thickly suspended in air, may on application of sufficient flame to them while so suspended, produce explosive effects; behaving, in fact, similarly to mixtures of inflammable gases or vapours with air, with this difference, that the mobility of the molecules of these insures the ready production of complete mixtures of them with the air, so that combustion, when once established, proceeds almost instantaneously throughout such mixtures, whereas, in the case of a mixture of solid dust particles and air, the rapidity with which combustion spreads

---

[1] Abstract of Lecture at the Royal Institution, April 28, 1882, by Prof F. A. Abel, C.B., F R.S.

through it depends upon the state of division of the solid, and the abundance of its distribution through the air. Under the most favourable circumstances, the rapid combustion or explosion of such a mixture is of a comparatively moderate kind, as it has to spread from one isolated particle to another. With highly inflammable solids, the rapidity of combustion under such conditions is greatest, because, as each particle burns it also evolves inflammable vapour, and is enveloped in flame which produces corresponding effects upon the immediately adjacent particles. In order to ensure rapid and complete transmission of flame through a mixture of inflammable dust and air, it is essential that the former should be present in great abundance, for the foregoing reasons, and that it should therefore be considerably in excess over the supply of oxygen in the air. The facility with which, under these conditions, flame may be transmitted by a dust-and-air-mixture, with a rapidity calculated to produce more or less violently destructive effects, according to the scale upon which the combustion occurs and the degree of confinement of the burning mixture, has been abundantly demonstrated by accidents, many of them very disastrous, which have occurred in works where large quantities of inflammable dust are unavoidably produced. Thus, in the grinding of sulphur, the inflammation of dust of that substance, consequent upon the over-heating of a shaft-bearing, has produced an explosion sufficiently violent to destroy the chambers within which the operation was conducted. In cotton mills, the accidental ignition of finely divided cotton fibre floating in the air has led to the very rapid spread of conflagrations throughout extensive buildings. Even in a factory where the spent madder, or guaracine, is ground, whereby a much less inflammable dust than that of cotton is produced, an important explosion occurred a few years ago. But the most numerous and extensive calamities of this kind have taken place, and are still of frequent occurrence, in flour and rice mills. Many such explosions, or very rapidly spreading conflagrations, occurring in different parts of the continent and here, prior to 1872, appeared enveloped in mystery, until their probable cause was indicated by an Austrian observer, and soon afterwards made clear by Dr. Watson Smith, and especially by the careful inquiry which Messrs. Rankin and Macadam instituted into the very serious and fatal explosion which occurred at the Tradeston Flour Mills, in Glasgow, in 1872. The origin of this explosion was conclusively traced to the striking of fire by a pair of millstones, through a stoppage in the feed of grain, the results being the ignition of the mixture of flour-dust and air by which the mills, inclosed in a chamber, were surrounded, and the rapid spread of flame to the mixture of dust and air which filled the conduits leading to the exhaust box, which communicated with the several other mills and with the stive-room. In this way flame was so quickly transmitted through and to various channels and confined spaces in different parts of the building as to produce violently explosive effects almost simultaneously in different parts of the buildings. Messrs. Rankin and Macadam ascertained that accidents of this nature had increased in frequency since exhaust arrangements (for collection of the fine flour) had been adopted in the more extensive mills. The precautionary measures suggested by them were, the adoption of efficient precautions for preventing the stoppage of the feed to the millstones, the exclusion of naked flames from the vicinity of these and the dust passages, and the construction of the exhaust boxes and stive-rooms as lightly as possible, and their location outside the main buildings.

The liability to the development of fire or of heat sufficient to char or inflame portions of flour by the stoppage of the feed of grain, appears from all accounts to be extremely difficult to guard against, and to have been the cause of many serious calamities even since the Tradeston explosion, examples of which are the great explosion of six mills at Minnesota in 1878, when eighteen lives were lost and much property was destroyed; and the fatel and destructive explosion of a flour mill at Macclesfield in September last, which has been made the subject of a Report to the Home Office by Mr. Richards, of the Board of Trade. It appears to be the opinion of experienced men in the trade that, although special attention to the feed arrangements may reduce the number of explosions, this cause of accident is almost impossible to guard against; while on the other hand, many fires or explosions, ascribed to it, have been due to the employment of naked lights in mills near localities where the air is laden with flour-dust. Considering that flour- and rice-mill-owners have to bear the the burden of very heavy rates of insurance, it is to their interest, independently of their responsibilities as the guardians of the lives of their workmen, to adopt most stringent regulations and efficient precautionary measures for abolishing this source of danger, and to devote their energies to the application of improved arrangements for reducing the quantity of dust which passes away from the millstones and from other parts of a flour mill.

The important part played by coal-dust, which exists in greater or less abundance in coal-mines, in aggravating and extending the injurious effects of fire damp explosions, was originally pointed out early in 1845 by Faraday and Lyell, when they reported to the Home Secretary the results of their inquiry into an explosion which occurred at Haswell Collieries in September, 1844. That Report, which was published in the *Philosophical Magazine* for January, 1845, dealt exhaustively with the cause of the explosion, and the means by which a recurrence of such a calamity might be guarded against, and the latter subject was again discussed by Faraday in a lecture delivered at the Royal Institution in February, 1845, and in a letter published directly afterwards in the *Philosophical Magazine*. It is pointed out in Faraday and Lyell's Report, that in considering the extent of the fire from the moment of the explosion, fire-damp must not be supposed to be the only fuel, for that the coal-dust swept up by the rush of wind and flame from the floor, roof, and walls of the working would instantly take fire, and, in support of this statement, they refer to considerable deposits of dust in a partially coked condition which they found adhering to the faces of pillars, props, and walls where the explosion had occurred and the fire had extended. An examination of these deposits showed that the coal was deprived more or less completely of its bituminous constituents, and they concluded from this that the exposure of the dust to the flame of the exploding gas-mixture gave rise to the generation of much coal-gas from it, the carbon, or coke, remaining unburnt only for want of air.

Ten years after the publication of Faraday and Lyell's Report, M. de Souich, an eminent French mining engineer, published, as original, some very similar observations made by him on examining the effects of a coal-mine explosion at Firminy; he noticed, moreover, that men near the pit's mouth had received burns, while others who were in the workings near the seat of the explosion, but out of the main air current, escaped unhurt, and he ascribed this to the action of coal-dust in carrying flame along the principal air-way. Later on, De Souich extended his inquiries into the part played by coal-dust in explosions, and the subject was afterwards pursued from time to time in France by Verpilleux and other authorities in mining engineering, and especially by M. Vital in 1875, when an explosion occurred at Campagnac, the destructive effects of which appeared to him in a great measure ascribable to coal-dust. Vital made experiments upon a very small scale for the purpose of ascertaining whether flame, such as that projected into the air of a mine by the firing of a charge of powder, in a very strong blast-hole, was increased in size by the presence of suspended coal-dust; and soon afterwards Mr. W. Galloway commenced a series of experiments of a similar nature, but upon a larger scale, which he has continued from time to time up to the present date; while Messrs. Marreco and Morison, in connection with the North of England Institute of Mining Engineers, and a committee of the Chesterfield and Derby Institute of Engineers, have also contributed valuable experimental data bearing upon the influence exerted by coal-dust, not merely in increasing the magnitude of explosions resulting from the ignition of mixtures of fire damp and air, but also in propagating or even actually developing explosions, when only small quantities of fire-damp are present in the air of a mine, or where fire-damp is believed to be entirely absent. The conclusion to which Mr. Galloway was led by his earlier experiments was to the effect that coal-dust, when thickly suspended in air, had not the power to originate an explosion, or to carry on to any distance the flame from a blown-out shot, but that the presence in the air of such small quantities of fire-damp (2 per cent. and under) as an experienced miner would fail to detect by means of his Davy lamp, with which the gas is generally searched for, would impart to a mixture of coal-dust and air the property of burning and carrying flame. But he held the view at the same time, that a fire-damp explosion in one part of a mine might be propagated to some extent by coal-dust raised by the effects of the explosion in parts of the mine where no fire-damp existed. Marreco, on the other hand, considered that the results of certain experiments made in the entire absence of coal-dust, by firing shots in air travelling at some considerable velocity, and containing coal-dust thickly suspended in it, warranted the conclusion that coal-dust also might, under certain conditions, originate an explosion as well as carry it on to some considerable extent. The results obtained by the corresponding experiments of the Chesterfield Committee appear to support this view, and Mr. Galloway has also, by his later experimental results, been led to the same conclusion, and considers that the results of his examination into the effects produced by some of the most serious of recent coal-mine explosions (at Penygraig, Risca, and Seaham) demonstrate that those explosions were chiefly, if not entirely attributable to coal-dust.

Notwithstanding the considerable light that was thrown on this subject so far back as 1845 by Faraday and Lyell, and the accumulation of experimental and other observations relating to the action and effect of coal-dust in colliery explosions, these have not until quite recently received the attention which they merit at the hands of mine owners, and many of those in authority connected with coal-mines. Evidence collected by the Royal Commission on Accidents in Mines, from mine inspectors and leading mining engineers (and published with the preliminary Report of the Commission), show the preponderance of opinion to be against the view that explosions could originate, or be to any great extent propagated, by coal-dust, in the absence of fire-damp, though the belief is entertained by many that the coal-dust may be credited with an extension or aggravation of explosions caused by fire-damp. On the other hand, there is a great tendency exhibited always to ascribe explosions which do not admit of satisfactory explanation, by an accidental failure of ventilation or other evident causes, to a sudden disengagement, or outburst, of fire-damp, such as is of no uncommon occurrence in fiery mines, and is sometimes very serious in its magnitude and duration. That such outbursts, following upon falls of roof and the firing of blast holes, have been the cause of many disastrous explosions, there can be no doubt, but, in some instances, the conclusion that an explosion had been due to this cause, is based upon assumptions and upon very doubtful evidence. Under any circumstances, it is extremely difficult to realise how sufficient gas to produce an explosive atmosphere, can be conveyed, even by the most powerful currents, from the seat of such a sudden outburst to far distant portions of the mine, to which the burning effects of an explosion have been found to extend, within the period believed to have elapsed between the first outburst of gas and the ignition of an explosive atmosphere formed in its vicinity. On the other hand, the evidence of severe burning, after an explosion, such as could not be produced by the rapid explosion of a gas-mixture alone, and the deposition of partially burned coal-dust in distinct parts of a mine, distant from each other and from the point to which the origin of the explosion has been traced, seem to leave no doubt that coal-dust has played an important part in many of the explosions which have of late been subjected to rigorous investigation.

The strong impression entertained by many, during the inquiry into the great explosion at Seaham Collieries, in September, 1880, that coal-dust might have had much to do with the accident, and that the explosion was possibly even entirely due to the ignition of coal-dust by a blown-out shot, in the absence of any fire-damp, led to Mr. Abel's being requested by the Home Secretary to make experiments with samples of dust collected in the mine, and to an extension of these experiments to dust collected from collieries in different parts of the kingdom where explosions had occurred.

The results of experiments conducted with great care and on an extensive scale at a colliery in Lancashire, where a constant supply of fire-damp was brought to the pit's mouth from a so-called blower, confirmed the fact demonstrated by M. Vital and Mr. Galloway, that the propagation of fire by coal-dust, when thickly suspended in air, is established or greatly promoted by the existence, in the air, of a proportion of fire-damp, which may be so small as to escape detection by the means ordinarily employed (such for example as exists in the return-air of a well ventilated mine).

It was also established that a mixture of fire-damp and air approaching in proportion those required to be explosive, would be ignited by a flame if only a small proportion of dust were floating in it. Further, it was demonstrated that, although those dusts which were richest in inflammable matter, and most finely divided, were the most prone to inflame and to carry on flame, in the presence of small quantities of fire-damp, some dusts which contain coal only in comparatively small proportions were as sensitive as others much richer in inflammable matter, and that even certain perfectly non-combustible dusts possessed the property of establishing the ignition of air- and gas-mixtures which, in the absence of dust, were not ignited by a naked flame. This action of non-combustible dusts appeared to be due to physical peculiarities of the finely-divided matter, and to be perhaps analogous to the contact-action well known to be possessed by platinum and some other bodies, whereby these bring about the rapid oxidation of gases which, in their absence, may exist intact in admixture with oxygen or air.

Many experiments were tried with sensitive coal-dust from Seaham and other collieries, for the purpose of ascertaining whether results could be obtained supporting the view that coal-dust, in the complete absence of fire-damp, is susceptible of originating explosions and of carrying them on indefinitely, as suggested by some observers, but, although decided evidence was obtained that coal-dust, when thickly suspended in air, will be inflamed in the immediate vicinity of a large body of flame projected into it, and will sometimes carry on the flame to some small extent, no experimental results furnished by these experiments warranted the conclusion that a coal-mine explosion could be *originated* and carried on to any considerable distance in the *complete absence* of fire-damp. Some experiments made in a large military gallery at Chatham showed that the flame of a blown-out shot of 1½ lb. or 2 lb. of powder might extend to a maximum distance of 20 feet, while in a very narrow gallery, similar to a drift-way in a mine, the flame from corresponding charges extended to a maximum distance of 35 feet. These distances are considerably inferior to those which flame from blown-out shots has been known to extend, with destructive results, in coal-mines, and there appears no doubt that, in the latter cases, of which the lecturer gave examples, the flame was enlarged and prolonged by the dust raised by the concussion of the explosion. But, in these examples (with charges of 1 lb. of powder), the flame did not extend much beyond a distance of 100 feet, and therefore the power of the dust to carry an explosion or flame in these cases was limited. It was found, in experiments with the large Chatham gallery, in which the flame from a blown-out shot reached, in the absence of dust, to a maximum distance of 20 feet, that, when the atmosphere was thickly laden with a highly inflammable coal-dust, from Seaham Collieries, the flame was carried on to nearly double, and in one case a little more than double, the distance.

Although it may be very doubtful whether coal-dust, in the *complete absence* of fire-damp, can be credited with the production of extensive explosions, as has been recently maintained by some, there can be no question that, in the presence of only very small quantities of fire-damp, it may establish and propagate violent explosions; and that, in the case of a fire-damp explosion, the dust not only, in most instances, greatly aggravates the burning action and increases the amount of after-damp, but that it may also, by being raised and swept along by the blast of an explosion, carry the fire into workings where no fire-damp exists, and thus add considerably to the magnitude of the disaster. The supposition that extensive coal-mine explosions may be produced by coal-dust alone, in the complete absence of gas, necessitates the fulfilment of conditions which cannot but be at any rate very exceptional, but its acceptance is unnecessary to add to the formidable character of coal-dust as a source of danger and an agent of destruction in mines. The possibility of dealing with the dangerous dust in mines should therefore be as much an object of earnest work as has been the improvement of ventilating arrangements in mines.

The actual removal of dust-accumulations being in most instances impracticable, the laying of the dust by an efficient system of watering the mine ways, is a matter deserving serious attention. Although in some instances such a measure is not readily applicable, without injury to the workings, it has been already proved in some districts to be unobjectionable and susceptible of very beneficial application. The employment of deliquescent substances (calcium chloride, sea-salt, &c.), in conjunction with watering, has also been advocated and tried to some extent with success.

The elaboration of really safe and sufficient methods of getting coal where blasting by powder is now resorted to, and of removing the harder rock in the working of drifts, &c., where fire-damp may exist, must most importantly contribute towards the diminution of danger arising from the accumulation of dust in mines, both by avoiding the projection of flame into the air, and by avoiding powerful concussions, whereby dust is raised; and the lecturer referred in conclusion to the various plans, in addition to coal-cutting machines, which had been devised to dispense with powder, or render its employment safe. The use of compressed air had been attended by some measure of success, and the dispersion of water, used as tamping, by the explosion of a powder charge in the form of a spray, had been shown to have frequently, though not reliably, the effect of drowning the flame developed by the explosion. The employment of water-columns, by which the force developed by the detonation of dynamite was uniformly transmitted throughout the entire length of the hole, had been proved, by experiments in coal-mines in Lancashire, and special test-experiments at Cardiff, to render that material very suitable for coal-getting, and at the same time to render blasting possible without liberation of flame. Lastly, the employment of cylinders or cartridges of compressed quicklime, according to a simple system elaborated by Professors Smith and Moore, was referred to as ranking before all other methods of getting coal, yet proposed, in point of simplicity, cost, and above all, safety, and the lecturer described operations witnessed by himself with this system of coal-getting at Shipley Collieries. In concluding, Mr. Abel exhorted those interested in, or entrusted with the working of coal-mines, to spare no pains to test rigorously and fairly the merits of any processes or methods of affording promise of dispensing with the employment of powder in the ordinary way, and thus of securing protection to the miner against combined dangers of fire-damp and dust.

THE INFLUENCE OF TEMPERATURE ON CERTAIN SEEDS

ON regarding seeds of our hardy trees which are sown in autumn, and which do not germinate before the return of spring, we feel forced to admit that however the other conditions may vary, the cause which causes the germination in the commencement of the fine weather is the rise in the temperature, and one is equally tempted to think that the higher the temperature, as long as this rise does not equal that which would destroy the seeds, the more active and pronounced would be the germination. Nevertheless this is not by any means always the case, at any rate in the seeds of the walnut and almond trees. Anxious to germinate some of these seeds in winter, Prof. H. Baillon thought to obtain a more rapid development in a warm house, in which the temperature varied within the twenty-four hours from 15° to 25° (59 – 77 F.), than in a cool house in which during the same time the temperature varied between 5° and 15° (41 – 59 F.), but the trial proved a failure. In the cool-house, in the course of six weeks, the walnuts had stems of about two decimetres in height, whereas the most advanced of those in the warm house had only stems of from two to three centimetres in the fully developed leaves. The experiment was several times repeated. The same quality of earth, and the same quantity of water was used, and the results were the same. After a space of two and a half months the greater part of the nuts sown in the warm house had only roots occasionally well developed, but little or no caulome outside the fruit. Moreover, the greater part of the walnuts which germinated in a house, where there was good bottom-heat, had roots which did not behave like those of walnuts, germinating in the cool house and without bottom heat, the tap root of the latter grew well in length before any egress of the plumule, whereas the tap-roots of those grown in the warm house were early arrested in their development, and this through growing in a very friable soil, consisting of moist sawdust, much less resisting than the sand or the earth of the cool-house, in which the tap-roots developed so well. This was very nearly the same with the almonds, and would seem to point to the fact that in the case of some seeds there is no advantage to be gained by forcing them. Some, like *Eranthis hiemalis*, at whatever period they are sown in the open air, will develop themselves at a fixed time, as it does in January (H. Baillon in No. 39 of the *Bulletin Periodique de la Soc Linn. de Paris*, January, 1882.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

PROF. HENRY ALLEYNE NICHOLSON has been appointed to the chair of Natural History in Aberdeen, vacant by the removal of Prof. Cossar Ewart to Edinburgh.

DR. SORBY, F.R.S., has been elected president of Firth College, Sheffield.

THE Nottingham University College Committee have appointed Mr. Wm. Garnett, of St. John's College, Cambridge, to the Professorship of Mathematics and Physics, at the College, vacant by the resignation of Prof. Fleming.

SOCIETIES AND ACADEMIES

LONDON

Zoological Society, April 29.—Anniversary Meeting.—Prof. W. H. Flower, F.R.S., president, in the chair.—After some preliminary business the report of the council on the proceedings of the Society during the past year was read by Mr. Sclater, the secretary. It stated that the number of fellows on December 31, 1881, was 3213, against 3309 at the same time of the previous year. The total receipts for 1881 had amounted to 25,810*l.*, against 27,388*l.* for 1880. The ordinary expenditure for 1881 had been 24,651*l.*, against 24,753*l.* for 1880; and the extraordinary expenditure 1036*l.*, against 1825*l.* for the preceding year. The sum of 1000*l.* had been devoted to the repayment of the mortgage debt on the Society's freehold premises, which had thus been reduced to 6000*l.* This expenditure had left a balance at the bankers of 1203*l.* to be carried forward for the benefit of the present year. The assets of the Society on December 31 last, after payment of all liabilities, were estimated to amount to nearly 20,000*l.*, exclusive of the value of the library and collection of living animals. As regards the gardens in the Regent's Park, little has been done in the way of special works during 1881, but the buildings and walks had been kept in good repair, and several of the former had been thoroughly repaired and painted. The number of visitors to the Society's Gardens in 1881 had been 648,604, against 675,979 in 1880. The zoological lectures having been well attended during the past year, would be continued during the present season. The number of animals in the Society's collection on December 31 last was 2294, of which 617 were mammals, 1389 birds, and 258 reptiles. Eleven mammals, 17 birds, and 11 reptiles belonging to species new to the collection had been exhibited in 1881, and during the same year a considerable number of mammals, birds, and reptiles of a different species (of which detailed lists were given) had reproduced their kind in the Society's Gardens.—It was moved by Viscount Powerscourt, seconded by Mr. Howard Saunders, that the best thanks of the meeting be given to the Council for their report. The motion having been adopted, the meeting proceeded to elect the new Members of the Council and the officers for the ensuing year, and a formal ballot having been taken, it was declared that Mr. H. E. Dresser, Prof. Mivart, F.R.S., Mr. Henry Pollock, Mr. W. Ayshford Sanford, and Capt. George E. Shelley had been elected Members of the Council in place of the retiring Members; that Mr. F. Du Cane Godman had been re-elected into the Council in the place of Mr. Edward R. Alston, deceased; and that Prof. Flower, LL.D., F.R.S., had been re-elected president, Mr. Charles Drummond treasurer, and Mr. Philip Lutley Sclater, M.A., Ph.D., F.R.S., secretary to the Society until the next anniversary.

Physical Society, April 22.—Prof. Clifton, president, in the chair.—New member, Dr. E. Hopkinson.—The president announced that copies of the Report of the Lightning Rod Committee could be obtained from Dr. Guthrie, Science Schools, South Kensington, price five shillings per copy.—A paper was then read by Mr. W. F. Stanley on the evidence of a flowing liquid moving by rolling contact upon the interior surface of a pipe. In his experimental work on fluids, published last year, the author has endeavoured to show that liquids flowing in a tube move by rolling contact on or past the resistent surfaces of solids, and upon like principles that the moving parts of a flowing liquid move by rolling contact on the more quiescent parts of its own mass, so that in no case is there any element of sliding, gliding, or shearing motion such as is generally assumed. Further experiments tend to support this view in the case of liquids flowing through pipes. The difficulty in the experiments arose from the friction of the pipe impeding the free motion of the particles. The principle was investigated by allowing liquids o various kinds, such as solution of mastic varnish, to flow through pipes, the liquids containing colouring matter, or air particles to assist the eye. The author illustrated the effects by diagrams on the screw.—Dr. W. H. Stone, Mr. Blaikley, Dr. Guthrie, and the President, offered some remarks on the paper.—Mr. J. M. Whipple exhibited the magnetograph curves obtained at the Kew Observatory during the past week, showing the progress of the recent magnetic storms. After stating that two unusually large spots were now passing over the sun's disc, he remarked that although the magnets at Kew were somewhat disturbed on the 14th, they were nearly stationary until the night of the 16th, when, about 11.45 p.m., they became strongly affected, and from then till 8 p.m. on the 17th, the magnetic storm raged. The horizontal component of the earth's magnetic force was at one time reduced more than 0.05 mm. mgrs. below its average value, and the vertical component by about 0.07 of the same units. This happened about 6 a.m. of the 17th. A little after noon of the same day both forces became so increased, that the light spot left the scale of the instrument for nearly two hours. A second period of magnetic disturbance commenced at about 3.40 a.m. of the 20th, and was violent up to 2 p.m., subsiding gradually until 7.45 p.m. of the 21st. During this period, the magnetic force, though fluctuating largely, did not experience such great changes of intensity as were indicated by that of the 17th. Mr. Whipple then alluded to the work of Prof. W. G. Adams, and suggested that sun-spots only produced such effects when cutting certain lines of force, which he imagined might extend for a limited angular distance round the earth's radius vector. Prof. Adams pointed out the desirability of increasing the number of self-recording magnetic observatories, especially in the southern hemisphere, and after mentioning that the French were about to equip such an observatory at Cape Horn, expressed the wish that the Cape of Good Hope Observatory might again be provided with magnetometers.—The Rev. S. J. Perry remarked on the exceptional nature of the storm which he had seen recorded at Brussels, and stated that in Belgium the telegraph service bad been disorganised by it. Attention was also called to the auroral displays in America, and Mr. Lecky, Dr. Guthrie, the President, and others, spoke on the general phenomena of the storms.—It was then announced that the meetings of the Society in May would be held on the 6th and 20th, instead of on the 13th and 27th, as previously announced; also that the Society would hold a meeting at the Clarendon Laboratory, Oxford, on June 17, by invitation of the president.

Victoria (Philosophical) Institute, May 1.—Prof. Reinsch gave the results of his researches into the mode of the formation of coal. The lecture was illustrated by several large drawings and photographs. The professor stated that he had examined with the microscope no less than 2500 sections of coal, and had come to the conclusion that coal had not been formed by the alteration of accumulated land plants, but that it consisted of microscopical organic forms of a lower order of protoplasm, and although he carefully examined the cells and other remains of plants of a higher order, he computed that they have contributed only a fraction of the matter of coal veins, however numerous they may be in some instances, he referred to the fact that Dr. Muck, of Bochum, held that algæ have mainly contributed to the formation of coal, and that marine plants were rarely found in coal, because of their tendency to decompose, and that calcareous remains of mollusks disappeared, on account of the rapid formation of carbonic acid during the process of carbonic action.

Royal Horticultural Society, March 28.—Sir J. D. Hooker, in the chair.—*Savagus floccosus:* Mr. Pascoe exhibited specimens of this beetle from Queensland, attached apparently by a species of *Isaria*, while living.—*Doryanthes Palmeri:* Sir J. D. Hooker exhibited a leaf, some five feet long, and a cluster of flowers from a spike twelve feet in length, bearing a fanicle of flowers, eighteen inches in length.—*Coryanthes macrantha*, exhibited by S. T. Laurence; the fertilisation of which, by insects, is described by Mr. Darwin, in his "Fertilisation of Orchids."

EDINBURGH

Royal Socety, April 17.—The Rev. Dr. Lindsay Alexander, vice-president, in the chair.—Prof. Blackie communicated a paper on the definite article in Greek, with special reference to the revised version of the New Testament. He showed by quotations from classical Greek authors, that the Greeks were anything but particular in the use of the article, and apparently attached little importance to it; and hence a slavish rendering of the article when it occurred into English, not only led in many cases to bad English, but displayed ignorance of true scholarship. This fault, the author maintained, the revisers had in not a few instances made their own.—Prof. Blyth, in a paper on the action of the microphone, pointed out that the action due to the aërial waves of sound directly, and that due to the tremor of the frame-work which supported the microphone, must be carefully distinguished, the latter being probably the source of the jarring that so commonly accompanies telephonic sounds. As the result of a series of ingeniously-contrived experiments, he concluded that the true microphonic action, as far as it related to the transmission of articulate sounds, is due to the direct action of air-pulses upon the temporary minute "arc-lights" which exist as soon as the carbon points are shaken asunder by the tremor of the frame.—Prof. Marshall submitted an account of experiments made by Prof. C. Michie Smith, Mr. R. T. Omond and himself, in reference to the lowering of the maximum density point of water by pressure. The lowering was measured indirectly by calculation from observed thermal effects when the pressure in a mass of water at a given temperature was suddenly diminished from several tons' weight on the square inch to the atmospheric pressure. This thermal effect is a heating effect when the temperature of the water is below that of the maximum density, a cooling effect when above. A thermoelectrical junction let into the pressure apparatus, and connected to a delicate galvanometer, noted the changes of temperature, while the pressure was measured by means of one of Prof. Tait's high-pressure gauges, formerly described. From their first and preliminary series of experiments, they had deduced a lowering of the maximum density point of water by 2° C. per ton's weight increase of pressure.

Paris

Academy of Sciences, April 24.—M. Jamin in the chair.—The following papers were read:—Movements of various parts of a liquid in a vessel or reservoir, whence it flows through an orifice (continued), by M. de Saint Venant.—Researches on the distribution of heat in the dark region of solar spectra, by M. Desains. With a rock-salt prism, he found the position of the cold bands and the maxima always nearly the same. But there was not the same agreement in the relative values of the intensities of successive maxima and minima (especially in the region of great wave-lengths). The maxima were much greater in 1882 than in 1879 (doubtless owing to dryness of the air).—Memoir on the temperature of the air at the surface of the ground, and of the earth to 36 m. depth, also of two pieces of ground, one bare, the other turf-covered, in 1881, by MM. Becquerel. The mean air-temperature, 11°·15, is higher than in the two immediately preceding years.—On quarantines at Suez, by M. de Lesseps.—Separation of gallium, by M. Lecoq de Boisbaudran. He uses advantageously cupric hydrate, instead of carbonate of baryta or lime, for precipitation of galline; the copper is easily eliminated with sulphuretted hydrogen.—Report on a memoir relating to the hygienic and economical properties of maize, by M. Fua. M. Fua proves the value of maize as food; maladies attributed to it have been really due to badly kept and diseased maize.—On hypercycles, by M. Laguerre.—On the theory of uniform functions of a variable, by M. Mittag-Leffler.—On Fuchsian functions, by M. Poincaré.—Solution of the general problem of indeterminate analysis of the first degree, by M. Méray.—The minima of sun-spots in 1881, by M. Ricco. The northern hemisphere was observed (at Palermo) without spots, 23 days; the southern, 94 days. There were 12 periods of minima in the north, and 18 in the south. The intervals of minima differ little from the time of a solar rotation. A certain stability of minima thus indicated, especially in the northern hemisphere, was confirmed by observations of longitude.—On the actinic transformation of Foucault mirrors and their applications in photography, by M. de Chardonnet. A plate of rock crystal, silvered so as to be opaque to sight, forms a filter, permeable exclusively by dark rays of short wave-length, and which may be used for photography without intervention of visible light. Very white crown glass or thin Saint Gobain glass may be used instead of rock salt.—On magnetic perturbation, by M. Mascart. A magnetic storm of large extent seems to have begun (after some preliminary indications) on the night of April 13, and continued a week or more; strong shocks occurred on the 16th and 20th.—Winter of 1881-1882 at Clermont and at Puy-de-Dôme, by M. Alluard. These stations showed interversion of temperature with altitude on 78 nights in four months (November to February), or nearly two-thirds; the minima on Puy-de-Dôme ranging from 7 to 13 degrees above those at Clermont. New proof was had of the rule that whenever an area of high pressures covers central Europe, and especially France, the interversion in question occurs. M. Faye, referring to the fact that Mont Blanc is sometimes seen from Puy-de-Dôme, distant 280 km., suggested observation of geodesic refraction between them.—On the equivalent of carbon determined by combustion of the diamond, by Prof. Roscoe. Representing O by 15·46, C becomes 11·07.—On the decomposition of salts of lead by alkalies, by M. Ditte.—Action of sulphuretted hydrogen on solution of sulphate of nickel in the cold state, by M. Baubigny.—Researches on ozone, by M. Maillefert. He describes its action on sulphur, selenium, tellurium, sulphides, and some organic matters.—On the absorption of volatile bodies with the aid of heat, by M. Schlœsing. He illustrates this by several experiments; *e.g.* powders of carbonate of ammonia pass into a small tower of coke, sprinkled with dilute sulphuric acid; a part of the alkali is carried beyond. If the temperature be raised to 100°, the absorption is total, and almost instantaneous. M. Schlœsing proposes to apply the principle to determination of nitric acid in the atmosphere.—On the oxidation of pyrogallic acid in an acid medium, by MM. Clermont and Chautard.—On the insoluble modification of pepsine, by M. Gautier.—On nuclei with intense polychroism in dark mica, by M. Lévy. These are due to zircon.—On the action of permanganate of potash against accidents from the poison of Bothrops, by M. Couty. His conclusions, from experiment, are adverse to use of the permanganate as antidote.—On the abyssal malacological fauna of the Mediterranean, by M. Fischer. From 555 m. to 2660 m., about 120 species of mollusca were dredged, of which only about 30 are really abyssal. The number of species diminishes sensibly with the depth. All the deep species are also found in the Atlantic.—On some attempts at hybridation between different species of Echinoideæ, by M. Kœhlen. These were successful, *e.g.* in the case of a Spatangus and a Psammechinus.—On some points of the anatomy of Holothurians, by M. Jourdan.—On the pyloric ampullæ of Podophthalmate crustaceans, by M. Mocquard.—On the vitality of trichinæ encysted in salt meat, by M. Fourment. In salt meat prepared fifteen months back were live trichinæ, which were fully evolved in the alimentary canal of a new host, and caused death.

BRITISH FOSSIL CEPHALOPODS

A Monograph of the British Fossil Cephalopoda. Part I. Introduction and Silurian Species. By J. F. Blake, Esq., M.A., F.G.S., Professor of Natural Science in University College, Nottingham. (London: J. Van Voorst, 1882.)

FOR the first time has just appeared Part I. of a monograph upon the British Palæozoic Tetrabranchiate Cephalopoda, and important as this group of Mollusca has ever been regarded by all palæontologists and badly as such has been wanted by all students of British Palæozoic geology, no one has hitherto attempted any history of this group for Britain. Barrande has elaborately done so for Bohemia and De Koninck for Belgium, both have extensively written upon the older Cephalopoda [Cambrian, Silurian, Devonian, and Carboniferous]. Barrande in his exhaustive work illustrates no less than 1620 Silurian species. De Koninck in his last important work upon the Carboniferous Limestone of Belgium enumerates 170 species, amongst them many new forms and many common to British strata. Prof. J. F. Blake intends completing this history of the British Palæozoic Cephalopoda in two volumes. The part now issued, being part or vol. i., treats only of Silurian species. No less than 244 quarto pages and 31 plates are devoted to the description of 11 genera and 6 sub-genera, and 143 species. The great genus *Orthoceras* being illustrated by 76 species, and its 4 sub-genera by 6 species, *Cyrtoceras* 23 species, *Poterioceras* 2, *Gomphoceras* 11, *Phragmoceras* 7, *Ascoceras* 3, *Nautilus* 4, its sub-genus *Trochilites* 3, *Trochoceras* 12, *Lituites* 2, *Ophidioceras* 2, and *Goniatites* (?) 2 species. These 143 species range from the Tremadoc Rocks, of the Cambrian series, to the Tile-stones of the Upper Ludlow. Forty of the 145 species also occur in Europe and America, or 32 are common to Europe and 6 to America, thus showing the wide distribution of certain genera and species. Thirty-one plates accompany the letterpress or text, every species being figured, and more than 2000 specimens have been examined by the author having reference to the history and description of these 143 species. Prof. Blake has given on pp. 233-6 a table of the distribution in time of all the species, and on p. 237 a condensed table showing the "growth, culmination, and decay of the genera and group." These two tables are suggestive, and the outcome of their study shows that there were two maxima of individual abundance, one occurring in the older group of rocks, the Caradoc or Bala, and the other, in the Lower Ludlow, yet we feel assured that there was no real diminution or falling off in the variety of forms between these two deposits. The tables clearly show that the species in the Wenlock Limestone were (or are now found to be) comparatively few as compared with those in the shales above and below, and would indicate that the Cephalopoda of the Wenlock seas were not commonly frequenters of clear and shallow waters, but were partly pelagic and possibly gregarious in more or less turbid waters, as indicated by the impure sediments composing the Ludlow shales.

Prof. Blake has proposed a classification of the Nautiloidea based upon the general form of the shell, and having a variable siphuncle. He places all the Palæozoic forms under four groups: 1, the *Conici;* 2, the *Inflati;* 3, the *Spirales;* and 4, the *Irregulares.* The 18 genera being naturally distributed through these four groups.

Group 1. The Conici.—Receives the genus *Orthoceras,* with its 5 sub-genera: *Endoceras, Actinoceras, Tretoceras, Conoceras,* and *Gonioceras,* all having straight conical shells; also the curved genus *Cyrtoceras* with its sub-genus *Piloceras.*

Group 2. The Inflati.—Receives the well-known genera *Poterioceras, Gomphoceras, Phragmoceras, Ascoceras,* and *Glossoceras,* all possessing species with curved inflated shells, and contracted apertures.

Group 3. Spirales.—Those species with the whorls in contact, of simple form and considerable curvature, illustrate this group. The characteristic genera are *Trocholites* (Silurian), *Clymenia* (Devonian). *Aturia* (Tertiary and Cretaceous), *Discites* (Carboniferous), and *Nothoceras* (Silurian), a Bohemian form.

Group 4. Irregulares.—The genera comprising this group are all unsymmetrical in form, and greatly curved, the genus *Lituites, Trochoceras,* and *Ophidioceras* illustrate this division.

Prof. Blake does not lay much stress upon the contraction of the aperture in the shell classification, although it is important and recognised by Barrande as of much significance, doubtless other features in the general structure of the shell weigh equally in the determination of species. Such variations as are seen in rare or little known forms become matters of individual opinion to the species maker. As no Dibranchiate Cephalopod is known, or has no representative in the Palæozoic rocks, they may be dismissed as having no place or value amongst the Silurian species; therefore the whole group, whose entire history Prof. Blake has so ably described, belong to the Tetrabranchiata in its two great families, the *Nautilidæ* and *Orthoceratidæ,* especially the latter. Most, if not all, naturalists now agree in separating or excluding the *Bellerophons* from the Cephalopoda, although Prof. McCoy, Ferrussac, D'Orbigny, Latreille, and Sowerby formerly believed they belonged to the "Argonautidæ," and so placed them.

There is still difference of opinion as to the exact limits and sub-divisions of the order Orthocerata. Barrande has given all the known classifications, and the characters on which they have been founded by different authors. They are based (1) upon the position of the siphuncle; (2) the form of the suture; (3) the involutions of the shell; (4) the form of the aperture; (5) the symmetry or asymmetry of the shell; (6) the direction of the septa: (7) the simplicity or complexity of the siphuncle.

In Palæozoic forms the siphuncle played a very important part in the life and history of the species, being simple in one genus, complicated in another, dorsal in one, and ventral in another, and medial in some; the genera and species have been mostly founded on these changes and elements.

The earliest group to make its appearance in time was that of the Orthocerata, and out of it from the peculiarities of the siphuncle and shape of transverse sections, have been formed or established six genera, viz. *Gonioceras, Tretoceras, Endoceras, Actinoceras, Bathmoceras,* and *Bactrites,* all these constitute one natural group, placed by Mr. Blake under the "*Conici*," diverging from this and more restricted in time, having variously shaped apertures, and singularly inflated, fusiform, pyriform, or flask-shaped shells, are the genera *Phragmoceras*, *Gomphoceras*, *Poterioceras*, and *Ascoceras*, and placed under the group "*Inflati*" by the author. The other two groups of the Nautiloidea—the *Spirales* and the *Irregulares*—possess so great a shell curvature that they assume the form of whorls, which may or may not be in contact. This fact appears of sufficient importance to justify Mr. Blake in regarding it as the basis for establishing the group "*Spirales*," in which is placed the genera *Nautilus*, *Gyroceras*, *Trochilites*, and *Clymenia*, &c., finally through peculiarity of form, such as want of symmetry, or loss of, or changes in curvature, are many of peculiar aspect, which Mr. Blake places under the group "*Irregulares*," the genera contained in which are *Trochoceras*, *Lituites*, *Ophidioceras*, and *Cryptoceras*. These researches have led to the construction of the table of classification above given.

Prof. Blake commences his systematic description of the species with the genus *Orthoceras*. No less than 70 species in this genus are described by the author, ranging from the Tremadoc rocks to the uppermost Ludlow beds (the Tile-stones). The species mostly abound in the Bala beds, the Wenlock shales, and the two Ludlows. The literature or bibliography of the species of the Orthocerata, their descriptions, and that of the 5 sub-genera is of the greatest value, and an addition to our knowledge of this oldest known genus in the British rocks; Cyrtoceras being its only associate in the Tremadoc beds. The sub-divisions of the genus by Quenstedt, M'Coy, De Koninck, and Barrande are given. Mr. Blake adopts Barrande's views and grouping of the Orthocerata into two groups: (1) the *Breviconcs*; and (2) the *Longicones*. The latter, which is very numerously represented, Mr. Blake divides into the *Annulati*, the *Angulati*, the *Lineati*, the *Imbricati*, and lastly the group *Leves*. In this latter group is temporarily placed all species whose *external* surface is unknown. Then follows concise but clear descriptions of the five sub-genera—*Actinoceras*, *Endoceras*, *Tretoceras*, *Conoceras*, and *Gonioceras*. For the first time we now have the 70 British species of Orthocerata brought together, and most ably described and figured; 3 species belong to the group "*Brevicones*," and 67 to the group "*Longicones*." Of these, 20 species fall under the group *Annulati*, 6 under the *Angulati*, 13 under the *Lineati*, 7 under *Imbricati*, and 22 in the group *Leves*. We are now able to investigate all the known species of this extensive Palæozoic genus, and no student need be at a loss to determine, either through original description and drawing, or the reproduction of type species, any forms that he may meet with in the Silurian rocks of the British Islands. The author's plan of first describing in every instance the type of the species, is of extreme value, as it at once (if a known species) clears up its history; this with reference to the original figure and description by the author, and its reproduction in the monograph, ensures and affords every chance of right determination. Following the "type" is the general description, then its relation to other known forms, British or foreign, followed by its distribution in time or space; this plan is implicitly followed throughout the entire volume—it is clear, definite, and systematic. The next important group described by Mr. Blake are the Cyrtoceri, numbering 22 species. These curved Cyrtoceri Deshayes termed Campulites, restricting the term to those species having the siphuncle on the inner side. Goldfuss, however, regardless of the position of this organ, named them Cyrtoceras; Billings, De Koninck, Sandberger, Giebel, and Barrande have all proposed divisions for the classification of Cyrtoceras. Blake follows Barrande, who divides them into two series, according to the position of the siphuncle: (1) the *Exogastric*, in which that organ is external; and (2) *Endogastric*, in which it is internal. Prof. Blake proposes a third grouping for these species, in which the siphuncle is near the centre, calling it "Mediogastric." The Bala, Wenlock, and Lower Ludlow beds contain most species of Cyrtoceri. The species *C. precox*, from the Tremadoc beds of Garth, in North Wales, and from Llanerch in Pembrokeshire, with *Orthoceras sericeum* are probably the oldest forms known.

The singular genus Gomphoceras receives much careful analysis from Prof. Blake. Six of the 11 species are new, and there appears to be good reason for their establishment; with one exception the species are all (10) Upper Silurian, 8 of the 11 are in the Lower Ludlow beds, and 5 in the Wenlock Limestone. Two quarto plates are devoted to this remarkable genus. Four of the 7 species of Sowerby's genus Phragmoceras are also new, and for the first time figured. Like Gomphoceras this genus is chiefly Upper Silurian, the Wenlock and Ludlow strata being characterised by them. Mr. Blake adds much to our knowledge respecting the species of the genus Ascoceras of Barrande, hitherto little known or understood; the species in Britain are confined to the Ludlow rocks.

The group Spirales, illustrated by the genus Nautilus and its sub-genera, receives ample and critical notice, and shows how varied have been the views of naturalists upon the affinities of this old genus, established by Breynius in 1732. The value of the sub-genera in this as in all the large groups is of much significance in tracing the history of the obscure forms classed under the genus Nautilus or *Nautiloid* remains in the Lower Palæozoic rocks. Five of the so-named genera—Trocholites, Clymenia, Aturia, Discites, and Nothoceras are placed under the genus Nautilus as sub-genera. Mr. Blake gives Quenstedt's, D'Orbigny's, and De Koninck's classification or sub-divisions, and suggests one of his own. Quenstedt proposed to subdivide the genus Nautilus into 8 groups: (1) the Insecta, (2) *Clymenia simplices*, (3) *Clymenia angulosæ*, (4) the Moniliferi, (5) Bisiphites, (6) Simplices, (7) Undulati, (8) Aganides.

This and the classification by De Koninck ("Terr. Carb. de Belg."), in which he partly follows Quenstedt, are the only two hitherto recognised divisions of the genus. The Belgian Professor places his Palæozoic species under the following six heads: (1) Imperfecte, (2) the Striati, (3) the Radiati, (4) Lævigati, (5) *Clymeniæ simplices*, and (6) *Clymenia angulatæ*; four of the six being those of Quenstedt. Prof. Blake proposes or suggests a simpler grouping. No. 1, *Simplices*, illustrated by the sub-genus *Trocholites*; 2, the *Radiati*, those species having radiating, sigmoidal, or angular ribs; 3, the *Ornati*, variously ornamented, chiefly Carboniferous, equivalent to M'Coy's sub-genus *Temnocheilus;* 4, the *Sinuosi*, those with sinuous sutures; and 5, those species with nummuloid siphuncles (Trias only).

Probably only three species of Nautilus occur in the Silurian rocks—*Nautilus quadrans*, *N. Holtianus*, and *N. Bohemicus*. This last-named species appears to be the *Lituites Biddulphi* of Sowerby (1838); but his insufficient description, in the "Sil. Syst." of Murchison, prevents true identification. They are all three Upper Silurian forms. The Lower Silurian rocks of Newfoundland and Canada have yielded eleven species. In the Carboniferous strata Nautilus attains through Discites its maximum development. In the Permian only one species is British, and three American, and is now the only living representative of the Tetrabranchiata. The sub-genus *Trocholites* (three species are Lower Silurian. These six forms are the only *true* Nautiloidea in the Silurian rocks.

The last group (4, the *Irregulares*) in Mr. Blake's classification receives three genera: *Trochoceras*, with 12 species; *Lituites*, 2; and *Ophidioceras*, 2 species. We have no representative of either the *Endogastric* or *Exogastric* group of Barraude in this country. American and Swedish Lower Silurian species are somewhat abundant, in Britain it is chiefly an Upper Silurian genus. Of the 12 species known 8 are Upper Silurian—Wenlock and Ludlow—and the Llandilo, Bala, and Llandovery beds yield the remaining *Trochoceri*. Five of the 12 species are *new* to Britain, described and figured by Prof. Blake for the first time. The two type species—*Trochoceras* (Lituites) *cornu-arietes* (Sowerby), and *Trochoceras* (Lituites) *giganteum* (Sowerby)—are admirably refigured and described by Mr. Blake, the general descriptions adding to their specific value, and the determiuation of Bohemian forms of Lituites in Britain materially adds to the correlation of the two faunas. Barrande's genus Ophidioceras (*Lituites, auct.*) seems to have been recognised by Mr. Blake; it differs from typical Lituites by the whorls being accurately in contact. The *Lituites articulatum*, Sow., was long ago figured as Lituites in the "Sil. System," p. 622, t. 11, f. 5, and adopted by Salter. The straight ribbing and band distinguishes this genus from Lituites. This volume concludes with general observations, and highly suggestive many of them are. Prof. Blake endeavours to throw some light upon the laws which govern the appearance and disappearance of forms of life, and into the nature of those groups of individuals to which we assign the term species.

Mr. Blake prepares a table, condensed from the larger and preceding one on pp. 233-236. This condensed table shows the numerical value of the species occurring in the 11 genera, and ranging through the ten formations or horizons, thus showing their increment, decrement, and stratigraphical distribution. Both tables show three maxima in the Ludlow, Wenlock, and Bala beds—in the Ludlow 65 species, the Wenlock 43, and the Bala 39. Mr. Blake does not believe that there was a corresponding falling off between these epochs; he draws conclusions from the comparative fewness of species in the *Wenlock Limestone* as compared with the Ludlow shales above and Wenlock shales below that formation. Of the four groups given the *Conici* first appear, and constitute the bulk of the Lower Silurian fauna, 31 species occurring in the Bala rocks [the Tremadoc only yielding two species, the Llandeilo 9, and the Lower Llandovery 8, or 19 for the three horizons]. The *Conici* and *Spirales* are the only two groups which continue on in time or range into the higher divisions of the Palæozoic rocks (the *Devonian* and *Carboniferous*), the *Inflati* being represented by *Poterioceras*, &c., in the Carboniferous series.

Mr. Blake next considers the characters of the individual genera and their appearance in time, but somewhat begs the question to suit his particular view upon evolution; it surely can hardly be safe to speculate upon any particular curve or part of the curve in any particular genus, to argue for descent through evolution, other conditions not known. Neither *Cyrtoceras precox* or *Orthoceras sericeum*—which are the oldest species known in Britain —"are transitional forms, both being well characterised," and it is questionable whether the group which has been longest in existence in a given area, will there most abound, many physical conditions may tend to prevent that, "though we grant that possibly the greater the abundance of individuals, the greater is their chance of preservation in the rocks, the nature of the deposit admitted.

In the paragraph on p. 239, having reference to the genera Cyrtoceras, Phragmoceras, and Gomphoceras, more evidence is wanting before we can draw any conclusion as to priority of appearance, or show that those having the siphuncle internal (Endogastrica) appeared first or preceded the Exogastrica (with the siphuncle external); it is true we must take the evidence as it stands, or as we find it; it is, however, wiser not to theorise upon such slender materials.

Prof. Blake next notices and discusses the question of species (pp. 239-243), and has pronounced opinions upon this vexed, complicated, and philosophical question, naturally the old idea of the independence of species is rejected. Mr. Blake adopts all through his book the method of "actually describing a type-specimen around which the other forms designated by the same name may cluster." When the original type has not been seen or found, a type is selected to which others are compared. In attempting the explanation of the phenomenon of distinct species or specific groups, it is well known that two theories are now held: (1) that which considers each species a "special creation, though inexplicable"; or, (2) "that which asserts the development of one from the other by a process of evolution." Mr. Blake appeals to palæontology to show, through its researches, the gradations between one species and another. The result to Mr. Blake's investigation in this and other groups is against "fixity of species." He states, that "if species were such definite entities as they were once supposed to be, they ought to be much more easily distinguished than they are, and that the many variations of form which will be found included, and necessarily included under one specific title, whose 'general description' thereby becomes one of considerable latitude, show that different specimens are not so closely linked as that theory would imply." On the other hand, "Does this present study," asks Mr. Blake, "give any positive aid to the theory of evolution?" He fails to see any reasonable solution or answer. It is evident that among "the many forms which flourish in any one epoch, it must be impossible to say with certainty which was the descendant of any particular form in the preceding epoch, especially as the intervening links are, in all probability, absent."

Mr. Blake selects certain species of Orthocerata which may have been produced by descent; at the least it is only supposition, and he states that there is no proof that they are actually so connected, but to the general theory of evolution—which merely states that every form of life has been developed from a preceding one nearly allied to it—the present study affords no contradiction or difficulty, but affords aid—which if not so great as could be desired, is yet as much as could be expected. In the present study of the Palæozoic Cephalopoda we have a fair representative of a successive fauna of the same class, and the species are grouped round a series of central types; and so long as the surrounding circumstances remain constant and the same, the process of evolution by indefinite variation and survival of the fittest should either be uniform, and leave relics having no special grouping, or it should cease when the best adaptation to the surrounding circumstances or conditions had been acquired. These views are expressed and carefully argued by Prof. Blake, in the concluding pages of his work. "The great defect," writes Mr. Blake, "of the theory of natural selection is that it leaves the original variation, which is the basis of the whole to chance; chance variations are not likely to lead to any law." "The part which it has effectually performed is to show how variations of the individual may produce permanent changes in the species, and thus break down the idea of the fixity and independence of the latter." "We are, perhaps," says the author, "as yet too dazzled by the brilliancy of the theory to perceive its inadequacy as a complete account of life or to place it as one link only in the chain of explanations."

The "General Observations" of Prof. Blake on pp. 237-44 are a fitting termination to the laborious part undertaken by him in describing the 145 Silurian species. The work has been most carefully and honestly done, and now for the first time we possess a complete monograph upon the Tetrabranchiate Cephalopoda of the oldest Palæozoic rocks; no less than 31 quarto plates illustrate the species, and all are drawn life-size. Mr. Blake has examined 2000 well-characterised specimens, and has visited all the museums and private collections in Britain likely to contain materials for his work, and as he remarks, the work includes a description of every known specimen so far as it presents any available characters.

The fragmentary state of nine-tenths of the specimens collected, demanded from the author the most careful examination, whether by comparison or through description of specimens, and those who know the condition of Silurian Cephalopoda as occurring in this country will indeed appreciate the critical labour of Prof. Blake; he has rendered great service to palæontology. The book was the one want, as a completion to the works of Murchison, McCoy, Salter, and Sowerby in Britain; a companion to the grand monographs by Barrande upon the Cephalopoda of the Silurian Rocks of Bohemia, also a fitting accompaniment to the monograph by De Koninck upon the same group for the Silurian and Carboniferous Rocks of Belgium. No library devoted to natural science should be without this first volume, and no student of Palæozoic species can do without it. No group of invertebrata are of such importance to the stratigraphical geologist as the Cephalopoda; in Britain alone the Palæozoic species number nearly 400, and in Bohemia the *Silurian Cephalopoda*, as described by Barrande, reach the great number of 1600, the Devonian species 500, and the Carboniferous species of Europe 350 species; these totals will at least give some idea of the life and distribution of this class of mollusca through time in Europe, and as Prof. Blake's first volume only treats of the Silurian of Britain, we wish him further success in his continued work upon the British Devonian and Carboniferous species, the fossil forms in which require the most minute, careful, and detailed study. R. E.

OUR BOOK SHELF

Social History of the Races of Mankind. Fifth Division: Aramæans. By A. Featherman. (London: Trübner, 1881.)

We do not like to discourage a student who has evidently a zeal for knowledge, and must have given great labour to compiling the comprehensive account of human society, of which this volume is the first instalment published. But we are bound to say he does not seem alive to the differences of value among the travellers' books of which he gives a list at the end of each section, and out of which he has pieced together extracts describing Jews, Arabs, Egyptians, &c. Thus some statement about the Copts may be out of Lane's "Modern Egyptians," or it may be out of Miss Lot's "Nights in the Harem," and the reader would rather like to know which is which. Mr. Featherman writes in his preface: "The facts have been selected with critical discernment, and no doubtful or incredible statements are admitted in the text, unless controverted in a footnote." Then follows an introduction, which begins: "The primæval man did not spring from a single stock, or from one ancestral type. He arose under varying conditions, and at different geological periods. The initiatory forces of nature which caused his primitive development, existed in the same degree in all the isothermal regions of the earth, and whenever the favourable circumstances were capable of producing and fostering into maturity the human animal, there he appeared," &c., &c. Putting preface and introduction together, it is plain that the author's critical discernment does not enable him to know a doubtful statement when he sees it, even when it is of his own making. In fact he does not quite know where he is, or a casual look into his volume would not show the ancient Egyptians classed among the Aramæan or Semitic nations without mention of their great physical difference from Jews and Arabs, nor would there be found in the account of the Egyptian religion a mention of Isis as being Ceres and Proserpine, mother and daughter at once. The book deserves a place on the library shelf, and will be useful to students, especially for its descriptions of Druses, Talmud Jews, and other little-known minor groups. It is doubtful if its reception by the public will justify the series being continued; but in case it goes on, the materials ought to be more carefully selected, and references given.

Commercial Organic Analysis. By A. H. Allen. Vol. II. (London: Churchill, 1882.)

The first volume of Mr. Allen's work treated of cyanogen compounds, alcohol derivatives, phenols and acids; in this second part the very useful and practical character of the work has been fully maintained in the description of the properties, tests and assay of the hydrocarbons, fixed oils, and fats, sugars, starch and its isomers, alkaloids and organic bases, &c. The author has omitted, as stated in his preface, all mention of dyes and colouring matters, coal-gas, and animal products, on the ground that their consideration would have inconveniently increased the size of the work. This is somewhat to be regretted, as they are matters of quite as much importance as fixed oils, &c., to which a long chapter is devoted, and their inclusion would have certainly increased the value of the book for all general purposes.

The chapters on paraffins, terpines, and homologues of benzene are very clear, and in many cases detailed methods of assay, as, for instance, with benzene, anthracene, &c., are given that will be found of practical value.

A large chapter is devoted to the description of methods of examination of fatty oils and fats employed in the soap manufacture, and the same section also gives considerable general information respecting varieties of soap with methods in some cases improved by the author, for the analysis of soaps ; in particular a tabular arrangement of analysis of a soap on p. 242.

About 100 pages are devoted to the important subject of sugars, and in this space we find an admirable condensation of methods in use, both optical and chemical, for the detection and determination of the various varieties of sugars met with commercially. The optical portion is prefaced by some short remarks on construction, and varieties of polometers in use, which might with advantage have been somewhat extended.

All the methods given in this section are up to date, and cannot fail to be of use not only to the practical man, but to the student.

The chapter on the alkaloids is also a very complete compilation of methods of detection, &c., that have been proposed and found to be reliable up to date. No doubt the book will be found valuable as a reliable compilation of methods, &c., as such, saving much time and trouble in referring to the original publications. The author is an eminently practical chemist, and in his preface to the first volume seems to deride the teaching of "ultimate organic analysis" and the "ringing the changes on the everlasting-chloro-bromo and nitro derivatives of bodies of the aromatic series."

The quality of Mr. Allen's production atones somewhat for this ebullition, for his book requires a considerable amount of theoretical knowledge to be possessed by the user ; and it is very desirable, if we are to maintain a position as chemists at all, that the cant about "purely practical work" should cease, and a more thorough foundation in theoretical chemistry be imparted to students, so that they may become reliable practical men, and not mere machines for manipulating test-tubes.

Nordenskjöld's Arctic Voyage Round Asia and Europe. A Popular Account of the North-East Passage of the *Vega*, 1878-80. By Lieut. A. Hovgaard. Translated from the Danish by H. L. Brækstad. Maps and Illustrations. (London : Sampson Low and Co., 1882.)

LIEUT. HOVGAARD, of the Danish Navy, was one of the most efficient members of Baron Nordenskjöld's well-selected staff on board the *Vega*. When he returned from the remarkable voyage, he very naturally felt impelled to tell his countrymen how he had fared and what he had seen. This he has done in a pleasant and popular style, utilising to some extent the material collected by his chief. Lieut. Hovgaard, while dealing mainly with its lighter aspects, gives a fairly complete sketch of the voyage. The translation is well done, and the translator deserves special credit for the intellgible way in which he has rendered Russian names. The illustrations are not up to a very high mark.

The Sphygmograph; its History and Use as an Aid to Diagnosis in Ordinary Practice. By R. E. Dudgeon, M.D. 8vo., pp. 72. (London : Baillière, Tyndall, and Cox).

THIS book may be of some service to beginners, as it gives rudimentary instruction in the use of the instrument, but this is all it does. The history is carelessly written, the account of the indications given by the sphygmogram is imperfect, and the deductions drawn are sometimes, we think, incorrect. From a curve in the upstroke the author concludes that the ventricular contraction is of a peristaltic character, a conclusion which would be most important if it were correct. But he does not at all take into consideration the great probability that this curve is due to instrumental error, inasmuch as it does not appear in the tracings obtained by Marey's sphygmograph, in which the connection of the writing-lever with the artery is more perfect than in Dr. Dudgeon's instrument. The chief value of the book consists in the description and directions for applying Dr. Dudgeon's sphygmograph, which certainly possesses the great advantage over other instruments, that it is much cheaper, and can be applied much more quickly, and with much less trouble.

A Great Mathematical Question. By T. Wakelin, B.A. (Melbourne : G. Robertson, 1881.)

A PAMPHLET of 16 pp., with a coloured diagram, the object of which is to show the fallacy of the *measure* of kinetic energy. It is an account of the old dispute originated by Leibnitz, and about seven pages are taken up with extracts from Whewell's "History of the Inductive Sciences" (vol. ii. pp. 68-70) ; *Penny Cyclopædia*, "Vis Viva" ; *Encycl. Brit.*, "Energy" ; Balfour Stewart, "Heat" (pp. 301-4) ; and Routh's "Rigid Dynamics" (pp. 260, 263, 270-1), with a reference to Todhunter's "Mechanics" (pp. 210, 211). We would suggest, as additional references, Clerk Maxwell, "Matter and Motion" (§ lxxvii.), and Tait's "Recent Advances in Physical Science." Mr. Wakelin concludes : "It will therefore be seen that the *distance* through which a body *falls* during the time of falling, is not a measure of the work of the force of gravity during that time. This, of course, means that the ordinary measure of the kinetic energy of a mass in motion is an erroneous one."

LETTERS TO THE EDITOR

The Existence of a Voice in Lizards

THE letters on the existence of a voice in lizards, by M. Pascoe and S. P. Oliver, in NATURE, vol. xxv. pp. 32, 174, gave me much pleasure, being a confirmation of observations first made and published by myself in 1874, but doubted in different quarters. In my paper, "Zoologische Studien auf Capri, II. Lacerta muralis coerulea, ein Beitrag zur Darwinschen Lehre, Leipzig, Engelmann, 1874" (p. 20), I have laid down the result of my observations, in the first instance, concerning the habits of the bluish-black wall-lizard, *Lacerta muralis cærulea*, discovered by me on the Faraglione rock near Capri, and subsequently on those of other wall-lizards. There, I say : "To the harmlessness (or fearlessness, mentioned previously) of the blue inhabitant of rocks—*Lacerta muralis cærulea*—I owe the discovery of the animal's intonating capacity, a peculiarity generally ascribed among reptiles to the geckoes and chamæleons, but never observed in wall-lizards till now."

One summer-day I heard in the room where I kept a cage of lizards a peculiar sound, similar to the piping of a nestling, only softer. Having listened attentively, I was surprised to find it proceeding from the throat of one of my male blue lizards. Leisurely resting on a stone, the animal repeated the sound a dozen times, perhaps at intervals of about a quarter of a minute, each time opening its mouth a little way. For several consecutive weeks I noticed the same kind of voice in other individuals of both sexes, after which period I did not hear it for months. A series of these calls were taken down by me from ear ; I give them here : "chri, bschi, riä, bi, bschiä."

Among these slightly protracted notes the ch, sch, i, and ä predominated. As to their possible meaning I am still in the dark; I was not even able to discern whether they were to express a sensation of pleasure or comfort, pain, or passion. The animals seemed to be in quite a normal condition. As I shall relate further on, I overheard afterwards a common wall-lizard of Capri, grown blind by conjunctivitis, in the act of producing the same sounds.

After it had been attempted to reject my statements, without any reasoning, indeed by declaring the voice described by me to have been the effect of a rheumatic affection of the mucous membranes, which the Italian lizards had contracted in our cold German climate, I happened to hear the same sounds from a lizard under circumstances wholly excluding every supposition as to its being an abnormal voice. I have shortly communicated the fact in my paper "Untersuchungen über das Variiren der Mauereidechse, ein Beitrag zur Theorie von der Entwicklung aus constitutionellen Ursachen, sowie zum Darwinismus," in Troschel's *Archiv für Naturgeschichte*, xlvii. Jahrgang, 1881, and separately in Nicolai's Library, Berlin, 1881 (pp. 66-68), I quote the following passage:—

"In 1877, having ordered a man to search the middle Faraglione rock for lizards, I waited for his return in a little boat at the foot of the rock. After a while, the man came down with a number of captured lizards tied up in his pocket-handkerchief. I was going to take a specimen of *Lacerta muralis cærulea—Cærulescens mihi*—which he had just released, in my own hand, when it uttered repeatedly, in swift succession, a series of very sharp tones, sounding like 'bschi,' and reminding me of the hoarse piping of a mouse or a young bird."

Moreover, I mentioned that Dugès already tells us of *Lacerta Edwardsii*, a little lizard peculiar to the shores of the Mediterranean, that it is apt to utter a sound resembling the creaking of a Cerambyx. And he further reports that *Lacerta ocellata*, a large lizard of the south, when angry, will expel its breath so vehemently that a sort of voice is produced. And M. H. Landois, of Münster, at my request, informed me last year that *Lacerta viridis* was able to utter a distinctly hissing or blowing sound. These reptiles on being approached on a hot summer day, would rush furiously at their enemy, at the same time making use of their voices, so that they were distinctly heard.

Excepting the few instances above mentioned, in which the existence of voices in lizards has been observed, I am not aware of any corroborative evidence preceding that discovery, a circumstance which is easily explained by the general taciturnity of the animal, which but rarely makes use of its voice.

On the other hand, the *Tapoya Douglasii*, a kind of lizard living near the Oregon Lake, when irritated, hisses very audibly. In like manner are the Iguanas reported to hiss and blow on being caught. TH. EIMER,

Professor of Zoology in the University of Tübingen

Sea-shore Alluvion--Langley Point

THIS spit of shingle, thrown up under the lee of Beachy Head and to the eastward of Eastbourne, is formed, like Dungeness, to windward of what was anciently a large tidal estuary forming Pemsey or Pevensey Haven. At the Roman period the mound on which stand the ruins of the castle, was washed by the sea. The windward supply of shingle forming this ness came from the beach at Brighthelmstone, a fortified town below the cliff, in Elizabeth's reign, on the site of the chain pier, gradually undermined by the sea, and not wholly destroyed until the end of the last and commencement of the present century, and the growing out of Langley Point is coincident in time with the destruction of the Brighton beach as its subsequent retreat and decline are coeval with the rapid increase of Dungeness to the leeward. In effect, Langley Point in 1736 projected three-quarters of a mile further into the sea than at present, and it is a curious fact that the breakwater proposed by the Harbour of Refuge Commission of 1840, parallel to, and one mile from the shore in Eastbourne Bay, opposite the "Wish Tower" site and the Grand Redoubt touched at the north-east end of its eastern *kant* the low-water line of 1736, as shown by the surveys of Desmaretz, the well-known ordnance surveyor of that period, but situate in three to four fathoms of water in 1840. This is a striking illustration of the amount of speculation respecting any increased area of anchorage to be obtained and maintained by artificial works in the vicinity of these shingle moles or inclosing recessions therein. In Desmaretz's time the bays west and east of this formation, viz. Eastbourne and Pevensey bays, like those now at Dungeness, must have afforded considerable shelter with three fathoms of water, now, however, reduced to one, and the area of shelter correspondingly curtailed.

Dummer's plan of 1698 shows that then the haven was open up to the castle, with the site of an old outfall about one mile west of the then entrance, which had been deflected eastward by the travelling shingle, and about this period, from its becoming constantly blocked up, the land-owners appear to have taken steps to render the drainage permanent by placing a sluice and trunk at the entrance, so that the haven has lapsed into a marsh sewer or drain.

A reference to well-known maps shows that this Ness must have advanced seaward up to a certain period, at the rate of ten yards per annum, when, however, the western supply became greatly diminished by the old Brighton beach being gradually used up, the subsequent diminution and retreat of this point afforded material for the continued increase of Dungeness to the leeward of it.

From 1724, downwards, the recession of the point has averaged over certain terms a rate of from seven to ten yards per annum, entailing the abandonment of several of the Martello Towers which fringe this portion of the coast, as well as the west fort at the Point, dismantled forty years back, also constant expenditure in heavier and deeper retaining walls in front of the fosse of the circular redoubt, at its western extremity, to check the repeated local encroachment of the sea.

It results from this continued recession of the shore that the works at the circular redoubt form an advanced point. In the early part of this century the shore in front of this work was much more seaward, and in front of particular Martello Towers in Eastbourne Bay it has retreated over certain terms of years at the rate of one yard per annum. This is shown by the known distance from the towers to high-water mark at the time of their construction. The waste since the erection of these towers has been mainly westward in Eastbourne Bay, accompanied by a certain local increase for a short distance to the eastward of the Point in Pevensey Bay, a similar result to that experienced at Dungeness.

From Dungeness to Langley Point, a stretch of thirty miles, except where intersected by harbour mouths, there is an uninterrupted belt of shingle. Over the last century an elongation of the east point (Dungeness) appears to have consumed the western surplus supply, as shown by the corresponding retreat of the western (Langley) point. The intermediate belt has with less fluctuation been driven more landward, showing that a littoral wasting away from wave action at one point is balanced by a corresponding increase at another.

The plan by Grenville Collins, 1693, shows Pemsey Haven clearly defined with two arms or branches, and a considerable entrance, but contains no notice of such a projection as Langley Point. The topographical survey by Yeakel and Gardner, 1778, a well-executed map to a scale of two inches to the mile, shows it stretching one and a quarter mile into the sea in a south-easterly direction. Of course the accuracy of the rates of progression and retrocession given above are based on a comparison of Desmaretz's surveys with those of recent date, and depend on the character of the former. The remarkable changes in the coast-line along Eastbourne Bay, its small depth, the little protection afforded by Beachy Head, and the eastward movement of Langley Point, are, as in the Dungeness case, arguments against artificial works in either of these bays.

Colour Perception

MR. HANNAY'S explanation of the colours observed in his dark rooms, seems quite in accordance with orthodox science. It is not the explanation I should myself offer, but as that would occupy too much space, and as I am conscious I should not carry the public with me, I refrain from entering on it.

What I do object to is the notion apparently entertained by Mr. Hannay, that his attempted explanation of this single phenomenon, explains also the experiments in the formation of colour I showed him. How can this explain the fact that I can show in the space of a few inches, from mixture of black and white alone, a dozen different colours side by side, mostly as clear and bright as if painted? And how does it explain the fact, that using the exact same proportion of black and white, and working at the same speed, the motion to the one hand will produce *red*, and when reversed, *blue?* Mr. Hannay also seems to imply that the colours of my experiments to be seen well, should be looked at passively or without keen attention. On the contrary, the more light thrown on them, and the keener, fresher, and younger the eyes of the observer, the more brilliant are the colours, and if a boy of ten or twelve years old, who never saw anything of the sort before, be called in, he will describe them better than grown people.

Scientific men have hitherto considered it a sufficient explanation of these experiments to say the effects are "physiological," as if colour were ever anything else. Newton says, speaking of *coloured rays*, that he uses the term merely to suit the understanding of the vulgar, as they are nothing but a certain power and disposition to stir up a sensation of this or that colour. Prof. Ogden Rood again classes these as *subjective* colours, a word which, if it has any meaning at all beyond a very limited one, can have none with reference to colours which remain permanent so long as the machine is in motion.

How may Clouds consisting of Liquid or of Frozen Water be Distinguished?

IN NATURE, vol. xxv. p. 529, M. de Fonvielle asks my opinion as to what observations may be made in a balloon to discover whether in a cloud whose temperature is below zero the minute particles of water are liquid or solid.

There may be difficulties in the way of deciding by direct observation of the form of the particles, whether they are globules or crystals. But since H. B. de Saussure, a century ago ("Essai sur l'Hygrométrie), by means of a single lens, could distinguish in the air over heated water, globules of condensed water of different size, greater ones which appeared to him full, and smaller ones which he regarded as hollow; and when in more recent times A. Waller (*Philosoph. Transactions*, 1847) could make his "microscopic observations on the so-called vesicular vapour of water as existing in the vapours of steam and in clouds, &c.," with the result that he denied the existence of mist-vesicles, it seems possible that by means of a magnifying instrument the form of the particles suspended in the air can be recognised.

A sure evidence, but obtainable only under favourable circumstances, that the particles forming a cloud are ice-crystals would be the observation of the halos of 22° and 46° radius and of parahelions as produced by the cloud. HERMANN KOPP

Heidelberg, May 3

On the Conservation of Solar Energy

Dr. SIEMENS's theory of the constitution of the sun implies that there is an absorption of solar rays constantly going on in space. If this is so, space cannot be perfectly transparent.

An astronomer of the early part of the present century—I think it was Olbers—came to the same conclusion, though from different reasons. He found that as the space-penetrating powers of the telescope is increased, the number of stars that become visible does not increase so rapidly as it would if they were evenly scattered through space, and if space were perfectly transparent; and he concluded that most probably space is not perfectly transparent. This, however, is by no means conclusive, because it is possible that the reason why the number of stars that become visible does not increase as it ought to do on the supposition, is that the number of stars in the universe is limited.

Old Forge Dunmurry, co. Antrim, May 3

CYCLONES[1]

II.

IN our former article we dwelt on the deductions arrived at by the author from a consideration of the mechanical theory of cyclones. We will now proceed to examine how far such theoretical relations are corroborated by the results of observation. The results of observation utilised by the author comprise those of the Rev. W. Clement Ley, published in his "Laws of the Winds"; those of Prof. Loomis, deduced from a study of the U.S. Signal Service charts; those of Dr. Hildebrandsson, with regard to the upper currents from an examination of the Danish synoptic charts; those of Capt. Toynbee, from a study of the Atlantic storms; and lastly, some contained in a recent work on the hurricanes of the Antilles, by Padre Viñes of Habana. Mr. Ferrel at the outset pointedly remarks that for a mariner to be able to make use of the laws deduced from a study of the theory of cyclones, not only a knowledge of such laws is requisite, "but likewise of the *normal* states of the wind and of the barometric pressure in all parts of the ocean and at all seasons of the year, unaffected by the abnormal disturbances of these progressive cyclones; since with a knowledge of the normal conditions of the winds and of the barometric pressure at any time and place he can perceive the first indications of the abnormal disturbances which are the forerunners of these storms, and so can be on his guard, and then with a knowledge of these storms or cyclones, he can generally avoid at least their most dangerous part."

With regard to the first result from theory, viz. the general incurvature of the winds in a cyclone, which was formerly altogether denied by the cyclonists—so-called—Reid and Piddington (not Redfield), or inordinately magnified in every case by Espy, and other upholders of the radial theory, there seems to be no doubt from the results of observation here given, as well as from others not cited by the author, that the wind deviates to a considerable extent from the tangent to the isobars inwards towards the low centre. Moreover, in accordance with theory, this inclination is greater at inland stations where there is more surface friction than at or near the sea when it is less. Thus Ley found the inclination to be about 29° for inland stations, but only 13° for those on the coast. This difference between the inclination at sea and on land may perhaps account for the tenacity with which sea captains still cling to the notion that the wind blows in circles coincident with the isobars; since it is precisely at sea where the incurvature should theoretically be least. The increase in the inclination corresponding to a decrease in the latitude is likewise borne out by observation. Thus from Ley's observations, which embrace North and South Europe, the mean inclination to the isobar is about 25°, from those of Capt. Toynbee on latitude 50° it is 29°, from those of Loomis nearer the equator in America 47°,[1] from those of Padre Viñes in the Antilles 45°, and we may add from some in the Bay of Bengal, mentioned by Blanford, about 42°.

It is thus pretty evident, as the author remarks, that "though the horn-cards of Piddington based on the strictly circular theory of the winds may still be used at sea in high latitudes without great error, yet nearer the equator they must become more erroneous, and entirely fail at the equator if cyclones could exist there." Mr. Meldrum, of Mauritius, as far back as 1867 drew attention to the disasters which resulted in consequence of vessels having estimated the direction of the centres of cyclones according to the rules of the circular theory, and since the publication by M. Faye of his "Défense de la loi de tempêtes," has strenuously opposed the resuscitation of this exploded doctrine. He has also lately given an admirable proof of the truth of the incurvature, by publicly announcing when the wind, in a cyclone on March 21, 1878, was from the north-east in Mauritius, that the centre of the storm was not to the north-westward according to the circular theory, but to the west-south-westward, which was afterwards found to have been the case.

It is a manifest duty therefore which mankind owes itself, if the dangers of the sea are to be minimised, that the amount of inclination of the wind to the isobar should be determined by observation in different seas and for

---

[1] "Methods and Results of Meteorological Researches for the use of the Coast Pilot." Part II.—On Cyclones, Waterspouts, and Tornadoes. By William Ferrel. (Washington, 1880.) Continued from p. 12.

[1] Some of these included very gentle winds.

different latitudes, in order that the navigator may be able to modify his rules accordingly, and so avoid such a fatal error as that of running gradually into the centre of a storm, which a rigid adherence to Piddington's rules would be certain to entail.

So far we have not considered what effect is produced on the inclination by the progressive motion of a cyclone. Were a cyclone regular in form and stationary, the inclination should obviously be the same at every point on the surrounding isobars. When, as is generally the case, it has a progressive motion, this—on the supposition that it is mainly due to the general motions of the atmosphere—should, by a simple application of the parallelogram of velocities, alter not only the velocity but the direction of the inflowing winds, increasing their inclination in the rear, and diminishing it in the front part of the cyclone.

This conclusion tallies remarkably well with the observations of Padre Viñes in the Antilles, where the cyclones travel westwards, as well as with those of Prof. Loomis in North America, where they travel towards the east. When we come to Europe, however, a remarkable exception to this rule occurs, since here the inclination is much *greater* on the east or front side (especially south-east) of a cyclone than on the west or rear side.[1] The author attempts an explanation of this fact on p. 40, but a better one both of this and of the equally enormous though opposite difference found by Loomis between the inclination in the rear and front parts of cyclones in the United States, which can hardly be altogether due to the admittedly small velocity of the general motion of the air over America from west to east is given by Lieut. Spindler, of the Russian Navy, in a recent number of the *Repertorium*,[2] where he considers it to be mostly due to the friction encountered by the wind on the Continental side of cyclones, increasing the inclination in the west and therefore rear part of the American cyclones, and that in the east or front part of the European cyclones.

If the general truth of the difference between the inclination in the front and rear of cyclones at sea, due to their progressive motion, be admitted, the case of the poor navigator becomes still more complicated, as in addition to considering latitude, distance from the centre, and velocity of the wind, he must likewise consider in what quadrant of the cyclone he is situated, since the direction of the vortex with reference to that of the wind, is so different in different quadrants. Fortunately it is just in front of a cyclone—the most dangerous position for a ship to be in—where the old circular rules are least at fault, since it is precisely here where theoretically the inclination should be least.

With respect to upper currents, the results derived from theory are remarkably confirmed by those from observation. In general, since the air flows in towards the centre below, it must flow out from it above, and also somewhat across the current which flows below, so that if we stand facing the wind at the earth's surface, and at no very great distance from the low centre, the upper current should almost invariably flow from some point to our right. This agrees with observation, since, according to Clement Ley, the average direction of the upper currents is 44° to the right of the direction from which the surface-winds blow. The general conclusion arrived at by Mr. Ley regarding upper currents, that they "manifest a centrifugal tendency over areas of low pressure, and a centripetal over those of high," is identical with that arrived at by Dr. Hildebrandsson, and with the author's theory as far as it applies to ordinary, or as he calls them, warm-centred cyclones.

Cold-centred cyclones, to which we alluded in our previous article, do not seem to have been identified by the author except in a stationary form surrounding either pole. The observations of the upper currents hitherto made indeed argue powerfully against their existence at all in the progressive form, since in their case the upper currents should flow in towards the low centre, accompanied by a gentle outflow below, a state of things diametrically opposed to all present experience in connection with a central area of low barometer.

The author next discusses the effect of the general progressive motion of the atmosphere on the upper currents, which is similar to that on the lower currents, but larger in consequence of its increase with the altitude.[1] In winter when the progressive motion is theoretically larger than in summer (Part I.), the upper currents in our region should in nearly all cases move from some westerly point, acquiring their greatest velocity on the south side of the low centre. In summer the directions should be more variable, and the wind's velocity less. Observation verifies both these conclusions; thus Clement Ley found the greatest velocities of the upper currents, such as 120 miles an hour, to occur generally in the winter, when the cyclone centre was to the north or north-east, and it was travelling eastwards. On the other hand the cases in which the upper clouds were found to be stationary most commonly occurred in summer, and near the centre of areas of high pressure. These facts, both as regards the strength and direction of the upper currents, are confirmed by Prof. Loomis's observations of the winds on Mount Washington. The author then proceeds to show how the upper currents may be employed to indicate through the medium of their visible accompaniments—the cirrus clouds—the approach and direction of a distant cyclone; a point most valuable to the seaman, who cannot command a daily weather chart. He says: "The almost universal precursor of a distant storm is the appearance of more cirrus-clouds than usual, not only differing from those of the general currents in form, but also in the *direction* of the currents indicated by those clouds."

In low latitudes, where according to theory the upper and lower currents are more nearly radial to and from the centre respectively, the direction from which these clouds come, especially while the storm is still at some considerable distance, is found to indicate very nearly the direction of its vortex. In higher latitudes matters are more complicated, since the currents are more tangential, the upper currents flowing anticyclonically at great distances from the centre, but even here, the observer will not, as a rule, be far wrong according to the author's diagrams, and those of Clement Ley, if he places the centre of the approaching storm a little to the right of the direction from which the cirrus advances.

Regarding the existence of an anti-cyclone in connection with every cyclone, and the broad annulus of high barometer with its maximum at the dividing limit between them, the author finds ample confirmatory evidence; though from the fact that the depression at the centre is more marked than the rise of pressure near the border of the cyclone, the latter is often so masked by other irregularities as not to be readily discernible on a synoptic chart. In our own islands, where we frequently encounter a string of small cyclones travelling over us from the Atlantic, the barometer rises briskly after the passage of each low centre only to warn us of the approach of its successor, from whence no doubt arose the old maxim, "Quick rise after low foretells stronger blow." The author mentions that the approach of the hurricane of September, 1875, was indicated at Havana by a sudden rise of the barometer,

---

[1] In the north-west quadrant the inclination according to Ley is only 9°, while in the south-east quadrant it is 35°.

[2] Ueber die Abhängigkeit der Stärke und Richtung des Windes von der Grösse und Richtung des Gradienten an den Küsten des Baltischen Meeres. "Rep. für Met., tom. vii. No 5. St. Petersburg, 1880.

[1] This increase in the velocity of the general atmospheric drift with the altitude is shown in Part I. p. 45, to result from the relations between the velocity of the wind and the observed barometric pressures and temperatures in different parts of the world. For the latitude of the British Isles the eastward component of velocity at the elevation of five miles—the height of the cirrus-clouds—is estimated to average about sixty-three miles per hour in January, twenty-nine miles per hour in July, and throughout the year about fifty miles per hour. At the surface, the mean velocity is calculated to be four miles per hour in January, and two and a half miles in July.

while the cyclone was yet at the Windward Islands, about 1200 miles distant.

A sudden and abnormal rise of the barometer thus constitutes as important a warning to a navigator as a similar fall, or a band of cirrus-cloud, only to be able to make effective use of this danger-signal he ought accurately to know the normal height of the barometer where he is, and at the time of year. The author shows how this may be done in Part I., where he has constructed charts, based on a large series of observations in the northern hemisphere, showing not only the curves of mean annual pressure, but also those which represent the coefficient of annual inequality. From a simple equation involving these two elements, the normal pressure at any time and place can be approximately reckoned, and hence the amount of abnormality determined.

The author next applies the cyclone theory in explanation of the various inequalities of barometric pressure, which are observed on the same latitude in different longitudes. These inequalities he considers to be mainly dependent on the deviations of the mean temperature (annual or monthly) from the mean of all longitudes, which he gives in a tabular form for every fifth degree of latitude and every tenth degree of longitude in the northern hemisphere, by means of interpolation from the observations discussed in Part I. From these tables it appears that in addition to, and superimposed upon, the general system of two polar cyclones due to the normal differences of temperature between the Equator and the Poles, we have throughout the year, and more especially in the winter, the conditions for the existence of a large fixed warm-centred cyclone in the North Atlantic, with its centre near Iceland. The barometric pressure should consequently be lower here than the mean of the latitude taken round the globe. That this is the case is well-known, and also that the prevalence of south-west winds in these islands is due to our generally lying on the south-east edge of this nearly perpetual cyclone. A similar cyclone similarly produced lies in the North Pacific.

Two corresponding regions of abnormally low temperature lie one on the east side of Asia, and the other on the east side of America, which, according to the author's theory, should give rise to cyclones with cold centres. As a matter of fact, however, these conditions are found to be completely reversed; the pressure being above the average, especially in winter, when the temperature-gradients are steeper, and therefore, according to the author's views, the cyclonic conditions should be more developed; while the motion of the air at the surface is anticyclonic, and outwards from the region of greatest relative cold.

The least satisfactory part of the author's work is that which relates to these cyclones with cold centres. Their non-existence in the progressive form is admitted, and where they should occur according to theory in a stationary form, they are notably absent, except in the two circumpolar cyclones. It is possible, however, that they may be identified, though in a modified form, and lacking the central barometric depression *at the earth's surface*, with what are termed "winter anticyclones," which usually coincide with areas of great cold, and which, while they exhibit at the earth's surface an anticyclonic outflow of air, are fed above a certain level by a cyclonic inflow.

Finally, as regards rainfall, which is an almost unfailing accompaniment of cyclones, the author, while admitting its assistance in helping to maintain a cyclone when once started, by the forces which operate whenever vapour is condensed, is strongly opposed to its being a *primary* source of energy, and cites in favour of this notion the following conclusion, arrived at by Prof. Loomis, after a careful study of the U.S. Signal Service charts. "Rainfall is not essential to the formation of areas of low barometer, and is not the principal cause of their formation or of their progressive motion."

The last chapter of the author's work which relates to tornadoes, waterspouts, and hailstorms, has already been referred to in a special article in NATURE, and it only remains for us to observe in connection therewith, that while tornadoes differ specifically in many respects from cyclones, the condition of the atmosphere in the latter is eminently favourable to their production. To this circumstance, according to Ferrel, may be attributed the occurrence of sudden blasts of tornado violence in the middle of cyclones, accompanied by a rapid oscillation of the wind-vane. It is these sudden gusts which do the main damage in such cases, since, as might be expected, the velocity of the wind increases *per saltum* where the gyrations of the tornado and the cyclone coincide in direction. They are found to occur more on the cold or clearing-up side of a cyclone, which Ferrel explains to be due to the cold upper strata overlapping the warmer central part of the storm, and thus promoting a condition of vertical instability of equilibrium in which tornadoes are generated with facility. Viewing the work as a whole, Mr. Ferrel may be congratulated on having presented to the world a memoir of such luminous research as well as practical utility. When we compare it with the numerous other crude treatises and hypotheses evolved during the past half-century on the same subject, which have not only brought the science of meteorology into ridicule, but encumbered our libraries, we feel a deep sense of relief at finding the question dealt with by a mathematician of more than ordinary ability, and one who does not shrink from tackling the real difficulties of the subject. He has for some time been known by his writings on hydrodynamical questions of great importance, especially those applying to the general motions of the atmosphere. The present work will go far towards placing him in the very front rank of physical and theoretical meteorologists. The deductive method has been fairly applied throughout to the equations of motion, and its success will do much towards counteracting the too prevalent tendency at the present time to induct from every solitary phenomenon, or experiment, to some otherwise baseless hypothesis. If the author has not accounted for all the peculiarities of cyclones, he has at least shown that the views entertained by the leading meteorologists regarding their formation, characteristics, and general movements accord with their mechanical theory, and that the sources of energy ordinarily assumed to act, such as heat, gravitation, and terrestrial rotation, are sufficient, without having recourse to any wild hypothesis founded on some unknown function of electricity. The valuable practical hints and suggested modifications of existing rules will do much to avert disasters at sea, the main purpose, doubtless, for which the work was designed, while its thoroughness and comprehensive character will materially help to advance our knowledge of a meteor, which in one form or another comprises almost every condition of the atmosphere included under the term "weather."

E. DOUGLAS ARCHIBALD

ON PHOTOGRAPHS OF THE SPECTRA OF THE NEBULA IN ORION[1]

FOR about eighteen months I have been giving attention to the nebula in Orion with two objects in view, first to ascertain whether any changes are taking place in that body by making a series of photographs to be compared in the future with a similar series; and second, to photograph the spectrum of the nebula in various parts so as to see whether any new lines could be found, and also whether the composition is uniform throughout.

As to the first of these objects I have recently suc-

[1] Read before the National Academy of Sciences, April, 1882, at Washington, U.S., by Henry Draper, M.D. Communicated by the author.

ceeded in taking a very fine and extensive photograph of the nebula containing most of the delicate outlying parts which were not in my earlier photographs. This is in the hands of the photolithographer now and will shortly be published. The experiments have been very difficult because an exposure of more than two hours in the telescope has been necessary, and an exceedingly minute motion of the stars relative to the sensitive plate will become apparent on account of the high magnifying power (180) employed.

In carrying out the second object two contrivances have been used; first, a direct-vision prism in the cone of rays from the objective before they had reached a focus, and second the two-prism spectroscope with which I have taken photographs of stellar spectra for some years past.

During the month of March I have made two good photographs with each of these arrangements. Those with the direct-vision prism, without a slit, have of course demanded that the image should be kept stationary on the sensitive plate throughout the exposure, viz. two hours, and they are as difficult to get as good photographs of the nebula itself. On the contrary, those obtained with the slit spectroscope do not require the same steadfast attention.

The results derived from these photographs are interesting partly from what they show and partly from what they promise in the future. A number of photographs, under various conditions, will be needed for the full elucidation of the subject.

The most striking feature is perhaps the discovery of two condensed portions of the nebula just preceding the trapezium, which give a continuous spectrum. At those places there is either gas under great pressure or liquid or solid. I have not been able to detect any stars of sufficient magnitude in these portions to produce this effect either in my photographs of the nebula or in any of the well-known drawings of this object. It seems to me also that the photographs show evidence of continuous spectrum in other parts of the nebula. In these respects the conclusions arrived at by Lord Rosse in his memoir (*Phil Trans.* Royal Society, June 20, 1867, p. 70) are to a certain extent borne out.

The hydrogen line near G, wave-length 4340, is strong and sharply defined; that at *h*, wave-length 4101, is more delicate, and there are faint traces of other lines in the violet. Among these lines there is one point of difference, especially well shown in a photograph where the slit was placed in a north and south direction across the trapezium; the Hγ line, λ 4340, is of the same length as the slit, and where it intersects the spectrum of the trapezium stars, a duplication of effect is visible. If this is not due to flickering motion in the atmosphere, it would indicate that hydrogen gas was present even between the eye and the trapezium. I think the same is true of the Hδ line, λ 4101. But in the case of two other faint lines in this vicinity, I think the lines are not of the length of the slit, one being quite short and the other discontinuous. If this observation should be confirmed by future photographs of greater strength, it might point to a non-homogeneous constitution of the nebula, though differences of intrinsic brightness would require to be eliminated.

The April number of the *American Journal of Science* contains an account of a photograph of the spectrum of this nebula taken by Dr. Huggins. I have not found the line at λ 3730, of which he speaks, though I have other lines which he does not appear to have photographed. This may be due to the fact that he had placed his slit on a different region of the nebula, or to his employment of a reflector and Iceland spar prism, or to the use of a different sensitive preparation. Nevertheless, my reference spectrum extends beyond the region in question.

As illustraring the delicacy of working required in this research, it may be mentioned that in one of these photographs the spectrum of a star of the tenth magnitude is easily discerned. It is only a short time since it was considered a feat to get the image of a ninth magnitude star, and now the light of a star of one magnitude less may be photographed, even when dispersed into a spectrum.

EPPING FOREST

ON Saturday last, May 6, the Queen declared free to the public the 5600 acres of open land to the north-east of London, known as Epping Forest. The history of the rescue of this magnificent tract, so long the favourite resort of London naturalists, has been told many times since the Corporation of London took up the question, and by their well-directed efforts not only checked the encroachment of rapacious land-owners, but restored to the people about 1000 acres of forest land that had been illegally inclosed. The total cost of this philanthropic movement may be estimated at nearly half a million of money, and the Corporation has deservedly earned the gratitude of all Londoners, and more especially of those lovers of nature who have for long been in the habit of regarding the Forest as a preserve from which they could obtain materials for their studies. It is a common complaint with our natural history students, that the open spaces around London are gradually being destroyed as the pressure of population necessitates increase of buildings in the suburbs, so that the preservation of this large area is really a matter of considerable scientific importance, and as such will be regarded with satisfaction by the readers of NATURE. Fortunately for naturalists, the Act of Parliament declares that the woodland tract under consideration shall be kept as far as possible "in its natural aspect." There has thus been secured to the public at large, and to the metropolitan field naturalists, a recreation-ground of a quite peculiar character, and one which will be looked upon as a great boon by botanists, zoologists, and microscopists.

The value of Epping Forest, from our point of view, lies chiefly in its wildness; by far the greater portion is primitive woodland, which has been but little interfered with by man in comparison with the heaths and commons to the north, west, and south of London. Such an expanse requires little in the way of "improvement." The Conservators have acquired a power of dealing with one of the few surviving remnants of primæval Britain, and in the interests of that continually increasing class of the public who devote themselves to the various branches of out-door natural history, it is to be hoped that this authority will be exerted judiciously. We are disposed to believe that the requirements of the ordinary holiday-maker and of the field naturalist are in this case identical. To be able to roam through many miles of wild forest is as truly a pleasure and novelty to the former as it is a necessity to the latter. From whichever side we view the question of the conservation of the forest, any attempts to destroy its natural features cannot but be deprecated, and in view of the fate of so many of the open spaces round London, this position cannot be too strongly emphasised by those to whom the preservation of our rapidly-disappearing natural history resorts is a matter of importance.

The problem of managing a tract of country which consists of a large proportion of primitive forest and a smaller proportion of land formerly under cultivation, so as to comply with the conditions of the Act and with the requirements of all classes of the public, is not so difficult as might appear at first sight. It is not as though the interests of field-naturalists in any way clashed with those of the general public. We have here a wide expanse *pro delectatione populi*, which is to be distinguished and to be kept distinct from all other public spaces in the vicinity of the metropolis by virtue of its forestal wildness, and in order to maintain it in its "natural" condition it would have been better if the Conservators had taken counsel with some of the numerous scientific societies of London which are representative of the various classes of natural history students and investigators. This is indeed the only point—but it is a serious one—on which we feel compelled to express our disappointment at the line of management taken up by the Conservators. The Epping Forest Committee consists of twelve members of the Corporation and four Verderers chosen septennially by the commoners of the Forest parishes. Now a Committee appointed to deal with a scientific question—and as such we regard the management of a forest—cannot altogether ignore the claims of natural history without incurring the risk of having their proceedings compared with the tragedy of Hamlet with the Prince of Denmark left out. The present Verderers are Sir T. Fowell Buxton, Mr. E. N. Buxton, the Chairman of the London School Board, Mr. Andrew Johnston, late High Sheriff of Essex, and Mr. D. J. Morgan. The names of these gentlemen encourage us to think that it is no fault of theirs if the claims of natural history science are altogether ignored.

How to deal with those waste stretches of land formerly under cultivation is a question quite distinct from the management of the wooded portions of the forest. While for the latter a minimum of interference would in our opinion be most in accordance with the views of all parties, there are ample opportunities of "landscape gardening" the former. In face of this fact it is somewhat surprising that the energies of the Conservators should thus far have been chiefly directed to alterations in the *natural* portions of the area under their charge, and we are glad to see that the Essex Naturalist's Field Club has taken the initiative in inviting the co-operation of all natural history students interested in the preservation of open spaces in their natural condition, in signing a protest against the destruction of the natural features of Epping Forest. The form of petition has been forwarded to all the scientific societies of London most concerned in this question, and has already received many influential signatures. If the dedication ceremony of last Saturday makes the freeing of the Forest an event in the history of this country, it seems but just that in a period pre-eminently distinguished for its scientific culture, the naturalists of London should urge their claims ere it be too late. R. M.

THE WINTER OF 1881-2

THE fine winter months of 1881-2, from November to March, have been characterised by a mildness rarely equalled in our British climate. Nowhere in the British Islands, from Scilly to Shetland, or from Dover to Valentia, was the mean excess above the normals of the temperature of these five months less than 2°·0. This was the excess in the south of England; in central districts, such as Oxford and York, it rose to 3°·0; and the excess increased on advancing northward till it reached 4°·0 in the upper districts of the Tweed, Clyde, Tay, and Dee, and at Culloden, and Lairg. Everywhere on the coasts the temperature was from half a degree to a degree, relatively lower than in strictly inland situations.

In Scotland the mean temperature of each of the months exceeded its normal, except in a very few localities in December, when temperature was slightly under the average. Each of the other months had a temperature from 2°·5 to 6°·0 above the normal. In England, on the other hand, the temperature of January was pretty generally under the average, the deficiency amounting in some cases, as at Spurnhead, to nearly 2°·0; and in the central districts of Ireland the deficiency was even greater. In February, in a few districts of England, temperature fell slightly below the normal, whereas, over large districts of Scotland, in the same month, it rose to at least 5°·0 above the normal.

As regards atmospheric pressure, its geographical distribution during these months was strikingly abnormal. In each month, as regards departures from the normals, there was an excess in the south, whereas in the north there was a deficiency, or if there was an excess at all, it was much less than in the south. The averages of the five months give an excess above the normal of 0·188 inch at Torquay, and 0·171 inch at Greenwich; 0·116 inch at Llandudno; 0·063 inch at Lissan, Tyrone, and 0·088 inch at Silloth; 0·023 inch at Islay, and 0·061 inch in East Lothian; 0·011 inch at Monach, Outer Hebrides, and 0·045 inch at Aberdeen; but a deficiency from the normal of 0·019 inch at Kirkwall, 0·048 inch at North Unst, and 0·103 inch in Farö. It was to this unprecedentedly steep barometric gradient from south-east to north-west from the normals of these winter months, and the equally unprecedented predominance and force of south-westerly winds which resulted therefrom, that we owe the remarkable mildness of last winter. The extraordinarily high pressures which so frequently ruled on the Continent during the winter, and the all but rainless weather which accompanied these anti-cyclones, and the low state of many of the rivers on the one hand, and on the other the almost unbroken succession of storms which swept the Atlantic with their low pressures and destructive tempests of wind, may be pointed to as the outstanding features of the great atmospheric disturbance which has signalised the winter of 1881-82, of which the mildness of the weather in the British islands was merely an accompaniment.

If the winters of the north-east of Scotland, from which there are temperature observations since 1764, be examined, it is seen that the mean temperature of the five months from November to March have been 2°·0, or more, above the normal during eighteen winters. These winters, with the amounts of the excess above the normal, are given in the following table, to which is added the excess or deficiency from the normals of each of the six summer months immediately following:—

Winters.	Excess above the normal.	April.	May.	June.	July.	Aug.	Sept.	Mean of six months.
1772-73	+2°·0	+1°·2	-1°·4	-0°·7	-1°·5	+1°·4	-1°·2	-0°·4
1777-78	+2·0	-0·2	+3·8	+4·4	+3·6	+1·8	-1·2	+2·0
1778-79	+5·2	+2·9	+1·7	+3·4	+7·4	+6·8	+3·5	+4·3
1780-81	+2·0	+3·5	+2 6	+5·1	+1·4	+0·0	-1·1	+1·9
1789-90	+4·2	-2 0	+1·2	-1·2	-3·3	0·2	-3·3	-1·5
1793-94	+3·6	+4·2	-0·7	+2·6	+3·6	8	+0·5	+1 6
1795-96	+2·3	+7·9	-0·9	-1·3	-3·5	+0·5	-0·2	+0·4
1827-28	+2·7	+0·6	+1·5	+1·8	-0·5	0·2	+1·7	+0·8
1831-32	+2·5	+1·2	-1·0	+0·8	-0·4	+0·2	+1·3	+0·4
1833-34	+3·2	+0·5	+2·6	+1·8	+1.2	+1·2	+1·2	+1·4
1834-35	+2·4	+0·0	-0·7	-0·8	-0·5	+1·9	-0·6	-0·1
1843-44	+3·8	+5·1	-0·9	-0·0	-1·2	1·6	+0·4	+0·3
1845-46	+4·1	+0·1	+3·5	+6·5	+1·3	+2·7	+6·5	+3·4
1848-49	+2·3	-1·9	+1·3	-2·2	-1·3	0·2	-0·4	-0·8
1850-51	+2·1	-1·4	+0·2	-0·9	-1·3	0·7	-0·4	-0·7
1857-58	+2·8	+0·1	-0·3	+4·4	-2·8	+1·2	+0 8	+0·6
1868-69	+2·2	+2·5	-4·5	-2·0	+1·7	0 9	+0·5	-0·5
1881-82	+4·1							
Means ...	+3·0	+1·4	+0·5	+1·3	+0·2	+0 8	+0·5	+0 8

Thus, so far as the north-east of Scotland is concerned, the mildness of the winter of 1881-82 has only been twice exceeded, viz. in 1789-90, when it was 4°·2, or 0°·1 more, and in 1778-79, when it was 5°·2, or 1°·1 more. The winter of 1845-46 showed the same excess as last winter.

We also gather from the table that these winters, which gave a mean excess of 3°·0, were immediately followed by summers warmer than usual, the mean six months' excess being about a degree (0°·8). Indeed, of the whole seventeen summers, only one, viz. the summer of 1790, can be considered as showing a deficiency of temperature sufficiently great and prolonged to be regarded as attended with serious consequences to agriculture. The table is a striking general confirmation of the prognostic long and widely entertained that a mild winter is the precursor of a fine warm summer.

SEVRES PORCELAIN AND SCIENCE

THAT the French should know better than any other nation how to enlist art in the service of science is just what might be expected. Such a service on the part of art to science is only a fair return for the immense resources which scientific research has been able to place at the disposal of art. Nowhere have the discoveries of science been more useful or more utilised than at the celebrated porcelain manufactory of Sèvres, and the illustrations which we give to day will afford some idea of the beautiful results which are thus produced. As a permanent record of successful scientific efforts, nothing could be more satisfactory and appropriate. In Fig. 1 the characteristic features of the Arctic regions are rendered with almost perfect success and truthfulness; while the allegorical representation in Fig. 2, in commemoration of the last transit of Venus, is happy in conception, and charming in effect. Of the artistic merits of the two vases our readers can judge for themselves. It may be interesting to give some idea of the difficulties attending the manufacture of such delicate productions, which we are able to do, from a lecture by M. Ch. Lauth, Administrator of the Sèvres manufactory, published in *La Nature*, to which journal also we are indebted for our illustrations.

Fig. 1 represents a vase which has been presented to King Oscar of Sweden, and is one-eighth of the original size. The splendid vase represented in Fig. 2 is still only in course of execution, and when complete will be placed in the Mazarin Gallery of the French National Library; it will be ten times the size of the illustration. M. Lauth thinks the national institution at Sèvres should be organised more as a school for the training of workers in the delicate art, than as a mere manufactory. The art of fixing colours on pottery, M. Lauth tells us, differs essentially from that which deals with the colouring of any other medium. There is required in the materials perfect adhesion, absolute resistance to atmospheric influences, and a brilliancy which will make the colours seem part of the object itself. As the colours must be subjected to a very high temperature, there must be eliminated from the palette of the ceramic artist all organic colouring matter, and all the unstable mineral colours; he must have recourse to oxides, metallic silicates, or to metals. And the fixation of these colours is always the result of a chemical action, of a combination which takes place at a high temperature between the body of the porcelain and the matters used in its decoration. Many different methods are used for the purpose, but they are divided into two great classes—decoration at great heat, and the decoration by muffle, an oven of a special kind.

The former consists in applying to the porcelain, colouring substances, which are fixed and developed at the same temperature as that at which the porcelain is baked; this is how the most valued results are attained; as the enamel covers the colour, it assumes an extreme brilliancy and depth—it becomes part and parcel of the object itself. This is how the magnificent blue of Sèvres is obtained, as well as certain browns and blacks, and a few other combinations. The colours may be either mixed on the paste, or put upon the object when moulded, before enamelling, or mixed on the object itself when complete; they may be also applied to porcelain already baked, which may be again baked at the higher temperature. This is notably the process employed at Sèvres for their blues. One of the most brilliant varieties of decoration at high temperature consists in what is called the process of *pâtes d'application*. This method consists in painting by the brush on porcelain unbaked or heated; by successive and carefully adjusted applications, a very great thickness is attained, by sculpturing which the artist can give the decoration a re-

FIG. 1.—Sèvres Vase, commemorative of the North-East Voyage of Baron Nordenskjöld (1/8).

Fig. 2.—Vase, commemorative of the Transit of Venus in 1874, by M. Joseph Chéret ($\frac{1}{13}$).

markable finish and value. The object is then heated, enamelled, and baked.

It is different with the decoration accomplished by means of a muffle oven; in this method the painting is always made on baked porcelain, and consequently on enamel, and the heat employed is relatively low. In this process there is necessary, in order to make the colours on the metals adhere, a medium, which is called the *fondant;* it is generally a silicate, or silico-borate of lead. By raising the temperature, these bodies are fused, attack the object, combine with it, and at the same time determine by that reaction the adhesion of the colour. According to the nature of the *fondants* and colours, a greater or less heat may be applied; and as certain colours are more sensitive than others, it is frequently necessary to bake at successive fires of different temperatures. The baking of colours by this process requires very great experience; the absence of any instruments of precision is greatly felt, and there is no other means of ascertaining the temperature that prevails in the muffle, than to observe on samples of porcelain the changes of colour which are undergone by certain preparations very sensitive to differences of temperatures.

PHYLLOXERA

DR. MARION has recently published (Dupont, Paris, 1882) a *résumé* of the results attending the efforts of the Paris, Lyons, and Mediterranean Railway Company to stay the ravages of phylloxera. These efforts were inaugurated in 1876 at a time when the wine growers of Hérault were on the point of relinquishing the struggle. Dumas having demonstrated the great value of alkaline sulphocarbonates as insecticides, this company energetically planned and organised its distribution, with such success that in the period between 1877 and 1881 the number of barrels distributed through their agency rose from 1085 to 14149. The sulphocarbonate is injected twice a year in doses of 12 grammes into holes half a metre apart, being either administered in simple doses or double doses, with an interval of three or four days. The doses vary, however somewhat, according to the nature of the soil and condition of the vines, and much is therefore left to the intelligence of the operator. The remedy acts imperfectly in clayey or stiff soils, and when the ground is saturated.

The first injury manifested when vines are attacked is the loss of their finer radicles, which perish through the suction of the aphid. The consequent loss of nutrition next causes the partial death of old wood and feebleness in the young shoots, followed by a gradual diminution in the fruit. If badly attacked, old vines cannot be saved, as much of the woody stem is dead beyond recovery, but young vines almost always recover under the sulphocarbon treatment, when applied under favourable conditions; new radicles appear, then an increasing luxuriance in the foliary organs, and finally the renewed production of fruit. Dr. Marion strongly advocates the use of this remedy, and sustains his arguments by well selected examples which thoroughly demonstrate its efficacy. It is capable of a wide application, the prices realised for wines in most districts being well able to support its cost.

Other remedies found practicable, but not discussed in Dr. Marion's work, are submersion, and replacement by American stock, with or without grafting. The former can only be practised in comparatively flat or low-lying vineyards in proximity to rivers or canals. These are surrounded by strong embankments of from one to one and a half metres high; and the waters are either let in by mere difference of level at flood times or by centrifugal pumps. The water must not be less than 40 to 50 centimetres in depth, and remain forty to fifty days, and the process is repeated each year. Some waters help to fertilise the soil, and this treatment has invariably produced the best results.

The introduction of American vines has also in certain districts been attended with great success, both in clayey soils, and where the smallness of the vintage per acre precludes the sustained use of costly remedies. The species, however, possess most varying powers of resistance in different soils, and require to be selected with great care. In the vineyards of Medoc, and of high-class vines generally, American stocks are only used for grafting, a clever workman being able to operate on 100 to 200 vines per diem, 70 to 90 per cent. of which will be successful.

Among partly successful remedies may be mentioned the system *Garros*. This consists in uncovering the roots of the vines as far as possible, and treating them with a litre of powdered quicklime, sulphate of copper, and sea-salt. The remedy has been found efficacious, but seems to act, not fatally, on the insects, but in diminishing their number and stimulating the plants to overcome their ravages. The system *Sabaté* is directed towards the destruction of the winter egg, which produces the winged or reproducing stage of the phylloxera. The treatment consists in removing the dead bark from the trunk, and dusting with powdered quicklime, but, like the last, it is not fatal to the insect. A third remedy, that of *Dunay*, consists in exposing the roots of the vine, and coating them from the surface-roots to some 20 centimetres in depth with coal-tar.

I saw, while staying with Leland Cossart, in Madeira, a plan somewhat similar to this practised with great success. Mr. John Leacock, its inventor, removes after the first autumn rain, the soil to a depth of some 20 inches, so as to expose the upper roots, peels off the loose bark and paints the roots with resin dissolved in turpentine, at the same time manuring the vines. This mixture being unaffected by water remains viscid for three or four years, and destroys the insects on their passage up and down. Its cost is less than a halfpenny per vine, and while those so treated were luxuriant in bright green foliage, all around were yellowing and weak.

J. S. GARDNER

THE EXTENSION SEAWARD OF THE WATERS OF THE CHINESE RIVERS

THE following notes, on the extension seaward of the waters of the Yang-tse, were made in the months of September and October (1878), a period of the year when the river first commences to fall, after its waters have attained their maximum height. The four points to which I turned my attention were—the colour and general appearance of the water, the taste, the specific gravity, and the relative amount of chlorides in solution. Owing to the powerful revolving tides of the estuary of the Yang-tse, the river-water and sea-water are churned up together in such a manner that the patches of green and yellow water may be plainly observed, and their line of union as sharply defined. It is from this cause that the density of the water may fluctuate to a very marked degree in the limit of a single mile; and it was not an uncommon experience, on passing from a patch of yellow water into one of green colour, to observe a sudden increase in the density from 1·005 to 1·015. The specific gravity is never constant in the same locality; and it is only by taking all the four points into consideration that a reliable inference could be drawn: thus, the first evidence of the proximity of salt water, which was found at a distance varying from fifteen to thirty miles from Wusung, was not afforded by any marked increase of the density or by any alteration in the taste or colour of the water, but merely by a very perceptible increase in the amount of chlorides held in solution; whilst in the midst of the islands of the Chusan archipelago, which are removed about a hundred miles to the southward, it was often necessary to depend more on the density of the water, on account of the subsidence of the sediment.

Without entering into the details it may be sufficent to state that, whilst the waters of the Yang-tse, according to my observations, became permanently free from sediment, and assumed the more marked characters of sea-water, with a minimum density of 1·018, at a distance of about forty miles east of Wusung, they still retained their yellow colour and turbid appearance, with a density varying between 1·005 and 1·011, on the outskirts of the Chusan archipelago, about a hundred miles to the southward. From these data the conclusion may very naturally be drawn that the main body of the water discharged by the Yang-tse flows comparatively undisturbed in a southerly direction across the Hang-chu Bay to the Chusan archipelago. The southerly extension of the muddy waters of the Yang-tse in the neighbourhood of Chusan[1] must have been a frequent subject of remark to any one approaching Shanghai from the southward, and should he at some subsequent period undertake the voyage from that port to Nagasaki, he will be very probably surprised to find himself, some four or five hours after leaving Wusung, surrounded by the green waters of the Eastern Sea. The situation of the Great Yang-tse bank, which extends one hundred and fifty miles to the north-east from the mouth of the river, would appear to negative the conclusion at which I have arrived; but I am inclined to view this bank—lying as it does rather off the entrances to the river, and composed as it is of fine grey sand—as rather the work of a past period, when perhaps the bulk of the waters found a passage to the north of the island of Tsung-ming, than as being in actual formation at present. That a vast amount of sediment is deposited to the southward of the estuary at the present time we have the most undoubted testimony in the rapid shoaling of the sea amongst the islands of the Chusan archipelago, and along the shores of the Hang-chu Bay, which has caused channels at one time navigable for junks to be now impassable.

With reference to the general effect of the water discharged by the Chinese rivers on the density of the Yellow Sea and of the Gulf of Pe-chili, I may observe that in the month of October I found the specific gravity to rise slowly from 1·019 at the base of the Great Yang-tse bank—a point between fifty and sixty miles east of Wusung—to 1·023 amongst the islands of the Corean archipelago; and that the maximum of 1·024 was attained at a point mid-way between this archipelago and the Shantung promontary. North of this cape the density does not vary in any marked degree, but after the Miau-tau Islands were passed—a group which separates the Gulf of Pe-chili from the Yellow Sea—there was a gradual diminution, until, at our nearest point of approach to the Yellow River, the mouth of which was forty-five miles distant, the specific gravity was 1·021. This slight fall in the density was the *only indication* of our proximity to such a large river as the Hoang-ho—a circumstance which has a particular bearing on the excessive amount of sediment which this river has been estimated to discharge (*vide* NATURE, vol. xxii. p. 487). From this point to the mouth of the Pei-ho the specific gravity continued to decrease, until at a point about twenty-three miles from the mouth of this river, where the discolouration from sediment was first observed, it was 1·020. Thence to the Taku forts the density rapidly fell.

We may thus place the specific gravity of the Gulf of Pe-chili at from 1·020 to 1·023, and that of the Yellow Sea at from 1·022 to 1·024, whilst the difference between these densities and that of oceanic water—1·027—will represent the combined effect of the discharge of the Pei-ho, the Yellow River, and to a less degree of the Yang-tse, on the specific gravities of the seas in question.

I must conclude with an observation on the erroneous notion which the appellation of "Yellow Sea" must convey to the minds of most men. For however much the Yellow Sea may have merited the epithet of "yellow" when it received the waters of the Hoang-ho about a quarter of a century ago—though if an inference is to be drawn from the present condition of the Gulf of Pe-chili it could scarcely have been entitled to it even at that period—it has no claim whatever to it now. Free from sediment and dark green in colour, except in the immediate vicinity of the estuary of the Yang-tse, the Yellow Sea has been more appropriately named by Chinese sailors—"The Black-water Ocean." H. B. GUPPY

H.M.S. *Lark*, Sydney

PROFESSOR GEIKIE IN ARRAN

AMONG the many features which have lent attraction to the study of geology at Edinburgh University, Prof. Geikie's field demonstrations have always held a conspicuous place. Few favourable Saturdays have been allowed to pass, on which he might not be seen rambling with his class through some wooded glen, or climbing some rugged brae, with hammer, sketch-book, and map-case, and every now and then stopping to point out some striking rock section, or to examine a "find," made perchance by one of his students. But at the end of the session, when a week or ten days are devoted to the exploration of some district possessing an interesting geological structure, the "long excursion" is always looked forward to with the keenest delight by professor as well as by students. The first long class-excursion ten years ago was to Arran, and the Professor decided that his last should also be to that island—famous alike for the beauty of its scenery and for the interest attaching to its geological framework. Quarters were taken up at Corrie Hotel on Monday April 24, and that afternoon saw the whole party, numbering about a score, roaming with bags and hammers along the coast towards North Glen Sannox, and making the acquaintance of the coarse red sandstones and brecciated white quartz conglomerates of the Upper Old Red, or Lower Calciferous Sandstone series, which extend in a broad belt round that part of the island. Further inland, a coarse conglomerate made up of well-rounded pebbles of pinkish quartz interstratified with characteristic dark chocolate-coloured sandstones and occasional argillaceous beds, was ascertained some years ago by the Professor to belong to the Lower Old Red Sandstone, and to be brought down by a fault against the schists that fringe the mountainous granitic core of the northern half of the island. He had already made some progress with a geological map of the island on a scale of six inches to a mile, and he now purposes to continue this work with the co-operation of his students. Resuming his geological boundary-lines at Glen Sannox, the party was soon scouring the hillsides far and near, in search of rock-sections and exposures, while he, map in hand, remained within ear-shot, and superintended operations, marking down the lines of junction, and unravelling the geological structures with the skilful hand of one long acquainted with the art of geological mapping. In this way several miles of the boundary between the granite and schists were mapped. In the course of a walk along the steep craggy Suidhe Fearghus, on the north side of Glen Sannox, the trend of this remarkable ridge was found to coincide with that of the vertical joint in the granite, and the deep gashes which indent its profile were observed to be due sometimes to cross joints, sometimes to basalt dykes which, decomposing, have weathered down much faster than the surrounding granite. The view from Caisteal Abhail, the highest peak (2735 feet) of the ridge, was magnificent, extending

---

[1] I may take this opportunity of observing, that on one occasion when off the northern extremity of Chusan, I noticed several large medusæ floating on the surface of the water, which was not only muddy in appearance but had a density of 1·006.

southwards to Ireland, and northwards to the mountains of Mull and Arrochar. On the way down a dyke much more vitreous and obsidian-like than the other Arran pitch-stone, was crossed on the ridge between Caisteal Abhail and Cir Mhor, at the head of Glen Sannox. Another day the steps of the party were turned southwards, and as the red rocks of Glen Shurig, which runs inland from Brodick, had hitherto yielded no organic remains capable of identifying their precise geological position, the Professor instituted a methodical search, which resulted in the discovery of numerous more or less distinct impressions of the lycopod *psilophyton*, clearly proving them to be, as he had inferred, of Lower Old Red Sandstone age. Striking southward into Glen Dubh, the geologists then crossed the very perfect series of moraines, left there by the last valley glacier, and returning by Glen Cloy, and the well-known pitchstone dyke behind the Brodick Schoolhouse. The fossiliferous limestones and shales of Corrie were also well explored, and the position of this strata far down in the heart of the red sandstone series was remarked.

The concluding ramble of the week brought the party to the celebrated dyke of pitchstone at Corriegills, and the quartz-porphyry of Dur Dubh, both possibly of Tertiary age.

The latter rock is alike remarkable for its petrographical characters and its geological structure and history. The quartz in it has crystallised into singularly perfect doubly-terminated pyramids, which can be picked up in handfuls from weathered crannies of the rock. Viewed from the north, the end of the quartz-porphyry ridge is seen to present a remarkable columnar arrangement, the columns radiating from a common centre like the ribs of a fan. The Professor pointed out the resemblance of this structure to that of the west end of the Scuir of Eigg, where a stream of vitreous lava has flowed into and filled up a narrow valley, the sides of which have disappeared, and where the radial structure of the pitchstone is due to the rock having cooled in an approximately semicylindrical gorge, perpendicular to whose sides the columns were formed. In each case the superior durability of the mass has enabled it to resist denudation better than the surrounding rocks, which have long ago been carried off, leaving the lava standing up as a prominent ridge. Most of the students left Brodick by the afternoon steamer on Saturday, after a most enjoyable week of geologising with Prof. Archibald Geikie on the last of the delightful long excursions with his Edinburgh class. H. M. C.

NOTES

THE following telegram from the Special Correspondent of the *Daily News* with the Eclipse Expedition to Egypt, appears in Tuesday's issue:—"Sohag, Monday, 7.20 p.m.: Every facility has been granted to the Eclipse Expedition by the Egyptian Government. The site chosen is close by the bank of the Nile. The instruments are being set up. The Khedive has shown great interest in the Expedition, and the English party, who are his guests, owe much to the arrangements made by the Governor. The officials and natives are everywhere civil and obliging. The weather apparently is quite settled." Under date of May 9 the *Times* correspondent telegraphs as follows:—"The various Eclipse expeditions arriving at Sohag are being entertained by the Khedive. Most important help has been given by Muktar Bey, the Colonel of the Staff representing the Khedive, and the Government, who have also provided a steamer and a military guard."

SINCE we noticed the pamphlet of Prof. Bloxam on the state of affairs at the Royal Military Academy, the subject has been brought before the House of Lords with some prominence; but the main points of complaint appear to have been ignored. If only a portion of the charges in Prof. Bloxam's pamphlet can be sustained, they reveal a very deplorable want of discipline in an important and expensive public establishment, and also a feeling on the part of the authorities that subjects like physics and chemistry are of such minor importance to the scientific soldier as to warrant the withholding of the moral support to maintain discipline that Prof. Bloxam complains of. Some of the statements in the pamphlet are so severe that we hesitated to repeat them, but they do not appear to have been controverted. The position of a professor of a subject that is only looked upon as a sort of useless "extra," deprived to a great extent of the moral support of the heads of the establishment, cannot be a satisfactory one, and if the late Professor's charges and statements are correct, his successor is not to be envied.

WE regret to record the sudden death of Mr. Charles Hockin, at the early age of forty-two, in the midst of an active career as a civil engineer and electrician, on Wednesday, April 26 last. C. Hockin entered St. John's College, Cambridge, in October, 1859, from Aldenham Grammar School, and was elected scholar in the following May. After a successful career in mathematical work at his college he graduated as Third Wrangler in 1863. Choosing engineering as a profession he became pupil to Messrs. Forde and Fleeming Jenkin, and devoted his attention mainly to submarine telegraphy, a province in which his great mathematical abilities found scope, and in which he did much good work. He made, however, opportunities for other purely scientific pursuits, and co-operated with the late Dr. Matthiessen in his researches on the reproduction of electrical standards by chemical means, and also with Sir William Thomson and Clerk-Maxwell in the determination of the B.A. units of electrical resistance and capacity, as well as in the design and construction of the large standard electro-dynamometer for the Committee of the British Association. He was one of the earliest investigators of the resistance of selenium, a material to which so much attention has lately been devoted. His researches on the subject are referred to in the B.A. Report for 1867. In 1872 he joined as a partner the firm of Clark, Forde, and Co., and in the execution of his professional work visited every quarter of the globe, winning the respect and esteem of all with whom he came in contact and the affection of the few he admitted to his intimacy. While there have been few scientific men less eager than he was for personal fame, it is seldom that equal powers have been placed so readily as his were at the service of others, and there was no one whose opinion on the subjects to which he devoted himself was held in greater respect by scientific men. He devoted much time to mathematical investigations chiefly in connection with electricity, but comparatively little of his work has been published by himself, and it is to be hoped that his executors will see their way to the editing and publication of his mathematical papers.

WE learn from Prof. Ray Lankester that another zoological laboratory is to be erected on the shores of the Mediterranean. The French Government has decided to establish at Villafranca near Nice a zoological station, the sole object of which will be to provide accommodation to the numerous naturalists who every year are attracted to this locality by its great reputation as a hunting ground for marine animals. Dr. Jules Barrois, the distinguished embryologist, has been appointed director of the zoological station of Villefranche-sur-Mer. The existence near Nice of a laboratory accessible to strangers, approved by the director, will be an immense boon to English naturalists especially, since the Riviera is not separated from us by a very long journey, is a favourite resort of our countrymen, and is on the whole salubrious. It is the most favourable spot for the study of the Mediterranean fauna by the naturalists of northern countries; and though the new laboratory will by no means compete with or diminish the value of that at Naples, yet it will render possible a short visit to the Mediterranean for the purpose of zoological work, whereas a long sojourn is rendered almost necessary by the much longer journey to Naples. Further it is well known that forms occur at Villafranca which are not found at Naples, as also many occur at Naples not to be found at Villafranca.

AN interesting account has been lately furnished by M. Plateau, the eminent Belgian physicist (who has been blind nearly forty years), of the sensations he experiences in his eyes. He has no sense of objective light even when directing his eyes towards the sun. But his visual field is always divided into spaces, some of which are pretty bright and others sombre or nearly dark, and which merge into each other. Their general tint alternates, in time, between grey and reddish. The relative arrangement of those different spaces is always the same, but the intensity of their tints varies. The central space seems now rather bright, now very dark; above and below, and on the left to the limits of the field, there is sometimes brightness, sometimes darkness, but on the right there is generally a vertical band, nearly black, and beyond this a space which is nearly always bright and reddish. These appearances follow all the movements of the eyes, which probably do not participate in the same way in the tints, but M. Plateau cannot distinguish what belongs to one from what belongs to the other. No connection of the general tint with the work of digestion is observed. The author states that he became blind through looking fixedly at the sun for some time, with a view to observing his after-sensations; it was not till about fourteen years after this that inflammation of the choroid set in, destroying vision, but, during the interval, he often saw coloured and persistent halos round flames, &c., and he advises those who have such vision to consult an experienced oculist.

WITH the approval of the Treasury, Mr. P. Edward Dove, of Lincoln's Inn, has been appointed Secretary to the Transit of Venus Commission.

THE University of London have determined to prosecute with energy before the City of London Livery Companies Commission their claim to administer the funds of Gresham College. For reasons which are given, it is alleged that the founder, Sir Thomas Gresham, intended to found a University for London without limitation to the City proper; and it is urged that his bequest, as at present administered, does not subserve that purpose, being merely devoted to occasional lectures.

SEVERAL commissions have been appointed by the French Government to report on the advisability of undertaking to flood the Algerian Sahara on the plan proposed by M. Roudaire. It is believed, on good grounds, that the report will be in favour of M. Roudaire's great scheme, and that the objections laid before the Academy of Sciences will be put aside.

THE fate of Capt. De Long, the commander of the *Jeannette* Arctic Expedition is now only too certain; Mr. Melville telegraphs from the mouth of the Lena, March 24, that he has found the Captain's dead body and those of his companions, as well as all papers and books. Mr. Melville was to search for the party under Lieut. Chipp in the other cutter.

THE *Daily News* Naples Correspondent writes:—"The illustrious Italian travellers, Capt. Bianchi and Signor Licata, secretary of the Naples African Club, are about to undertake a new expedition, the plan of which is as follows:—From the Bay of Biafra, in Guinea, they will traverse the hitherto unexplored high levels of the Cameroon Mountains in the direction of the Labi Lakes, and study the country in which rise the Congo, Niger, Gazelle Rivers, and Lake Tsad, to find the key of the hydrographic system of tropical Africa. From the lakes they will descend to Lake Luta, which was partly explored by Signor Gassi. They will then traverse the Uganda territory, going north-east towards the Gallas country, already known to Capt. Bianchi, and return to Italy *viâ* Abyssinia and the Red Sea, having thus crossed Africa from west to east. They believe it will take four years to complete this immense journey, which will have principally a scientific aim."

THE *Natal Mercury* records the death of Mr. G. W. Stow, F.R.G.S. The telegram announcing his death reached Bloemfontein from Heilbron *viâ* Bethlehem. He was not only known by his geological surveys of Griqualand West and Natal, but he had been engaged for many years on a work on the Bushmen tribes, and another on the influx of the native races into the southern portion of Africa.

THE last news from Dr. O. Finsch, who has for the last two years and a half been exploring the Pacific Islands, is dated from Thursday Island, in Torres Straits, January 8, 1882 From September, 1880, to March, 1881, he had been in the little coral island of Matupi, near New Britain. After a visit to Sydney and New Zealand, he had gone to Thursday Island; thence he intended to visit North Australia and various islands in Torres Straits, after which he was to go to New Guinea, there to stay several months. Dr. Finsch has already sent to Berlin many boxes of collections in natural history and ethnology. He has already concluded from his researches, that all the Pacific races may be referred back to two stems—a straight-haired (Polynesians and Micronesians), and a crisp-haired (Melanesians and Papuans), and he is doubtful whether there do not exist connecting links between the two.

WE have already given such full details of the objects and methods of the International circumpolar observing stations, that we need only bring the record up to date by giving the list of the stations so far fixed upon, and the countries that are to occupy them:—(1) Point Barrow (north-west America), by the United States; (2) Great Slave Lake, England and Canada; (3) Lady Franklin Bay, United States; (4) Godthaab (West Greenland), Denmark; (5) Pendulum Islands, Germany (probably); (6) Jan Mayen, Austria; (7) Spitzbergen, Sweden; (8) Bossekop, Norway; (9) Sodankylä (67° 24′ N., 26° 36′ E.), Finland (probably); (10) Novaya Zemlya, Russia; (11) Dickson's Harbour, Holland; (12) Mouth of the Lena, Russia. Some of them are already occupied, and all of them will be during the summer.

PROF. ARTHUR GAMGEE will, on Tuesday next (May 16), give the first of a course of four lectures, at the Royal Institution, on Digestion; and Prof. David Masson will give the first of a course of four lectures on Poetry and its Literary Forms, on Saturday (May 20).

WE have received a report of the meeting of the Essex Naturalists' Field Club, held on February 25, when the preservation of Epping Forest in its natural condition was the subject of discussion. It was decided that the Conservators should be petitioned by the Club, on behalf of the natural history students of the metropolis, and a form of petition has been circulated among the various scientific societies and individual naturalists interested in this question. Those wishing to sign the memorial should communicate with the Hon. Sec., Mr. William Cole, Laurel Cottage, Buckhurst Hill, Essex.

APART from absence of soil and moisture, the height of the "timber line," according to Mr. Gannett (*Am. Jour. of Science*, April) is purely a question of temperatures, and he shows that in several parts of Western America the line rises rapidly as the latitude decreases. On the volcanic peaks of the Mexican plateau, *e.g.* it is higher by several thousands of feet than anywhere else in the United States. Even in the same latitude there are very marked differences in its height. The less the elevation of the surrounding country, other things equal, the lower is the limit of timber. Considering that this limit must have approximately the same mean annual temperature everywhere, and that in abrupt ascent there is a decrease in mean annual temperature, of about 1° F. for every 300 feet, Mr. Gannett thought to determine the temperature at the timber line, from that of a station at or near the base (supposed, though not always correctly, to represent the average climate round the base), together with the height. The tabulated figures, for thirteen mountains, &c., yield the mean 30°·4, which is probably very near the true mean annual temperature of the timber line. Should the result hold good, after wider observation, it will afford, Mr. Gannett says, a very valuable and easily obtainable isothermal, and also enable one to estimate the height of the timber line from thermometric stations at the bases of mountain ranges.

On April 26 M. Broch, president, and the delegates of the Bureau International des Poids et Mesures, presented to M. Tirard, the Minister of Commerce, specimens of the facsimile reproductions of the standard metres and kilogrammes preserved since the beginning of the century in the French National Archives. These copies have been executed with an alloy of platinum and iridium, in compliance with the instructions given by MM. Henry Sainte Clair-Deville and Debray. This great work has taken not less than ten years. These facsimiles have been sent to the Bureau at Breteuil, where they will be used in executing the copies ordered by the several nations for their use.

A new edition of Kelland and Tait's "Introduction to Quaternions" has been published by Macmillan and Co. While refraining from making any changes in the late Prof. Kelland's part of the work, Prof. Tait has re-cast his own where he fancied he could improve it.

The Committee of the Sunday Society are more than usually active just now in connection with the motion for extending the opening of museums on Sundays, which Mr. George Howard is to propose in the House of Commons on the 19th inst. On the 17th inst. a National Conference of Delegates from Provincial Towns, Trade Societies, and other organisations, is to be held at the Westminster Palace Hotel under the presidency of Viscount Powerscourt, and in the evening of the same day a large meeting is to take place at St. James's Hall, when addresses are to be delivered by Lord Powerscroft, Lord Dunraven, Lord Dorchester, Mr. Thomas Burt, M.P., Mr. George Howard, M.P., Dr. Richardson, and others.

The additions to the Zoological Society's Gardens during the past week include Six Northern Marsh Tits (*Parus borealis*) from Russia, presented by Mr. A. H. Jamrach; four Pigmy Pigs (*Porcula salviana* ♂ ♀ ♀ ♀) from Nepaul, a Burmese Tortoise (*Testudo elongata*), a —— Terrapin (*Clemmys*, sp. inc.) from Burmah, received on approval; two Green Monkeys (*Cercopithecus callitrichus*) from West Africa, a Grey-headed Love Bird (*Agapornis cana*) from Madagascar, received in exchange; a Water Chevrotain (*Hyomoschus aquaticus*), a Golden-haired Tiger Cat (*Felis chrysothrix*) from West Africa, a Mercenary Amazon (*Chrysotis mercenaria*) from Columbia, three Chiloe Wigeon (*Mareca chiloensis* ♂ ♀ ♀) from Chili, a Silky Bower Bird (*Ptilonorhynchus violaceus*), two Blue-faced Honey-Eaters (*Entomyza cyanotis*) from Australia, a Red-handed Tamarin (*Midas rufimanus*) from Brazil, a Wild Duck (*Anas boscas* ♀), British, four Yellow-billed Cardinals (*Paroaria capitata* ♂ ♂ ♀ ♀) from South America, purchased.

OUR ASTRONOMICAL COLUMN

Anthelm's Nova of 1670.—The vicinity of this object will soon be in a favourable position for observation, and we may once more direct attention to the small star which occupies very nearly the place given by the observations of Hevelius and Picard in 1670. By a recent careful reduction of Picard's observations, the mean place of the object for the beginning of 1670 was found to be in R.A. 19h. 34m. 5s.·3, Decl. + 26° 31′ 42″, which, accurately brought up to 1880, give, R.A. 19h. 42m. 41s.·3, Decl. + 27° 0′ 56″. Near this point we find a telescopic star, which is No. 1814 of the Greenwich catalogue of 1872, the place there assigned differing from that reduced to the year from Picard's observations by + 3s..8 in R.A., and 33″ in declination, and the right ascension for 1670 is open to an error of quite two seconds, and in greater uncertainty than the declination. The small star is followed by one (*b*) 12s.·6, about 4′·9 N., and a second (*c*) at 22s.·4, about 2′·0 N. Its magnitude has been noted as follows:—1852, April 24, 10·11 m.; 1861, May 24, 12 m.; 1872, August 23, = *b*; 1874, November 13, 0·5 m. less than *b*, decidedly less at first view. Another star (*d*) follows the one nearly in the position of *Nova*, 32s.·6, and is N. 1′.7. Prof. Schönfeld found from the observations of Hevelius and Picard combined, a place differing from that given above by – 2s.·8 in R.A., and + 0′·3 in declination.

Variable Stars.—It is known that U Cephei had long been indicated as a probable variable star by the discordant magnitudes given by Schwerd's estimates of magnitude, as arranged by Oeltzen, and when taken in hand for regular examination, its short period was soon detected by Ceraski. Schwerd's estimates were from 6·7 to 10m. It appears by no means improbable that if several other stars for which the magnitudes in the various catalogues are very discordant, were systematically examined, similar cases might be found. For instance, we have 17 ι Andromedæ noted from 3½ to 7m., 16 Leonis Minoris 5 to 8m., 41 ι Aquilæ 3½ to 6m., and 35 Camelopardi 5½ to 8m.; the last, a double star, has already been found to be variable, as regards one component at least; but we have no approximation to the period.

The Comet 1882 *a*.—The following places are derived from the same elements that were employed last week, and are for Greenwich midnight:—

	R.A.	Decl.	Log. distance from	
1882.	h. m.	° ′	Earth.	Sun.
May 13	0 41·0	+74 5		
14	1 4·7	73 33	9·9571	9·9715
15	1 26·9	72 51		
16	1 47·5	72 0	9·9539	9·9481
17	2 6·3	71 1		
18	2 23·4	69 54	9·9518	9·9227
19	2 38·7	68 40		
20	2 52·5	+67 23	9·9508	9·8949

Next week we may probably be in possession of elements which will allow of a close prediction of the comet's track as it approaches the sun. All the later orbits assign for the date of perihelion passage June 10.

BIOLOGICAL NOTES

Fauna of the Suez Canal.—Dr. C. Keller, who is engaged upon a zoological investigation of the Suez Canal, with a special view to determining what exchange of animals may have taken place between the Red Sea and the Mediterranean, has recently sent his first report from Ismailia to the St. Gall Society for Commercial Geography. He states that the exchange is proceeding slowly, owing no doubt to the presence of the lakes of bitter-water through which the canal was traced. The inhabitants of these very lakes seem to have been the first to commence migrations. This fact Dr. Keller has unquestionably ascertained with regard to several species of the lower animals; a particularly interesting case being that of a violet species of sponges, belonging to the fauna of the bitter lakes. This is now migrating in the canal towards the Mediterranean. He named this form *Lessepsia violacea*. Several larger species of fishes, which are now caught in plentiful quantities in the Timsah lake, have migrated there from the Mediterranean; amongst these are *Anarrhichas lupus*, *Solea vulgaris*, and *Polyprion cernium*. Other species have migrated from the Red Sea to the Timsah lake, perhaps to Port Said; amongst these Dr. Keller mentions a large dark green mackerel and several brightly coloured but small Acanthopteri. The canal itself, in the direction from the Timsah lake towards Port Said shows but a poor fauna; that of the bitter lakes is also poor with regard to different species, while the representatives of the few species that are there are excessively abundant.

The Comparative Action of Isomeric and Metameric Compounds on the Growth of Plants.—In an interesting paper on this subject, lately laid before the Royal Irish Academy by Prof. Emerson Reynolds, F.R.S., he calls attention to an apparently neglected subject, and he shows that well-marked differences in physiological activity can be detected with the aid of plants, even in cases of metameric bodies of comparatively simple constitution. The bodies he selected for experiment were ammonium sulphocyanate and its metamer, theocarbamide or sulpho-urea. Both compounds are rich in nitrogen, and therefore capable of supplying a highly important element of plant food; they are easily soluble in water. The experiments were made in the summer of 1881 on plants of *Nicotiana longiflora*. They lasted over three months—August to end of November; a certain number of the plants were watered with rain-water—a certain number with the compounds in solution, otherwise all the plants were exposed to the like conditions. The following were among the chief results:—

	Water-rain.	Theocarbamide.	Sulpho-cyanate.
Total height in inches	31	23	12
Number of leaves	15	14	13
Maximum length of leaves in inches	9·5	15·25	8
Maximum breadth ditto	4·25	6	2·5
Number of seed pods	9	15	0
Ditto well developed	1	11	0

It would then seem (1) that the particular elements of which a body is composed exert less influence on the physiological activity of the compound than the intra-molecular grouping of the component atoms; (2) that in some instances at least differences of physiological activity between metameric bodies can be easily detected by the aid of plants.

Caucasian Milk Ferment.—The inhabitants of the high-lying lands in the Caucasus prepare, by fermentation of cows' milk, a drink which they call kephir. Kephir is used by the inhabitants of the mountains not only as an article of food, but also as a remedy against different diseases. As a ferment in the preparation of this drink, strange white lumps are used, which have a spherical or elliptical shape, and attain the size of from 1 m. to 5 cm. On a microscopical examination of these lumps, they showed that they consisted of two different substances—yeast cells and bacteria. The yeast cells may be regarded as the ordinary form, produced by cultivation, of *Saccharomyces cerevisiæ*, but Kern was unable to get these to the spore-bearing stage. As to the bacteria, they composed the chief part of the little lumps, and were in the Zooglœa state. The vegetative bacteria cells were 3·2 m. to 8m. in length, and ·8 broad. In preparations put up by drying, a distinct cell membrane could be distinguished. Treated after Koch's method, the vegetative cells show at one end a locomotive organ, which resembles a cat-and-nine-tails, of threads. When exposed to the action of acids or a high temperature, the vegetative cells grow out [probably through progressive cell-divisions] into long Leptothrix threads, which change generally precedes the spore-formation stage. The spores are round, always formed in twos in each vegetable cell, and are always placed standing on their ends; even by making use of Hartnack's immersion X, no partition wall could be discovered between the spores. In the Leptothrix-threads rows of spores could be observed, which are, however, always so situated that two spores belong to each cell. The spores while still in the cells are ·8 m. in size; those lying free attain the size of 1 m.; the germinating spores swell up 1·6 m. The germination of the spores generally takes place in such a manner that an exosporium and an endosporium can always be distinguished in them. The thinner endosporium arises out of the thicker exosporium, first as a small excrescence, which gradually increases, developing more and more into a long cylindrical tube, and then begins by cell-division to form vegetative cells. The whole course of the development to the spore-formation, beginning with the vegetative cell to the formation of a similar new cell, was followed. This newly described form of Bacteria, which undoubtedly belongs to the Desmobacteria of Cohn, is in its vegetative state not unlike the *Bacillus subtilis* of Cohn; it is, however, clearly distinguished not only from it, but also from all other kinds of Bacteria hitherto described by its spore-formation, since it always forms in each cell two round spores placed end to end, while in the species of Bacteria hitherto described, only one spore has been noticed in each cell. On account of this sharply-marked feature Kern places this form of Bacteria in a new genus, next to the genus Bacillus, and calls it *Dispora caucasica*, nov. g. et nov. sp. A more exhaustive essay on this subject, with explanatory plates, Kern promises in the next number of the *Bulletin de la Société Impérial des Naturalistes de Moscow*.—Prof. Dr. J. N. Goroschankin assisted Kern by kindly furnishing him with the necessary materials for his work, for which Kern expresses his deepest thanks.—*Botanische Zeitung*, April 21, 1882, p. 264.

New Freshwater Sponges.—Mr. Edward Potts describes three more curious freshwater sponges in the *Proceedings* of the Academy of Natural Sciences of Philadelphia (January 10, 1882, p. 12). One found in September, 1881, near Chadd's Ford, is of a very delicate structure; its framework of skeleton spicules is exceedingly meagre, and slightly bound together, scarcely amounting to a mesh system, and the numerous small white statospheres are found in recesses far larger than themselves. This sponge has been called *Meyenia crateriforma*. Another, forming beautiful green masses, often four to five inches in diameter, and about a quarter of an inch in thickness, was found in Cobb's Creek, near Philadelphia. The surface is irregular, occasionally rising into rounded lobes; the efferent canals are deeply channeled in the upper surface of the sponge, five or six sometimes converging to a common orifice. The statospheres are numerous—rather small. There are two series of birotulate spicules, and it has been called *Heteromeyenia ryderii*. The third species was found at Lehigh Gap, Pa., in November, 1881, and belongs to the genus Tubella. This genus, established by Carter, contained only four species, all from the Amazon River. The new species is small, encrusting, and has been called *P. pennsylvanica*. The skeleton spicules are arranged in a simple series of single non-fasciculated spicules, in the interspaces of which the statospheres are abundant. These spicules are very variable in size and shape, but all are entirely and coarsely spined. The dermal spicules seem absent.

Molluscous Fauna of Moscow.—The molluscous fauna of the neighbourhood of Moscow was very little known until now, the two former works dealing with this subject, by M. Ratchinsky and M. Madéjine, giving only fifty-one species of Gasteropods, that is, only a half of this class of Molluscs which are to be found in the neighbourhood of Moscow. M. Milachevitch fills up this gap (*Bull. de la Soc. des Naturalistes de Moscou*, No. 2) by giving a list of the Molluscs of this region, his determinations of species having been made with the help of, or revised by M. Clessin and Dr. Böttger. It is worthy of notice that of the 109 species described, 11 belong to the region of the Alps, and 17 to the boreal region, 7 of them being common to both regions, and all the Alpine species having been widely spread in Germany during the Quaternary period. A remarkable feature of the Moscow molluscous fauna is the absence of the larger species of *Helix* (*H. pomatia*, *H. nemoralis*, *H. arbustorum*, *H. hortensis*, &c.), whilst they are frequent in other parts of the boreal region—to which the Moscow molluscous fauna belongs too—nearer to the sea. As to the southernlimits of the boreal region in Russia, it is difficult to determine it, but M. Milachevitch supposes it to follow a line drawn from Riga to Tamboff and Saratoff.

Peristaltic Intestinal Movements.—The movements of the intestine have been recently studied by the graphic method, by Signori Mosso and Pelicani (*Reale Ist. Lomb.*), experimenting both on man and the dog. Among other results it appears that at every movement of respiration there occur strong contractions of the rectum. Emotions and cerebral activity have a very manifest influence on the muscular fibres of the intestine, causing strong contraction. Besides so-called spontaneous undulations in the tracings, the direct cause of which is not known, it is possible, the authors prove, to contract at will portions of the intestine that are a considerable distance from the sphimeter muscle. The authors study the influence of changes of temperature on the tonicity of the intestinal walls, indicate the variations of the latter in sleep, digestion, and under influence of medicaments, &c., and show how intestinal movements are related to changes of volume in the forearm and blood-pressure in the carotid.

On the Occurrence of Root-florets in Catananche lutea.—A paper on this subject by B. Daydon Jackson, Sec. L.S., was read before the Linnean Society on May 4.—M. J. A. Battandier, in writing to Sir John Lubbock, pointed out the occurrence of certain large single florets produced directly from the roots of this yellow-flowered composite. Examination of the large series of specimens of this species contained in the herbaria at Kew and the British Museum, showed that these florets were to be found in almost every instance, frequently in great numbers, but usually overlooked from their great resemblance to scales of the root-stock. M. Battandier further stated that the fruit was twice the size of those contained in the normal capitula ; also that the root-florets were not cleistogamic, a fact confirmed by finding specimens showing the anther-tubes and stigmata projecting. Similar instances were also recorded as occurring in two species of Scnipus and a Myosotis.

CHEMICAL NOTES

The formulæ deduced by Guldberg and Waage in their general theory of action of mass have been recently applied, with satisfactory results, by R. Warder (*Amer. Chem. Journ.* iii. No. 5) to the case of saponification of ethylic acetate. W. Ostwald continues his work in the same field ; he has recently studied the actions which occur when certain pairs of salts are fused together in equivalent quantities. His general result is that those salts which have the greatest heats of formation are always produced in greatest quantity. Berthelot's so-called "law of maximum work," viz. that of several possible products of a reaction that salt, in the formation of which most heat is evolved, is alone produced, is regarded by Ostwald as erroneous ; if it were true, chemical equilibrium would be established only in those exceptional reactions wherein some of the reacting bodies underwent dissociation. Berthelot's statement is a return to the old hard and fast ideas on which "tables of affinity" were constructed, ideas long ago overthrown by C. L. Berthollet (*Journ. Pract. Chem.* xxv. 1).

Data continue to be accumulated showing more definitely that there exists a close connection between the structure of molecules and the physical properties of the substances composed of these molecules. Pawlewski has recently published a short account of his researches on the "critical temperatures" of liquid compounds : he states that the critical temperatures of isomeric ethers are identical or very nearly so, that isomers containing "doubly linked" carbon atoms have a higher critical temperature than those in the molecule of which the carbon atoms are singly linked, &c. (*Berichte*, xv. 460).

In an important paper bearing on the same general subject, E. Wilson states, as a result of his collation of many determinations of specific gravities of solids, that it is not justifiable to assign, as is usually done, a certain definite volume to each elementary atom in a compound molecule, but that the volume to be assigned to each atom in a compound molecule depends on the nature of all the atoms in the molecule (*Proc. R. S.*, 32, 457).

In continuance of his experiments on the effects of pressure on chemical changes—before referred to in these notes, Spring states that he has prepared Wood's alloy (melting at 65°) by compressing, at 7500 atmospheres, iron filings, with bismuth, cadmium, and tin, in proper proportions. He has also obtained Rose's alloy (lead, bismuth, and tin), and also brass, by pressure of the constituent metals (*Berichte*, 15, 595).

As the results of an extended series of observations on the structure of metals, Kalischer (*Berichte*, 15, 702) concludes that most of the metals are naturally crystalline, and that when the crystalline structure has been lost by mechanical treatment it can, in most cases, be restored by the action of heat.

PHYSICAL NOTES

An important contribution to physico-mechanical science has been made by M. Berthelot in a memoir communicated to the Académie des Sciences of Paris, upon the rapidity of propagation of a wave of explosion. An explosion in a gaseous compound propagates itself, it would appear far more rapidly than a sound wave could travel in the medium. For example, the velocity of sound in mixed oxygen and hydrogen gases is 514 metres per second, while the explosion propagates itself at 2814 metres per second. M. Berthelot concludes that the wave is therefore not an acoustic wave at all, but a wave of chemical action. The characteristics of this new mode of propagation appear to be the following: uniform velocity of propagation (through tubes); independence of this velocity of the material of the tubes ; tubes of lead and gutta-percha of equal calibre conveying the explosion at equal rates. The velocity in a capillary tube is slightly less than in a wide one, being 2390 metres per second for oxyhydric gas as against 2840 metres. The velocity differs in different mixtures, being 1080 metres per second in a mixture of oxygen and carbonic oxide. The velocity is independent of pressure which, in the experiments varied from 1 to 3 atmospheres. M. Berthelot attempts to identify this velocity with that of the translation of the gaseous molecules at the temperature attained in the explosion, as calculated from the formula of Clausius—

$$v = 29{\cdot}354 \sqrt{\frac{T}{\rho}} \text{ (metres per second) ;}$$

where T is the absolute temperature and ρ the density at 0° of the gas relatively to the air. He *assumes* T as 3000° in each case, which would give for the oxyhydric mixture a velocity of 2000 to 2500 metres per second and 1300 for carbonic acid. M. Berthelot therefore propounds the following view as to the way in which explosive action is propagated. In the film of gas first kindled a certain number of molecules are urged forward with a velocity corresponding to the maximum temperature of the chemical combination. Their shock against the neighbouring films determines there the commencement of chemical action, and so the movement proceeds, a uniform rate being observed except for those molecules which are close to the walls of the tube which give up in the form of heat a portion of their kinetic energy to the solid matter of the tube. A comparison with certain properties of sound waves leads one to doubt the finality of Berthelot's conclusion that these waves are not sound waves ; for Regnault formed a similar retardation of sound-waves in narrow tubes, and it is known that their velocity is independent of pressure, and that it increases with an increase of temperature, and that the temperature which determines the velocity is not the temperature of the mass as a whole but the temperature of the molecules in the actual wave for the time being. The recent experiments of Galloway and of Abel on the propagation of an explosion in air charged with dust and contaminated with gas appear to deal with quite another phenomenon, namely, the velocity of spread of combustion in a space containing particles of solid matter floating in the air, and which has no more direct relation to the velocity of sound than has the velocity with which combustion is propagated along a train of gunpowder or a piece of slow-match.

Another contribution to experimental acoustics we owe to Mr. John Le Conte of California, who has published in the *American Journal of Science* some observations on sound-shadows in water. More than fifty years ago, when Colladon and Sturm were measuring the velocity of sound in the waters of the Lake of Geneva, Colladon remarked on the extreme sharpness with which an acoustic shadow was cast by a projecting wall that ran out into the lake. The greater sharpness of shadows might be expected from the mathematical theory of undulations, for waves of higher pitch than for those of lower, as the wave-lengths of the former are shorter, and therefore less liable to diffraction at the edges of acoustically opaque objects Mr. Le Conte's experiments were almost all made with the waves produced by the explosion of cartridges of nitroglycerine, each containing 15 lbs. of the explosive stuff. These cartridges were being used in blasting a shallow reef in the harbour of San Francisco, and the means taken to observe the propagation of the shock consisted in sinking soda-water bottles and glass tubes filled with air, so as to be wholly or partially concealed behind solid objects such as wooden piles. A cartridge was exploded about 40 feet away from a pile about 12 inches in thickness ; behind this obstacle, and for a distance of 12 feet behind it, a sharply defined sound-shadow could be traced. Another instance is given in the singular preservation of buildings on the occurrence of an explosion at San Francisco when situated within the geometrical shadow of other buildings. Mr. Le Conte seeks to explain the relative sharpness of shadows of explosive sounds by supposing that in this case the very short impulse gives rise to a disturbance whose wave-length is exceedingly short. In connection with the subject, it may be worth while to recall Lord Rayleigh's beautiful experiment on the sound-shadow behind an opaque circular disk, where (as in the case of light for which, as predicted by Poisson and verified by Arago, there is a luminous point at the centre of the shadow), at the centre of the acoustic shadow, a perceptible augmentation of the shrill note of a bird-whistle was observed.

The old device of exploring the vibrating column of air in an organ-pipe to ascertain the position of nodes and loops, by letting down into it a membrane of tissue paper on a wire frame, is familiar. König's method of introducing a small tube communicating with a manometric capsule and a flame indicator, was recently described in our Physical Notes. The latest device for a similar purpose is that of M. Serra-Carpi, who introduces a small microphone supported on an elastic membrane stretched over a wire ring. The microphone is connected by wires to a telephone and a battery. Hardly any sound is heard except when the exploring microphone is at a node, when it causes a buzzing sound to be heard in the telephone. The objection to all these methods is that the pressure of the explorer alters the position of the nodes in the tube. König's apparatus is probably least open to this objection, but it requires a special piece of apparatus of an expensive kind.

THE JOINTING OF ROCKS AND THE CHANNEL TUNNEL[1]

THE writer, referring in the first instance to his "Report" on Jointing, published in vol. xxv. (1875) of the *Transactions* of the Royal Irish Academy, in which the subject is treated of in its purely geological aspect,[2] remarks that his investigations in connection with it entitle him to take a part in the discussion of a question in engineering, which public enterprise has of late elevated to one of international importance.

At the outset, however, he feels himself compelled to express his doubts that rock-jointing has been sufficiently attended to by the active promoters of the proposed Channel Tunnel.

The remarkable divisional structure under consideration, often taken to be analogous to ordinary cracks or fractures due to rock-disruption, is, in the opinion of Prof. King, a phenomenon having only a distant relation in its origin to the latter.

In its normal state, jointing is a fissured condition of rocks—the fissures presenting even, smooth, regular, and close-fitting conjunctive planes, often standing vertically, or in an inclined position. Where the fissures have been affected by stratic disturbances, or have been acted on by water and other erosive agencies, they are more or less open, thereby converted into "crevices." It divides both sedimentary beds and igneous masses; and is separable into two or more series or systems, each having its respective fissures running in parallelism, also in a definite and an independent direction, over areas hundreds of miles in extent; and descending to considerable depths below the earth's surface. The fissures vary in their distance from one another from under half an inch to two or more feet.

That jointing demands the closest attention on the part of engineers engaged in sub-aqueous works requires no other proof than the fact of the utter failure which attended the scheme for opening out, during the famine of 1845-48, a water communication, about four miles in length, between Lough Corrib and Lough Mask, in the west of Ireland. After an expenditure of 40,000*l*. it was found that the jointing in the carboniferous limestone, through which the excavation had been made, carried off all the water. The work had, therefore, to be abandoned; thus resulting in nothing more than a dry ditch!

As regards the chalk and other rocks to be penetrated for the Channel Tunnel, Prof. King admits that they may not be so highly jointed as the much older carboniferous limestone; nevertheless, he shows that the former deposits are not altogether free from dangers, which, to be overcome, require the closest attention.

From the numerous occurrences, noticed by writers, and observed by himself, of faults, true jointing,[3] ordinary disruptive fractures, inclined bedding openings, dry submarine swallow-holes of Pliocene age (now filled with clay, sand, gravel, in some cases containing sub-fossil sea-shells) and rock porosity in the chalk formations of Kent, Prof. King infers that these detriments are equally present in the same deposits, well known to exist at the bottom of the Channel; where some of them cannot but turn out to be sources of water-leakage, greatly interfering with the success of the proposed Channel Tunnel.

Precisely similar detriments, giving rise to the same apprehensions are to be met with on the opposite seaboard of France. Reference may be made to the great lines of fracture which have moulded the river-drainage system of the Bas Boulonnais; and especially to the marvellous jointing (represented by the distinguished geologist, M. Daubrée, in his "Etudes Synthétiques de Géologie," parte prem.), which vertically intersects the chalk cliffs near Tréport, north of Dieppe.

Still, such serious drawbacks Prof. King admits must not be held as unsurmountable. He is fully satisfied that engineering in the present day is quite able to cope with them; but only by an enormous expenditure. It has been proposed to line the Tunnel with concrete; but in his opinion it is absolutely necessary that nothing short of lining it, and in its entire length, with the most resisting, impervious, and endurable stone, should be attempted.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The accommodation recently provided for practical biological work has already proved seriously deficient, owing to the rapid growth of the classes in physiology and comparative morphology. The class-room for practical morphology was built to accommodate thirty students working at the same time, and the room for histology, 36. Additional temporary accommodation has been made for an increased number of students, but there are grave inconveniences in consequence. This year there are about fifty-five students in elementary morphology, and twenty in the advanced class; seventy students attend elementary physiology, and about fifteen the advanced course. The only possible alternative to the provision of new rooms, is the division of classes into sections, and repeating the practical work with each section; rendering a large increase in teaching power necessary. Moreover, such an arrangement will interfere with the rule that the practical work belonging to the lecture is gone through immediately after. Under these circumstances it is recommended by the Museums and Lecture Rooms Syndicate that a third floor should be added to the New Museum Building in its central portion, giving a new class-room sixty feet long, and new private rooms for Mr. Balfour's classes, while Mr. Balfour's present class-room could be added to Dr. Foster's department. The cost is estimated at about 1500*l*.

The increasing need for a new lecture-room for biology has not been lost sight of; and it is suggested that it will be advisable to adapt the present bird-room to the purposes of a lecture-room; while the Museum of Comparative Anatomy should be extended so as to be capable of accommodating the birds. This alteration would necessarily involve considerable expense, and it is postponed for the present.

Part I. of the Natural Science Tripos will begin on May 22; Part II. on June 1.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 3.—Photometric researches, by E. Ketteler and C. Pulfrich.—Theory of elliptical double refraction, by E. Lommel.—On differences of tension between a metal and liquids of different concentration, by E. Ketteler.—On galvanic conbinations consisting only of elements, and on the electric conductivity of bromine and iodine, by F. Exner.—Reply to an observation by Herr F. Exner, on Volta's fundamental experiment, by F. Schulze-Berge.—Vaporisation, fusion, and sublimation, by M. Planck.—On new electric figures, and on the gliding of electric sparks, by K. Antolik.—Representation of longitudinal and transversal waves by projection, by R. Weber.—On the theory of stationary motion, by S. Oppenheim.

Kohlrausch.—Tangent-compass for absolute measurements, mirror-galvanometer, electro-dynamometer, and magnetometer free of metal, by the same.—Remarks on the mechanical bases of the laws of Ohm and Joule, by E.

---

[1] Abstract of a paper "On the Jointing of Rocks, in Relation to Engineering, especially the Tunnelling of the Strait of Dover," by William King, D.Sc., Professor of Mineralogy and Geology, Queen's College, Galway, read April 24 at the Royal Irish Academy, Dublin.

[2] Jointing in its relation to Physical Geography has been lately treated of by the author in "Thalassa and Xera in the Permian Period," appended to the work—An Old Chapter of the Geological Record, &c., by Professors King and Rowney.

[3] The "many small faults" and "very marked and constant joints"—the latter sometimes containing infiltrated flint—which characterise the chalk "cliffs in many places near Margate" (Whitaker) must be familiar to numbers of the citizens of the metropolis. "Numerous vertical crevices," doubtless originally jointing, intersect a bed of chalk fifty feet thick, close to Dover, at the base of Shakespeare's Cliff.—(W. Phillips.)

Budde.—Experimental researches on the intensity of diffracted light, II., by J. Fröhlich.—Some observations on the works of Herren Lommel, Glazebrook, and Mathieu, by E. Ketteler.—On the condensation of gases on surfaces, by H. Kayser.—Researches on the dependence of the molecular refraction of liquid combinations on their chemical composition, by H. Schröder.—On Legrange's equations of motion, by B. Weinstein.

Journal of the Franklin Institute, April.—A new theory of the suspension system with stiffening truss, by A. J. du Bois (concluded).—Adaptation of Euler's formula to American long column experiments, by W. H. Barr.—The Flannery boiler-setting for the prevention of smoke, by C. A. Ashburner.—Milk, by F. Haines.—The fire-underwriters' regulations respecting the use of the electric light.—On the filtration of water for industrial purposes, by P. Barnes.—The sugar-beet industry, by L. S. Ware and R. Grimshaw.—The Hudson River tunnel, by S. H. Finch.

Bulletins de la Société d'Anthropologie de Paris, tom. iv. fasc. iv. Paris, 1881.—This, the latest quarterly number of the *Bulletins*, contains the concluding part of M. Topinard's paper on his facial goniometer.—Observations by L. Manouvrier on the relations between the weight of the cranium and that of the maxillaries and the femur, with a view of trying to determine the relations between the several parts of the body connected with the cerebral, digestive, and motor functions.—Reports by M. Ledouble of a case of variation in the clavicular trapezius; and on the occurrence in man of the abnormal muscle named by Wood, the supercostalis"; a case of atavism in the occurrence, in a woman, of the flexor profundus digitorum of the ourang-outang, by M. Chuzinski.—On the crania of criminals preserved at Brest, by M. Corre.—On the craniology of criminals, by Dr. Ardouin, who also contributes an interesting paper on the results of the Medical Statistical Tables of Japan, published at Tokio in 1880.—M. Leon Metchnikoff gives the result of his ethnological observations while in Japan on the different races occupying the country, and his views as to their probable origin.—M. Verneau considers the type and origin of the ancient inhabitants of the Canaries; and M. Manouvrier describes at great length the result of his observations on eleven natives of Tierra del Fuego, in the Jardin d'Acclimatation, at Paris. His remarks gave rise to prolonged discussions among the Members of the Society, and were supplemented by a communication from M. Topinard, based on personal observation of these savages, and by a *résumé* by M. Hovelacque of all that is known of the people and their country, through the reports of English and French travellers.—M. Magitot describes the abnormal characters of a dwarf, presented last October by Baron Larrey to the Académie de Médecine; and M. de Quatrefages reports the case of a dwarf smaller than Tom Thumb, and in whom, he believed, that the disproportionally large size of the head was due to hydrocephalus.—M. Parrot brought forward a case of megaloglossis, combined with idiocy, in a child of two years of age.—M. Laborde presented to the Society his essay on the experimental and morphological function of the semi-circular canals in animals, in which be believes we may discover that of a "sensitvo-motor" apparatus, intended to render the sense of hearing more complete. M. Delaunay, in summing up the conclusions he has arrived at in his labours in the field of general pathology, considered the various degrees of liability towards certain diseases shown at different ages, by either sex, and among different races. The only contributions towards palæontological inquiry contained in this number are: M. Hamy's report of the progress of the excavations at Bollwiller, whose deposits would appear to belong to the latest neolithic age; Prof. Carl Vogt's communication of the discovery by M. Roth, in the Pampas of La Plata, of a human skeleton lying below the carapace of a fossil glyptodon; and the presentation, by M. Vinson, of a chromolithographic reproduction of a celto-iberian inscription, found near Siguenza. M. Vinson is of opinion that we have as yet no authority for accepting the theory of any close affinity of the Basques with the ancient Iberians.

Memorie della Società degli Spettroscopisti Italiani, March.—Solar observations made at the Royal Observatory of Palermo in the fourth quarter of 1881, by Prof. Ricco.

SOCIETIES AND ACADEMIES

London

Zoological Society, May 2.—Prof. W. H. Flower, LL.D., F.R.S., president, in the chair.—Before commencing the usual proceedings, the president called attention to the fact that one of the communications made to the previous meeting was from the pen of Mr. Charles Darwin; and took the opportunity of referring to the labours and character of the illustrious naturalist, whose work had so profoundly modified not only zoological science, but so many other departments of human thought.—Mr. Sclater exhibited a drawing of a Tapir presented to the Society by Mr. Fritz Zurcher in August last, which had been captured on the Yuruari River in Venezuela. Mr. Sclater observed that in form and colour this animal seemed to agree better with *Tapirus dowii* than with the ordinary *T. americanus*, and suggested that it was quite likely that the former species might be the Tapir of the northern coast-region of Columbia and Venezuela.—Mr. J. E. Harting, F.Z.S., made some remarks on the desirability of adopting a standard of nomenclature when describing the colours of natural objects.—Dr. Hans Gadow, C.M.Z.S., read a paper on the structure of feathers in relation to their colour, in the course of which he endeavoured to show how the optical appearances of the various colours met with in the feathers of birds were produced.—Prof. Flower, F.R.S., gave an account of the cranium of a Cetacean of the genus *Hyperoodon* from the Australian Seas, upon which he proposed to found a new species, *H. planifrons*.—A communication was read from Dr. O. Staudinger containing the description of some new and interesting species of Rhopalocera from the New World.—A communication was read from Mr. H. J. Elwes, F.Z.S., containing a description of a collection of butterflies made on the Tibetan side of the frontier of Sikkim, amongst which were examples of several species new to science.—A communication was read from Mr. Edgar L. Layard, F.Z.S., describing a new species of Parrot of the genus *Nymphicus* from Uvéa, one of the Loyalty group, which he proposed to call *Nymphicus uvænsis*.

Geological Society, April 16.—J. W. Hulke, F.R.S., president, in the chair.—The President remarked that it would argue a degree of indifference with which the Society could not be charged, if the meeting were to proceed to the transaction of the ordinary business, without some reference to the sad loss sustained by the whole scientific world within the last few days, in the death of that illustrious naturalist, whose remains had been consigned that morning to their last resting-place at Westminster. He added that the spectacle presented by the vast assemblage of people who came together to witness the obsequies of Mr. Darwin, was of the most soul-stirring kind, and constituted the grandest conceivable testimony of respect for the memory of the distinguisbed philosopher who had just passed from among us.—S. S. Buckman, Hugh Salvin Holme, Collet Homersham, and Joseph B. Tyrrell were elected Fellows of the Society.—The following communications were read:—On fossil Chilostomatous Bryozoa from Mount Gambier, South Australia, by Arthur W. Waters, F.L.S., F.G.S.—*Thamniscus*: Permian, Carboniferous, and Silurian, by George W. Shrubsole, F.G.S.—On the occurrence of a new species of *Phyllopora* in the Permian limestones, by George W. Shrubsole, F.G.S.—On the relations of the Eocene and Oligocene strata in the Hampshire Basin, by Prof. John W. Judd, F.R.S., Sec.G.S. The section at Whitecliff Bay, in the Isle of Wight, affords us the means of determining the true order of succession of nearly 2000 feet of Tertiary strata, and is therefore employed as a standard to which to refer the strata seen in sections where the order of succession is not so clear. The author supported the views of Prof. Prestwich as to the limits of the Bracklesham series, as opposed to the opinions expressed on the subject by the Rev. O. Fisher. He pointed out the confusion which has arisen from the correlation of certain strata in the Hampshire basin with the barren Lower and Upper Bagshots of the London area, in which fossils are so rare as to render their geological age somewhat doubtful. To the Lower Bagshot some authors have referred 660 feet of the strata seen at Alum Bay; while other authors have restricted that name to about 73 feet of the same section. The age of the Upper Bagshot of the London basin is admitted by all authors to be very doubtful. The only way to avoid the confusion unavoidable from using the same names for strata, the correlation of which was so hypothetical, was to employ local names for both sets of beds. He proposed to refer to the freshwater sands below the Bracklesham and Bournemouth strata, containing a distinctive flora, as "the Studland beds," and the sands above the Barton clay by the old name of "the Headon Hill Sands." Above these sands are a series of clays only about 40 feet thick at Whitecliff Bay, but much thicker at Headon Hill and Hordwell Cliff. These sands and clays form the Headon group; they consist of freshwater strata with bands of limestone and lignite, but including numerous inconstant intercalations of layers containing marine shells, for the most part much dwarfed. The age of the Headon group, as shown by the fossils which it contains, is that of "the zone of *Cerithium concavum* of continental authors. The brackish-water Headon group is succeeded at Whitecliff Bay by nearly 100 feet of purely marine strata. These marine beds, which had been shown to rest on an eroded surface of the Headon beds, contain the remarkable fauna which had been recognised by many British and foreign geologists as that of the Lower Oligocene. Similar strata with the same fossils are found in the New Forest, at Lyndhurst, Brockenhurst, Roydon, and other points, and there also attain a considerable thickness. It was pointed out that this marine series is quite distinct from the Headon, or zone of *Cerithium concavum*, with which it had been confounded. The author had been very severely criticised for the views which he had put forward in a former paper as to the manner in which the Brockenhurst series is represented in the section at the west end of the Isle of Wight. There was much difficulty in these variable estuarine beds in correlating the beds seen in Colwell Bay with those exposed in the cliffs of Headon Hill. With several previous authors on the subject, he maintained that the great series of sandstones and limestones forming Warden Point and How Ledge are continuous with those exposed in the face of Headon Hill, and, consequently, that the marine beds of Colwell Bay, overlying those limestone series are younger than the brackish-water bands interstratified with the Heddon beds of Headon Hill. His critics, however, insisted that these two beds agreed with one another in such a manner that they must be regarded as parts of the same bed, separated by denudation. In opposition to this view, it was pointed out that the Colwell Bay bed is of the most inconstant character, and long before reaching Headon Hill is seen to be on the point of thinning out and disappearing altogether. In conclusion, the author pointed out that his own interpretation of the succession and correlation of the strata in the Hampshire basin brings them into complete harmony with that which is maintained by the great majority of continental geologists, while that of his critics appeared to be hopelessly irreconcileable with their views.

Chemical Society, May 4.—Dr. Gilbert, president, in the chair.—Prof. J. Dewar, F.R.S., delivered a lecture on the recent development of the theory of dissociation. The lecturer, after referring to the earlier work of Black on "Physical Chemistry," pointed out the origin of the term dissociation, and the experiments made thereon by Deville. Troost proved that dissociation is a function of the temperature, that it is independent of mass, and that the action is reversible; the process resembles in many respects the condensation and volatilisation of a vapour. The experiments in which vapours are conducted along heated porous tubes, only prove that dissociation takes place, but do not tell us the extent of the dissociation. Exact determinations of the partial pressures obtained by heating various substances, as ammoniochloride of silver, water, &c., to certain temperatures have been made, and thus curves have been drawn, which, by inspection, show the pressure necessary to prevent the decomposition of a substance at any particular temperature. Recent investigations have shown that solid substances have a temperature analogous to the "critical point" of gases, above which they cannot exist; thus, when hydrogen sulphide and water are subjected to great pressure at low temperatures, a crystalline hydrate is formed, but above 40° C. this substance cannot be shown to exist, however great the pressure may be. If a mixture of hydrogen and iodine be heated to about 300° C., some hydriodic acid is formed; if hydriodic acid be heated to 300° C., free hydrogen and iodine are formed, and the resulting mixture of hydrogen, iodine, and hydriodic acid has in each case the same composition. The lecturer then explained the cycle of Carnot, and showed how a formula could be deduced from it, by which the latent heat of a chemical compound could be calculated. The importance of the researches of Andrews on the liquefaction of carbon-dioxide was insisted upon, and the analogy of some of the results with the dissociation of chemical bodies pointed out. In conclusion, the author discussed the probability of the dissociation of elements in the sun's atmosphere, and reasoning from a legitimate extension of the known laws of dissociation, inferred that if hydrogen be considered as the elementary form of matter, the sun's atmosphere is most unfavourable to dissociation.

Anthropological Institute, April 25.—Hyde Clarke, vice-president, in the chair. It was announced that Alfred Morrison, F.G.S., and Frederick Harold had been elected Members of the Institute.—The Chairman referred at some length to the great loss that anthropological science had suffered by the death of Mr. Darwin, an Honorary Member of the Institute; Prof. Flower, F.R.S., also offered a tribute to Mr. Darwin's memory. Mr. E. H. Man read a second paper on the aboriginal inhabitants of the Andaman Islands. He touched first upon the important subject of language, and pointed out certain peculiarities connected with the varying use of several sets of possessive pronominal adjectives with particular classes of nouns: in expectation at an early date of a paper on the South Andaman language by the president of the Philological Society, this subject was but briefly dealt with by the author, who next proceeded to describe the Andamanese system of adoption and the recognised degrees of affinity, especially as bearing on the question of marriage, bringing to notice at the same time the erroneous opinions hitherto held on this latter point, as also anent their death and burial customs. Numerous superstitions, beliefs, and traditions were related, the latter treating of the account given by the aborigines regarding the Creation, Deluge, and Dispersion. Mr. Man was careful to state that he had taken the precaution to obtain his information from members of distant tribes who had had no opportunity of intercourse with Europeans or other aliens residing at Port Blair, and added that it was extremely improbable, for the reasons noted in his paper, that any previous generations of these islanders, within historic times, by whom these traditions had been handed down, could have obtained their versions from strangers.

Royal Horticultural Society, April 25.—Sir J. D. Hooker, in the chair.—*Larches attacked by larvæ:* Mr. Maclachlan reported upon some specimens of larch twigs received from Mr. R. Clutton, of Hartwood, Reigate, who stated that thousands of young larches were attacked by larvæ at Box Hill—"the affected trees swarm with little grubs which move about in their cocoons, and seem to suck the juices from the young foliage, leaving it dead, and so kill the trees." They proved to be the larvæ of a minute moth, *Coleophora laricella*, which lays its eggs on the twigs or buds. The larvæ hatched in autumn construct cases of cuticle, &c. The young *autumn* larvæ attach their cases to the young leaves in spring, which they soon mine and destroy. Mr. Maclachlan is of opinion that the damage done by this insect is not likely to seriously injure larches. He remarked that Box Hill being chalk and dry, was not well suited for the growth of larches.—*Fertilisation of Hoya:* Mr. W. G. Smith referred to this subject, and exhibited flowers with flies attached to the glutinous disks of the pollen-masses. The Hoya is highly fragrant. This fragrance is very attractive to insects, which are necessary for fertilisation of this plant. The pollinia are concealed, excepting the dark viscid disks, which are exposed. When an insect alights on the flowers, one foot at least slips and gets caught by one of the fine little glutinous disks. In its effort to escape two, three, or even four other feet are almost sure to get similarly caught. The insect then tries with all its power to free its limbs. If successful the pollen-masses are withdrawn out of the pouches by the feet. The basal appendages of each pair of pollinia are elastic, and when in the pouch they are like an extended spring, but the instant the masses are drawn out, the spring closes, and the two pollen masses quickly cross each other and hold tightly on to the insect's little claws. If the insect is weak, it cannot withdraw its legs at all, and so perishes on the flower; but if strong, it flies away with one to five pairs of pollinia clasped round its feet. Sometimes an insect breaks part of its leg off in trying to withdraw it. The five stigmas are not ready to receive the pollen at the time the pollen is mature; so that it is only when the insect realights on some neighbouring Hoya-flower in a more advanced stage of growth that cross-fertilisation takes place by its treading on the exposed stigmas.

EDINBURGH

Royal Society, May 1.—Mr. Milne Home, vice-president, in the chair.—Prof. Piazzi Smyth, Astronomer-Royal for Scotland, read a paper on some points in the meteorology of Madeira, both absolute and comparative. By a careful comparison of the mean monthly temperatures, the maximum temperatures, and the mean daily range, during the months of June and July at Madeira and Lisbon, it appeared that the temperature at the former was markedly more equable. A like comparison was also instituted for the corresponding *annual* variations at Madeira, Lisbon, Jerusalem, and Scotland, and the same wonderful equableness was shown to exist. Observations with the wet- and dry-bulb thermometer, and spectroscopic indications of the "rain-band" proved the climate of Madeira to be at the same time remarkably humid, which at once explains its cold summers and warm winters. This striking humidity the author traced to the influence of the Gulf Stream, a branch of which trends south from the Bay of Biscay past the coast of Portugal. That the ocean waters around Madeira are peculiarly warm, was demonstrated by the late Sir Wyville Thomson in the *Challenger* Expedition. The abundant presence of watery vapour in the atmosphere also seems to have a marked influence upon the flora and fauna, which are very different from what would be expected when latitude alone is considered.—Mr. P. Geddes communicated a paper by Mr. F. E. Beddard, B.A., on the anatomy and histology of *Pleurochacta Moscleyi*, a new genus and species of earthworms, which had been brought home by Prof. Moseley from Ceylon. The chief characteristics of this species noted were, that the setæ are not arranged in continuous lines round the body, but in two lateral groups, that there are no segmented organs, and that the capillaries extend into the hypoderm, as in the leech.—Prof. Heddle, in the first of three notes, described a leaf-bed which he had discovered at the base of a high precipice at the north-west corner of the island of Canna. The bed consists of a highly laminated brown clay, easily split by tapping or by inserting the edge of a knife. This clay, when it comes down to the water's edge, is acted upon by the waves to form the so-called Fuller's earth. In the second note, the author intimated that the inner Hyskier—a group of skerries some nine miles from Canna—was formed of the pitchstone porphyry of the Scuir of Eigg, which is about twenty-two miles distant. The third note related to a supposed organism from the marble of Sutherland, which the author, from his intimate acquaintance with the structure and mode of occurrence of minerals, was certain was not a mineral. A specimen had been sent to Dr. Carpenter, who, without any knowledge as to where it had been got, described it as being very Eozooic.—Mr. J. Aitkin communicated a brief note on the selective absorption of sea-water for light, on which he had made some spectroscopic observations.

PARIS

Academy of Sciences, May 1.—M. Jamin in the chair.—The death of Mr. Darwin was commented upon by the President and by M. de Quatrefages.—On some reactions of bichloride of mercury, by M. Debray.—On the employment of liquefied gases, and particularly ethylene, for production of low temperatures, by M. Cailletet. A thermometer immersed in liquid ethylene indicated about – 105°; whereas protoxide of nitrogen boils at – 88°. In utilisation the liquid was, on opening an orifice in the receiver, projected through a glass tube on the apparatus to be cooled. Suddenly diminishing the pressure of compressed oxygen cooled to at least – 105°, one observes tumultuous ebullition for a little; (at – 88° oxygen gave merely a fine mist). Ethylene has the property of remaining liquid and transparent at temperatures where protoxide of nitrogen and carbonic acid become solid and opaque.—Separation of gallium, by M. Lecoq de Boisbaudran.—Report on a memoir of M. C. Stephanos, entitled "Memoir on Groups of Binary Forms having the same Jacobian."—Determination of the difference of longitude between Paris and Besançon, by MM. Barnaud and Leygue. A chronometric observatory is being founded at Besançon, for the benefit of the watchmaking industry there, and the difference of longitude between the site chosen and the Montsouris Observatory is found to be 14m. 36·267s.—Developments in series of a holomorphous function in an area limited by arcs of the circle, by M. Appell.—On certain ternary quadratic forms, by M. Picard.—On photographs of the spectrum of the nebula of Orion, by Prof. Draper.—On the polarisation of electrodes and on the conductivity of liquids, by M. Bouty. From experiments in which the electromotive method of M. Lippmann was applied to measuring the conductivity of acidulated water with a very weak electromotive force (*e.g.* that of a zinc-cadmium element), he concludes that a liquid has only one way of conducting electricity (not *two*, an *electrolytic* and a *metallic*, as some physicists suppose), whatever the special phenomena of the electrodes.—Influence of a metal on the nature of the surface of another metal placed at a very small distance, by M. Pellat. Two metal surfaces placed opposite each other at an interval of a few millimetres or tenths of a millimetre, have their superficial layers temporarily altered (as one finds on measuring the difference of potential); after separation the change gradually disappears. The author regards the action as not electric, but purely material, and depending on the nature of the influencing metal (it is great with lead, less with copper, *nil* with zinc). Metals seem to emit, at ordinary temperature, a volatile substance, which, deposited on the surface of objects, chemically modifies their nature.—On the liquefaction of ozone, by MM. Hautefeuille and Chappuis. By compressing, at about 125 atm., a mixture of oxygen and ozone in a bent tube, part of which was cooled with a jet of liquid ethylene (see above), they obtained ozone in liquid drops of a dark indigo blue colour. The vaporisation of the liquid is not very rapid, even at atmospheric pressure.—Action of insoluble metallic sulphides on a solution of acid sulphate of nickel in presence of sulphuretted hydrogen, by M. Baubigny.—Oxidation of pyrogallol in presence of gum arabic, by MM. de Clermont and Chautard.—Chemical study of various products of Uruguay, by M. Sace. This relates to caoutchouc from various fig trees, the camphor tree, a blue-flowered vetch, and chickweed.—Observations relative to a group of fossil Suidæ, whose dentition has some Simian characters, by M. Filhol. These fossils are from the upper eocene. Other points of similarity are the shortening of the skull and the form of the temporo-maxillary articulation.—Researches on the anatomy of some Echinida, by M. Kahler.—The Grotto Lympia, by M. Riviere. He finds evidence of the contemporaneity of the brecciform deposits of this grotto (discovered at Nice in 1878, and containing remains of *Elephas*, *Lagomys*, *Capraprimigenia*, *Cervus*, *Bos*, &c.), with quaternary man.—On the reptiles found in the gault of the east of France, by M. Sauvage. Eleven have been discovered. *Inter alia*, crocodiles existed of much larger size than those of the Cambridge strata. The principal Dinosaurian was a *Megalosaurus* (*superbus*) of gigantic size, differing in several features from the *M. Bucklandi* of the oolite in England.—A hypsometric map of the rivers of European Russia, by Col. de Tillo, was presented by M. Daubrée. It is observed that the principal water-courses of that country change pretty abruptly in general direction. M. Holtz noted several observations relative to intermittent springs.

THURSDAY, MAY 18, 1882

CHARLES DARWIN

I.

THE object of this notice is to give a brief account of the life, and a proportionately still more brief account of the work, of Mr. Darwin. But while we recognise in him perhaps the greatest genius and the most fertile thinker, certainly the most important generaliser and one of the few most successful observers in the whole history of biological science, we feel that no less great, or even greater than the wonderful intellect was the character of the man. Therefore it is in his case particularly and pre-eminently true that the first duty of biographers will be to render some idea, not of what he did, but of what he was. And this, unfortunately, is just the point where all his biographers must necessarily fail. For while to those favoured few who were on terms of intimate friendship with him, any language by which it is sought to portray his character must seem inadequate, to every one else the same language must appear the result of enthusiastic admiration, finding vent in extravagant panegyric. Whatever is great and whatever is beautiful in human nature found in him so luxuriant a development, that no place or chance was left for any other growth, and in the result we beheld a magnificence which, unless actually realised, we should scarcely have been able to imagine. Any attempt, therefore, to describe such a character must be much like an attempt to describe a splendid piece of natural scenery or a marvellous work of art; the thing must itself have been seen, if any description of it is to be understood.

But without attempting to describe Mr. Darwin's character, if we were asked to indicate the features which stood out with most marked prominence, we should first mention those which, from being conspicuous in his writings, are already more or less known to all the world. Thus, the absorbing desire to seek out truth for truth's sake, combined with a characteristic disregard of self, led not only to the caution, patience, and candour of his own work—which are proverbial—and to the generous satisfaction which he felt on finding any of his thoughts or results independently attained by the work of others; but also to a keen and vivid freshness of interest in every detail of a new research, such as we have sometimes seen approached by much younger men when the research happens to have been their own. And indeed what we may call this fervid youthfulness of feeling extended through all Mr. Darwin's mind, giving, in combination with his immense knowledge and massive sagacity, an indescribable charm to his manner and conversation. Animated and fond of humour, his wit was of a singularly fascinating kind, not only because it was always brilliant and amusing, but still more because it was always hearty and good-natured. Indeed, he was so exquisitely refined in his own feelings, and so almost painfully sensitive to any display of questionable taste in others, that he could not help showing in his humour, as in the warp and woof of his whole nature, that in him the man of science and the philosopher were subordinate to the gentleman. His courteous consideration of others, also, which went far beyond anything that the ordinary usages of society require, was similarly prompted by his mere spontaneous instincts of benevolence.

> For who can always act? but he
> To whom a thousand memories call;
> Not being less but more than all
> The gentleness he seem'd to be,
>
> Best seem'd the thing he was, and join'd
> Each office of the social hour
> To noble manners, as the flower
> And native growth of noble mind;
>
> Nor ever narrowness or spite,
> Or villain fancy sweeping by,
> Drew in the expression of an eye,
> Where God and Nature met in light.

And this leads us to speak of his kindness, which, whether we look to its depth or to its width, must certainly be regarded as perhaps the most remarkable feature of his remarkable disposition. The genuine delight that he took in helping every one in their work—often at the cost of much personal trouble to himself—in throwing out numberless suggestions for others to profit by, and in kindling the enthusiasm of the humblest tyro in science; this was the outcome of a great and generous heart, quite as much as it was due to a desire for the advancement of science. Nothing seemed to give him a keener joy than being able to write to any of his friends a warm and glowing congratulation upon their gaining some success; and the exuberance of his feelings on such occasions generally led him to conceive a much higher estimate of the importance of the results attained than he would have held had the success been achieved by himself. For the modesty with which he regarded his own work was no less remarkable than his readiness enthusiastically to admire the work of others. In fact, to any one who did not know him well, this extreme modesty, from its very completeness and unconsciousness, might almost have appeared the result of affectation. At least, speaking for ourselves, when we first met him, and happened to see him conversing with a greatly younger man, quite unknown either in science or literature, we thought it must have been impossible that Mr. Darwin—then the law-giver to the world of biology—could with honest sincerity be submitting, in the way he did, his matured thought to the judgment of such a youth. But afterwards we came fully to learn that no one was so unconscious of Mr. Darwin's worth as Mr. Darwin himself, and that it was a fixed habit of his mind to seek for opinions as well as facts from every available quarter. It must be added, however, that his tendency to go beyond the Scriptural injunction in the matter of self-approval, and to think of *others* more highly than he ought to think, never clouded his final judgment upon the value of their opinions; but, spontaneously following another of these injunctions, while proving all things, he held fast only to that which was good; in malice be ye children, but in understanding be ye men.

On the whole, then, we should say that Mr. Darwin's character was chiefly marked by a certain grand and cheerful simplicity, strangely and beautifully united with a deep and thoughtful wisdom, which, together with his illimitable kindness to others and complete forgetfulness of himself, made a combination as lovable as it was venerable. It is, therefore, not to be wondered at that no man ever passed away leaving behind him a greater void of enmity, or a depth of adoring friendship more profound.

But, as we have said, it is impossible to convey in words any adequate conception of a character which in beauty as in grandeur can only, with all sobriety, be called sublime. If the generations are ever to learn, with any approach to accuracy, what Mr. Darwin was, his biographers may best teach them by allowing this most extraordinary man to speak for himself through the medium of his correspondence, as well as through that of his books; and therefore, as a small foretaste of the complete biography which will some day appear, we shall quote a letter in which he describes the character of his great friend and teacher, the late Prof. Henslow, of Cambridge. We choose this letter to quote from on account of the singular manner in which the writer, while describing the character of another, is unconsciously giving a most accurate description of his own. It is of importance also that in any biographical history of Mr. Darwin, Prof. Henslow's character should be duly considered, seeing that he exerted so great an influence upon the expanding powers of Mr. Darwin's mind. We quote the letter from the Rev. L. Jenyns' Memoir of the late Prof. Henslow.

"I went to Cambridge early in the year 1828, and soon became acquainted, through some of my brother entomologists, with Prof. Henslow, for all who cared for any branch of natural history were equally encouraged by him. Nothing could be more simple, cordial, and unpretending than the encouragement which he afforded to all young naturalists. I soon became intimate with him, for he had a remarkable power of making the young feel completely at ease with him, though we were all awe-struck with the amount of his knowledge. Before I saw him, I heard one young man sum up his attainments by simply saying that he knew everything. When I reflect how immediately we felt at perfect ease with a man older, and in every way so immensely our superior, I think it was as much owing to the transparent sincerity of his character as to his kindness of heart, and perhaps even still more to a highly remarkable absence in him of all self-consciousness. We perceived at once that he never thought of his own varied knowledge or clear intellect, but solely on the subject in hand. Another charm, which must have struck every one, was that his manner to a distinguished person and to the youngest student was exactly the same: to all the same winning courtesy. He would receive with interest the most trifling observation in any branch of natural history, and however absurd a blunder one might make, he pointed it out so clearly and kindly that one left him in no way disheartened, but only determined to be more accurate the next time. So that no man could be better formed to win the entire confidence of the young and to encourage them in their pursuits. . . .

"During the years when I associated so much with Prof. Henslow, I never once saw his temper even ruffled. He never took an ill-natured view of any one's character, though very far from blind to the foibles of others. It always struck me that his mind could not be well touched by any paltry feeling of envy, vanity, or jealousy. With all this equability of temper, and remarkable benevolence, there was no insipidity of character. A man must have been blind not to have perceived that beneath this placid exterior there was a vigorous and determined will. When principle came into play, no power on earth could have turned him an hair's breadth. . . .

"In intellect, as far as I could judge, accurate powers of observation, sound sense, and cautious judgment seemed predominant. Nothing seemed to give him so much enjoyment as drawing conclusions from minute observations. But his admirable memoir on the geology of Anglesea shows his capacity for extended observations and broad views. Reflecting over his character with gratitude and reverence, his moral attributes rise, as they should do in the highest characters, in pre-eminence, over his intellect."

Charles Robert Darwin was born at Shrewsbury on February 12, 1809. His father was Dr. R. W. Darwin, F.R.S., a physician of eminence, who, as his son used frequently to remark, had a wonderful power of diagnosing diseases, both bodily and mental, by the aid of the fewest possible number of questions; and his quickness of perception was such that he could even divine, in a remarkable manner, what was passing through his patients' minds. That, like his son, he was benevolently inclined, may be inferred from a little anecdote which we once heard Mr. Darwin tell of him while speaking of the curious kinds of pride which are sometimes shown by the poor. For the benefit of the district in which he lived Dr. Darwin offered to dispense medicines *gratis* to any one who applied and was not able to pay. He was surprised to find that very few of the sick poor availed themselves of his offer, and guessing that the reason must have been a dislike to becoming the recipients of charity, he devised a plan to neutralise this feeling. Whenever any poor persons applied for medical aid, he told them that he would supply the medicine, but that they must pay for the bottles. This little distinction made all the difference, and ever afterwards the poor used to flock to the doctor's house for relief as a matter of right.

Mr. Darwin's mother was a daughter of Josiah Wedgwood. Little is at present known concerning his early life, and it is questionable whether we can hope to learn much with reference to his boyhood or youth, till the time when he entered at Edinburgh. We can, therefore, only say that he went to Shrewsbury School, the head-master of which was at that time Dr. Butler, afterwards Bishop of Litchfield. He was sent to Edinburgh (1825) because it was intended that he should follow his father's profession, and Edinburgh was then the best medical school in the kingdom. He studied under Prof. Jameson but does not seem to have profited at all by whatever instruction he received; for not only did it fail to awaken in him any special love of natural history, but even seems to have had the contrary effect.

The prospect of being a medical practitioner proving distasteful to him, he was, after two sessions at Edinburgh, removed to Christ's College, Cambridge, with the view of his entering the Church. He took his B.A. in 1831, and his M.A. in 1837. There being no Natural Sciences Tripos at that time, his degree was an ordinary one. While at Cambridge he attracted the notice of the late Rev. Prof. Henslow, who had just previously exchanged the Professorship of Mineralogy for that of Botany. From the above description of this man's character and attainments, it is sufficiently evident that he was a worthy teacher of a worthy pupil; and the world owes an immense debt of gratitude to him for having been the means of enthusiastically arousing and sagaciously directing the first love and the early study of natural science in the mind of Darwin. No one can be more deeply moved by a sense of this gratitude than was Mr. Darwin himself. His letters, written to Mr. Henslow during his voyage round the world, overflow with feelings of affection, veneration, and obligation to his accomplished master and dearest friend—feelings which throughout his life he retained with undiminished intensity. As he used himself to say, before he knew Prof. Henslow, the only objects of natural history for which he cared were foxes and partridges. But owing to the impulse which he derived from the field excursions of the Henslow class, he became while at Cambridge an ardent collector, especially in the region of entomology; and we remember having heard him observe that the first time he ever saw his own name in print was in connection with the capture of an insect in the fens.

During one of these excursions Prof. Henslow told him that he had been commissioned (through Prof. Peacock) to offer any competent young naturalist the opportunity of accompanying Capt. Fitzroy as a guest on the surveying voyage of the *Beagle*, and that he would strongly urge its acceptance on him. Mr. Darwin had already formed a desire to travel, having been stimulated thereto by reading Humboldt's "Personal Narrative;" so after a short hesitation on the part of his father, who feared that the voyage might "unsettle" him for the Church, the matter was soon decided, and in December of 1831 the expedition started. During the voyage he suffered greatly from sea-sickness, which, together with the fasting and fatigue incidental to long excursions over-land, was probably instrumental in producing the dyspepsia to which, during the remainder of his life, he was a victim. Three years after returning from this voyage of circumnavigation, he married, and in 1842 settled at Down in Kent. The work which afterwards emanated from that quiet and happy English home, which continued up to the day of his death, and which has been more effectual than any other in making the nineteenth century illustrious, will form the subject of our subsequent articles.

(*To be continued.*)

ECLIPSE NOTES[1]

II.

On the present occasion these notes will be more geographical than astronomical, for since the last notes were written, the English Government Eclipse Expedition has traversed through storm and sunshine the distance separating London from Cairo, and is now at the latter place, making final arrangements before it starts to-night up the great river.

The first thing I have to say, is, that the arrangements made for astronomers of all nations by His Highness the Khedive and by his government have been all that could have been desired. Indeed, so universal has been the wish to do everything that could in any way tend to the success of the observations, that it is almost invidious to mention names; but still it is impossible not to recognise that the sympathy for everything scientific which distinguishes Stone Pasha, the chief of the staff, and the important influence which his high position gives him, has done much in kindling the enthusiasm which we find,—an enthusiasm shared in a great degree by the Khedive himself, who has insisted that the astronomers shall be his personal guests during their sojourn on the Nile. But this is to anticipate; it will be better perhaps, in order to give an idea of the thoroughness with which the arrangements have been carried out, to begin at the beginning of our stay in Egypt.

When the *Kaisar-i-Hind* got into harbour at Suez, after a rapid passage through the canal, a passage accelerated at the request of the Egyptian Government, as the canal had been blocked for three days, the Governor of Suez and Ismatt Effendi at once came on board to welcome the party. A special train had been provided with a car for the instruments, which were at once sealed up and guarded after their arrival at the station in Suez Town. Nothing could exceed the kindness of the authorities; the Custom House, which sometimes gives trouble to those who land in Egypt, was never once even thought of, and after spending the night at Suez, a train brought us yesterday to Cairo, his Excellency Stone Pasha himself, with some of his officers detailed for service with the Expedition, being on the platform to welcome the scientific party. The instruments were at once taken to the river-side, where provision had been made to ferry the car containing them, still sealed, across the Nile.

Acting on a suggestion made some time ago, the exact latitude and longitude of Sohag has been absolutely determined; on the old French map its position had been got by rough traverses from Siut. With this new position and a rapid reconnaissance, a new map has been prepared by General Stone, a copy of which I hope to be able to send with these notes. This shows the point at which the line of central eclipse will cross the Nile with no doubt the greatest possible exactitude. In order to prevent any mischance or delay owing to the low Nile interfering with the arrangements, and causing a loss of time, the steamer placed at the disposal of the astronomers by the Egyptian Government is already moored at Sohag, close to the central line, and indeed the French party are already aboard. Communication between Siut and Sohag will be kept up by the Postal steamers, for the Nile is no longer a river of mystery, and a regular postal service is kept up for thousands of miles. But the hotel steamer, as it is called here, will likewise be locomotive. The French party has already erected its instruments to the south of the arm of the Nile shown below Sohag, and in all probability the English party will occupy the high ground shown on the map to the north of Akmim; a position desirable on account of the Khamseen—the terrible dust-laden desert wind—which, however, this year, up to the present moment, has been very merciful; this we may regard as a good or bad presage during the next fortnight, to which its devastating effects are generally confined.

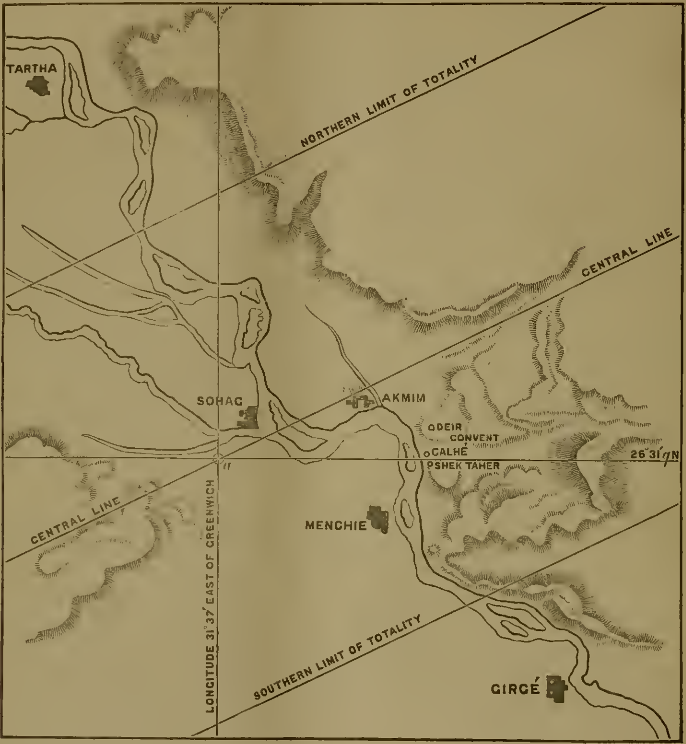
Between these stations the special boat will keep up constant communication.

The Italian Expedition is under the charge of Prof. Tacchini, of Rome, whose long-continued observations of the spectra of prominences are so widely known and

---

[1] Continued from vol. xxv. p. 578.

well appreciated by men of science. He has brought out a small equatorial telescope with spectroscope attached, and it is believed, intends to devote himself exclusively to spectroscopic work during the eclipse. He joins the eclipse boat a few days later on.



The French party consists of MM. Thollon, Trépied Director of the Observatory at Algiers, and M. Buisseux; as above mentioned, they are already at their station; their work will be chiefly spectroscopic.

The Egyptian Government has deputed Moukhtar Bey, Colonel on the Staff, to assist the English party at the place of observation. J. NORMAN LOCKYER

Cairo, May 5

(*To be continued.*)

THE TOTAL ECLIPSE

THE following telegram in the *Times* of to-day from its Special Correspondent with the English expedition to Egypt, gives the following results of the observations of the total solar eclipse of yesterday:—

Sohag, May 17

The total eclipse of the sun was successfully observed here to-day by the English, French, and Italian astronomers.

A fine comet was discovered close to the sun, its position being determined by photographs.

The spectroscopic and eye-observations just before and during the period of totality gave most valuable results, the darkening of the lines observed by the French astronomers indicating a lunar atmosphere.

A series of good photographs of the corona was obtained, and the spectrum of the corona for the first time was successfully photographed.

The astronomers will probably leave on Saturday on board the Government steamer.

THE THEORY OF DESCENT

Studies in the Theory of Descent. By Dr. Aug. Weismann. Translated and Edited by Raphael Meldola, F.C.S. Part III. The Transformation of the Mexican Axolotl into Amblystoma; On the Mechanical Conception of Nature. (London: Sampson Low, Marston, Searle, and Rivington, 1882.)

THE present issue completes the excellent translation of Dr. Weismann's valuable and suggestive work. The first two essays of which it consists is devoted to a careful discussion of the real meaning of the transformation of the Axolotl into Amblystoma. Experiments are detailed showing that the metamorphosis may be induced with much constancy by obliging the Axolotls, at a proper stage of growth, to leave the water, when they lose their gills and undergo a number of other changes constituting a veritable metamorphosis. Dr. Weismann states that many zoologists have expressed an opinion (which was formerly held by himself) that this change is to be considered to be a true advance in development from a species which had hitherto remained in the larval stage, but which, through the influence of certain changed conditions, now advances, *per saltum*, to a higher stage. This view he gives many excellent reasons for considering to be quite erroneous; holding that the facts are best interpreted by supposing that the animal formerly underwent metamorphosis, but that owing to changed conditions it was unable to survive in the perfect state, and therefore remained in the larval condition in which it acquired the power of reproduction.

The causes which led to this change are believed to be a progressive drying up of the Mexican lakes (as long since proved by Humboldt), and a consequent increased aridity of the atmosphere inimical to land amphibia. The axolotl, therefore, presents us with a case of degeneration; and its metamorphosis under changed conditions in confinement is not due to any advance in organisation, but is really a reversion to a not very remote ancestral habit. The whole of the facts at present ascertained with regard to these animals and allied forms in their native habitats, are shown to agree well with this view, which is quite in harmony with the author's explanation of seasonal dimorphism in butterflies, given in Part I. of the same work (see NATURE, vol. xxii. p. 141), and is also more in accordance with the true principles of evolution than the alternative hypothesis.

The second, and concluding essay, is entitled "On the Mechanical Conception of Nature," and is chiefly occupied with an inquiry into the true character of variation as the chief factor in evolution, and into the comparative importance of external conditions, and the constitution of the organism in determining the particular direction of the course of development; the object being to show that all takes place according to fixed laws without the interference of any "teleological principle," whether in the form of a "phyletic vital force" or the interposition of any "designing power." The writers whose views on these subjects are combated are Von Hartmann and Karl Ernst von Baer, and, after an elaborate and often subtle argument, Dr. Weismann concludes that the facts can all be explained on "mechanical" principles, or, as we should say, by the action of fixed laws. He is however careful to add that this does not imply a materialistic view of nature. "Those who defend mechanical development will not be compelled to deny a teleological power, only they would have, with Kant, to think of the latter in the only way in which it can be conceived, viz. *as a Final Cause*." And on the great question of the nature and origin of consciousness he thus expresses himself:—"If it is asked, however, how that which in ourselves and in the remainder of the animal world is *intellectual* and *perceptive*, which *thinks* and *wills*, is ascribable to a mechanical process of development—whether the development of the mind can be conceived as resulting from purely mechanical laws? I answer unhesitatingly in the affirmative with the pure materialist, although I do not agree with him as to the manner in which he derives these phenomena from matter, since thinking and extension are heterogeneous things, and one cannot be considered as a product of the other." And he intimates that the fundamental notion of conscious matter may get us out of the difficulty. However this may be, he maintains that the theory of selection by no means leads—as is always assumed—to the denial of a teleological Universal Cause, and to materialism, but only to the belief that any mode of interference by a directive teleological power, other than by the appointment of the forces producing the phenomena, is, to the naturalist, inadmissible. "The final and main result of this essay will thus be found in the attempted demonstration that the mechanical conception of Nature very well admits of being united with a teleological conception of the Universe."

The work, of which the translation has now been completed by Mr. Meldola, must be considered a very important contribution to the theory of Natural Selection, since it applies that theory to explain in the minutest detail how the more prominent characters of several distinct groups of animals, not obviously useful to them, may have been developed under its action. Such are the distinct markings often occurring in two annual broods of butterflies termed "seasonal dimorphism," the origin of the markings of caterpillars, and the unexpected phenomena of the transformation of the Mexican axolotl; and we are therefore led to conclude that an equally careful and minute study of other cases of difficulty would probably lead to an equally satisfactory explanation. This argument is not, however, conclusive, because the cases here chosen may not be really test cases; and among the countless forms of nature, and especially among the higher animals, there may well be characters or organs the origin of which are due to other and altogether unknown causes. To students of evolution, Dr. Weismann's volume will be both instructive and interesting, but it is a work that requires not merely reading, but study, since its copious facts and elaborate chains of argument are not to be mastered by a hasty perusal. The book is beautifully got up and illustrated by a number of coloured plates admirably executed in chromo-lithography, and it will form a handsome as well as an indispensable addition to every naturalist's library.

ALFRED R. WALLACE

OUR BOOK SHELF

Land and Freshwater Mollusca of India. Edited by Lieut.-Col. H. H. Godwin-Austen, F.R.S., &c. Part I. February, 1882. (London: Taylor and Francis.)

THIS work is announced as "supplementary to Messrs. Theobald and Hanley's 'Conchologia Indica,'" but it is much more than a supplement, and is framed on far more scientific principles. The "Conchologia Indica" was published in 1870; and the editors in their preface say that "after an interval of two or three years it is hoped that materials for a supplement (the malacological portion of which will be edited by Major Godwin-Austen) will be accumulated." The "Conchologia Indica," however, is only what it professed to be—"Illustrations of the Land and Freshwater Shells of British India." The letterpress gives a dry list of species and synonyms, not arranged in classified order, with occasional notes. This is admitted by the editors, who state that they "do not acknowledge the validity of many of these species, but merely illustrate them." They also state their "regret that the figures of some of the more minute shells are not so well executed as they expected; but lithography is scarcely compatible with sharp definition." We fully concur in the last remark. Although this is not a review of their work, we cannot help noticing the fact that certain species of freshwater shells belonging to the northern portion of British India, and which are enumerated in the "Conchologia India," are also natives of Europe. Such are *Limnæa auricularia* and *stagnalis* of Linné, *L. peregra* and *truncatula* of Müller, and *Valvata piscinalis* of Müller; but there is no species of *Unio*, *Anodonta*, *Sphærium*, or *Pisidium* common to the two regions. The occurrence of the first-named five species in countries so geographically and widely separated, may be partly explained by these species having spread from Siberia, which they likewise inhabit; but the mode of their original distribution from Europe to Siberia, or *vice versâ*, still remains a problem. If water-fowl or other animals had been instrumental in such distribution, why should not any of the freshwater bivalves, which are likewise European and Siberian, have been similarly transported to British India?

The present work is intended to be published in parts, of which the first has now appeared. It contains seventeen octavo pages of letterpress and four quarto plates. The descriptions of new species, as regards both the shell and soft parts or animal, have been most carefully written, and the author has properly given the distinctive characters of each species in a correlative order, which is a point of material assistance in comparing one species with another. There are, nevertheless, a few exceptions to this useful rule in species of *Kaliella* and *Microcystina* (pages 5, 12, and 13), where the umbilicus is described first, and before the shape of the shell. The shells are admirably drawn, although the colouring is unsatisfactory. Without having critically studied the specimens figured, and especially "a hatful" of them, one might, on looking at the illustrations, be inclined to question the specific distinction of several. But all naturalists are never likely to agree in that matter; and perhaps it may be immaterial whether certain forms are called species or varieties. The minds of some naturalists have a synthetic and of others an analytic tendency.

Col. Godwin-Austen seems to attach considerable importance to the odontophore or lingual riband as an element of classification. We believe that this affords a good auxiliary character in defining genera or higher groups of the Solenoconchia and Gastropoda; but the recent investigation of the subject by Herr Friele in respect of northern species of *Buccinum* shows that the odontophore varies so greatly in individuals of the same species that it cannot be fully relied on for distinguishing species. Some Gastropods, *e.g.* *Odostomia* and *Eulima*, have no odontophore, in consequence of their food consisting of soft polyparies.

The work now noticed is a very valuable contribution to the natural history of India, and has been intrusted to a naturalist who is by no means less competent because he is actuated by modest aspirations.

J. GWYN JEFFREYS

Mémoires de la Société des Sciences Physiques et Naturelles de Bordeaux. 2^{e} série, tome iv. 3^{e} cahier. (Bordeaux, 1881.)

THIS cahier contains nine papers, all mathematical. We recently called attention (vol. xxv. p. 408) to an article in the second cahier, by M. Paul Tannery, on the Arithmetic of the Greeks. The same writer now furnishes two contributions—one, "Sur la mesure du cercle d'Archimède," in which he discusses how far Archimedes (in his κύκλου μέτρησις) was acquainted with methods which form the base of the solution of what is now called the Pellian problem; the second is entitled "De la Solution Géométrique des problèmes du second degré avant Euclide," and in it he discusses questions very nearly allied to those considered by Dr. Allman in his "Greek Geometry from Thales to Euclid."

M. Ordinaire de Lacalouge also contributes two papers—one on the tramways of Bordeaux ("en regardant poser les rails et marcher les premières voitures des tramways on a tout naturellement là l'idée de rechercher le rayon minimum des courbes où ces véhicules peuvent circuler. Ils ont, sous certains rapports, de l'analogie avec les wagons de chemin de fer, mais en diffèrent, surtout par leur vitesse de translation"); the second discusses the "théorie géométrique du pendule de Foucault" as against M. Yvon de Villarceau; it is modestly written, and is valuable from its furnishing many interesting historical references. Regarding the views broached in the article, the author concludes with "le temps dira si c'est une illusion."

M. Kowalski, in a "Note sur les systèmes coordonnés d'unités électriques spécialement sur celui de l'Association Britannique et ses applications," does good work in giving a concise elementary account of these systems of units, "notions que les traités classiques de physique publiées jusqu'ici en France passent à peu près complètement sous silence."

The remaining four papers are by M. Saltel, viz. "Réflexions sur la mesure du volume de la sphère" (with a demonstration); "Étude de la variation du cercle osculateur en un point M d'une section plane d'une surface"; "Théorèmes généraux sur la décomposition des enveloppes, théorème sur les surfaces développables"; "Contribution à la théorie du changement des variables dans le calcul des intégrales simples et multiples."

On and Off Duty: being Leaves from an Officer's Note-Book. By S. P. Oliver. (London: W. H. Allen and Co., 1881.)

THE chief contents of this handsome volume are derived from the rough notes and sketches made by Capt. Oliver, some years ago, when a young subaltern of artillery. They show that, whether in Turania, Lemuria, or Columbia, he took notes of all the strange things he saw, and although many of his observations have appeared from time to time in the journals or proceedings of various societies, or as articles in periodicals, they were, we think, interesting enough to be collected into a more permanent form, which we trust may stimulate others of Her Majesty's officers to follow Capt. Oliver's example.

The first part of the volume is devoted to an account of the author's visit to China and Japan. There is a graphic description of the visit to Tsing-Yuen, to see that the treaty (1860) of peace was properly posted up as required. Snakes are mentioned as abounding; and we learn that snake's flesh is eaten from choice not rarely by the Chinese: indeed, boiled-snake soup is a favourite febrifuge for invalids. The author says that at Shao-K'ing numerous bodies of the rebels were floating past with the stream, and that though the majority were decapitated, all the bodies of the men floated on their backs, whereas all the bodies of the women floated "face downwards." The notes on Japan are of interest, as intercourse with foreigners is so improving the Japanese, that such peculiar games as Jon-noki are not now-a-days to be commonly seen played; and the author was fortunate to see Yeddo ere it ceased to be the exclusive city.

The second part is taken up with a visit to Lemuria, thereby meaning Madagascar and the Mascarene Islands of Bourbon and Mauritius. This visit was made in 1862. The Seychelles were not visited. Some noteworthy details are given of a visit to Madagascar. The home of the *Ouvirandra fenestralis* is well described, and the account of a Mauritius hurricane is true to the life. It is mentioned that in the hurricane of March 12, 1868, the iron girders, 200 feet in length, and weighing over 300 tons, were blown from the railway bridge over Grande Rivière, when a force of 100 pounds to the square foot must have been exerted by the wind down the ravine.

In an appendix to the second part, there is a chapter on the natural history of Madagascar, contributed by Mr. J. G. Baker, F.R.S., of Kew.

The third part of the volume describes a visit to Columbia along with Capt. Pim and Mr. John Collinson, for the promotion of a transit railway route through Mosquitia and Nicaragua.

The volume will commend itself to the general reader, and the scientific notices mentioned therein will be found very generally interesting and correct.

Modern Metrology. By Lowis D'A. Jackson. (London: Crosby Lockwood, 1882.)

It is no easy task to give an account of the various systems of weights and measures in use throughout the world, to trace their origin, and to express their equivalents in English and French weight and measure, but this the author has undertaken in one part of his book, and has brought together much valuable and interesting information. This work is so far a cambist or dictionary of weights and measures, both the scientific and commercial equivalents of all foreign units being given. It would have been well, perhaps, if the author had stated for each country the precise authority from which he obtained his equivalent, as works of this kind should as far as possible contain within themselves means for verifying the accuracy of the figures given.

The main object of the work appears, however, to be the discussion of a remedy for the evils of the complex systems of weights and measures which are unfortunately still in use in this country. To provide such a remedy is a serious task, and one well worthy of the attention of a great statesman such as Mr. Gladstone, to whom this work is inscribed.

The author discusses the vexed question of the relative values of standard temperatures at 32° and at 62°, and proposes a new English system based on a cubic foot of 1000 "fluid ounces," at the temperature of the maximum density of distilled water.

The "fluid ounce" is taken as equal to the weight of distilled water contained in a cubical vessel whose dimensions are equal to a "tithe," or tenth part of the linear foot, when weighed and measured also at the temperature of the maximum density of distilled water. The various parts and multiples of the cubic-foot and "foot-weight" would be built up by decimal progression, so that a strict correspondence would be always maintained between capacity, linear dimension, and weight. The effect of reducing the temperature of the cubic foot from 62° F. (the present legal temperature) to 39°·1 F. (the temperature of the maximum density of water), would bring the weight of the cubic foot more into accordance with modern research, as it would raise its weight from 62·321 lb. to 62·424 lb.

Although we have faint hope of present success in disturbing the deeply-rooted systems of measures now in use by this great commercial nation, or of substituting for the purposes of international science a more acceptable metrology than that based on the metre and gramme, we cannot but recommend this work to the consideration of all interested in the practical reform of our weights and measures.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Sun-Spots and Magnetic Storms

Some particulars of the remarkable double outburst of sun-spots in the latter part of April and of the magnetic disturbances which appear to have been connected with them, as recorded at Greenwich, may be of interest to your readers. It is in itself a noteworthy fact that there should be on the sun at the same time two spots, one of them double, sufficiently large to be visible to the naked eye, and this is made still more interesting by the occurrence of a violent magnetic storm a few days after the appearance of each of these large spots.

The larger of the two spots would seem to have first made its appearance at the east limb on April 11 at about 15h. G.M.T., though no photograph of it was obtained till April 14. It must have passed off the disk about April 25 8h., being well shown on a photograph on April 24. It extended over 10° of heliographic longitude, and measured more than 2′ of arc in length and breadth.

The group preceding it, consisting of two spots, was first photographed near the east limb on April 11, and was then comparatively small. Between April 16 and 17 it increased suddenly in size, becoming nearly as large as the other spot group, and far exceeding in area any of the spots previously recorded at Greenwich.

The areas of these groups on the photographs, expressed in millionths of the sun's visible hemisphere, and corrected for foreshortening were as follows:—

1882.	Great Spot		Preceding Group	
	Nucleus.	Whole Spot.	Nucleus.	Whole Spot.
April 11			17	141
14	351	2218	40	270
16	239	2086	24	156
17	391	1979	204	880
18	465	2030	244	1370
20	340	1916	294	1813
21	427	2105	440	2360
23	267	1786	167	1054
24	316	1727		

The total spotted area on 1882, April 17, was 881 for the nuclei, and 4668 for the whole spots, being about double of the greatest spotted area shown on any of the Greenwich photographs previous to this outburst.

On April 16 and 19 violent magnetic disturbances occurred. At Greenwich the declination, horizontal force, and vertical force magnets became violently disturbed on April 16 at 11h. 30m. G.M.T., the first movement for all three being simultaneous and sudden, and the storm movements continued till April 17, 7h. 30m. G.M.T. The magnets remained quiet till April 19, shortly after 15h. 30m. G.M.T., when another sudden and very sharp disturbance commenced, lasting till April 20, 20h. G.M.T.

In the magnetic storm of April 16-17, there were large oscillations of declination till April 17 0h., the greatest *recorded* motion being about 1°, from a diminished declination at 19h. + to an increased declination at $19\frac{3}{4}$h. Then until 4h. the register cannot be traced, the motions being either unusually rapid, or the magnet being disturbed by workmen in the upper room. About 7h. there were some sharp motions, after which time the magnet became quiet. The principal feature of the disturbance of horizontal force was at first an increase, followed by a much larger diminution, amounting to about 1-50th of the whole force at 16h., when the trace went off the sheet, and was lost until April 17 0h. There was then a great and rapid increase (in about 40m.) of about 1-40th part. Rapid motions were then shown till 7h. 30m. The whole range of these disturbances probably exceeded 1-25th part of the whole force. The vertical force at first decreased somewhat till April 16, 16h., and afterwards very considerably till about 18h., when it was diminished by about 1-100th part, then with the horizontal force it increased till about 1h., when the trace went off the sheet, its value being then greater than the normal by more than 1-100th part. Finally, the normal value was gradually reached again at 7h. 30m.

In the second magnetic storm, the range of the declination movements was 1° 30′, of the horizontal force about 1-50th part of the whole, and of the vertical force about 1·120th part.

Thus the vertical force disturbance on April 19-20 was comparatively small; that of the vertical force on April 16-17 is characteristic of the greatest storms, and since the great disturbances of 1872, February 4, and those of October 4 of the same year, no magnetic storm has been recorded equal to this. Earth-currents were shown throughout both storms.

Hypothetical High Tides

I regret that I am not able to accept the criticisms of Mr. C. Callaway on my notice of Prof. Ball's lecture. I have studied the effect of tidal and wind waves on many coasts through many years, and my observations do not warrant the statements he makes. Every schoolboy knows the distinction between waves of undulation and translation, and it is in no sense true that I have confused them. With waves of undulation such as occur in mid ocean we have nothing to do in this discussion, but it cannot be unknown to Mr. Callaway that all such waves when reaching a shore, become waves of translation, and more or less powerful denuding agents. If he will have the kindness to refer to my "Report on the Geology of Ohio," vol. i. pp. 52, &c., he will find that I have done ample justice to the efficiency of wind waves as agents of geological change. The great tidal current rushing arouud the earth, with which he credits me, exists only in his own imagination. I have suggested nothing of the kind, but the rapid ebb and flow over the shores of continents of tidal waves several hundred feet in height must necessarily act with great violence upon such shores, and I insist that such tidal waves as pictured by Prof. Ball would have left a very different record from that we find in our Palæozoic rocks. Some of our American Silurian strata were deposited on shores that faced toward the east, where they had an unbroken stretch of several thousands of miles of ocean over which the tidal wave would come to them without obstruction, and there the maximum effect of such tides as Prof. Ball describes would be produced, but no traces of them are found.

I am aware that the reef-building corals of the Devonian were zoologically distinct from any now living, and for that reason conditioned my inference from them; but we have satisfactory evidence that the Devonian coral reefs of Ohio and Kentucky were formed *along a shore* and in a *warm* sea, like the reef-building corals of the present day, and there are many reasons for believing that their mode of life was the same.

The point made by Mr. Searles Wood in regard to the coal, though objected to by Mr. Callaway, is well taken, for we know that the great coal marshes of America were located just at the sea level, and from time to time were inundated by the sea and covered with sheets of *marine* limestone. It requires no argument to show that the growth of the Carboniferous forests and the formation of beds of peat—now coal—could not have taken place with tides rising one-half or even one-fourth of the height of those described by Prof. Ball.

On carefully reviewing the facts which suggested my objection to Prof. Ball's theory, I am compelled to reiterate the statement before made, that on the east coast of North America the geological record bears positive and conclusive testimony against the high tide theory, and that at least since the Archæan ages no tides have swept this coast like those required by Prof. Ball's theory, even as modified by Mr. Darwin.

New York, April 10 J. S. Newberry

Aurora Borealis

A polar aurora of remarkable activity and brilliancy was observable here at 11.15 last night. The centre of energy at the time of origin was under Cassiopiea, a highly luminous streamer shooting upwards from the horizon, and covering, but not hiding the stars in that constellation. Brilliant white flickering streamers and rays, arising from the horizon, quickly spread towards the north-west, and an irregular shaped mass of crimson light, of an altitude of 45°, and many degrees in breadth, appeared, and suffused the northern hemisphere from Cassiopiea to Gemini. Between the horizon and the mass of crimson-coloured vapour the sky was of a light green hue, and upwards, through this area of greenish light, the rays and streamers shot.

During the period of greatest energy, a beam of vivid light arose towards the north-west, was projected over Gemini, and quite extinguished the light of the two large stars in that constellation. About midnight the meteor faded. Soon afterwards the sky became overcast. Throughout the day the wind had been blowing briskly and coldly from a point in the north-east. Barometer, highest during the day in the shade, 60; aneroid, 30·2. In the afternoon, curious slender-rayed cirri from the north-west, generally indicative to my mind of auroral disturbanie, crossed the northern sky towards the zenith. To-day, detached clouds and blue sky, and the wind is blowing stiffly and icily from the same point. Barometer and aneroid same as yesterday, the latter inclined to full.

An auroral display of the like splendour and activity is very rare, if not wholly unknown in this locality at this time of the year. X.

Worcester, May 15

At 10·55 p.m. last night, I observed a very beautiful aurora borealis, consisting mainly of three beams, nearly vertical, and then parallel to the direction of the stars α and δ of the Great Bear. They moved slowly towards the east, and about 11·5 faded away. About 11 o'clock they were very brilliant, and the central beam, then quite close to the Polar star presented a slightly purple or violet colour, as represented in the sketch inclosed. Near the earth, and at about 15° to 20° elevation, there was a mass or cloud of suffused light, from which the beams seemed to rise. It seems that an aurora was also seen about a fortnight ago from Dublin. The wind has been easterly, and to-day is somewhat colder than yesterday.

Spectrum of Wells' Comet

The continuous spectrum of this comet, especially of the nucleus, is remarkably bright. I observed it on April 18 and May 6 and 15. There were at least three bright bands, and perhaps more. I believe the usual three were visible, but they were so indistinct that I did not observe their positions. The middle one was much the brightest, and the only one plainly visible. I never saw a comet in which the bright bands were so faint, relative to the continuous spectrum.

May 16 T. W. Backhouse

The Recent Violent Storm

May I ask your permission to insert from me a curious circumstance, which came under my notice, soon after the tremendous storm which took place on Saturday, April 29 last. On the glass of some of the windows of the house in which I reside I perceived a very singular appearance upon them, somewhat resembling a deposit from milk. On looking at it through a microscope I discovered a number of very beautiful crystals, which, without doubt, were caused by the spray from the sea, as on applying it to the tongue, there was a strong taste of salt. The distance the spray must have been carried on this occasion could not have been less than sixty miles, taking into consideration the course of the wind, which was south-west.

Waddon, Croydon, Surrey, May 15

The Cuckoo

Is it a normal habit, or only an erratic freak of that quaint bird, the cuckoo, to sing at night. On the night of Monday, the 8th inst., I first heard, at 10 p.m., three or four calls, but took little notice of it, thinking the bird had been startled from his dreams, but in a short time he recommenced, and went on continuously with short intervals of silence, until 12 or 1, precisely as by day.

It was a dark night with only dim starlight. I should like to know whether others have remarked this nocturnal loquacity in the cuckoo. This particular bird has usually commenced his song or call at about 4 a.m. J. E. A. Brown

May 11

The Swedish Fisheries

In Nature of April 20 you ask for an explanation of the difference in the figures of Dr. Oscar Dickson and Dr. Lundberg relating to the Swedish fisheries.

1. You mention that Dr. Lundberg, in the "Notizen uber die Schwedischen Fischereien," 1880, valued the herring fisheries of Sweden at 5,000,000 marks (3,547,303, p. 27), but you forget that Lundberg's book only refers to the "Ostsee und Sussvasser Fischereien," and Dr. Dickson only speaks of the west coast or North Sea fisheries.

2. About the "millions of barrels representing millions of pounds sterling," the Swedish North Sea Herring Fisheries statistics value the barrel herring *now* only at 1 to 2 shillings in the first (fisherman's) hands. And you will notice that the millions of barrels mentioned by Dr. Oscar Dickson in the *Scotsman*, refer to a former period, nearly a century ago, not to the present period, commenced 1877.

Pyphis, Sweden, May 3 Gerhard von Yhlez

THE OLDEST EGYPTIAN TOMBS AND TENANTS

ALTHOUGH the existence of mankind in the dawn of civilisation at the Stone age, and using Palæolithic tools is distinctly proved in Northern Africa and Algeria, the specimens discovered on the soil of Egypt are not so unequivocally Palæolithic, although those published by Sir J. Lubbock approach the type. Of the Neolithic stone weapons, numerous examples have been found, some undoubtedly in use at the time of the eleventh and twelfth dynasty, others probably descending to the eighteenth and nineteenth dynasties. The indications, however, of sepulchres of the Palæolithic period are absolutely wanting on the soil of Egypt, and except the stone huts in the Arabian Peninsula, belonging to the more ancient period, there are no remains of contemporary construction.

In the graves around the oldest pyramids Neolithic remains are occasionally found, and there can be no doubt that flint weapons were extensively used at the oldest pyramidal period, which, however, was one of copper and bronze, copper and even iron objects having been found in the air passages of the great Pyramid, and indications of the use of the hollow bronze drill in the stone sarcophagi of the same epoch. The pyramids were arranged chequer-wise in groups, and each separate site belonged to a different dynasty, the kings and other royal personages being inhumed in them, while around the pyramid of each site were arranged the tombs of the courtiers and officers of the court. The arrangement of these tombs differs at the respective sites. At Sakkarah they are arranged in rectangular groups of streets, and the same arrangement prevails at Gizeh. At Abusir the last undulations of the step-shaped hills which crown the pyramids are occupied by some tombs scattered about of the time of the fourth and fifth dynasty. At Dashour there are also some tombs of a very early and unknown period, and at Meidum, tombs of the third dynasty. All these tombs bear a general resemblance to each other, and pass by the general Arab name of *mastabas*, "counters," or "beds." At first sight they look like the pedestals of pyramids, or truncated pyramids, being of rectangular shape, with sloping sides; they are, however, not square, but rectangular, and the angle of the sides is so great that the walls, if produced upwards, would rise to 600 feet, an impossible height for such a construction. Consequently they are not of the class of pyramids, but only show the Egyptian preference for converging lines, instead of purely parallel or rectangular forms; the short sides also in some instances are step-shaped, the layers of stone are squared and laid in horizontal courses, and not polygonal masses. These rectangular masses of masonry or brick-work, the details of which will be subsequently described, did not contain the sepulchral chamber, for that is always found in the solid rock beneath, the access to which was by a rectangular shaft or well, down which the coffin and mummy were lowered by ropes; the mass of masonry above had only in it the sepulchral chamber and the cell for the sepulchral statue. The general "cemetery," with its street of tombs, was called in Egyptian *kher* or *khel;* the individual tombs bore the general name of *maha* "sepulchres," which was applicable to any class of tomb, whether those of the kings or used by the inhabitants of the town or city. The term *mer* was applied to any tombs which had pyramidal construction, as those made of brick with pyramidal tops cut out of the flank of the hill at the time of the eleventh dynasty at the Drah Abu'-l Neggah, in the western quarter of Thebes; but the term applied to the syringes or hollowed passages and tunnelled tombs at Gournah and elsewhere is *asi*, a word applied to a plant, perhaps a "reed," but also meaning a chamber, and this word was used to express the so-called mastaba, or quadrilateral sepulchre of the early dynasties. The great necropolis of Sakkarah is supposed to be that of the ancient Ka-Kam, the city of the Black Bull, known to the Greeks under the name of Cochome, and the pyramid there to have been named *Ap*, the "elevation" or "Mount," and the pyramid was step-shaped, made of unbaked brick, probably when first built in seven stages.

The mastabas were the mausolea of the richer and more important personages of the court hierarchy and Egyptian bureaucracy, for the poor and slaves were not buried with any consideration; they were hustled into superficial graves about three feet deep beneath the soil, and at this distant period of time are found only as skeletons, with no linen wraps remaining or other traces of emblems, and must therefore be regarded as the oldest and most primitive examples of Egyptian interment, and their bodies were unprovided with coffins. Occasionally, perhaps, some of the least poor, or slaves of extraordinary merit, had rectangular vaulted chambers, constructed of brick-work, vaulted and covered with a white coating; in the interior of these rude graves are found small vases or cups of coarse pottery or calcareous stone or alabaster, but uninscribed. These graves recal to mind those of the later Roman period, although the Memphian ones belong to a period long anterior.

The mastabas vary in size and dimension, but their average or normal dimensions are nearly fifty yards long, twelve yards wide, and thirty deep. The chief of these mastabas is the Mastabat-il-Pharaoun, which recent discoveries show to have been the sepulchre of Unas of the fifth dynasty, who was not buried in a pyramid. The mastabas are said to be peculiar to Gizeh, and not to be found elsewhere, and a long interval of civilisation must have preceded the construction of these tombs, as they show a considerable knowledge of architecture by their regular and geometric construction, while the square blocks and regular layers, each vertical joint being overlapped by a square stone, evidence considerable technical experience in the art of masonry. The other mastabas are made of similar masses of brick-work, and the bricks are of two kinds, those of the oldest mastabas, made of rectangular yellow bricks, composed of sand, pebbles, and some Nile mud, their dimensions being 22×11×7 of a metre, and black bricks made of alluvial soil and straw, larger in size, being 38×18×14 of a metre; these bricks are not older than the middle of the fourth dynasty, while the others are as old as the second line. The black bricks continue till the time of the Romans, and both kinds are sun-dried, no burnt bricks, with the exception of the conical stamped bricks, found at the tombs of the Drah-Ahi' l'Neggah, having been employed in constructions till the age of the Cæsars.

In the masses of brick-work or masonry which stood above the soil over the sepulchral chamber, hewn out of the solid rocks beneath, were constructed the mortuary chapel, for the performance of masses or liturgies to the dead, which, however, must have been of a simpler nature than those in use at a later period. In all these mastabas which, as a rule, face northwards, generally towards the north-east angle, is a kind of stele or sepulchral tablet of limestone, some times like facade, composed of separate pieces, and having two square pillars or columns in front, without capitals or abaci, forming a kind of entrance hall. This part of the mastaba is rarely on the south, never on the west, and the ceiling is always continuous, sometimes slightly vaulted by the stones supporting one another. The tablet is often like a door, with jambs, lintels, and hieroglyphics; sometime the facade or stele has a kind of false door with large figures of the occupant of the tomb and his wife at the sides of the false door, with a semicylindrical tambour above the door and a kind of cornice above that, with a sepulchral dedication to Anubis, never to Osiris, and representations of the person for whom the sepulchre was made, at a repast or some other diversion, as the fowling represented on the mastaba at Meidum. On the portion of the soil covering the serdab or inner niche and the well by which the sarcophagus and its mummy were lowered, are found little vases filled with a coating containing inside the trace of the water with which they were filled. The interior chapel or *asi* was either single, or had more than one chamber, and the walls of these were covered with pictures and inscriptions engraved in intaglio and brightly coloured, still vivid after 6000 years, but no furniture itself or offerings are discovered in the rooms, which have been long open to the spoiler. The inscriptions refer to the calendar and festivals throughout the year, the titles of the deceased, adoration to Anubis, and tables of food, or *menus* in use at the period; and the gourmands of the Egyptian aristocracy fared sumptuously every day out of well-filled flesh-pots and jars of wine and beer. The paintings on the walls depict the chase, the farm, the industrial household, the amusement of dances by professional women, games, and other diversions, and were no doubt intended to recal to the spirit of the dead his favourite occupations and his former wealth. Such solaces were reserved for the rich; the poor reposed after death about as indifferently as during life.

When constructed of masonry, the walls of the chapel in the mastaba were often made of rubble revetted, and at the end, at the foot of the false door is often found the stone altar of libations, sometimes with two small obelisks engraved only on one face; at other times, instead of obelisks, two supports in the shape of altars. The stele or sepulchral tablet was at the earliest period made in shape of a facade, but often quite blank, a mere white slab. It is not till after the sixth dynasty that these tombstones were rounded at the top, like those of the present day. When the chapel was ornamented, the tombstones are often blank; when the walls of the chapel—the *asi* —were unadorned, the tablets were often inscribed. In the most ancient tombs the tombstones are often built up of pieces and are inscribed with hieroglyphics of an early and rude type. The art is bad, and the inscriptions are not in regular lines, but dispersed over the area; the hieroglyphics themselves are often peculiar, executed with more elaborate detail than at the later period of the middle Empire. The object of these early inscriptions is to record the name and titles of the departed, and it is remarkable that at this period persons had the *ran āā*, or "great name," and the *ran-nets*, or "little name." A tomb, for example, of the second dynasty, at Sakkarah, was made for a man whose great name was Sekarkhabau, or "Sochari's rising amongst spirits," whose small name was Hothes—that of a rat or some small animal; and his wife's great name was Atherhotep, and her little name Teps; and this as early as the second dynasty. These chapels now have no doors, if they ever had, and except the vases found strewed here and there on the floor, the other objects which may have been deposited there have entirely disappeared. Behind the wall, on the south side more often than the north, and on the north more often than the west, was a secret niche, which the Arabs call the *serdab*, occasionally communicating with the chamber by a square orifice. In this niche was deposited a statue of the deceased. In this statue was supposed to reside his *ka*, or spirit, a kind of manes, or ghost, which inhabited the tomb, went in and out of the sepulchre and Hades, and to which was attached a priest, who performed the liturgies or litanies, in certain ways, and with peculiar rites. In the earlier inscriptions this ka is not mentioned, but at the close of the twelfth dynasty, all the benefits conferred by deities on the deceased were said to be due to his *ka*. It was in this chapel and to this image that the ancestral worship was paid, and the *ka*, which was a kind of *idolon* of the dead, was supposed to receive the same satisfaction as the dead himself. Most of the statues in the museums of Europe at the time of the fourth and sixth dynasties, came from the serdab of the sepulchre of the period. They were portraits of the dead, and sometimes represented him holding the tools or other marks of his profession. The whole of the mastaba, or chapel, and its mass was superposed on the real sepulchral chamber beneath, which it covered. The descent to this was by a rectangular well or shaft, from six feet six inches, to nearly ten feet square, and this cell passed through the masonry or platform of the mastaba, and then through the living roots of the foundation, and was made of large blocks; it was down this well that the sarcophagus was lowered to the chamber, by a shaft from thirty to seventy-five feet deep. Hence, at the base of the shaft, a short passage led to the rectangular chamber, which was well built, but has only once been found uncemented, and in it was placed the sarcophagus of granite, or calcareous stone, and the mummy, or body. The cell itself was carefully blocked up with rubbish to prevent access to the chamber, and the mouth of it is generally found either in the long axis of the tomb, or else behind the tombstone. The sarcophagus of this period has no resemblance to the later cases in shape of the human form, generally made of wood, which prevailed from the eleventh dynasty, or about 1800 B.C., to the first century, A.D., but are rectangular chests with vaulted cover, with projections at the edges. The bodies found in these chests are distinguished by the absence of linen or wraps in which they may have been embalmed, and bones of the skeleton are only discovered generally, of a brown colour, with a faint odour of bitumen, which is the more remarkable as the mummies found in the pyramid had both linen and indications of bitumen.

Of course, the ethnological question here arises, to what race of men did these old Egyptians of the period of the second and subsequent dynasties belong; they have been referred to the Caucasian races, and some of the skulls show a high intellectual development, even frontal sutures occurring. Their colour is painted in the sculptures, and on their statues, either red or copper, the female yellow, but their profile is not Semitic, and shows, as at the period of their history, traces of African blood. Some of the servants are dolicocephalic, and are supposed to be the indigenous race, similar to the Libyans of Northern Africa, who, however, at a later period, are classed amongst the white races.

It is, however, in vain to look for the origin of Egyptian civilisation, either in Aethiopia or Nubia, or south of Egypt, or on the northern coast of Africa, which lies to the west, for there is no evidence of races in these parts having ever attained a nascent civilisation, such as the Egyptian might have started from. Recent discoveries in Southern Mesopotamia, however, show a similar civilisation, almost, if not as old as the Egyptian, with a form of written language developing from the ideographic to that of the conventional type, into which the original picture invariably declines. The physical type, too, of the Babylonian statues from Tel-lo, approaches the Caucasian rather than the Semitic type.

ON SOME RECENT AMERICAN MATHEMATICAL TEXT-BOOKS

In Nature (vol. xvi. p. 21) we drew attention to a "shaking" that was taking place among the "dry bones" of the mathematical text-books in common use in American colleges and schools, and upon the analysis we then furnished of a few works before us we ventured to predict a speedy awakening of mathematical life. Our prognostications have been quickly fulfilled, and we now propose to submit an account of five recent books, some of which are quite fitted to hold their own, in our opinion, with English text-books on the same subjects.

"The Elements of the Integral Calculus, with a Key to the Solution of Differential Equations," by Dr. W. E. Byerly (Boston, 1881), is a sequel to the volume on the "Differential Calculus," previously noticed by us. This work is founded upon Bertrand's classical treatise, supplemented by free use of the allied treatises by Todhunter, Boole, and Benjamin Peirce. The opening chapters give a clear exposition of the use of symbols of operation and of imaginaries. So early an introduction to these subjects is novel to us in this connection, but it shows how the subject of quaternions is coming to the front, and the passage from the subjects of these chapters to quaternions is but a short one The main portion of the book calls for no special comment. In Chapter XIV. we have a treatment of *mean value and probability*, founded upon the able contributions of Prof. M. W. Crofton, F.R.S., to Mr. Williamson's treatise.

The novelty of the book is Chapter XV., entitled "Key to the Solution of Differential Equations." This key is based upon Boole's work, and is a collection of concise, practical rules for the solution of these equations. An idea of its form will be best conveyed to some persons by saying that it resembles the analytical key so frequently prefixed now-a-days to handbooks of the British (and other) flora. By a series of references we run the particular equation to ground. Thus, taking the example, $(1+x)ydx+(1-y)xdy=0$, it is a single equation, this sends us to a number; it involves ordinary derivatives, this advances us a stage; it contains two variables, is of the first order, and finally of the first degree. The upshot is we arrive at the form $Xdx+Ydy=0$, under which head we learn how to solve the equation. Under this last head, as throughout the book, are given numerous illustrative exercises for practice.

Dr. A. S. Hardy's "Elements of Quaternions" (Boston, 1881) is intended to meet the wants of beginners. In addition to the works of Sir William R. Hamilton and Prof. Tait, the author has consulted the memoirs or works of Bellavitis ("Calcolo dei Quaternione" and the "Exposition de la Méthode des Équipollences" in Laisant's translation); Hoüel's "Quantités Complexes;" Argand's "Essai" (1806); Laisant's "Applications mécaniques du Calcul des Quaternions," and one or two other books and papers in the *American Journal of Mathematics*, vol. i. p. 379. It is a good introduction to such a work as Prof. Tait's, the originality and conciseness of which, however, Dr. Hardy thinks to be "beyond the time and need of the beginner."

Our next book is "An Elementary Treatise on Mensuration," by G. B. Halsted (Boston, 1881). Dr. Halsted is already known to mathematicians here as the author of a very full "Bibliography of Hyper-space and non-Euclidean Geometry," in the *American Journal of Mathematics*, vol. i., Nos. 3, 4. This treatise on Metrical Geometry is "the outcome of work on the subject while teaching it to large classes," so that it is no hastily prepared book, but has been founded on actual teaching experience. The methods have a German "smell," and this is justified by the author's residence, we presume as a student, at Berlin. There are eight chapters: (1) on the measurement of lines (triangles, method of limits, rectification of the circle; (2) on the measurement of angles; (3) of plane areas; (4) of surfaces (he uses *Mantel* for lateral surfaces, also *Steregon* and *Steradian* in connection with a solid angle); (5) of volumes (*Quader* is new for De Morgan's "right solid"). In these last two chapters the solids discussed are the prism, cylinder, pyramid, cone, and sphere; an article is also devoted to Pappus's theorem. (6) The applicability of the prismoidal formula; (7) approximative methods, as Weddle's method; (8) on the mass-centre, with a paragraph on the mass-centre of an octahedron, which gives Clifford's construction (see *Proc.* Lond. Math. Soc., vol. ix. p. 28). There are numerous exercises, these we have not tested. The book is most effectively "got up," the printing, figures, and paper being, to our mind, excellent.

Our last two books are by Prof. Simon Newcomb, so well known as the author of "Popular Astronomy." The first, "Algebra for Schools and Colleges" (New York, 1881), has already reached its second edition. It is a capital book; indeed we are disposed to rank it as the best manual on the subject that we have seen for school purposes. It is divided into two portions, "the first adapted to well-prepared beginners, and comprising about what is commonly required for admission to colleges, and the second designed for the more advanced general student." We shall perhaps best serve the end we have in view in noticing this work by giving an analysis of the author's preface. The principles of construction are (1) that an idea cannot be fully grasped by the youthful mind unless it is presented in a concrete form. Hence numerical examples of nearly all algebraic operations and theorems are given—so numbers are preferred to literal symbols in many cases. The relations of positive and negative algebraic quantities are represented by lines and directions at the very earliest stage. "Should it appear to any one that we thus detract from the generality of algebraic quantities, it is sufficient to reply that the system is the same which mathematicians use to assist their conceptions of advanced algebra, and without which they would never have been able to grasp the complicated relations of imaginary quantities." Principle (2) is that all mathematical conceptions require time to become engrafted upon the mind, and the longer, the abstruser they are. "It is from a failure to take account of this fact, rather than from any inherent defect in the minds of our youth, that we are to attribute the backward state of mathematical instruction in this country, as compared with the continent of Europe." Prof. Newcomb considers the true method of meeting this difficulty is to adopt the French and German plan of teaching algebra in a broader way, and of introducing the more advanced conceptions at the earliest practicable period in the course. A third feature is the minute subdivision of each subject, and the exercising the pupil on the details before combining them inta a whole. This remark especially applies to the solution of the exercises. Some subjects have been omitted (as G.C.D. of polynomials, square roots of binomial surds, and Sturm's theorem), as they have no application "in the usual course of mathematical study, nor advance the student's conception of algebra," and in studying them there is a waste of power. "Thoroughness" has been our author's aim rather than "multiplicity of subjects." There are other points of interest in this preface which show that the writer is a very experienced teacher, and which we commend to the consideration of teachers here, but we must pass on to indicate the contents of the two parts.

Part I. embraces algebraic language and operations, equations, ratios and proportion, powers and roots, equations (quadratic), progressions, seven books in all.

Part II. treats of relations between algebraic quantities (functions, &c.), the theory of numbers (also continued fractions), the combinatory analysis (including probabilities), series and the doctrine of limits, imaginary quantities (operations with the imaginary unit and the geometrical representation of imaginary quantities: note our remarks above on this head under Byerly), the general theory of equations.

The second of Prof. Newcomb's works before us is "Elements of Geometry" (New York, 1881). An article in our columns (NATURE, vol. xxi. p. 293), headed "The Fundamental Definitions and Propositions of Geometry, with especial Reference to the 'Syllabus' of the Association for the Improvement of Geometrical Teaching," gives its readers a hint that some such work as the one before us was even then in the author's mind—"A summary of my own, the latter [*i.e.* the summary] still in an inchoate state." The remarks in this article showed that their writer was well fitted to address himself to the subject of a geometrical text-book, and the execution is not at all inferior to the promise. The ground taken up is the Euclidian geometry as comprised in the treatises of Euclid himself, Legendre, and Chauvenet. As with the "Algebra," here let Prof. Newcomb speak for himself. As he himself says, the question of the best form of development is one of great interest at the present time among both teachers and thinkers. The object not being to teach geometry merely, but the general training of the powers of thought and expression being a main object, Prof. Newcomb considers it most important to guard against habits of loose thought and incomplete expression to which the pupil is prone. This he considers is best secured by teaching the subject on the old lines. The defects he finds in Euclid's system are (1) in the treatment of angular magnitude; here he makes two additions, the explicit definition of the angle which is equal to the sum of two right angles, and the recognition of the sum of two right angles as itself an angle. He adopts, from the "Syllabus," the term "straight angle," though he himself inclined (NATURE, *loc. cit.*) to the use of "flat angle," and considers the German "gestreckte Winkel" to be more expressive. Then (2) the restriction of the definition of plane figures to portions of a plane surface. "In modern geometry figures are considered from a much more general point of view as forms of any kind, whether made up of points, lines, surfaces, or solids." In an appendix, "Notes on the Fundamental Concepts of Geometry" he returns to a consideration of this subject.

Features of the book are (1) the practising the student in the analysis of geometrical relations by means of the eye before instructing him in formal demonstrations; (2) the application of the symmetric properties of figures in demonstrating the fundamental theorem of parallels (*cf.* German methods and Henrici's conguent figures); (3) the analysis of the problems of construction, to lead the pupil to discover the construction himself by reasoning; (4) the division of each demonstration into separate numbered steps, and the statement of each conclusion, where practicable, as a relation between magnitudes; (5) the theorems for exercise have been selected with a view to interesting the student in the study, and the author has endeavoured to graduate them in order of difficulty; (6) some of the first principles of conic sections have been unfolded, more especially for the use of students who do not propose to study analytical treatises on those curves; (7) Euclid's treatment of proportion is "perfectly rigorous, but has the great disadvantages of intolerable prolixity, unfamiliar conceptions, and the non-use of numbers. The system common in American works of treating the subject merely as the algebra of fractions, has the advantage of ease and simplicity." But to this last system there are obvious objections, and our author essays with some reserve, a *via media*. In this part and in the following Prof. Newcomb submits his methods to the judgment of teachers. Feature (8) involves the treatment of the fundamental relations of lines and planes in space. "In presenting it he has been led to follow more closely the line of thought in Euclid than that in modern works. At the same time he is not fully satisfied with his treatment, and conceives that improvements are yet to be made."

It will be gathered that the book covers most of the ground passed over by young students in plane and solid geometry, and conics in their school training. We cordially commend both Prof. Newcomb's works to teachers in this country, and we feel sure they will not regret our having called their attention to them so fully in the author's own words, as they will thus see in what way his books are likely to be helpful to them. We have read them with much interest, and feel sure our readers will endorse our favourable verdict upon them. We need only say that the author considers that the study of geometry as here unfolded can be advantageously commenced at the age of twelve or thirteen years. The volumes, with a third, which we have not seen, on Astronomy, form part of "Newcomb's Mathematical Course."

R. TUCKER

ELECTRICITY AT THE CRYSTAL PALACE

IV.—*Submarine Telegraphy*

IN the stall of the South Eastern Railway Company at the Crystal Palace may be seen a specimen of the first cable core ever submerged. It consists of a slender copper wire coated with gutta-percha, and was prepared at Streatham by Mr. J. Forster. On January 10, 1849, it was submerged by Mr. Walker, at Folkestone, and a copy of the telegram announcing the completion of the work is still preserved. It runs: "I am on board the *Princess Clementine*. I am successful; 12.49 p.m." Next year a cable was laid between Dover and Cape Grisnez by Mr. Wollaston, but lasted only a few hours. Several specimens of it are shown in the Exhibition by the South Eastern Railway Company and the Post Office. The gutta-percha core was quite unprotected, and it was sunk by means of lead weights attached at intervals. Next year a core, protected by hemp and iron sheathing, was laid by Mr. T. R. Crampton between Dover and Cape Grisnez, and proved so successful, that it is still working. Specimens of this cable, which has proved the type of all subsequent ones, are also to be seen.

There are now some 97,200 miles of cable at work in the world, and before this year is ended the hundred thousand miles will have been attained; for the second Jay Gould Atlantic cable is still unfinished, and the s.s. *Silvertown* of the India-rubber and Gutta-percha Telegraph Company is now on her way to lay some two thousand miles on the West Coast of Central America. Nearly all this cable has been made in London, and the Telegraph Construction and Maintenance Company alone has manufactured 65,400 miles, and laid it in almost every sea, in depths varying from shoal water to 3000 fathoms. In 1863 the firm was resolved into the existing Company. Specimens of all the cables made by them are exhibited in a large glass case, together with a large map of the world, showing all the submarine and land lines in existence; those constructed by the Company being marked in red. The most novel feature of their exhibit is, however, a plan for keeping up telegraphic communication between a lightship and the shore. In 1870 an attempt was made to establish a floating telegraph station in the chops of the Channel; an old man-of-war corvette, the *Brisk*, being fitted up, and moored in deep water about sixty miles from the Land's End. It was found, however, that as the ship swung with the tide, the telegraph cable fouled with the ship's riding-chain, and likewise became twisted into kinks, which crushed the gutta-percha core and destroyed the insulation of the cable. Means were taken to prevent this trouble, but as passing ships did not leave a sufficient number of telegrams, the project was abandoned. Nevertheless, it is clear that such a scheme is worthy of further trial; and even with ordinary lightships it is eminently desirable that they should be in telegraphic communication with the nearest Coast Guard Station. At present, guns and rockets are the only available messengers, and when the wind is off the shore, guns are sometimes not heard; or when the weather is thick, rockets are not seen. The result is, that ships are sometimes lost on shoals close by the lightships, without the Lifeboat Station knowing it. Carrier-pigeons have been tried, but these birds fail to make good progress in snow-storms or thick weather, and in heavy gales are driven hither and thither at the mercy of the elements. The plan for cable communication adopted by the Telegraph Construction and Maintenance Company is to moor the lightships by chains to two mushroom anchors sunk a considerable distance apart. One of these chains is made double, and the cable runs through the middle of it between the double links, as shown in Fig. 1. The chains meet at a mooring swivel. which is made so as to allow the cable to pass through it, as shown in Fig. 2. Between the swivel and the bow sheave of the ship, a revolving joint in the cable, designed by Mr. Lucas, prevents the cable becoming twisted as the ship swings to the wind and tides. A sufficient length of cable is coiled in a tank on board, for paying out, when from stress of weather it is necessary to employ more chain. A pretty model of a lightship moored on this plan is exhibited by the Company, and on touching a press-button let into the edge of the tank, an electric current is sent through the communicating cable, and strikes a bell on board the ship. It is satisfactory to know that the Trinity House have agreed to test the plan by means of a cable between the *Sunk* lightship moored some eight miles off the Essex coast, and the Post Office of Walton-on-the-Naze, from whence telegrams can be sent by day or night for any assistance required.

Of the total 97,200 miles of cable in the world, some 36,420 are owned and worked by the Eastern Telegraph Company and its affiliated companies the Eastern Extension Telegraph Company and the South African Telegraph Company. The Eastern Telegraph Company is perhaps the most enterprising of cable corporations, and makes a very fine display at the Crystal Palace. Cable operations have been of great assistance to the geographer, and the soundings taken in order to ascertain the nature of the sea-bottom, where a cable route is projected, have enriched our charts quite as much as special voyages. There is, however, another way in which these operations could be made subservient to the cause of natural science; but it is a way which has not been sufficiently taken advantage of. Besides the specimens of stones, mud, and sand, which the sounding-lead brings up from the deep, the cable itself, when hauled up for repairs, after a period of submergence, is frequently swarming with the live inhabitants of the sea-floor—crabs, corals, snakes, molluscs, and fifty other species—as well as overgrown with the weeds and mosses of the bottom. Some attempt was made to describe these captures of the wire, as taken from the tepid seas of the Amazon mouth, by the writer in our pages several years ago (vol. xi. p. 329),[1] and the suggestion was there made that cable repairing might serve as a novel method of dredging; but the hint has probably not been taken, for we cannot learn of any competent naturalist having taken his passage on board a cable-repairing ship, say in the Brazilian and West Indian waters, or better still, the East Indian waters traversed, by the lines of the Eastern and Eastern Extension Telegraph Company, from Aden to Bombay, and from Madras to Penang, Singapore, Batavia, and soon to Port Darwin, in Australia. The result is that cables have again and again been lifted richly vestured with the spoils of the bottom, and many an unknown species has passed over the drums unnoted, to rot and fester in the general mess within the cable tanks. We venture to predict a rare harvest to the first naturalist who will accompany a repairing ship, and provide himself with means to bottle up the specimens which cling to the cable as it is pulled up from the sea.

Some idea of these trophies may be gathered from the stall of the Eastern Telegraph Company, where a few of them are preserved. Two of these are a very fine grey sea-snake, caught on the Saigon cable in a depth of thirty fathoms, and a black and white brindled snake, taken from the Batavian cable in twenty-five fathoms. Twisting round ropes seems to be a habit of this creature, for the writer remembers seeing one scale up a ship's side out in the River Amazon, by the "painter" hanging in the water.

A good example of a feather-star is also shown; these animals, being frequently found grasping the cable by their tentacles. A handsome specimen of the blanket sponge, picked up in the Bay of Biscay, is also exhibited; but the most interesting object of all is a short piece of cable so beautifully encrusted with shells, serpulæ, and corals, as to be quite invisible. It was picked up and cut out in this condition from one of the Singapore cables. The rapid growth of these corals is surprising, and some valuable information on this head might be gained if the electricians of repairing ships in these eastern waters would only make some simple observations. Curiously enough, so long as the outermost layer of oakum and tar keeps entire, very few shells collect upon the cable, but when the iron wires are laid bare, the incrustation speedily begins, perhaps because a better foothold is afforded.

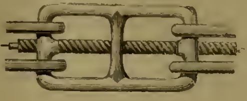

Fig. 1.

Fig. 2.

Fig. 3.

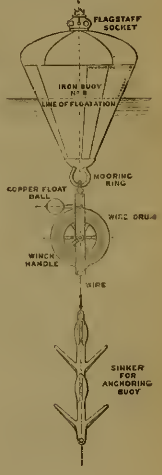

Fig. 4.

A deadly enemy to the cable, in the shape of a large boring worm, exists in these Indian seas; and several of them are shown by the Company. The worm is flesh-coloured and slender, of a length from $1\frac{1}{2}$ inches to $2\frac{1}{2}$ inches. The head is provided with two cutting tools, of a curving shape, and it speedily eats its way through the hemp of the sheathing, to the gutta-percha of the core, into which it bores a hole similar to that shown in Fig. 3.

---

[1] "On some South American Phenomena" (J. Munro).

A full account of this particular worm, with anatomical illustrations, is given in the *Journal* of the Royal Microscopical Society for October, 1881, by Dr. Charles Stewart, secretary of the Society. The bore-holes, after passing through the oakum of the inner sheathing, either pursue a tortuous course along the surface of the gutta-percha core, or go right into the copper wire, thereby causing a "dead earth" fault. Dr. Stewart classes the worm as one of the Eunicidæ, but proposes for it the generic name of *Lithognatha worslei*, because of its possessing a pair of calcareous mandibles or cutting jaws, and after Capt. Worsley, the Commander of the repairing ship which picked up the worm-eaten cable. The pair of calcareous jaws, in addition to three pairs of chitinous ones, is the most remarkable feature about the animal, and the white plates which form them make the creature look as if it were in the act of swallowing a tiny bivalve shell.

The best protection hitherto formed against it is to cover the core with a ribbon of sheet-brass, laid on without a lap. First the gutta-percha is covered with cloth, then the brass is overlaid. Canvas is then put over the brass, and the hemp and iron wires over all. A close layer of iron wires is not a sufficient protection, for the worm can sometimes wriggle in between the wires where they are not close enough; and, moreover, the rapid decay of iron wires in tropical seas is certain to leave the core a prey to these pests in a few years.

The Eastern Extension Telegraph Company also exhibit some interesting samples of stones picked up from the sea-bottom; for example, limestone blocks and shells bored by the bivalve, *Saxicava ragosa*, the worm Sabella, and the sponge *Hymeniacidon celata*; wood honeycombed by the teredo, a red stone pitted by the bivalve shell (pholas), and a ferruginous flaky stone brought up from the bottom between Penang and Singapore. Most interesting, however, of these inanimate waifs is a flat piece of black flinty rock hollowed into cup-like pits by the sucking feet of the sea-hedgehog. The pits are excavated as lairs for the animal and some of them are nearly three inches in diameter by one inch deep. To make the rocky bed softer to the feel, the hedgehog has lined it with a calcareous enamel, probably secreted by its body, much in the same way as the pearl oyster coats its shell.

In the earlier days of submarine telegraphy, Sir William Thomson declared the life of a cable to be practically inviolable; and Robert Stephenson, on the other hand, was of opinion that no cable would last out ten years. The latter view has proved the more correct, for the average life of a cable hitherto has been about eleven years. Thanks to the improved means of repairing them, however, the outbreak of faults does not mean the loss of a cable, for these flaws can be cut out in water, however deep, and the cable put to rights again. Indeed every cable company expects a recurrence of faults, and provides a fully-equipped repairing ship always on the spot. A fine model of such a ship is exhibited by the Post Office, after the designs of Mr. R. S. Culley. Messrs. Johnson and Phillips also exhibit a variety of buoys and grapnels for cable operations. The ordinary grapnel is liable to have its prongs broken off in dragging over a rocky bottom, as may be seen from one exhibited which had every prong bent back among the coral reefs of the Brazilian coast. Centipede grapnels are therefore fitted with removable prongs; and Mr. A. Jamieson has invented a grapnel with spring teeth which bend back when they meet a rock, so as to slip over it, but catch and hold the cable. A sample of this grapnel is shown in the Western Gallery, and a sample of Messrs. Johnson and Phillips' grapnel for cutting the cable and holding one end is shown in front of the Roman court, together with a very large buoy for buoying the cable in deep water. A very convenient and novel "mark" buoy for marking positions in cable work is exhibited by the same firm in the Western Gallery. The buoy is suspended by a line from the ship's quarter or stern, and when the line is cut, the buoy drops into the water. The copper float ball (see Fig. 4) is then raised, and lifts a detent which allows the drum of steel wire to revolve. The centipede anchor then sinks to the bottom, and moors the buoy. A winch handle is provided, so that the moorings can be recovered if need be, but the cost of the sinker, drum, and wire is so slight that it may readily be abandoned. While upon the subject of deep-sea operations, we may also mention the "nipper lead" of Mr. Lucas, by which specimens of the sea-bottom are caught in two spoons or tongs hinged to the bottom of the lead, and kept apart by a trigger arrangement, which is sprung by the lead striking the bottom.

Coming now to the working of submarine cables, there are several very neat mirror galvanometers exhibited by Messrs. Latimer Clark, Muirhead, and Co. The Eastern Telegraph Company exhibit the siphon recorder of Sir William Thomson, working through one of Dr. Muirhead's artificial cables on the duplex system, the counter instrument being placed at the stall of the School of Telegraphy. The bold electromagnets of this fine instrument have been excited hitherto by Sir W. Thomson's large tray-form of Daniell cell; but quite recently Mr. Clement Chevallier, electrician to the Eastern Telegraph Company at Aden, has substituted permanent magnets, with a great gain in economy. These magnets were specially made by Mr. Le Neve Foster, at Silvertown, and their magnetic power is much heightened by a small percentage of tungsten in the steel. An interesting experiment, showing the retardation of signals through a long submarine cable, is made by the School of Telegraphy. Ten mirror galvanometers, throwing ten light-spots in a vertical row on a white screen, are connected in turn at different points of a long cable, and the travel of the charge when the circuit is closed by a key is shown by the successive movements of the light-spots across the screen.

Mr. C. F. Varley, F.R.S., who by his application of condensers to the submarine circuit did so much to improve cable signalling, has a very interesting exhibit of his past inventions. These include his gravity battery patented in 1854 (No. 2555), and repatented in 1861 by Menotti, whose name it bears. In the same patent the sulphate of mercury battery, subsequently known as the Mariè-Davy, was also described. This patent, like most of Mr. Varley's, was very rich in devices, and contains his application of the condenser not only to telegraphy, but to electric lighting, a plan subsequently patented by Jablochkoff. Mr. Varley's exhibit also includes the first polarised relay used in this country, and the rotary electrical machine made and patented in 1860, and held by him to be the parent of the Holtz and other induction machines, such as the mousemill of the siphon recorder and the replenisher of the quadrant electrometer. But it is probable that Mr. Varley's claim must give way in favour of M. Belli, who invented a similar induction machine many years ago, which the writer saw in the Retrospective Museum of the recent Paris Electrical Exhibition.

THE EARLIEST USE OF THE INCANDESCENT ELECTRIC LIGHT

A CORRESPONDENT writes:—

The following extract from a memoir by Sir William Grove, published more than thirty-six years ago, will be of interest to future historians of the progress of lighting by electricity. The memoir is entitled "On the Application of Voltaic Ignition to Lighting Mines," by W. N. Grove, F.R.S., and is published in the *Philosophical Magazine*, May, 1845. It begins by stating that M. De la Rive had proposed the use of the voltaic arc for illuminating mines; it describes the apparatus employed by him, and the difficulties that prevented its practical application, and continues as follows:—

"I substituted the voltaic ignition of a platina wire for the disruptive discharge. Any one who has seen the common lecture-table experiment of igniting a platina wire by the voltaic current nearly to the point of fusion, will have no doubt of the brilliancy of the light emitted; although inferior to that of the voltaic arc, yet it is too intense for the naked eye to support, and amply sufficient for the miner to work by. My plan was then to ignite a coil of platinum wire as near to the point of fusion as was practicable, in a closed vessel of atmospheric air, or other gas, and the following was one of the apparatus which I used for this purpose, and by the light of which I have experimented and read for hours:—A coil of platinum wire is attached to two copper wires, the lower parts of which, or those most distant from the platinum, are well varnished; these are fixed erect in a glass of distilled water, and another cylindrical glass closed at the upper end is inverted over them, so that its open mouth rests on the bottom of the former glass; the projecting ends of the copper wires are connected with a voltaic battery (two or three pairs of the nitric acid combination), and the ignited wire now gives a steady light, which continues without any alteration or inconvenience as long as the battery continues constant, the length of time being of course dependent upon the quantity of the electrolyte in the battery cells. Instead of making the wires pass through water, they may be fixed to metallic cups well-luted to the necks of a glass globe.

The spirals of the helix should be as nearly approximated as possible, as each aids by its heat that of its neighbour, or rather diminishes the cooling effect of the gaseous atmosphere; the wire should not be too fine, as it would not then become fully ignited; nor too large, as it would not offer sufficient resistance, and would consume too rapidly the battery constituents; for the same reason, *i.e.* increased resistance, it should be as long as the battery is capable of igniting to a full incandescence."

The memoir concludes with the description of experiments on the illumination power of this contrivance under different conditions.

THE ENGLISH ECLIPSE EXPEDITION

THE following communication, under date lat. N. 37·8, long. E. 11·10, April 27, has appeared in the *Daily News*, from the special correspondent of that paper with the English Eclipse Expedition:—

Your correspondent so far has not had a very easy time of it, although it must be confessed his difficulties have been in no way connected with lack of material. Chronicling attempts to advance beyond the frontiers of the known must always be a pleasant task to the chronicler, who is thus enabled to be among the first to reap the rich intellectual rewards always gained, or nearly always gained, in such forays. But when the task brings him in full view of other interests, and especially when it compels him to observe phenomena for himself, a correspondent's task may become complicated beyond measure, and not only the *embarras de richesses*, but even a mental revision of his instructions, however precise they may have been, may give him trouble. Thus, in the present case, my clear duty is to keep pace with the thoughts and doings of the Eclipse party now on the *Kaisar-i-Hind*, between Gibraltar and Malta; but am I therefore to be blind to the fact that each P. and O. ship does not leave Gravesend with two tons of telescopes and eyes to use them, and that the infusion of a scientific party into the general run of passengers on this the most important of England's seaways, cannot but cause what our American cousins would call a "ripple" on the ordinary routine of ship-life.

Those who have made their way to the far East many times, and who are therefore quite familiar with this routine, will at once recognise the possibility that at first such *raræ aves* were looked at askance. Was there not at least some strange power of divining secrets in sextants, spectroscopes, and cameras brought now and then, and with a kind of furtive air, from hidden recesses? And this being so, what conduct was more natural on the part of the non-scientific members of the party, than that they should show a keen anxiety to assure everybody that they at least knew next to nothing of science—in short, that though they might deplore these strange and aberrant tendencies, they were powerless to interfere, even if the studies were less harmless than they believed them to be. This, at first, of course confirmed the general impression, but it did not take long for the ice to melt; the strange feeling soon wore off, and after a fierce gale which the *Kaisar-i-Hind* encountered in the Bay of Biscay had abated, the keenness of everybody on board to hear something of a world of marvels new to most of them, and the anxiety of every servant of the P. and O. Company, from captain to boatswain, to help, whenever help was needed, were the predominant features.

The delight of the Somali boys at being photographed was a sight to see, their broad grins being in strange contrast with the evident anxiety of the Arabs among the crew to escape the influence of such a possible evil eye. While this is going on in one part of the ship, the reflection of the summer sun shimmering from a thousand Mediterranean waves through which the noble ship ploughs her way on an even keel is utilised to show the wondrous work which has already been done by the spectroscope. Nor are the other worlds, still left to conquer, forgotten in the demonstration; among them, those secrets of the Sun which it is hoped may be unveiled during the coming precious seventy seconds. And this brings me to the proper subject matter of the present letter. What, then, are the astronomers going to do? or, to put it more modestly, what are they going to try to do? Before a categorical answer can be given to this question there is some preliminary matter to be got over; we have, in fact, to consider the changes in thought and methods introduced by ten years of work. A volume might be written on this, but a very brief *exposé* is really all that is required on the present occasion. The brilliant achievements of physical astronomers in the domain of solar physics during the last twenty years have dealt in the main with the chemical and physical construction of the atmosphere of our central luminary; that is, those parts of it which are furthest from the centre. In fact, it has been a question of meteorology, and not a question of geology, to use terrestrial equivalents. One of the first things made absolutely certain was that the outer atmosphere for tens and perhaps hundreds of thousands of miles above the surface of the round orb we generally see and call the Sun, is intensely hot—hot enough to have its clouds built up of vapour of iron, as in our own air we have clouds built up of the vapour of water. Next, as the work went on, two things happened. First, certain and sure evidence was obtained that the outer atmosphere extended much farther from the sun than had been previously supposed by those most competent to form a just opinion; and, further, while the extent of the atmosphere was thus engaging attention, the chemical inquiry had been carried so far that we thought we were justified in saying, not only that the sun's atmosphere contained just such substances as ours would do if our little earth were suddenly turned into a mass of vapour, but that certain substances occupied such and such positions in the atmosphere, while others were to be sought for elsewhere.

Thus outside all, it was imagined, there was a substance about which we know nothing here, because we cannot find anything which produces the same spectrum. Inside this, at mid-height in the sun's atmosphere, we got indications about which there could be no mistake—we were in presence of hydrogen: incandescent hydrogen, be it observed, which plays as important, or indeed a still more important part in the solar air than nitrogen does in our own. Next it was imagined that close to the sun itself there was a vaporous sea containing all the other substances which had been detected by the spectroscope—magnesium, calcium, iron, barium, cobalt, nickel, and some twenty other bodies termed "elements" by the chemist, because he cannot reduce them to a condition of greater simplicity. As the sum total of these inquiries, then, we had some such idea of the sun's atmosphere as this: Physically it was incandescent, of enormous extent, very irregular in outline, its extent and outline varying almost every time it could be observed. Chemically it was built up of substances known to terrestrial chemistry; it was very simple at top, and very complicated at bottom. This mental image was the joint product of both laboratory and eclipse work. The solar spectrum—that is, the beautiful rainbow ribbon which is produced when light from the sun is made to pass through a prism—enabled us even in our laboratories, without a telescope, to study the chemistry of the sun's atmosphere as a whole, but such work as this localised nothing. Further, the outer atmosphere is so dim as compared with the intensely brilliant interior nucleus, that it, like the stars in the daytime, is put out, and remains invisible so long as the sun itself is in a position to illuminate our upper air. In this we have the use of total eclipses, for at such times the moon prevents the sunlight from falling on our atmosphere, and the sun's atmosphere shines out in all its weird splendour, as the stars show themselves when the light of day is withdrawn. It is fair to add, that there is a method which enables us to study the chemistry and even the meteorology of the very brightest portion of the sun's atmosphere, called the chromosphere, without waiting for an eclipse, but still, every allowance being made, it should be now clear that to study the physical attributes of the atmosphere as a whole, we are strictly limited to total eclipses. So much, then, for our brief *exposé*. There is still some more ground to be gone over before the question with which we set out is answered. What was the sum total of the work done during the last eclipse—that observed in the United States in 1878, with a wealth of instrumental appliances such as had never been used before? How did it deal with our received notions? Did it endorse them or demolish them?

It certainly endorsed them in the main, while it enabled us to accumulate a vast amount of new knowledge on many important points, and showed us how every effort should be made to secure these precious records. Among other things, it intensified the difference between eclipse and eclipse, for the spectroscopic record of the outer corona—as the exterior atmosphere is sometimes called—differed very considerably from the one secured in 1871, and it was a noteworthy fact that the eclipse of 1871 happened when there were most spots on the sun, while that of 1878 took place when there were fewest. I said "in the main." But during the eclipse one observation was made, which in the light of former laboratory work suggested that after all there was a rift in the lute, and that our view of the solar economy might be much more wrong than we had any idea of. Since 1878 that same laboratory work has been continued, and a long series of observations of the spectra of sun-spots has been made, and the tendency of all this extra eclipse-work has all been in one direction. We are now face to face with the idea that, in the hottest part of the sun, the temperature is so high that our so-called elementary bodies are broken up into simpler ones, and that the reason that the sun seems to contain so many of our terrestrial elements is simply that both in the sun and in a powerful electric spark these bodies are really broken up into their finer constituents, the spectral lines of these finer constituents being observed in both cases. Now it is obviously the duty of men of science, if there be any tests of this new view, any crucial observations possible during an eclipse, to apply these tests, to make these observations, as soon as possible—not, of course, to the neglect of the old methods of attack, but, if possible, in addition to them; and as the problem is one of such general interest, and one which is sure to be keenly debated, as many records independent of personal error or personal bias should be obtained as possible. These permanent records, to which reference has been made, are of course photographs, and here we are brought face to face with another fact; we have not only a new view to test, but we have new photographic processes to apply to test it, as well as to obtain a series of records comparable with those secured during prior eclipses. We have in this case an instance of the way in which an observation, apparently trivial, is at last seized hold of and made to furnish a stepping-stone for a further advance in scientific inquiry. It is now many years since Faraday, experimenting on gold leaf, which is green when a bright light is observed through it, found that he could change its colour, and he fancied that this might be taken to indicate that the gold in the leaf did not consist of particles all of the same size, but that they existed of almost an infinite series of finenesses. This was in the pre-spectroscopic days. When the spectroscope could be brought to bear, it became apparent that two orders of fineness only were required to produce all the colours observed by Faraday, and Mr. Lockyer soon produced other evidence which went to show that we were here in presence of a general law. From this time we heard the words "blue molecules" and "red molecules"—terms invented to indicate that in the same chemical substances there were some molecules with such physical attributes that they were turned to and could therefore absorb blue light, while others were made active by red light falling upon them.

Capt. Abney, in a series of painstaking researches, has shown that precisely those salts of silver employed by photographers obey this general law, and hence we can now use blue light and red light indiscriminately, and so, for the first time we can photograph the red end of the spectrum of the sun's external atmosphere. Nor is this all; other advances in the photographic art enable us now to replace minutes by seconds in the time of exposure; indeed, in these days of "instantaneous" processes, the difficulty often lies in exposing the plate for a time short enough to the influence of the light. It is as well to insist upon this point, as in the eclipse of next month the totality or period during which the moon entirely covers the sun is very short; but short as it is, it is more than made up for by the increased rapidity of the processes to be employed. Now, the most important phenomena to be recorded, whether by eye or photography, are, first, the spectrum of the lowest stratum of the sun's atmosphere revealed to us at the moment of disappearance and reappearance of the sun by a sudden flashing out of bright lines; next, the spectrum of the outer atmosphere, best observable at mid-eclipse; and then the extent and structure of the atmosphere itself. Now it is imagined, that if the new view to which reference has been made is correct, the spectrum of the lower stratum will differ from what it is supposed to be, and we say supposed to be, because up to the present time the observations have been of such a general nature that it has been impossible to be quite certain about details. The intention this time is to observe a small portion of the spectrum with great minuteness, so far as the eye observations go, while an attempt will be made to actually photograph the flash of bright lines, and obtain a reference spectrum afterwards by obtaining a photograph of the solar spectrum on the same plate after the eclipse is over.

Among the most interesting observations made during the total eclipse of 1878—duly chronicled in the *Daily News* at the time—was one by which Prof. Newcomb demonstrated a tremendous extension of the corona in the direction of the plane of the sun's equator, or very near it. It will be important to see, whether on the present occasion the extension will be so great, especially since Dr. Siemens has thrown down the gauntlet to astronomers by his bold speculations touching the circulation of the solar gases. Such, then, are some of the things which the Eclipse Expedition is going to do, or going to try to do. If all goes well, I shall be able in my next letter to tell your readers something of a definite nature as to the actual camping-ground and the local arrangements in Egypt.

The following telegram from its special correspondent is given in Tuesday's *Daily News* :—

Sohag, Monday

The preparations are complete for the eclipse on Wednesday, thanks to the assistance rendered by the representatives of the Egyptian Government to the English, French, and Italian observers alike. The weather is apparently settled. There is little probability of dust-storms. The greatest heat experienced is 108 in the shade. The temperature is now cooler. The English party will probably return by Carthage, leaving Suez on the 31st.

ALGÆ[1]

IT is little more than a year since the Latin edition of Dr. Agardh's work on the "Morphology of the Florideæ" was noticed in the pages of NATURE. The author now sends us another contribution to the systematical study of algæ. The present is, however, not a distinct work, but a continuation of a series of Essays or Monographs, the first instalment of which appeared in vol. ix. of the *Transactions* of the University of Lund, in the year 1872. The subjects of the first instalment were the genera Caulerpa and Zonaria, and the classification and description of the Australian species of certain tribes of Sargassum.

The present work consists of essays on the CHORDARIEÆ, and on some of the DICTYOTEÆ. Although it bears a Swedish title, it is written in Latin. It commences with a monograph of the family Chordarieæ, which is entirely reconstructed, and is enlarged by the introduction of several new genera. Under the present arrangement it comprises seventeen genera.

From the increased activity recently shown by British algologists whose exertions have been rewarded by the discovery of many species of Algæ new to these shores, it would seem desirable to mention more particularly a few of the changes which have been made in the present work by Dr. Agardh in the classification of some of the plants of the olive series of Algæ.

Beginning with Elachistea, as the author, restoring the old spelling, prefers to call it, we find that this genus is removed to the CHORDARIEÆ. This is in accordance with the views of Dr. W. H. Harvey, expressed in the "Phyc. Brit. Tit." *E. fucicola.* This genus is especially interesting from the fact that out of the nine species, seven are British. *E. velutina* (of the "Phyc. Brit." pl. xxviii. B), removed by Thuret to Streblonema, is placed by Dr. Agardh in his new genus Herponema (see p. 55).

The next genus, Myriocladia, includes *M. Loveni*, an extremely rare species, which has been obtained growing on oysters in deep water in the Baltic, and which Dr. Agardh ("Sp. Alg.", p. 53) states was found by the late Mr. Borrer on the Sussex coast; it has not, however, been met with by succeeding observers; neither has Dr. Agardh seen the plant in other collections. The name of this rare plant does not occur in the published lists of Algæ found by Mr. Borrer. A representation, much enlarged, of some of the details of the plant, will be found on Pl. 1, Fig. 3.

The genus Mesogloia is now restricted to two species, *M. Mediterranea* and *M. vermicularis. M. virescens* is removed to Eudesme, of which another species inhabits Tasmania and South Australia. *Chordaria divaricata* and *Mesogloia Griffithsiana* are now respectively *Castagnea divaricata* and *C. Griffithsiana.* The observations on the structure and fruit of the epiphytic plants, which constitute the genera Myrionema and Herponema, will be interesting to British algologists.

Among the new Algæ which have been recently added to the British Marine Flora, is the handsome plant found by Mr. G. W. Traill, in the Firth of Forth, and issued to British collectors under the name of *Dictyosiphon Hippuroides.* The plant was first described and figured by Lyngbye in the "Hydrophytologiæ Danicæ," under the name of *Scytosiphon Hippuroides;* then, in Agardh's "Sp. Gen. et ord. Alg.", vol. i. p. 66, as *Chordaria flagelliformis*, var. *B. Hippuroides.* Areschoug subsequently distributed dried specimens of the plant, and published (*Bot. Notiser*, 1873, No. 6., and *Obs. Phycol.*, iii. 1875) descriptions of it under the name of *Dictyosiphon Hippuroides.* In the present work Dr. Agardh maintains the opinion he had expressed in "Sp. Alg." more than thirty-three years ago, that the *Scyt. Hippuroides* of Lyngbye is a form of *Chord. flagelliformis*, and not a Dictyosiphon. He supports his views by a minute description of the structure of the frond, and gives at length (pp. 67-70) his reasons for differing in opinion from his old friend Dr. Areschong. As a proof of the care with which Dr. Agardh conducted his examination of the plant, it may be mentioned that he describes and names six forms of it, including among them, *Scyt. Hippuroides*, Ll., and *Scyt. tomentosus* or Fl. Dan. and Lyngb. British algologists will find this part of Dr. Agardh's work particularly interesting.

Among the Algæ which have been recently added to the British Marine flora are *Phlæospora tortilis* (Rupr) Aresc., and *Dict.* (*Coilonema*) *mesogloia*, Aresc.; it may be mentioned incidentally that Dr. Agardh considers both Phlæospora and Coilonema as distinct genera.

The DICTYOTEÆ.—The author commences with preliminary remarks on the limits of the family, and the structure and fructification of the different genera (pp. 77-83). Then follows an elaborate essay on the genus Dictyota (pp. 83-92); and after that a description of the species, and the tribes under which they are arranged. Of the twenty-six species, one only, *D. dichotoma*, is a native of our shores. Six other species are referred to Dilophus, J. Ag., and two to Glossophora, J. Ag.

The genus Spatoglossum, Kg., includes *Taonia Solierii*, *T. Schrœderi*, and two others. Then follow a few observations on *Taonia atomaria.* Padina is treated at greater length. To this succeed elaborate observations on the structure and fructification of Zonaria (pp. 120-131), and some remarks on certain species. This part of the work, it must be observed, is supplementary to the article on Zonaria in the first part of the "Bidrag," p. 45. before referred to, in which the several species are described.

It may here be remarked that the *Zonaria collaris* of the "Phyc. Brit." has no claim to be considered as a native of the British Isles. It is found in the Mediterranean and Adriatic, and occasionally in Granville Bay, on the French coast. It is not a Zonaria, but a Cutleria.

The work concludes with some observations on the species of Halyseris.

In the selection of the preceding subjects for remark, the writer has been guided by the interest which, it was thought, would be taken in them by British algologists; it must, however, be observed that the work has also many points of interest as regards Australia, Tasmania, and New Zealand. Among the species belonging to the

---

CHORDARIEÆ, sixteen are natives of these colonies; while in Dictyota, Dilophus, and Glossophora, which, together contain thirty-four species, no fewer than fifteen belong to the same localities.

It is almost superfluous to say that the work in every part gives evidence of the careful and patient observation which characterise all the writings of Dr. Agardh, and render them so valuable an aid to the study of algology. It is to be hoped that before long we may have the pleasure of welcoming another instalment of his contributions to the study and classification of the Melanosperms.

M. P. M.

NOTES

THIS week we give the first of a short series of articles on the life and work of the late Mr. Darwin. The series is under the general care of Dr. G. J. Romanes, F.R.S., who also will take special charge of the Zoology and Psychology. The Geology will be by Prof. Geikie, F.R.S., Director of the Geological Survey, and the Botany by Mr. W. T. Thiselton Dyer, F.R.S.

THE first meeting of the Executive Committee of the Darwin Memorial was held in the rooms of the Royal Society on Tuesday, May 16, at which it was resolved that subscriptions be invited in order to promote such a memorial of the late Mr. Darwin as shall seem most fitting, having regard to the amount that may be collected. Subscriptions will be received by Mr. J. Evans, Treasurer, Royal Society, Burlington House, W.

AT a meeting of Convocation of the University of London held May 9, the following resolution was unanimously passed:—"The Graduates of the University of London, in Convocation assembled, desire to record their sense of the irreparable loss which science and philosophy have sustained in the death of Mr. Darwin, whom they recognise as an acute and patient investigator, an earnest seeker after truth, and an original thinker, whose discoveries have exercised a profound influence upon scientific research and upon the progress of scientific thought throughout the world."

A NOVEL feature at the meeting of Convocation of London University, last week, was the appearance for the first time of female graduates in academical costume. Sir George Jessel, who presided, gave some statistics to show the rapid progress in the numbers availing themselves of the University's examinations, while Sir John Lubbock pointed out the progress that had been made in scientific education during the past year, referring especially to the City Technical Institute. "What is wanted," he said, "is not so much money or men, as method and organisation, and to utilise the resources we already possess." He referred to the wasted resources of Gresham College, which, he said, ought to be "placed on a footing more in accordance than it has been with the wise designs of its noble founder." It was agreed to request the Senate to take definite steps with regard to this fossilised institution.

A WELL-DESERVED baronetcy has been conferred upon the eminent scientific agriculturist, Dr. John Bennet Lawes, F.R.S. The vast services rendered to agriculture by Sir John B. Lawes, in connection with Dr. Gilbert, are well-known. The new baronet, we learn from the *Times*, was born in 1814, and succeeded to his estate at Rothamstad, in Hertfordshire, in 1822. Mr. Lawes was educated at Eton and at Brasenose College, Oxford, where he remained from 1832 to 1835. During his academic career he displayed at once a strong partiality for the laboratory, and on leaving the University, spent some time in London, for the purpose of studying in a practical manner the science of chemistry. Possessed of independent means, a handsome property, and a beautiful old manor-house and demesne, Mr. Lawes at once interested himself in agriculture. In October, 1834, he first commenced regular experiments in agricultural chemistry on taking possession of his property and home at Rothamstead, and from that date up to the present time Mr. Lawes has unceasingly been applying his scientific knowledge to the solution of questions affecting practical agriculture. Sir John Lawes, we believe, has not only entirely maintained his experimental farm of 500 acres, but has further set apart a sum of 100,000*l.* and certain lands for the convenience of the undergraduates after his death. This is indeed a gift to the nation, a gift, too, which no money value adequately represents.

MR. F. V. DICKINS, M.B., B.Sc., has been appointed Assistant Registrar to the University of London, in succession to Prof. Moseley.

THE second meeting of the Bohemian Naturalists and Physicians will take place at Prague during May 24-30, to celebrate the foundation of a Slav University in that city.

M. COCHERY, the Minister of Postal Telegraphy in France, has printed a circular extending the use of telephones to provincial cities. The charge for telphonic communications in the cities where the government will establish central halls, is 10*l.*, and in the cities where the number of subscribers will exceed 300, the subscription will be reduced to 8*l.* a year. The subscribers will have the right of supplying their own telephones from among those approved by the Government. Special rooms will be fitted up in Paris, as well as in the provinces for telephonic conversations. The charge will be 5*d.* from each interlocutor for each five minutes. The time allowed will not exceed ten minutes if there are other would-be interlocutors waiting. The telegrams received for the subscribers to the telegraphic offices will be telephoned to them if desired. The subscribers will enjoy the privilege of telephoning their letters to the Post Office for immediate despatch, on paying a charge of 5*d.* for each 100 words; this privilege is limited to 200 words, the postage must be paid besides. Telegrams will be received in the same manner and on the same scale.

DURING the last two or three years a bark containing quinine and quinidine has been imported into this country from Columbia in such enormous quantities as to equal or even sometimes exceed the whole of the importations of cinchona bark from all other countries. The botanical source of this bark, which is known in commerce under the name of Cuprea Cinchona, on account of its peculiar coppery tint, has hitherto been a mystery. M. Triana, the well-known quinologist, has recently succeeded in tracing it out, and has stated, in the *Pharmaceutical Journal* for April 22, that it is derived in great measure from two species of the nearly allied genus *Remijia*, none of the members of which were previously known to contain quinine. Several species of *Remijia* have leaves resembling those of the true Cinchonas, and of these M. Triana has determined that *R. Purdieana*, Wedd., and *R. pedunculata*, Karsten, certainly yield Cuprea bark, the former being the species which contains the alkaloid Cinchonamine, recently discovered by M. Arnaud. It appears probable that other species also yield the Cuprea Cinchona of commerce, but definite information on this point is still wanting. The value of this bark has led, according to M. Triana, to great devastation of the forests in which the trees grow, and has produced a financial stagnation, business being neglected in order to follow the more profitable occupation of collecting the bark. Fortunately seeds of the tree have been received and are now in cultivation at Malvern House, Sydenham. The tree is likely to prove valuable for cultivation in countries where malarial fever abounds, since it grows at an elevation of 200-1000 metres above the sea, at which even red Cinchona bark will not flourish.

A SATISFACTORY *Report* for 1881 has been issued by Mr. Paton, curator of the Kelvingrove Museum, Glasgow. The natural history collections especially have greatly increased during the past year, and if displayed properly, would themselves fill the Museum. It seems strange that so wealthy a city as Glasgow should be content to have their growing and valuable museum so inadequately housed.

DR. P. A. BERGSMA has resigned his appointment as Director of the Batavia Observatory, and is returning to Europe. We have often had occasion to refer to the good work done by Dr. Bergsma at this Observatory, especially on Meteorology.

MR. HENRY DYER, the efficient principal of the Imperial College of Engineering, Tokio, Japan, is about to return to this country.

THE death is announced of Col. J. T. Smith, R.E., F.R.S., for many years Master of the Mint at Madras, and the author of some valuable optical discoveries.

WE regret to learn of the death, at the early age of thirty-two, of a promising young science teacher and lecturer, Mr. Thomas Dunman, lecturer on Physiology at the Birkbeck Institution, and Physical Science Lecturer at the Working Men's College. His brief career furnishes a remarkable instance of what may be done by energy, perseverance, and a strong faith in one's own powers. Mr. Dunman has done excellent work in science teaching at both of the institutions mentioned. In 1879 he published a glossary of "Biological, Anatomical, and Physiological Terms," and finding his Lectures on Popular Scientific Subjects were so much appreciated, he commenced last year to issue them in pamphlet form.

MESSRS. BAILLIÈRE, TINDALL, AND COX have the following announcements:—A revised and enlarged edition of Harris and Power's "Manual for the Physiological Laboratory" will appear on June 1; a second edition of the Portrait-picture of the International Medical and Scientific Congress of 1881 is in course of preparation, with a few additional portraits; a second part of the President of the Royal College of Veterinary Surgeons' (Mr. Fleming) work on "Animal Plagues," from the beginning of the present century, will be published during the next few days.

PROF. ROSCOE, with other members of the Royal Commission on Technical Instruction, visited Vienna during the past week. Mr. Samuelson, M.P., the president of the Commission, and Mr. W. Woodall, M.P., left on Friday to join their colleagues at Dresden. After inspecting the schools and manufactories in Saxony, it is the intention of the Commissioners to proceed to Berlin.

WE have received copies of a circular letter and inclosures which have been issued to the scientific societies of the United Kingdom (with the exception of the Chartered London Societies, and the medical and some few other societies of a similar character) within the last few days. These papers are issued in pursuance of the resolutions adopted at the second Conference of Delegates of Scientific Societies held at York. Any society desirous of receiving these, or intending to send a Delegate or Delegates to the Southampton Meeting of the British Association, should apply to Mr. W. G. Fordham, Odsey Grange, Royston. Mr. Fordham would be obliged to secretaries of scientific societies, or any of our readers, who would assist him in compiling a complete list of the scientific societies of the United Kingdom, by sending him information, particularly with reference to the smaller provincial and local natural history societies, and similar bodies.

WE have received the Annual Reports of three local scientific societies—East Kent, West Kent, and Wellington College. They all speak favourably of the work of the past year and of the progress of the societies. The Report of the West Kent Society contains a sensible address on Evolution, by the president; and that of the Wellington Society shows that considerable improvement has taken place since the last report.

ON Saturday afternoon last the members of the Essex Field Club met in the private lecture-room in the Natural History Museum, South Kensington, at the invitation of Dr. Henry Woodward, F.R.S., who delivered a very interesting and instructive lecture on the "Ancient Fauna of Essex." The lecture was amply illustrated with specimens and diagrams, many of the latter being specially prepared for the occasion, and at its close Prof. Morris gave a brief *résumé* of the principal facts of the geology of the Thames and Roding Valleys. Dr. Woodward afterwards conducted the party through the palæontological galleries, and practically demonstrated many of the more remarkable forms referred to in his lecture.

THE funds voted by the French Government for the next Transit of Venus Expedition not being deemed sufficient, the great commission presided over by M. Dumas in consequence of the deficiency, is making an application to the Minister of Public Instruction for an extension of credit.

M. ELOY, a young aëronaut who executed on Sunday, May 7, an interesting ascent, reported at full length to the Academy of Sciences on the following day, is to make a series of scientific ascents from La Villette Gasworks, and has submitted to M. Dumas a detailed programme of his proposed observations. We may state that their bearing is mostly on the nature of clouds, their dimensions, their formation, their propulsion by the wind, and their situation in the several strata of air by which they are propelled. The questions proposed by M. W. de Fonvielle to Dr. Hermann Kopp will be solved as far practicable.

A LARGE Lacustrine canoe, in excellent condition, has been found near Bex, 4000 feet above the sea-level, and nearly 3000 feet above the Valley of the Rhone. No Lacustrine relics have ever before been met with in Switzerland, at such an elevation.

AN International Hygienic Conference is to be held in Geneva in September next.

WE regret to learn that the Hygienic Exhibition which was in preparation in Berlin has been almost destroyed by fire; but the Committee have resolved to carry out the enterprise next spring.

HIS EXCELLENCY the Marquis of Lorne, Governor-General of Canada, has instituted a Society for the "Advancement of Literature and Science in the Dominion of Canada," the first meeting of which is fixed to take place in the city of Ottawa on May 25, 26, 27. The President is Principal J. W. Dawson, C.M.G., F.R.S.

THERE is an interesting paper in the last number of the *Revue Scientifique*, by M. Ch. Cornevin, on the Domestication of the Horse.

IN connection with the election of M. de Freycinet to the Paris Academy of Sciences, it may be noted that not less than twenty-four members of the Sénate belong to the several classes of the Institute of France, seven to the Academie Française, five to the Academy of Sciences, Morals, and Politics, five to the Academy of Inscriptions and Belles Lettres; of these twenty-four, not less than twenty are life-senators, whose number is only seventy-five, and seven have been ministers. In the French Lower House the number of Academicians is very small, only three—two of the Academy of Sciences, one of these having been minister, and one of the Academie Française.

PROF. FOREL distinguishes three regions in a glacier:—1. The *nevé* (*infancy* of the glacier). Excess of snow; the summer heat not sufficient to melt the snow of the year. All the water produced is absorbed and assimilated by the ice-layers; deep temperature below zero. 2. The *glacier adolescent.* Summer heat fuses all the snow of winter, and attacks by ablation a part of the ice. All the water of imbibition is absorbed and assimilated by the ice; deep temperature below zero, even at the end of summer. 3. The *glacier senile.* Summer heat is in excess. The water of imbibition exceeds the quantity necessary to reheating of the ice, which rises to 0°, and the excess of water flows away in the glacial torrent. Temperature of the glacier at 0° during summer.

ON May 8 three shocks of earthquake were felt at Laibach (Carniola), the first occurring at 9h. 38m. p.m., the last, at midnight, was the most severe, and, lasting two seconds; it was accompanied by a loud subterranean noise.

ACCORDING to statistics recently worked out, the number of railway travellers killed in France is one in each 1,600,000,000 km. run, which is a distance equal to 40,000 times the length of a voyage round the world. This excursion would last during 3044 years travelling day and night at the rate of 60 kilometres per hour. So that, supposing an average life-time of sixty years for a healthy man, before he could be killed by a railway accident according to the law of probabilities, he would have died fifty times a natural death.

IN the Report of the Paris Academy of Sciences for April 24 (NATURE, vol. xxvi. p. 24) the statement with regard to Prof. Roscoe's paper "On the Equivalent of Carbon determined by Combustion of the Diamond" should read "Representing O by 15·96, C becomes 11·97." In the *Comptes Rendus* it is 11·07.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus radiatus* ♀) from India, presented by Mr. H. B. Hamer; a Common Paradoxure (*Paradoxurus typus*) from Java, presented by Mr. F. E. Spellerberg; a Black-faced Kangaroo (*Macropus melanops* ♀) from South Australia, presented by Mr. C. T. H. Bower; two Silver-backed Foxes (*Canis chama*) from South Africa, presented by Major-General E. A. Bacon; two Long-eared Owls (*Asio otus*), British, presented by Mrs. E. Brewer; two Alligator Terrapins (*Chelydra serpentina*), a Box Tortoise (*Terrapene*, sp. inc.), a Floridan Terrapin (*Clemmys floridana*) from North America, presented by Mr. G. E. Manigault; two Beautiful Finches (*Estrelda bella*) from Australia, presented by Mr. J. Abrahams; an Allen's Galago (*Galago alleni*) from Fernando Po, a Levaillant's Cynictis (*Cynictis penicillata*) from South Africa, a Common Otter (*Lutra vulgaris*), British, a Swinhoe's Pheasant (*Euplocamus swinhoii* ♀) from Formosa, five White-winged Choughs (*Corcorax leucopterus*), a Spotted Bower Bird (*Chlamydora maculata* ♂) from Australia, four Common Sheldrakes (*Tadorna vulpanser* ♂ ♂ ♀ ♀), European, two Talpacoti Ground Doves (*Chamæpelia talpacoti*) from South America, purchased; a Bennett's Wallaby (*Halmaturus bennetti* ♂), an American Bison (*Bison americanus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE COMET.—On May 12 the comet was within naked-eye vision, and will nightly increase in brightness. Writing from Cuckfield on May 13 Mr. G. Knott says: "The sky was very clear here last night, and I found that I could just see the comet with the naked eye, on knowing just where to look for it. I fancy that its visibility must have been in part due to the fact that its tail is pretty bright for about $\frac{3}{4}$°. When viewed with an opera-glass its light seemed hardly equal to that of neighbouring stars rated 6·7 (*i.e.* 6$\frac{1}{3}$) by Heis, and 6·5 by Argelander in D.M. In the telescope the light of the head seemed about equal to that of a 7 mag. star." This estimate by so careful and experienced an observer of star-magnitudes will furnish a reliable criterion as to the future increase in the brightness of the comet, assuming that it follows the ordinary theoretical rule.

The following orbit has been calculated by Mr. Hind from the observations at Harvard and Albany, U.S., on March 19, one at Paris on April 11, and a position obtained at the Royal Observatory, Greenwich, on May 4:—

Perihelion passage, 1882, June 10·51851 G.M.T.

	°	′	″	
Longitude of perihelion	53	54	23·2	Mean Equinox, 1882·0.
,, ascending node...	204	53	31·3	
Inclination...	73	46	23·2	
Log. perihelion distance... ...	8·783187			

Motion—direct.

By a meridian-observation at Greenwich on May 12 (eight days after the last observation employed for the orbit), which Mr. Christie has caused to be reduced with every precision, the corrections to the computed place were: $\Delta\alpha \,.\, \cos\delta = -9''\cdot0$; $\Delta\delta = +28''\cdot5$. Differential observations at the Collegio Romano, in Rome, on May 10, kindly communicated by Prof. E. Millosevich, give $\Delta\alpha \,.\, \cos\delta = -20''\cdot6$, and $\Delta\delta = +26''\cdot0$, parallax and aberration being taken into account.

The ephemeris subjoined is calculated from these elements for Greenwich midnight:—

	R.A.			Decl.		Log. dist. from Earth.	Intensity of light.
	h.	m.	s.	°	′		
May 20	2	53	31	+67	15·1	9·9494	1·67
21	3	5	49	65	51·0	9·9494	
22	3	16	51	64	22·5	9·9496	1·92
23	3	26	46	62	50·1	9·9502	
24	3	35	42	61	14·2	9·9511	2·24
25	3	43	45	59	35·2	9·9523	
26	3	51	2	57	53·1	9·9538	2·64
27	3	57	39	56	8·1	9·9557	
28	4	3	42	+54	20·6	9·9580	3·18

Considering that the comet is still at a great angular distance from the perihelion and the heliocentric motion slow, the following places for the beginning of June can be regarded as approximate only:—

At Greenwich midnight

	R.A.		Decl.		Log. distance.	Intensity of light.
	h.	m.	°	′		
June 2	4	27·1	+44	35	9·9747	6·0
3	4	30·8	42	27	9·9794	7·1
4	4	34·5	40	12	9·9845	8·8
5	4	37·8	37	51	9·9902	11·2
6	4	41·2	35	20	9·9965	15·2
7	4	44·8	+32	36	0·0036	22·6

The intensity of light on May 12, when Mr. Knott made his estimate of the comet's brightness, is here taken as the unit.

At noon on June 10, the intensity of light referred to this unit is 147, and at noon on June 11 it is 154. The probability of seeing the comet near the sun on these days is not now so great perhaps as it appeared to be from the earlier orbits.

At the meeting of the Royal Astronomical Society on the 12th inst., the Astronomer Royal referred to the absence of bright lines in the spectrum of the comet, according to repeated observation at Greenwich. It will be interesting to watch the comet's development as it approaches the sun.

BINOCULAR PERSPECTIVE

THAT a near object, of small size, presents an aspect slightly different to each one of a pair of eyes directed upon it seems to have been known since the time of Euclid; but not until the present century has binocular vision been made a subject of special study.

In 1838 Wheatstone presented a communication on the Physiology of Vision (*Phil. Transactions*, 1838, Part 2, reprinted in *Phil. Magazine*, s. 4, vol. iii. April, 1852) to the Royal Society, in which he described his invention of the reflecting stereoscope, by which rays from two slightly dissimilar pictures were conveyed into the right and left eyes respectively, producing the visual illusion of binocular relief. The essential feature of this instrument he describes by saying (*Phil. Mag.* April, 1852, p. 245): "The two pictures, or rather their reflected images, are placed in it at the true concourse of the optic axes."

In 1844 Brewster published an essay (Edinburgh *Transactions*, vol. xv. Part 3, p. 360) "On the Knowledge of Distance given by Binocular Vision," in which he elaborated the idea that the apparent position of the combined image produced by rays, from a pair of conjugate pictures, upon corresponding retinal points of the two eyes, is determined by the intersection of visual lines passing through conjugate points. He deduced a formula and constructed a table of apparent distances, thus determined, for various values of the angle of convergence between the visual lines.

In 1849 Brewster described his invention of the lenticular stereoscope (*Phil. Mag.* 1852, p. 16) and of the binocular camera, by which slightly dissimilar pictures of the same object may be simultaneously obtained for examination in the stereoscope. Various modifications of the instruments already in use were explained, and in all of them the apparent position of the combined image was referred to the point of convergence of the visual lines, these being determined by the direction of rays on entering the eyes after reflection or refraction in the stereoscope.

In 1852 Wheatstone published a second paper (*Phil. Mag.* 1852, p. 504) on the Physiology of Vision, in which he discussed the effects of varying the angle of convergence between the visual lines, and also the distance of the pictures from the mirrors of the reflecting stereoscope. He makes no reference to divergence of visual lines, but, like Brewster, he subjoins "a table of the inclinations of the optic axes, which correspond to the different distances," which is also applicable to the binocular camera.

In direct binocular vision of a single point in front the interocular line is the base of an isosceles triangle, whose two sides are the visual lines. Helmholtz ("Optique Physiologique," p. 93) has shown that the latter are not coincident with the optic axes, but practically they may be regarded as axial in relation to the crystalline lens. For distinction it will be convenient to call them visual axes, their intersection the optic vertex, and the angle inclosed the optic angle, as has been customary.

Let i = interocular distance,
,, α = optic angle,
,, D = distance of optic vertex from each eye,
Then
$D = \frac{1}{2} i \operatorname{cosec} \frac{1}{2} \alpha$.
If $\alpha = 0$, $D = \infty$, and visual axes are parallel.
If $\alpha < 0$, $D < 0$, and visual axes are divergent.

Wheatstone notices the exaggeration of perspective produced when a pair of conjugate pictures, taken with a large angle between the camera axes, are viewed in the stereoscope with the visual axes nearly or quite parallel. He mentions, as a remarkable peculiarity (*Phil. Mag.* 1852, p. 514), that "although the optic axes are parallel, or nearly so, the image does not appear to be referred to the distance we should from this circumstance suppose it to be, but it is perceived to be much nearer. It seems as if the dissimilarity of the projections, corresponding as they do to a nearer distance than that which would be suggested by the former circumstance alone, alters in some degree the perception of distance."

The last explanation is obviously inapplicable if two perfectly similar pictures can be binocularly seen as one, with parallelism or divergence of visual axis. This condition is easily imposed by placing before one eye a thin prism with its edge outward. A single object in front is seen double until the visual axis diverges enough to make the two images coincide in retinal position. To test the strength of the external rectus muscles of the eye-balls, this method has now been in use for many years by oculists. The same effect may be attained by drawing a pair of conjugate pictures apart until binocular fusion of their images ceases to be possible. Divergence of visual axes, to the extent of 8°, has been thus obtained by Helmholtz ("Opt. Phys.," p. 616), and of 7½° by the present writer. Since this point of meeting is, in these cases, in the rear of the observer, the theory of binocular prospective held by Wheatstone and Brewster is incorrect. It is nevertheless given without qualification, either directly or implicitly, in most, if not all, of our text-books of physics.

No analysis of the phenomena of binocular vision by axial divergence has thus far been published,

Helmholtz mentions the exaggeration of apparent distance thus produced, and adds ("Opt. Phys. p. 828") that "in our visual conceptions infinity is not presented as an impassable limit." He accounts for this by stating that in abnormal vision "all we can do is to compare the sensation produced with that which it resembles most in normal vision."

By examination of a large number of stereographs and lenticular stereoscopes, I have found (*Am. Journ. of Science*, November and December, 1881) that in using them, slight axial divergence is very frequently practised. It is nearly always necessary when binocular fusion of images is obtained, in regarding stereographs by voluntarily diminishing the natural convergence of visual axes without the aid of the stereoscope. The assumption of axial convergence, as if in normal vision, is unnecessary and misleading; it should be entirely discarded in explaining vision through the stereoscope. What is really necessary is that the camera axes from corresponding points of the stereograph, at the moment the picture is taken, shall converge; and that these points shall be imaged upon corresponding points of the two retinas. The visual axis may then be either convergent, parallel, or divergent. The visual effect will vary with these conditions, but by no means in accordance with the mathematical formula given above. I have described elsewhere (*Am. Journal of Science*, November and December 1881) a method of determining approximately the apparent position of the object regarded in the stereoscope, rejecting the hypothesis that the visual axis must necessarily converge. It remains to discuss the effect of making the optic angle alternately positive and negative. Helmholtz's conclusion that the only resource, when the visual axes diverge, is to compare the sensation produced with that which it resembles most, is unnecessary. No such resource in the present case would have been needed, even temporarily, had not undue stress been laid upon the convergence of visual lines.

From the fact that a pair of similar images upon corresponding retinal points produce the same impression, as if coming from the same external point, there result two consequences of fundamental importance in binocular vision, on which depends tde explanation of all vision with axial divergence. One is that both eyes are subjectively combined into a single central binocular eye, composed of two eyes coincident in position, each of them receiving its own image, which is wholly or partly superposed on that of the other. This observation is due to Hering (Hering, "Beiträge zur Physiologie," 1861, p. 35-64, or Helmholtz, "Opt. Phys," p. 777), and has been extended and applied by Prof. Le Conte (*Am. Journal of Science*, S. III. vol. i., p. 33, and vol. ii. p. 1, or "Sight," Appleton and Co., New York, 1881, pp. 213-261). The two visual lines terminating on corresponding retinal points are hence subjectively combined into a single median line, to some point of which the binocular image is referred. The apparent position of this point of sight, however, is the result of a judgment, and not a mathematical determination. In normal binocular vision the judgment of distance may accord very nearly with what might be determined by the intersection of visual lines, but there is no necessary coincidence.

The second consequence is that a point farther or nearer than the point of sight is necessarily seen double, because imaged upon retinal points that do not correspond. Conversely, if conjugate points of a stereograph are imaged upon non-corresponding retinal points, fusion can be accomplished only by changing the relation between the visual axes. To the binocular eye, therefore, such points will appear farther or nearer than the point of sight. On these two principles depends, in large measure, the perception of binocular relief.

The perception of relative distance depends upon a variety of conditions, which must be eliminated before binocular perspective is studied. There are then left still three elements to consider:—

1. The optic angle.
2. The focal adjustment of the crystalline lens.
3. The retinal magnitude of the binocular image.

The import of the first of these depends upon the relative degree of tension in the rectus muscles of the eyeballs; of the second on the tension of the ciliary muscle; of the third on the relation between the magnitude and distance of the object. The judgment of distance and size depends upon the acquired skill of the observer in interpreting the sensations due to variation of these elements. This variation is best accomplished with the aid of a modified Wheatstone stereoscope.

Let the stereoscope be so arranged that the visual axis may successively inclose every possible angle between the limits beyond which vision becomes impossible. On its arms let a pair of conjugate pictures be kept at a fixed distance each from its mirror. If the arms be so placed that the optic angle is that of normal vision, the point of sight approximately coincides with the optic vertex, and to the distance of this the focal adjustment is adapted.

Let α = optic angle, varied by means of the stereoscope.
,, α' = optic angle of normal vision for given distance.
,, D = distance of optic vertex from each eye, determined by the formula, $D = \frac{1}{2} i \operatorname{cosec} \frac{1}{2}\alpha$.
,, D′ = distance of radial point measured in the direction from which the reflected ray enters the eye. It is hence the distance of the virtual image in normal vision.
,, A = distance of point of sight from binocular eye.

Under the conditions given above we have—

$\alpha = \alpha'$, and $A = D = D'$. Assume $D' = 50$ cm., then $\alpha' = 7° 20'$.

If now we make $\alpha = 37° 20'$, we have $D = 10$ cm. But to secure distinct vision, the focal adjustment must be adapted to D′, and therefore dissociated from the axial adjustment. This to some extent antagonises the effect of tension of the internal rectus muscles, and this antagonism is increased by the fact that the visual angle remains constant. The combined effect is that $A > D$ but $A < D'$. The apparent size of the image is diminished in the ratio of A to D′. The effect of increasing the optic angle is hence to make the image appear nearer, smaller, and less deep in proportion to its area, but more distant nevertheless than the new optic vertex.

If now we make $\alpha = -5°$, we have $D = -73·4$ cm., but the relaxation of the internal rectus and contraction of the external rectus muscles causes the image to appear to recede in a positive direction. This illusion is opposed by the constancy of the visual angle, and the ciliary effort to keep the focal adjustment adapted to D′. The result is that $A > D'$, and the apparent size of the image is enlarged in the same ratio, while its depth is increased still more. The effect of making the optic angle negative is hence to cause the image to appear farther, larger, and deeper in proportion to its area.

If in the discussion just given we make α the angle between a pair of camera axes, and D the distance of its vertex, while i is the distance between the two lenses, the formula is readily applicable, but α can have only positive values. The optic angle for the observer while using the stereoscope is not necessarily, or even generally, the same as that between the camera axes when the picture was taken. Apparent distance in the stereoscope is thus not determined by the intersection of the observer's visual lines, and no mathematical formula can be made to apply to the interpretation of muscular tension in the muscles of the eyes. The error into which Wheatstone fell, and which was repeated and emphasised by Brewster, consists in the application of geometry where physiological conditions are such as to destroy the value of all geometric constructions. Unfortunately this error is still repeated in most of our text-books of physics, wherever diagrams are employed to explain the theory of the stereoscope.

W. LE CONTE STEVENS

New York

SCIENTIFIC SERIALS

The Quarterly Journal of Microscopical Science for April, 1882, contains—Pringsheim's researches on chlorophyll, translated and condensed by Professor Bayley Balfour (with plates 8 and 9).—Dr. D. H. Scott, on the development of articulated laticiferous vessels (plate 10). In the plants investigated, the vessels arose from rows of cells, of which the cross walls, and where two were in contact, the side walls in part became gradually absorbed. This took place very early; when not in contact, connection took place by means of cross rows of cells, which underwent fusion, or by inoculating outgrowths, before absorption; such cells showed the probable presence of latex.—Dr. E. Klein, on the lymphatic system and the minute structure of the salivary glands and pancreas (plates 11 and 12).—Prof. F. M. Balfour and F. Deighton, a renewed study of the germinal layers of the chick (plates 13–15).—Isao J. Iijima, on the origin and growth of the eggs and egg-strings in Nephelis, with some observations on the "spiral asters" (plates 16–19).—Dr. A. A. Hubrecht, a contribution to the morphology of the Amphineura.—Prof. E. Ray Lankester, on the chlorophyll-corpuscles and amyloid deposits of Spongilla and Hydra (plate 20). These forms are not of the nature of parasitic bodies, but they correspond in structure with the chlorophyll bodies in plants.

Journal of the Royal Microscopical Society for April, 1882, contains the President's address, by Prof. B. Martin Duncan.—On mounting objects in phosphorus, and in a solution of biniodide of mercury and iodide of potassium, by J. W. Stephenson.—On the threads of spider webs, by Dr. J. Anthony.—With the usual most useful summary of current researches relating to geology and botany, and the Proceedings of the Society.

Journal of Anatomy and Physiology, Normal and Pathological, vol. xvi. Part 3, April, 1882, contains—Dr. A. M. Marshall, the segmental value of the cranial nerves (pl. 10).—Dr. G. E. Dobson, the anatomy of *Microgale longicauda*, with remarks on the homologies of the long flexors of the toes in mammalia.—Dr. T. P. A. Stuart, the curled hair and curled hair follicles of the Negro.—Dr. G. Sims Woodhead, some of the pathological conditions of the medulla oblongata, in a case of locomotor ataxia (pl. 11).—Dr. M. Hay, on the action of saline cathartics.—W. J. Walsham, abnormal origin and distribution of the upper seven right intercostal arteries, with remarks.—Dr. W. Stirling, on the digestion of blood by the common leech, and on the formation hæmoglobin crystals (pl. 12).—Prof. Turner, on a specimen of *Mesoplodon bidens*, captured in Shetland; and on a specimen of *Balænoptera borealis*, or *laticeps*, captured in the Firth of Forth.—G. S. Shattock, note on the anatomy of the Thyro-arytenoid muscle in the human larynx.

Johns Hopkins University. Studies from the Biological Laboratory, vol. ii. No. 2 (March, 1882), contains: W. K. Brooks, Medusæ found at Beaufort, N.C., during the summers of 1880 and 1881, and on the development of the ova in Salpa.—J. P. McMurrich, on—the origin of the so-called "test cells" in the Ascidian ovum.—G. M. Sternberg, bacterial organisms commonly found on exposed mucous surfaces and in the alimentary canal of healthy persons;—on a fatal form of Septicæmia in the rabbit from the subcutaneous injection of human saliva;—on experiments with disinfectants.—H. N. Martin, observations on the direct influence of variations of arterial pressure upon the rate of beat of the mammalian heart.—W. H. Howel and M. Warfield, the influences of changes of arterial pressure upon the pulse rate in the Frog and the Terrapin.—H. Garman and B. P. Colton, notes on the development of *Arbacia pustulata*.—K. Mitsukuri, on the structure and significance of some aberrant forms of lamellibranchiate gills.—E. B. Wilson, on the early developmental stages of some polychætous annelides.

The American Naturalist for April, 1882, contains—On mound pipes, by E. A. Barber.—On the flowers of *Solanum rostratum* and *Cassia chamæcrista*, by J. E. Todd.—Is Limulus an arachnid? by A. S. Packard; a criticism on the views of Prof. Lankester.—On a pathogenic Schizophyte of the hog, by H. J. Detmers.—On Mexican caves with human remains, by Ed. Palmer.—The Editor's table.—Recent literature.—General notes, and scientific news.

May, 1882, contains—The acorn-storing habits of the Californian woodpecker, by R. E. C. Stearns.—Observations on some American forms of *Chara coronata*, by T. F. Allen.—The löess of North America, by R. Ellsworth Call.—The ichthyological papers of G. P. Dunbar, with a sketch of his life by J. L. Wortman.—Problems for zoologists, by J. G. Kingsley.—Recent literature.—General Notes.—Scientific news.

Verhandlungen der k. k. zoologisch-botanischen Gesellschaft in Wien, Bd. xxi. Heft 2, 1882, contains: Josef Mik, dipterological studies, II. (pl. xvi.), and notes on G. Strobl's discoveries of Diptera at Seitenstetten.—Ed. Ritter, on the Pselaphidæ and Scydmaenidæ of Syria; analytic key to the European Coleoptera, V. (pl. xix.).—C. R. Osten-Sacken, list of the entomological writings of Rondani (supplementary to Hagen).—J. Freyn, supplement to the flora of South Istria.—H. B. Möschler, contributions to the butterfly fauna of Surinam, IV. and end (pls. xvii. and xviii.).—A. Rogenhofer and Dr. R. W. v. Dalla Torre, on the Hymenoptera of Scopoli's "Entomologica Carniolica."—August Pelzeln, on the second package of birds sent by Dr. E. Bey from Central Africa.—Dr. L. W. Schaufuss, zoological results of an excursion to the Balearic Islands (pl. xxi.).—Dr. L. Koch, the Arachnida and Myriopoda of the Balearics (pl. xx. and xxi.).—Schulzer v. Müggenburg, mycological notes, VI.—L. Ganglbauer, analytic tables of European Coleoptera (pl. xxii.).—A. B. Meyer, on birds from some of the southern islands of the Malay Archipelago.—Johann Bubela, list of the wild plants of Bisenz in Moravia.

Archives des Sciences Physiques et Naturelles, April 15.—The grain of the glacier, by F. A. Forel.—Note on the extension of a property of gases to liquids and to solids, by C. Cellèrier.—Recent changes in the appearances of Jupiter, by E. Gautier.

Atti della R. Accademia dei Lincei, vol. vi. fasc. 8.—Observations on the topography of the planet Mars, by G. Schiaparelli.—Communication on a geyser discovered at Montrond (Loire), by F. Lauri.—On the same subject, by F. Keller.—On the embryo of *Cuphea*, by G. Briosi.—Influence of different electric resistances on the dimensions of the excitative spark of condensers, by E. Villari.—On the dynamical value of a calorie, by G. Cantoni and G. Gerosa.—Oxidation of titanic acid, by A. Piccini.—Reports.

Morphologisches Jahrbuch. Eine Zeitschrift für Anatomie und Entwickelungsgeschichte, Bd 7, Heft iv., 1882, contains—Dr. Hans Virchow, on the lens and retinal vessels of the eel (pl. 27).—Dr. Sigbert Ganser, comparative anatomy studies of the brain of the mole, pp. 590, 725 (plates 28-32.—A most minute and painstaking account of the mole's brain), Dr. W. Pfitzner.—On nerve-endings in epithelium (pl. 33).

SOCIETIES AND ACADEMIES

London

Mathematical Society, May 11.—S. Roberts, F.R.S., president, in the chair.—Mr. A. L. Daniels was elected a Member.—Dr. Hirst, F.R.S., communicated an account (similar to that he had given before the Royal Society in the afternoon of the same day) of a paper by M. Vanecek entitled "Sur l'Inversion générale."—The following further communications were made:—Elementary analytical proof of Graves's and MacCullagh's theorems, with an extension of the former, by J. Griffiths.—Note on a system of confocal bicircular quartics, by R. A. Roberts.—On the vibrations of an elastic sphere, by Prof. Lamb.—On a formula relating to elliptic integrals of the third kind, by Prof. Cayley, F.R.S.; and a short note by the president.

Physical Society, May 6.—Prof. Clifton, president, in the chair.—New Member, Mr. W. H. Heaton.—Mr. Lecky described a form of battery arranged by Mr. A. R. Bennet, of Glasgow, at a cost of *6d.* per cell. The vessel and electro-negative plate consists of an iron meat or milk tin, into which is placed a porous pot containing a zinc plate stuck in a paraffined cork cover, fitting the porous pot. A solution of caustic soda is the liquid. In it iron does not rust, and is electro-negative to zinc. The electromotive force is 1·23 volts where the Daniel is taken as 1 volt and the Leclanché as 1·30 volts. Iron filings round the iron plate facilitate depolarisation by the escape of hydrogen from their points. The cell pitted against a Leclanché was found to ring an electric bell even longer than the latter.—Prof. Guthrie (in the absence of Dr. F. D. Brown, the author) gave a summary of a paper entitled "Notes on Thermometry." This described a method of calibrating the tubes by means of a microscope having an extra half-lens before the object-glass, which focussed the end of the mercury column, whilst the other lens focussed the tube, so that no alteration of the focus of the microscope was necessary in making an observation. Dr. Brown also found that a constant zero temperature was better obtained from a mixture of ice and water than from drained ice; and that it was preferable to mix the ice with distilled water rather than ordinary water. Acting on the suggestion of Dr. Guthrie, Dr. Whipple, of Kew, had found that the ice itself might be from different sources without appreciably affecting the result. Dr. Whipple called attention to the change of zero in thermometers by heating, and recommended buyers to see that makers had not let them be heated after their calibration. Mr. J. Macfarlane Gray suggested that the thermometers used by Regnault should be examined now, as our standards are based on his results. Prof. Clifton pointed out that the half-lens in the microscope would probably distort the image of the mercury column.—Prof. Guthrie then read a paper on the repulsion of a suspended horseshoe magnet by a rotating copper disc below it. He gave tables of quantitative results and a plotted curve, showing that the repulsion varied on the square of the rate of rotation. For a surface velocity of the disc of 163 metres per minute the repulsion was ·41 grammes.

Anthropological Institute, May 9, Major-General Pitt Rivers, F.R.S., president, in the chair.—The election of Mr. Henry Ling Roth was announced. Mr. G. M. Atkinson made some remarks upon a palæolithic implement found eighteen feet below the bed of the Thames at Chelsea, and exhibited by Mr. Lambton Young, C.E., and a jet ornament from Garvagh, co. Londonderry, exhibited by Mr. A. G. Geoghegan.—Mr. Worthington G. Smith exhibited a series of large palæolithic implements recently discovered.—Dr. Beddoe, F.R.S., read a paper on the evidence of surnames as to ethnological changes in England. The discussion was sustained by Messrs. Hyde Clarke, Holt, Park Harrison, Prideaux, Atkinson, C. Roberts and the chairman.—Mr. Park Harrison, M.A., read a paper on the survival of certain racial features in the population of the British Isles at the present day. Dr. Beddoe, Prof. Thane, Mr. Atkinson, and the president joined in the discussion.

Institution of Civil Engineers, May 9.—Sir Frederick Bramwell, vice-president, in the chair.—The paper read was on "Coal Washing," by Mr. Thos. F. Harvey, Assoc. M. Inst. C.E.

Royal Horticultural Society, May 9.—Sir J. D. Hooker in the chair.—*Larches attacked by Larvæ:* From a communication received by Sir J. D. Hooker it would appear that the trees mentioned in the last report had suffered much more extensively than was supposed, whole trees having been stripped of their foliage.—*Fungus in Dilute Sulphuric Acid:* Mr. W. G. Smith exhibited a specimen of the vinegar fungus, *Penicillium crustaceum*, growing in dilute sulphuric acid. Sir J. D. Hooker suggested it should be ascertained what nitrogenous substance was present in the acid, which alone could not support life.—*Proliferous Mushroom:* He also exhibited a specimen in which one pileus was inverted and adherent to the summit of another mushroom growing in the ordinary way.—*Foliage Injured by the Gale:* Dr. M. T. Masters exhibited leaves injured in various ways by the late severe gale, which by destroying the growing parts only revealed the different developmental orders of leaves. It appeared that salt spray had injured trees in some cases; but it was thought that the duration and great cold of the wind was more generally the cause of injury. Beeches, it was noticed, withstood it better than oaks.

Victoria (Philosophical) Institute.—A paper was read by Prof. Lionel S. Beale, F.R.S., on "Dictatorial and Scientific Utterances and the Decline of Thought." The author tried to show that the opinion now generally entertained by scientific men that the phenomena of the living world are due to the properties of the material particles is erroneous.

Berlin

Physiological Society, May 5.—Prof. du Bois Reymond, president, in the chair.—Dr. J. Sander read a paper upon the distribution of the vaso-motor nerve-centres. In addition to the well-known centre of the vaso-motor nerves in the medulla-oblongata, several other centres in the spinal chord were determined by the experiments that were made. In the case of each of these centres the degree of stimulation was determined which produced the greatest effect, and beyond which no further excitation produced a rise in the blood-pressure. If this degree of maximum excitation was not reached, a cumulative effect was perceived by the simultaneous stimulation of two vaso-motor centres, and the weak excitation of two centres had always a much greater effect than that which would have been expected to result from the degree of stimulation. The increased blood-pressure that resulted from the stimulation of the centre lasted for a prolonged period, which proves that the smooth muscular tissue of the walls of the blood-vessels does not tire quickly.—In a previous meeting of the Society held on March 29, Dr. R. Koch had demonstrated his important discovery that tuberculosis is a parasitic disease, that its occurrence is connected with the presence of tubercle Bacillæ, which are always found in those tissues which had undergone tubercular change. The Bacillæ can be isolated and can be cultivated for long periods quite isolated; animals that were infected with the isolated bacteria by very different methods became, without exception, affected with tuberculosis. The important demonstration of these tubercle Bacillæ was accomplished by Dr. Koch by a staining method which consisted in the employment of an alkaline solution of methyl-blue and a watery Vesuvian solution (*Vesuvialösung*); under this treatment all tissues and cells became stained brown, while the tubercle Bacillæ alone became stained blue; by this means it was easy to demonstrate the tubercle Bacillæ in the excreta of consumptive patients, in which they regularly occur. This interesting relation of the tubercle-Bacillæ to the staining-fluids has been made the subject of investigation by Dr. Ehrlich, the principal results of which may be condensed into the statement that the cause of this extraordinary appearance lies in the particular properties of the ectoderm of the tubercle-Bacillæ, which is penetrable by alkaline fluids, and therefore also for alkaline methyl-blue, whereas it is impenetrable by neutral substances, and especially by acids. Even the application of the strongest mineral acids, such as sulphuric acid, nitric acid, and such like, produced no effect on the Bacillæ. This peculiarity of the tubercle-Bacillæ has, besides its scientific, also, a remarkable practical importance, as it teaches that no acid fluids are to be used in disinfection, or for the purpose of killing tubercle-Bacillæ, as their ectoderm is impenetrable by such, but that alkaline-solutions are to be used, as they become easily diffused into the interior and destroy the Bacillæ.—Prof. Baumann reported on the examination of two pieces of a Termite's nest, which Prof. Renlau had brought from Australia. The one piece was taken from the outer wall of a structure that was apparently inhabited by ants; the second came from the inner structure of the nest. The first was free from organic matter, and consisted almost entirely of clay containing iron; the second was of a brownish-colour, perforated in all directions with numerous passages, and consisted almost entirely of organic material. While the most careful microscopical examination did not reveal any trace of an organic structure, still on the other band a chemical analysis showed a chemical composition very like that of most woods. Both the proportion of carbon and the amount and composition of the ash showed that this structureless substance is most nearly allied to wood. Mr. Baumann, consequently, looked for cellulose in the wall of the nest, and found it present in large quantities, so that there hardly remained a shadow of doubt but that the mass was derived from wood. The specific gravity was found to be 1·36, *i.e.* greater than that of the heaviest woods. The other constituents of this substance, which consisted of 97 per cent. of organic materials, afforded no assistance in the solution of the question as to whether this structureless mass had been formed out of wood, or as to how it had been manufactured by the animals.

PARIS

Academy of Sciences, May 8.—M. Jamin in the chair.—The following papers were read:—On the effects produced in vacuum by the current of Gramme machines, by MM. Jamin and Maneuvrièr. In an electric egg, with carbons (vacuum about 12mm.), a phenomenon like that of Geissler tubes is produced by the two currents, which contribute equally; but it is much more brilliant; the carbons soon get heated to a pale white throughout, and volatilised, giving a blue vapour, which condenses, and makes the egg opaque. This volatilisation was mostly avoided, in another case, by using two groups of carbons (instead of the pair) diverging from the rheophores towards each other, cone-wise. A large number of *effluves* here take the place of one. Still brighter effects were had with copper rods so arranged.—General considerations on preventers of fire, or pyroscopes, by M. Ledieu. After noting the faults of some methods, he indicates a system in which a cylinder of strong insulating material, holding a liquid which is refractory to electrolysation, and has good conductivity, increasing decidedly with temperature, is interposed in a single circuit, a platinum rheophore entering the liquid at either end. Absolute alcohol is a suitable liquid.—M. de Freycinet was elected Free Member in place of the late M. Bussy.—Report on a memoir relating to albuminoid matters, was presented to the Academy by M. Béchamp. The author has determined the rotatory power of a large number of these matters, and given elementary analyses of the best characterised species. The power, which fibrine has, of decomposing oxygenated water, resides, M. Béchamp proves, in the granular substance (albuminoid), left as an insoluble residue, on treatment of fibrine with weak hydrochloric acid. Raised to boiling in water, this loses its power. Again, M. Béchamp shows that it is a property of all albuminoid matters (as of albumen), that their oxidation by means of permanganate of potash furnishes a certain quantity of urea.—Report of the Commission charged to examine the work presented by Rear Admiral Serre "On the Athenian Trireme."—Researches on one of the principal bases of doctrines relative to the mechanism of production of voluntary movements and convulsions, by M. Brown-Séquard. It must be allowed that the excitomotor zone of the cerebral surface and of all excitable parts of the brain can set in motion the limbs of the corresponding side like those of the opposite side, and this after transverse section of a lateral half of the bridge of Varoli, the bulb, or the cervical cord, or even after two sections—one of the right, the other of the left half of the base of the brain—provided there is a certain interval between the sections.—On the winter egg of phylloxera, by M. Henneguy.—On the spherical representation of surfaces, by M. Darboux.—On the tides of Campbell's Island, by M. Bouquet de la Grye. *Inter alia*, the retardation of the tide is twenty-four hours.—Remarks on the velocity of light, on the occasion of two memoirs of Lord Rayleigh, by M. Gouy. Both appear to have come to the same conclusions and formulæ independently. M. Gouy obtains the result (among others) that *perfectly homogeneous* light is necessarily formed of an indefinite series of equal waves, without perturbations or irregularities of any sort.—On the depression of the zero point in mercury thermometers, by M. Crafts. The greater the interval between the temperature that has produced a depression, and that at which the thermometer is kept to raise it again, the slower is the movement, and it may be incomplete if the interval considerably exceeds 100°. M. Crafts gives a table by which the depressions through heating Paris thermometers may be estimated.—On the polarisation of electrodes and the conductivity of liquids (continued), by M. Bouty. He results obtained by the method previously indicated. He gives extends to the case of mixtures M. Berthelot's law for that of simple electrolytes.—Magnetic variations of magnetised bars during thunderstorms, by M. de Lalagade. With a thin iron membrane mounted, as in a telephone, at the end of a magnetised steel bar, he heard a small dry sound at each lightning-flash. Better effects were had with twelve horizontal magnets, each having twelve coils at one end, the wires connected with two conductors and two telephones. Sounds were heard before as well as during each flash.—On a balloon ascent at Paris on May 7, 1882, by M. Eloy. Starting about midday they rose 300 m. in a south east current, then to 1400 m. in a north-east one, above which a south-east current was met with again. Up to 1400 m. the average fall of temperature was 1° for 100 m., but at 1900 m. (the highest point reached), the thermometer was above the indication at 1400°.—On the composition and the equivalent in volume of pernitric acid, by MM. Hautefeuille and Chappuis. The formula NO_6 is arrived at.—Action of potash on oxide of lead, by M. Ditte.—On phosphate of chromium, and its utilisation in chemical analysis and industry, by M. Carnot.—Studies on the photo-chemical reaction of peroxalate of iron, by M. Jodin. For several years he has used the substance in experiments on plant-physiology, to supply CO_2 to plants by decomposition in light. The quantity liberated varies considerably with the composition of the solutions.—On new carbo-siliciated compounds, by M. Colson.—On homologous and isomeric rosanilines, by MM. Rosenstiehl and Gerber.—Chemical composition of the ash thrown out by Vesuvius on February 25, 1882, by M. Ricciardi.—Study on the antiseptic properties of salicylic acid, by MM. Robinet and Pellet. They describe experiments with salicylised must, showing that beyond 0·3 gr. per litre, salicylic acid is a powerful antiseptic, and that at 1 gr. it destroys even the action of yeast.—A claim of priority, in the idea of the photographic gun, was put in for M. Leblond.

CONTENTS

THURSDAY, MAY 25, 1882

CHARLES DARWIN[1]

II.

NO man of his time has exercised upon the science of Geology a profounder influence than Charles Darwin. At an early period he took much interest in geological studies, and all through life, while engaged in other pursuits, he kept himself acquainted with the progress that was being made in this department of natural knowledge. His influence upon it has been twofold. It arises partly from the importance and originality of some of his own contributions to the literature of the science, but chiefly from the bearing of his work on other branches of natural history.

When he began to direct his attention to geological inquiry the sway of the Cataclysmal school of geology was still paramount. But already the Uniformitarians were gathering strength and, before many years were past, had ranged themselves under the banner of their great champion Lyell. Darwin, who always recognised his indebtedness to Lyell's teaching, gave a powerful impulse to its general reception by the way in which he gathered from all parts of the world facts in its support. He continually sought in the phenomena of the present time the explanation of those of the past. Yet he was all the while laying the foundation on which the later or Evolutional school of geology has been built up.

Darwin's specially geological memoirs are not numerous, nor have they been of the same epoch-making kind as his biological researches. But every one of them bears the stamp of his marvellous acuteness in observation, his sagacity in grouping scattered facts, and his unrivalled far-reaching vision that commanded all their mutual bearings, as well as their place in the general economy of things. His long travels in the *Beagle* afforded him opportunities of making himself acquainted with geological phenomena of the most varied kinds. With the exception of one or two minor papers written in later years, it may be said that all his direct contributions to geology arose out of the *Beagle* voyage. The largest and most important part of his geological work dealt with the hypogene forces of nature—those that are concerned in volcanoes and earthquakes, in the elevation of mountains and continents, in the subsidence of vast areas of the sea-bottom, and in the crumpling, foliation, and cleavage of the rocks of the earth's crust. His researches in these subjects were mainly embodied in the "Geology of the Voyage of the *Beagle*"—a work which, in three successive parts, was published under the auspices of the Lords of the Treasury.

The order chosen by Darwin for the subjects of these three parts probably indicates the relative importance with which they were regarded by himself. The first was entitled "The Structure and Distribution of Coral Reefs" (1842). This well-known treatise, the most original of all its author's geological memoirs, has become one of the recognised classics of geological literature. The origin of those remarkable rings of coral-rock in mid-ocean had given rise to much speculation, but no satisfactory solution of the problem had been proposed. After visiting many of them, and examining also coral-reefs fringing islands and continents, he offered a theory which for simplicity and grandeur strikes every reader with astonishment. It is pleasant after the lapse of many years to recall the delight with which one first read the "Coral Reefs," how one watched the facts being marshalled into their places, nothing being ignored or passed lightly over, and how step by step one was led up to the grand conclusion of wide oceanic subsidence. No more admirable example of scientific method was ever given to the world, and even if he had written nothing else, this treatise alone would have placed Darwin in the very front of investigators of nature.

The second part was entitled "Geological Observations on the Volcanic Islands visited during the voyage of H.M.S. *Beagle*, together with some brief notices on the geology of Australia and the Cape of Good Hope" (1844). Full of detailed observations, this work still remains the best authority on the general structure of most of the regions it describes. At the time it was written, the "Crater of elevation theory," though opposed by Constant Prevost, Scrope, and Lyell, was generally accepted, at least on the Continent. Darwin, however, could not receive it as a valid explanation of the facts, and though he did not adopt the views of its chief opponents, but ventured to propose a hypothesis of his own, the observations impartially made and described by him in this volume must be regarded as having contributed towards the final solution of the question.

The third and concluding part bore the title of "Geological Observations on South America" (1846). In this work the author embodied all the materials collected by him for the illustration of South American geology save some which had already been published elsewhere. One of the most important features of the book was the evidence which it brought forward to prove the slow, interrupted elevation of the South American continent during a recent geological period. On the western sea-board he showed that beds of marine shells could be traced more or less continuously for a distance of upwards of 2000 miles, that the elevation had been unequal, reaching in some places at least to as much as 1300 feet, that in one instance at a height of 85 feet above the sea, undoubted traces of the presence of man occurred in a raised-beach, and hence that the land had there risen 85 feet since Indian man had inhabited Peru. These proofs of recent elevation may have influenced him in the conclusion which he drew as to the marine origin of the great elevated plains of Chili. But at that time, there was a general tendency among British geologists to detect evidence of sea-action everywhere and to ignore or minimise the action of running water upon the land. An important chapter of the volume, devoted to a discussion of the phenomena of cleavage and foliation, is well known to every student of the literature of metamorphism.

The official records of the *Beagle* did not, however, include all that Darwin wrote on the geology of the voyage. He contributed to the *Transactions* of the Geological Society (vol. v. 1840) a paper on the connection of volcanic phenomena. In the same publication (vi. 1842) appears another, on the erratic boulders of South

---

[1] Continued from p. 51.

America; while a third, on the geology of the Falkland Islands, was published later.

While dealing with the subterranean agents in geological change, he kept at the same time an ever watchful eye upon the superficial operations by which the surface of the globe is modified. He is one of the earliest writers to recognise the magnitude of the denudation to which even recent geological accumulations have been subjected. One of the most impressive lessons to be learnt from his account of Volcanic Islands is the prodigious extent to which they have been denuded. As just stated he was disposed to attribute more of this work to the action of the sea than most geologists would now admit; but he lived himself to modify his original views, and on this subject his latest utterances are quite abreast of the time. It is interesting to note that one of his early geological papers was on the Formation of Mould (1840), and that after the lapse of forty years he returned to this subject, devoting to it the last of his volumes. In the first sketch we see the patient observation and shrewdness of inference so eminently characteristic of the writer, and in the finished work (so recently noticed in these columns) the same faculties enriched with the experience of a long and busy life. In bringing to light the operations of the earthworm, he called the attention of geologists to an agency, the real efficiency of which they probably do not yet appreciate. Élie de Beaumont looked upon the layer of grass-covered soil as a permanent datum-line from which the denudation of exposed surfaces might be measured. But, as Darwin showed, the constant transference of soil from beneath to the surface, and the consequent exposure of the materials so transferred to be dried and blown away by wind, or to be washed to lower levels by rain, must tend slowly but certainly to lower the level even of undisturbed grass-covered land.

To another of his early papers reference may be made, from its interest in the history of British geology. Buckland, following in the footsteps of Agassiz, had initiated that prodigious amount of literature which has now been devoted to the records of the Glacial period in this country, by reading to the Geological Society a paper "On Diluvio-glacial Phenomena in Snowdonia and in Adjacent Parts of North Wales" (1841). Darwin, whose wanderings in South America had led him to reflect deeply upon the problems presented by erratic blocks, took an early opportunity of visiting the Welsh district described by Buckland, and at once declared himself to be a believer in the former presence of glaciers in Britain. His paper (1843) in which this belief is stated and enforced by additional observations, stands almost at the top of the long list of English contributions to the history of the Ice Age.

The influence exercised upon the progress of geology by Darwin's researches in other than geological fields, is less easy to be appraised. Yet it has been far more widespread and profound than that of his direct geological work. Even as far back as the time of the voyage of the *Beagle*, he had been led to reflect deeply on some of Lyell's speculations upon the influence of geological changes on the geographical distribution of animals. From that time the intimate connection between geological history and biological progress seems to have been continually present in his mind. It was not, however, until the appearance of the "Origin of Species" in 1859 that the full import of his reflections was perceived. His chapter on the "Imperfection of the Geological Record" startled geologists as from a profound slumber. It would be incorrect to say that he was the first to recognise the incompleteness of the record; but certainly until the appearance of that famous chapter the general body of geologists was blissfully unconscious of how incredibly fragmentary the geological record really is. Darwin showed why this must necessarily be the case; how multitudes of organic types, both of the sea and of the land, must have decayed and never have been preserved in any geological deposit; how, even if entombed in such accumulations, they would in great measure be dissolved away by the subsequent percolation of water. Returning to some of his early speculations he pointed out that massive geological deposits rich in fossils, could only have been laid down during subsidence, and only where the supply of sediment was sufficient to let the sea remain shallow, and to entomb the organic remains on its floor before they had decayed. Hence, by the very conditions of its formation, the geological record, instead of being a continuous and tolerably complete chronicle, must almost necessarily be intermittent and fragmentary. The sudden appearance of whole groups of allied species of fossils on certain horizons had been assumed by some eminent authorities as a fatal objection to any doctrine of the transmutation of species. But Darwin now claimed this fact as only another evidence of the enormous gaps in geological history. Reiterating again and again that only a small fraction of the world had been examined geologically and that even that fraction was still but imperfectly known, he called attention to the history of geological discovery as furnishing itself a strong argument against those who argued as if the geological record were a full chronicle of the history of life upon the earth. There is a natural tendency to look upon the horizon upon which a fossil species first appears as marking its birth, and that on which it finally disappears as indicating its extinction. Darwin declared this assumption to be "rash in the extreme." No palæontologist nor geologist will now gainsay this assertion. And yet how continually do we still hear men talking of the stages of the geological record, as if these were sharply marked off everywhere by the first appearance and final disappearance of certain species. The boldness with which Darwin challenged some of these long-rooted beliefs is not less conspicuous than the modesty and deference with which his own suggestions were always given. "It is notorious," he remarked, "on what excessively slight differences many palæontologists have founded their species; and they do this the more readily if the specimens come from different sub-stages of the same formation."

Starting from this conception of the nature of the geological record, Darwin could show that the leading facts made known by palæontology could be explained by his theory of descent with modification through natural selection. New species had slowly come in, as old ones had slowly died out. Once the thread of succession had been broken it was never taken up again; an extinct species or group never reappeared, yet extinction was a slow and unequal process, and a few descendants of ancient types might be found lingering in protected and isolated situations. "We can understand how it is that all the forms of life, ancient and recent, make together one grand system; for all are connected by generation. From the continued tendency to divergence, the more ancient a form, is the more generally it differs from those now living. The inhabitants of each successive period in the world's history have beaten their predecessors in the race for life, and are in so far, higher in the scale of nature; and this may account for that vague, yet ill-defined sentiment, felt by many palæontologists, that organisation on the whole has progressed. If it should hereafter be proved that ancient animals resemble to a certain extent the embryos of more recent animals of the same class, this fact will be intelligible."

Again, what a flood of fresh light was poured upon geological inquiry by the two chapters on Geographical Distribution in the "Origin of Species!" A new field of research, or, at least, one in which comparatively little had been yet attempted, was there opened out. The grouping of living organisms over the globe was now seen to have the most momentous geological bearings. Every species of plant and animal must have had a geological history, and might be made to tell its story of the changes of land and sea.

In fine, the spirit of Mr. Darwin's teaching may be traced all through the literature of science, even in departments which he never himself entered. No branch of research has benefited more from the infusion of this spirit than geology. Time-honoured prejudices have been broken down, theories that seemed the most surely based have been reconsidered, and, when found untenable, have been boldly discarded. That the Present must be taken as a guide to the Past, has been more fearlessly asserted than ever. And yet it has been recognised that the present differs widely from the past, that there has been a progress everywhere, that Evolution and not Uniformitarianism has been the law by which geological history has been governed. For the impetus with which these views have been advanced in every civilised country, we look up with reverence to the loved and immortal name of Charles Darwin.

(*To be continued.*)

THE TOTAL ECLIPSE

THE Special Correspondent of the *Daily News* with the English Eclipse Expedition telegraphs as follows under date, Sohag, May 17:—

This eventful morning was the finest we have yet had, cool and without a cloud. A great crowd of natives in picturesque costumes lined the road and the hill between the camp and Sohag. The shore of the Nile, except before the observatories, was packed with dahabeeahs bringing the governors of the provinces and other notables to observe the eclipse and do honour to the strangers. Thanks to Moktar Bey, in charge of the camp, and a force of soldiery, there was no confusion. Along a line of 300 yards the French, English, and Italian observers were left in undisturbed possession of tents and observatories. Nevertheless, while the sky darkened and assumed a leaden hue, the hills bounding the Nile bathed in purple, the great silence gave way, and from river and palm-shaded slope arose a shout of wonder and fear, which reached its climax at the moment of the sun's disappearance; nor ceased then, for, in addition to the horror of an eclipse—which the natives here as in India, attribute to the act of a dragon—there appeared in the heavens on the right of the sun an unmistakable scimetar. The eclipse had, in fact, revealed the existence of a new comet. Despite the short totality, many valuable results have been obtained. I am permitted to send a copy of the collective telegram sent to the various Governments, showing many new facts touching the sun's atmosphere; though matters have not become much simpler, which means more work. The layer to which much absorption has been ascribed seems vanishing from existence. The band K in the spectrum of the corona fully explains the eclipse colouring. The collective note is as follows:—

"Unprecedented facilities have been accorded by the Egyptian Government for the observation of the eclipse. A plan was agreed upon between the English, French, and Italian expeditions. Among the results, the most satisfactory are photographs of the corona, and a complete spectrum obtained by Schuster on Abney's plates. H and K are the most intense lines. A study of the red end of the spectrum of corona and protuberances was made by Tacchini. A comet near the sun was a striking object; it was photographed and observed by the naked eye. Bright lines were observed before and after totality at different heights by Lockyer, with intensities differing from Fraunhofer's lines; by Lockyer and Trépied an absolute determination was made of the place of the coronal line 1474 in Kirchhoff's scale; by Thollon and Trépied the absence of dark lines from the coronal spectrum was noted. Tacchini and Thollon, with very different dispersions, noted many bright lines in the violet. Thollon observed spectrum of the corona, and Schuster photographed it. The hydrogen and coronal line were studied in the grating spectroscope by Buisieux, and with direct vision prism by Thollon. Rings were observed in the grating by Lockyer, of the first, second, and third order. The continuous spectrum is fainter than 1878, stronger than 1871. An intensification of the absorption lines was observed in group B, at moon's edge, by Trépied and Thollon.—(Signed), LOCKYER, TACCHINI, and THOLLON."

When our cases are packed, we shall start directly home.

Captain Abney writes as follows to the *Photographic News*:—

I have received a brief telegram from Egypt regarding the Eclipse Expedition, and as it is in cipher I give the gist of the news. "Very successful all round. The whole of the spectrum with blue lines on a continuous background has been photographed. Prominences photographed with the prismatic camera (showing, of course, ring spectrum). Three photographs taken of the corona. A comet close to sun photographed with the prismatic and also ordinary cameras."

A telegram from the Alexandria correspondent of the *Daily News* states that Mr. Lockyer was to leave for London yesterday by the Peninsular and Oriental Company's steamer *Clyde*, while the other members of the Eclipse Expedition, with their instruments, were to leave next week.

KANT'S CRITIQUE OF PURE REASON

Immanuel Kant's Critique of Pure Reason. In Commemoration of the Centenary of its First Publication. Translated into English by F. Max Müller. With an Historical Introduction by Ludwig Noiré. Two Vols. (London: Macmillan and Co., 1881.)

THE records of science and philosophy during the past few years have been especially fertile in indications of a desire to place the relations of these two departments of inquiry upon a better footing than that of their former history. The desire has its source not in a spirit of concession but in a consciousness of necessity. A deeper criticism of conceptions with which in scientific investigation it is not possible to dispense, has brought several of its chief apostles face to face with fundamental obscurities and even contradictions which seem to cast doubt upon the validity of these conceptions. On the other hand philosophy has of late been coming into extensive contact with results obtained by scientific methods, and has been compelled either to modify its position, or go to the wall. The result is that attention has been increasingly directed to that critical examination of the nature of human knowledge, which claims on its negative side to have finally destroyed the old metaphysics and assigned definite limits to investigation, on its positive side to have exhibited these limits as arising out of the ultimate constitution of mind. The translation, just published, of the "Kritik der reinen Vernunft," is one of the latest contributions to the literature of this subject. The cry of "Back to Kant" which has of late years been heard so frequently in this country and abroad, has been responded to by Prof. Max Müller with two well-appointed volumes. Of these the first contains the translator's preface, an "Historical Introduction" by Prof. Noiré, and a translation of those passages of the second edition of the "Kritik," which differ from the corresponding passages in the first. The second volume consists of the translation of the first edition. The merits of the introductions and translations will be best estimated after the consideration—as far as the compass of a review will allow—of Kant's position.

To understand the critical philosophy, it is essential to realise that its problem and subject-matter are entirely different from any thing that is or can be dealt with by science in the ordinary acceptation of the term, and in particular from the investigations of physiological or other psychology. Science deals with what it is customary in our aspect to call mind, and in another cerebral organisation, and inquires into the relations of this to the surrounding environment. It seeks to lay bare the mechanism of perception and ideation, and to exhibit the complete dependence of mental upon cerebral functions. And of late years it has pretty well justified its title to the exclusive occupation of the field as against the old introspective psychology. Mind and its environment are alike the objects of and given in what may be indifferently spoken of as knowledge, consciousness, or experience. That is to say, they presuppose knowledge (to use the appellation which is perhaps least encumbered with question-begging associations) as that through which, like everything else, they exist, and in which the meaning of existence is to be found. The old Berkeleian reduction of *esse* to *percipi* is matter of common knowledge, and the leaders of scientific thought show a very proper disposition to treat it as a truism. For the statement that the universe in ultimate analysis is reducible to a succession of states or groups of states of consciousness, amounts to no more than the statement that the universe exists, and may be dismissed as outside the region of scientific questions in exactly the same sense as is this assumption. But if the step from Berkeley to Hume be taken, and existence regarded as the "impressions and ideas" of a particular individual, whose consciousness itself exists only so far as it is the object of knowledge, there ensue logical consequences of the gravest description. The inquirer is then confronted with the conclusion that the universe in so far as real is nothing more than an arbitrary sequence of phases of his own mind, as to which there is not the remotest reason for believing that the uniformity of the past will be resembled in the events of the future. Scientific and indeed all propositions, particular as well as general, become a delusion and self-consciousness an unintelligible deception. Since Hume's "Treatise" was published, it has been characteristic of his would-be interpreters, until within the last few years, to misunderstand him, of scientific men to ignore him, and of that succession of distinguished writers who have sought to apply the canons of scientific method to the problems of philosophy, in a somewhat perplexing fashion to do both. Of late the significance of Hume's teaching has been better understood. Men have come to see that if reality consists in ultimate analysis of a succession of sensations which, existing only in so far as they are felt, cannot be connected excepting by a purely subjective process, they must accept the logical consequences that not only is the belief in a uniform constitution of nature no longer tenable, but that the subjective semblance of such a belief is as incapable of being accounted for as the fact itself. This was the teaching of Kant, and those who seek its detailed justification and the proof that Hume did more than show the unreliability of general propositions, will do well to turn to the pages of the late Mr. Green and of Mr. Arthur Balfour. It is characteristic of Kant, that although he grasped the serious and self-destructive character of Hume's conclusion as to the impossibility of knowledge much more fully than its originator, he yet speaks of it as though it were of importance, only because it detracted from the supposed necessary truth of mathematical and causal relations. He has accordingly misled the majority of his critics into the unfortunate idea, that in denying the necessity of these relations, they have displaced the foundation of the critical system. The problem stood thus. It was clear that existence had no meaning except the being perceived by an actually or possibly percipient consciousness; and the only known form of such a consciousness was the individual self. But to say that existence meant the being a mode of the consciousness of the individual self, involved the contradiction of facts by the implicit denial of the possibility of even a semblance of knowledge. There was only one alternative: to recognise that the self in which the meaning of existence was to be sought was not the finite self disclosed in experience—an apparent point in a boundless expanse, from which it was distinguished only by the fact of its being always "here and now," but constructive thought, which was always subject and never object in knowledge, of which it was wrong to predicate existence, because it was above the categories of existence in that only as its object could things be said to be. For Kant, such an intellectual activity was something very different from that "unknowable" of which so much has been written. Of the "unknowable" it may be said, that although it exists, is a cause and so forth, it can never be intelligible to a finite mind, but it is none the less the object as distinguished from the subject of thought.

Kant's (as the time went) great knowledge of physical science no doubt contributed to cause him to revolt keenly against Hume's apotheosis of the individual self. He had anticipated, and to a surprising degree grasped, the modern conception of evolution. He had worked out, independently of Laplace, the mechanical theory of the solar system, and had enunciated the hypothesis of development in the organised world. For him there was no possibility of supernatural interference, and Man was but the last link in a gradually evolved chain of life. He could not assent to conclusions which assigned to an individual consciousness—itself but a point in the boundless immensity of space and time—the position of being the foundation of the whole phenomenal universe, and which regarded knowledge as a fiction. He saw clearly enough that the problem was not an ordinary scientific problem of relations within experience, but the problem as to the constitution of experience itself. In science (as indeed in metaphysics) we are always concerning ourselves with some conceivable object of knowledge, and we assume that there is no question about the conditions of that experience in which that object is actually or conceivably included as a part. But Kant's problem was that of knowledge itself, with the relations of space, time, causality, &c., which enter into its constitution, and which, as the conditions of the possibility of objects of knowledge could bear themselves, are implied in such objects. His method was that which is the general method of inductive reasoning, to apply an hypothesis to certain data, and to modify it, as appeared necessary from the result of the test of adequacy to the explanation of these data. His findings were in outline these: Berkeley and Hume showed that things cannot create thought, or exist otherwise or in any other sense than for thought. Therefore, thought must create things. But we find an inexhaustible material in nature which cannot be understood as the product of thought—the *matter* of perception as distinguished from the formal relations which are found to be exclusively the work of thought in knowledge; this formless matter Kant declares to become the object of knowledge—that is to attain reality—in so far as it is brought under two pure *a priori* forms, which belong exclusively to mind, space, and time. But in the constitution of the real there is something more implied, for space and time, taken by themselves, are merely the *formal possibilities* of spatial and temporal arrangement. Kant now shows that the matter of perception—the raw material of sensation of which all we can say is that it is wholly meaningless and without reality, excepting as thought makes it otherwise—is determined in the two pure forms of perception in the fundamental relations which he terms "categories," and which include not only quantity, quality, substance, cause and effect, &c., but every other relation of experience. The main difficulty in understanding Kant arises from the tendency to forget that the process of creation, which has just been in outline indicated, is not a process taking place in space and time. It is a process of pure thought which can never be made the object of knowledge, because, as has been already stated, knowledge with its distinction between subject and object implies, these very spatial, temporal, and other relations which are themselves logical elements in the process. Such thought can never be the property of an individual organism, completely dependent on what surrounds and has been before it. The finite self cannot be taken to explain the process through which, like the rest of existence, it is created. In making itself its own object thought is presented as an individual, limited like other individuals and conditions, within the field of experience. We only grasp Kant's meaning when we realise that by the thought which he finds to be creative of the objective universe, he does not mean the mind of an individual, but an intellectual activity which cannot itself become an object of knowledge, because in it and by it is created the very distinction between subject and object. Thought in this sense is pre-supposed by and is logically prior to all existence. Since it can operate in its construction of the unformed manifold of sensation into reality, only in the forms of space and time, reality is limited in its possibilities to what can be represented as existent in space and time; and from this it follows that knowledge is limited by imagination. But though our reasoning is thus only valid in so far as it is confined to actual or possible experience, thought has still, according to Kant, a power of extending itself by means of the categories alone beyond these limits, a procedure which leads to inevitable contradictions when an attempt is made to apply conclusions reached in this way to experience. It is just here that Kant's teaching becomes of interest to science, for these contradictions are the very ultimate difficulties of science, about which so much has been said of late. Kant discusses them at great length, and reference may be here made, by way of illustration, to his solution of the difficulty in the conception of the atom. In actual *experience* we cannot meet with, or in possible *experience* imagine an atom that is not of finite dimensions. Yet *reasoning* without reference to experience leads us to the inevitable conclusion, that whatever is of finite dimensions is further divisible *ad infinitum*. We predicate of the atom simultaneously that it is, and is not of finite dimensions. But in the first case we mean a conceivable object of perception in space; in the second, an unrealisable conception of thought from which no valid inference can be drawn as to reality. The two sorts of knowledge are wholly distinct, and hence their apparently contradictory results are not real contradictions. The difficulty arises not from mistaken scientific reasoning, but from the intrinsic nature of knowledge itself.

Between the representations of the relations of matter in space and time and the figments of abstract *à priori* reasoning, Kant goes on to show that there is an intermediate operation of thought, which, while it does more than create mere figments, yet does not create the real, although it modifies it. Its results are exemplified in those aspects under which the world is presented as beautiful or the reverse, and as organised. Organisation, for example—the characteristic of which may roughly be said to be that the whole determines its parts—is a species of relation which is unreal, in that it cannot be represented as a fact in space and time. For *quâ* space and time what we call and must think of as an organised whole, is merely a mechanical aggregate of parts which are external to, and independent of each other. Yet the knowledge of nature implies that the conceptions of organisation are real in the sense that experience *suggests* and forces them upon us, and without them nature would not only seem quite different from what it is, but could not be a connected whole at all. In other words, while an aggregate of purely mechanical relations is logically conceivable, such an aggregate would necessarily be quite different from the universe as known to us. The recognition of nature as beautiful and as organised is essential to its existence as nature, and these aspects cannot be got rid of although they are not real in the sense that the mechanical aspects are real. There are thus different phases in, or kinds of knowledge, all arising out of the ultimate constitution of intelligence. This result carries with it the solution for Kant of a number of difficulties. To ask, for example, how that which is organised springs out of an environment which is not organised, is to mistake a problem of knowledge for a problem of the relation of the objects of knowledge. For there is no line of demarcation which separates the organism from its environment. We speak as if there were such a line, because, for the purposes of advancing the limited knowledge of the individuals (which, because it is conditioned by space and time, cannot comprehend the whole universe *sub specie æternitatis*), it is convenient to abstract now from one sort of relations, now from another, and to talk of things as if they presented the aspects *only* of mechanism, or *only* of organisation. Kant declared that the twofold aspect was everywhere potentially present, because of the twofold operation of thought in the constitution of things.

Whether Kant was right in his conclusion that there were different *kinds* of knowledge, or whether he ought not to have taught that there were rather different stages than kinds, this is no place to inquire. When the systems of the late German philosophical writers have been stripped of what is at the same time most prominent and most useless in them, it will be found that they contain much valuable and detailed suggestion upon this point. It may be that Kant's theory of knowledge is imperfect, and that his distinctions are in many cases artificial and unwarrantable. But his criticism forms the basis of a new departure in investigation, and it cannot be understood without being to a great extent assented to. Not the least of his achievements is that he has sifted to their foundation and placed in a new light such metaphysical abstractions of science as matter, cause, organisation and mind, and has shown why and in what sense they give rise to problems which appear insoluble. His method was intrinsically the same as that of science generally, and to him belongs the credit of having brought science and philosophy into a definite connection. Those who have best followed his teaching have most clearly understood that the future of philosophy is to be looked for, not in a slavish adhesion to Kant's or any other system, but in the detailed application of his principles, to the critical investigation of the methods of particular branches of empirical inquiry. Already the effect of such an application has been shown in the new conception of history which has resulted from it, and there are indications that the time is not far away when men of science will begin to consider the position of their special departments in the light of the theory of knowledge.

It remains to be considered how far Professors Max Müller and Noiré have succeeded in making Kant intelligible to an English-speaking public. One cannot help feeling how much better the work would have been had it consisted simply of one volume containing the translation of the first edition of the "Kritik," with that of the passages from the second edition printed in the first volume. Of Prof. Noiré's Introduction it is difficult to speak with any satisfaction. It presents just such a view of the history of philosophy previous to Kant's time as used to be current in the days of Sir William Hamilton. The author's study of philosophy has apparently been the work of his leisure moments. To suppose, as both he and Prof. Müller seem to suppose, that a further development of the theory of knowledge is to be looked for from philology, is simply to ignore Kant's distinction between knowledge as a fact of experience and as that which is constitutive of experience. As has already been pointed out, it is in the former sense only that thought can be treated as dependent upon a particular organism, and consequently as related to language. In the latter sense alone, on the other hand, is it that which is the subject of Kantian investigation. Those who desire an historical introduction to German philosophy will do well to consult the pages of Prof. Caird rather than of Prof. Noiré.

As regards the translation, the comparison of what has been recently published by Dr. Hutchison Stirling with the work of Prof. Müller is not to the advantage of the latter. No doubt the work is grammatically excellent, and the style and accuracy by far superior to that of the old translations, but it lacks that grasp of the subject which enables Dr. Stirling, in translating the first part of the "Kritik," to reproduce not merely German words by English words, but German ideas by English ideas. Yet while it may be that the "Kritik der reinen Vernunft" remains yet to be translated, this is because the reproduction in the English language of such a work must fulfil ideal requirements before it can be accepted as satisfactory. Prof. Müller has given to students of philosophy much that they did not possess before, and that is far superior to the ordinary work of this sort. His offering is indeed what he intended it to be, a fitting commemoration of the centenary of the date on which was published the treatise which was destined to revolutionise philosophy. A faithful and literal translation of that treatise is a boon for which he will not find the public ungrateful to him.

R. B. HALDANE

OUR BOOK SHELF

Insects Injurious to Forest and Shade Trees. By A. S. Packard, jun., M.D. Bulletin No. 7, United States Entomological Commission, pp. 275, 8vo. (Washington: Government Printing Office, 1881.)

THE industry and energy displayed by the United States official entomologists is astonishing, and the amount of the literature of economic entomology issued by them would, if collected, form in itself a goodly library. One of these most valuable reports forms the subject of the present notice, closely printed, teeming with information, and illustrated by a multitude of excellent woodcuts. The amount of sound biological teaching is very great, and put forward in a manner that renders it intelligible alike to the "scientist" and to those for whose benefit it is more particularly intended. The author notices all the insects (mostly in great detail) feeding on particular trees, such as oak, elm, hickory, willow, pine, &c., &c., without special reference, in the first instance, to the particular *species* of these trees. This is a good plan, for it is only occasionally that certain insects are attached particularly to certain species in a *genus* of trees: these are specially indicated under the larger headings. We have often found ourselves in a dilemma in attempting a notice of these American reports, and this condition is strikingly in force with regard to this one in particular. Almost without exception, they are sound and lasting additions to the scientific literature of entomology; this one is especially so. But then there is the economic side of the question to be considered, and that is the most difficult. Naturally every insect that is attached to a particular species of plant, by feeding upon it, may in a certain sense be said to be "injurious" to that plant. Thus, in this present Report, under "Willow" we find even the "Camberwell Beauty" (*Vanessa antiopa*) included in the list of enemies; but we are quite sure that no one (not even the author) seriously imagines that it (with myriads of other species mentioned) is an "injurious insect" from an economic point of view. Certain insects feed on certain plants, and will eat no other; if the plant is exterminated, the insect disappears, and to keep up the balance of nature, it is quite possible that if the insect were exterminated in the first instance, some more destructive enemy (or disease) might eventually attack the plant. But the greater part of the enemies to *trees* commit their ravages by attacking the wood or bark, and here especially we think economic entomologists keep too much in the background the fact that many insects (and many of those here under consideration) act mainly the *rôle* of scavengers. Undoubtedly a leaf-feeder often attacks the most healthy trees, and as a rule it only becomes really injurious when present in extraordinary numbers; but with regard to what may be termed lignivorous insects, we strongly incline to refuse to see in the insect itself (in the majority of instances) the initial cause of the unhealthy condition; on the contrary we regard it as only stepping in to hasten decay commenced by causes quite unconnected with its presence. Our author, apparently unconsciously, virtually acknowledges this in his suggestions of remedies with regard to a beetle infesting the spruce (p. 277), and also elsewhere, by recommending, above all, preventive measures, these consisting in destroying all dead and dying trees, in which the insects especially abound. An unhealthy condition of the tree is the most favourable for the development of the beetle; but we are not of those who suppose a prescience in the latter which induces it to attack healthy trees for the benefit of prospectively remote generations of its descendants.

We wish Dr. Packard had not gone out of his way to coin worse than useless "*English*" *names*, many of which must prove more difficult to the class for whose benefit they are intended than are the scientific ones. With this exception, we thank him heartily for having produced a most valuable report. R. McLACHLAN

The Law of Kosmic Order: An Investigation of the Physical Aspect of Time. By Robt. Brown, jun. (London: Longmans, Green, and Co.).

A SHORT while ago we gave an account of the origin of the zodiacal signs so far as recent Assyrian researches enable us to determine it. Mr. Robert Brown has now published a little book on almost the same subject, the object of which is to trace the mythological conceptions to which the names given to the signs by the Accadians were due. He comes to the conclusion that the year was regarded by them as an extended nycthemeron, half the signs being diurnal or relating to the deities of day, and the other half being nocturnal, concerned with myths of the night. Early man thus recognised that there was one and the same law of "Kosmic Order" pervading all conceptions of time. In the course of his investigation Mr. Brown draws upon Egyptian and Iranian sources, but his chief materials are necessarily derived from the monuments of ancient Babylonia. Unfortunately the progressive nature of Assyrian study often renders what was written on the subject a few years ago more or less obsolete, and hence it happens that some of the statements on which he relies have been corrected or modified by subsequent research. Thus the name of the second zodiacal sign, as has already been mentioned in NATURE, meant "the directing Bull" in Accadian rather than "the propitious Bull," as Mr. Brown gives it. It is true that the word had both significations, but the signification of "propitious" was a later and derivative one. The name of the seventh sign again was "illustrious mound," not "illustrious altar," and seems to have referred to the story of the Tower of Babel, whose building was placed at the autumnal equinox, while the builder himself was called "the king of the illustrious mound." Such corrections, however, seldom, if ever, touch Mr. Brown's arguments or diminish the value of his interesting book. We can thoroughly recommend it to those who care to study a curious chapter in primitive astronomy.

Uganda and the Egyptian Sudan. By the Rev. C. T. Wilson, M.A., F.R.G.S., and R. W. Felkin, F.R.G.S. Two vols. (London: Sampson Low and Co., 1882.)

THIS double narrative is one of great interest. Mr. Wilson was one of the Church Missionary Society's missionaries sent out to King Mtesa on account of the favourable report of Mr. Stanley with regard to the eagerness of the Uganda potentate for instruction. Uganda, our readers will remember, is a district on the north and north-west of Victoria Nyanza, visited long ago by Speke, when Mtesa was quite a youth. Mr. Wilson's stay extended over two years, 1877-79. During that time, he had excellent opportunities of becoming acquainted with Uganda and the Victoria Nyanza and the districts on its south shores. He reached his destination by travelling west and north from Zanzibar, and was favourably received by Mtesa. He had much intercourse with that monarch, and gives a very rational estimate of his character, not by any means so enthusiastic as that of Mr. Stanley. Mr. Wilson's notes of his journey contain many additions to our knowledge of the region he traversed. The most important part of his narrative is that which relates to the country and people of Uganda. His chapters on Life in Uganda, on Uganda and the Waganda, and on the government and language of the Waganda, are full of fresh and interesting information, and will be valued both by ethnologists and geologists. Mr. Wilson is a favourable type of the missionary, thoroughly practical, a good observer, and a hard worker. He collected many specimens of plants, a list of which is given in the appendix, with vocabularies, and meteorological and hypsometrical observations. Mr. Felkin reached Uganda by proceeding from Suakin to Berber on the Nile, and up that river to Uganda—the first time that the Victoria Nyanza had been reached by that route. Both he and Mr. Wilson returned to Suakin by making a circuit round by the sources of the Bahr-el-Arab, and across by Obeid to the Nile. They accompanied the ambassadors sent by Mtesa to this country. Mr. Felkin's notes on the hydrography and natural history, as well as on the social and political condition of the country traversed, are of much interest. The work is well supplied with good maps, and has a number of good and useful illustrations. It is well worth reading.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Dr. Siemens' Solar Hypothesis

I HAVE been waiting for several weeks for answers to the following rather obvious objections to Dr. Siemens' Solar Hypothesis, but I have not seen them either asked by others or answered by Dr. Siemens.

1. How the interplanetary gases near the sun acquire a sufficient radial velocity to prevent their becoming a dense atmosphere round him?

2. Why enormous atmospheres have not long ago become attached to the planets, notably to the moon?

3. Why the earth has not long ago been deluged when a constant stream of aqueous vapour that would produce a rain of more than 30 inches per annum all over the earth must annually pass out past the earth in order to supply fuel to be dissociated by the heat that annually passes the earth?

4. Why we can see the stars although most of the solar radiations are absorbed within some reasonable distance of the sun?

GEO. FRAS. FITZGERALD

40, Trinity College, Dublin, May 16

I HAVE the pleasure to reply to the very pertinent questions put by Prof. FitzGerald as follows:—

1. The gases being for the most part hydrogen and hydrogen compounds have a low specific gravity as compared with the denser gases forming the permanent solar atmosphere. On flashing into flame in the photosphere, their specific gravity would be vastly diminished, thus giving rise to a certain rebound action which coupled with their acquired onward motion, and with the centrifugal impulse they receive by frictional contact with the lower atmosphere, constitutes them a surface stream flowing from the polar to the equatorial regions, and thence out into space. (Lest I should be misunderstood, allow me to add that I do not look upon centrifugal action as sufficing in any way to overcome solar gravitation.) Astronomers are in the habit of regarding each spheroid possessed of an atmosphere as rotating in vacuous space; under such circumstances the atmosphere must partake of the rotatory motion of the solid spheroid, and after having attained an increased depth at the equator, will assume a state of static equilibrium unless disturbed by external influences. No such statical equilibrium is possible, however, if we assume the same spheroid with its atmosphere, surrounded by an ocean of indefinite dimensions, consisting of gaseous matter not partaking of the rotation of the spheroid, although subject to its attractive influence. Equal masses will under those conditions be equally attracted both in the polar and equatorial direction, and the continued disturbance of equilibrium by rotatory motion must result in continuous outflow. Nor need this outflow be accomplished entirely at the expense of rotatory motion of the spheroid because the inflowing polar current when once established, will only have to be changed in direction by frictional action in order to convert it into the outflowing current.

2. Regarding the second question, I assume that the atmosphere of each spheroid in space is precisely such as would result from its mass, and if this view is correct, the moon also must have an atmosphere, though of so attenuated a character as to be scarcely perceptible by means of optical instruments; for as Wollaston put it in his celebrated paper, read before the Royal Society in January 1822, "it would not be greater than that of our atmosphere is, where the earth attraction is equal to that of the moon at her surface, or about 5000 miles from the earth's surface." I am well aware that in assuming atmospheric air to be a perfectly elastic fluid, the atmospheric density would at a height of only 70 kilometers not exceed the 1-7000th part of atmospheric density, and would therefore at greater distances become inappreciable; but we have evidence to show that Boyle and Mariotte's law holds good only within comparatively narrow limits, and there is other evidence referred to in my paper in favour of the supposition that such gases as are contained in meteorites are diffused through space in appreciable amounts, or the meteorites could not for millions of years have retained these gases, notwithstanding the action of diffusion into empty space.

3. The amount of vapour that would condense upon the earth under the conditions here assumed, would depend upon its mean temperature on the one hand, and on the vapour-density of the stellar atmosphere surrounding it on the other. Assuming the density of the stellar atmosphere, which, while surrounding the earth does not partake of its rotatory motion to be 1·10,000th part of atmospheric density, and saturated with aqueous vapour, the point of condensation would be according to Regnault −50° C., if the outer regions of our atmosphere should be at that temperature, and saturated with aqueous vapour, the two would be in diffusive balance; if they were at a lower temperature they would acquire, and if at a higher they would part with aqueous vapour to the surrounding medium.

4. It has long been held by astronomers that there are stars beyond our range of vision, which hypothesis would involve that of absorption of heat and light rays in stellar space; some rays are more easily absorbed than others; thus it appears to be the yellow rays which are most efficacious in the decomposition of carbonic acid and aqueous vapour in the vegetable cell. May not the same conditions prevail in space, and allow probably the rays of highest refrangibility to pass on to the greatest distance without being absorbed—I should say utilised—in doing chemical work?

Porculia Salvania (Hodgson)

A MOST valuable and interesting addition has recently been made to the Zoological Society's collection in Regent's Park, of four—a male and three females—Pigmy Hogs (*Porculia salvania*, of Hodgson) from the Doars of Bhotan. The extreme rarity and difficulty of procuring this animal makes its presence here of the greatest interest, and these individuals will be examined eagerly, not only by naturalists, but by many Indian travellers, sportsmen, and others, who have heard of, but never had the opportunity of seeing the pigmy hog. My attention was directed to it many years ago by the late Mr. Blyth, then in Calcutta, who on my first expedition to the Nepaul Terai, in 1855, requested me to endeavour to obtain a specimen—as far as I remember, neither Blyth nor Jerdon had seen it living—Hodgson, who described and named it, had heard of its existence from the Nepalese or other denizens of the Terai, or neighbouring localities, long before he obtained a specimen. I was unable to procure one, though I made repeated attempts to do so, and enlisted many influential friends in the search, but without success; very few appeared to know even of its existence, whilst many seemed to regard it as mythical. Occasionally I met with natives who said they had heard of it, but I began to fear that it might be extinct. The four fine specimens now in the Gardens prove that such is not the case, and will furnish opportunity of supplementing Hodgson's description of the animal, which is to be found in the *Proceedings* of the Zoological Society, and in Jerdon's "Mammals of India."

These lively little pigs, weighing probably hardly as much as a hare, are most active and energetic; they resemble the ordinary pig in miniature, but probably may have some anatomical peculiarity which will interest naturalists as regards affinity with the Peccaries. The specific designation Salvania, is from the Sal (*Shorea Robusta*), as the pig is, I believe, found in that part of the Terai and along the sub-Himalayan tracts, where the Sâl tree abounds, and among the long grass in which the little creature hides itself. It is much to be hoped that they will breed, and thus enable other zoological collections to be supplied with specimens of a most rare and interesting species.

J. FAYRER

Pseudo-Glacial Phenomena

I BEG to call the attention of geologists to the following facts:—On the north-east coast of Australia, at the end of Trinity Bay, about lat. 17° S., there are steep ranges of granite abutting on the sea-margin. Every rainy season (December, January, and February) immense quantities of the granite become loosened from the upper part of the mountains, and fall in extensive landslips down the sides. These landslips or rockslips are so numerous, that in fine weather they are most conspicuous objects on the sides of the hills, and look like dry water-courses. One of these rockslips I witnessed at Cape Grafton, from a distance of three miles. The noise was terrific, and the ground trembled as though from an earthquake. On examining the blocks of granite which had slipped to the bottom of the ravine, I found many of them with their sides grooved and scratched, and one fragment was as beautifully polished on one side as if it came from the hands of a lapidary, excepting, of course, the scratches and grooves. In the course of a few centuries, much of the range will be worn away, and its sides represented by an alluvial deposit mainly consisting of angular boulders of every size and shape, many of which will be polished, scratched, and grooved. There are very few geologists who would not call it a glacial drift, even now, were not the cause so evidently before them. Will this help to explain those so-called drifts, which, like this instance, are found far within the tropics? T. E. Tenison-Woods

Variability of Number of Sepals, Petals, and Anthers in the Flowers of Myosurus minimus

In my article on "Different Modes of Self-fertilisation where Visits of Insects are wanting" (Nature, vol. x. p. 129), I gave a short account of the number of sepals, petals, and anthers in a hundred flowers of *Myosurus minimus* examined by myself. Some error must, however, have slipped into this account, the sum of the quoted flowers differing from a hundred. I have, therefore, lately repeated my examination and give here the results. In 200 flowers I now found 35 different proportions in the number of sepals, petals, and anthers. These were contained in—

Flowers	Sepals	Petals	Anthers	Flowers	Sepals	Petals	Anthers
1	4	3	4	2	5	5	3
1	4	3	6	3	5	5	4
6	5	2	3	*c* 7	5	5	5
4	5	2	4	7	5	5	6
1	5	2	5	4	5	5	7
1	5	2	6	3	5	5	8
1	5	3	2	1	6	2	5
4	5	3	3	1	6	2	6
10	5	3	4	1	6	2	7
a 33	5	3	5	1	6	2	8
23	5	3	6	1	6	2	10
24	5	3	7	1	6	3	7
9	5	3	8	1	6	5	7
1	5	3	9	1	7	2	7
6	5	4	4	1	7	3	6
7	5	4	5				
b 16	5	4	6				
14	5	4	7				
2	5	4	8				
1	5	4	9				

In general, the number of sepals, petals, and anthers increases and decreases with the size of the flower, the 12 first quoted flowers being exceedingly dwarfish ones.

It should further be considered that in combination with a certain number of sepals and petals a certain number of anthers seems to be the normal one, and from this normal (maximum) number of anthers, as to be seen under *a*, *b*, *c*, the numbers of flowers on the two opposite sides are constantly decreasing.

Lippstadt, May 16 Hermann Müller

"A Dead Heat"

Telegrams from Paris on Monday state that the "Prix du Jockey Club" had resulted in what is usually called a "dead heat." It is unnecessary for me to inform you, that there can be no such thing as a "dead heat." It is called so, I suppose, in consequence of a disagreement among the judges as to which horse first thrusts his nose beyond the winning-post. Are living judges any longer necessary to determine the results of a race? Five years ago I proposed to prove by indisputable evidence the winner of a trotting match which, in consequence of a dispute among the judges, had to be trotted over again. By means of a single thread stretched across the track, and invisible to either horses or their riders, twenty photographic cameras have been made to synchronously record positions impossible for the eye to recognise. With the aid of photography, the astronomer, the pathologist, the chemist, and the anatomist are enabled to pursue the most complex investigations with absolute confidence in the truth it reveals; why should those interested in trials of speed not avail themselves of the same resources of science? I venture to predict, in the near future that no race of any importance will be undertaken without the assistance of photography to determine the winner of what might otherwise be a so-called "dead heat."

Aurora Borealis

The auroral display mentioned by your two correspondents was particularly brilliant at Oldham on the evening of the 14th inst., at 11.10. I observed at 11.15 one very fine streamer reaching quite to the Pole Star; it was of a ruddy hue, dull, and changing to purple. The horizon was cloudy, the cloud being fringed with white light, changing to rose colour. The constellation Cassiopea was at times covered with a mass of light, from whence the streamer arose, lighting up the whole of the northern sky. W. Pullinger

Oldham

Bright Meteors

1882, May 16, 11h. 0m. G.M.T. Meteor many times brighter than Venus; green, then white; began of second magnitude, 5° above main cluster of *Coma*; passed 1½° above *Iota* Urs. Maj., where it changed colour suddenly; ended, of second magnitude, 5° left of *Beta* Aurigæ. Duration 8 seconds, may have been 10. No streak. Observed from the University Observatory. A few minutes later another was seen describing very nearly the same path. G. L. Tupman

Oxford

Curious Formation of Ice

In your issue of November 24, 1881 (vol. xxv. p. 78) Mr. J. F. Duthie described small wafer-like, rather funnel-shaped pieces of ice which he noticed in October, on the slopes of the Himalayas, and asked whether such forms of ice had been observed elsewhere.

On November 30, 1881, I observed, at a height of about 7000 feet, near the hill station of Chakrata, on the outer Himalayas, ice crystals which were grouped in bundles about one inch long and one inch in diameter. The bundles consisted of prisms up to a quarter of an inch diameter, and looked at from the side the long parallel prismatic faces, and the short rectangular outlines of the ends of the prisms suggested rather the orthorhombic system of crystallisation. On looking straight at the end of the crystals, it was, however, seen that all the prisms were hexagonal, and that they ended in hollow hexagonal pyramids, thus bringing out clearly the hexagonal system of crystallisation to which ice belongs.

The hollow hexagonal pyramids showed further development in other portions of the hoar frost, and there seems very little doubt that what Mr. Duthie describes were accumulations of small crystals originally grouped in the shape of hexagonal hollow pyramids, but more or less expanded and rounded off.

I may here mention another interesting occurrence of crystals which I had the opportunity of noticing at the salt works in Cheshire. During slow evaporation of brine in a steam-heated reservoir, crystals of salt formed at the surface in the shape of hollow hexagonal pyramids. This is easily explained. Whilst the ordinary well-known hollow salt pyramids with square base form, by the gradual sinking and growth of a cubical nucleus which floats with one pair of faces horizontally placed, these exceptional hexagonal pyramides form from an original cube which floats on the water with a solid angle as its lowest point. The six lateral edges are the beginning of the hexagonal pyramids. H. Warth

The Existence of a Voice in Lizards

The following may perhaps be of some interest in connection with the letter of Prof. Th. Eimer (vol. xxvi. p. 29). One evening as I sat in the verandah of my house in Madras, my attention was called by a peculiar cry, and on looking up I saw that it was being made by a small lizard, apparently in a state of great terror at a snake which was uncoiling itself from the rafters close to it. I cannot say what the species of the lizard was, but it was one of those so abundant on the walls of Indian houses; it was one of two that appeared every evening, when the lamp was brought out into the verandah, and feasted on the moths attracted by the light. THE ECLIPSE EXPEDITION

THE *Daily News* of Tuesday publishes the following communication from its special correspondent with the English Eclipse Expedition:—

On the Nile, between Siout and Sohag, May 6

The astronomers have now nearly reached their destination if all goes well, but it is by no means certain that everything will, for the Nile has never been known to be so low, and we have already been aground many times. To-morrow morning will see them and their instruments landed after their last water journey. The arrangements made by the Egyptian Government and by His Highness the Khedive himself, who takes the liveliest personal interest in the work, have been simply perfect. Everything seems to have been foreseen, every possible cause of delay obviated, and everything that could conduce in any way either to the comfort of the observers or the success of the observations provided. One officer of the Egyptian Government or another has been in constant attendance upon the expedition since they landed at Suez, and any indication of a desire that a certain course of action should be taken has been at once attended to. There is no shutting one's eyes to the fact, that there are many men occupying high positions in this wonderful country, through which we are now journeying, who take the keenest interest in scientific progress, and who are more than anxious, that Egypt should take her place among the more highly civilised nations, among whom science is cultivated to a greater or less extent; and there can be little doubt, that the efforts now being made to educate the people will in time bear more fruit of this soil. It is quite *apropos* to this train of thought to mention, that the fact that the admirably equipped observatory of Cairo will count for very little among the proposed observations is keenly felt. It must not, however, be imagined that because the metropolitan observatory counts for so little, Egypt possesses no astronomers. I mentioned in a former letter that it was hoped that Ismatt Effendi, a member of the Khedive's household, might be attached to the expedition. When the expedition reached Suez and the *Kaisar-i-Hind* steamed into the harbour, it was easy to see that something unusual was going on there. The Khedive had not only sent Ismatt Effendi to receive the expedition, but had sent orders to the Governor of Suez to welcome it in his name. Nor was this all. A special train had been provided for the instruments and observers, and every precaution taken for safe handling and safe custody of the former. In the morning the Governor of Suez speeded the parting guests, who were accompanied by M. Ismatt, and this gentleman soon showed how much he had profited by the long training he has received in the observatories of Paris and Washington, and it was soon acknowledged that in him the expedition not only found a most useful and agreeable companion, but a collaborator of the highest value.

On arrival at Cairo the party found General Stone, chief of the staff, accompanied by Moktah Bey, on the platform to welcome them. Of the former, it may be said that his influence for good on the higher education in Egypt and on the officers who have served under him is freely acknowledged. He has lost none of the enthusiastic love of truth for its own sake, and of science for the sake of the world, which characterises so many of the best of his countrymen; and many of his remarks touching his conception of the duty incumbent on the Government of Egypt, in aiding a work of international aim, strongly reminded me of General Sheridan's thoughts and words when he received at Washington one of the English observers of the eclipse of 1878. Moktah Bey, who has been detailed to accompany the expedition, is an officer who has greatly distinguished himself by his travels in the Soudan. He is not only an admirable administrator, but a capital linguist, while his love of work in the Soudan and in Upper Egypt in triangulation, determining latitudes and longitudes, and establishing, or endeavouring to establish, meteorological observatories, nileometers, and the like, render him also a valuable scientific ally.

General Stone, on the arrival of the instruments at Cairo, cut a Gordian knot by at once ordering the car containing them to be ferried across the Nile. There is no railway bridge over the Nile at Cairo, so that considerable time was saved and risk avoided by this measure. In fact it may be said that not only were the cases containing the instruments untouched from Suez to Siout, but that they were actually sealed up all this time. There was not much time to give to the strange sights and old memories of Cairo; even the Pyramids have remained unvisited so far, for after resting one night and spending part of the next day in official visits, the party was off again yesterday and travelled during the night down to Siout, the most southerly railway station in Egypt, and about 70 miles north of the point where the eclipse line crosses the Nile. At Siout, whither extra camels and porters had been summoned by telegraph, the sight at sunrise this morning was strange beyond all description, or at all events beyond the descriptive powers of your present correspondent. The telescopes to be used on the present occasion are of very great weight, and although they have been divided into as many separate pieces as possible, some of the cases are still very heavy, taxing the powers both of men and camels to the utmost. The camels, which were made to kneel down so soon as the cases had been got out of the railway car, groaned as they rose with such an unaccustomed weight; and giant Arabs, good-natured sons of Hercules, did the rest at the boat side. But here again a special arrangement was necessary. The Nile is so low and the steamer was already so crowded that the instruments were placed in a special boat taken in tow by the steamer. Events have shown that this precaution was by no means an improper one, for during the last hour and a half we have been firmly aground, and it does not seem as if all the shouting of the motley crew, or any manœuvring of the engine is going to get us off again. While these attempts, which seem born of confusion, are wearing themselves out, it will be as well to say a word about the final arrangements, so far as they are known to us, before we actually arrive at the station.

There are three expeditions in Egypt for observing the eclipse—a French, an English, and an Italian one. As there is so little choice of station, his Highness the Khedive has sent forward a steamer to Sohag, the point at which the eclipse track crosses the Nile, and has invited the various expeditions to use this as a *point d'appui* and floating hotel wherever their actual place of observation may be. Prof. Tacchini forms part of the Italian party, and MM. Thollon and Trépied of the French one. The latter have gone on ahead, and it is thought that their instruments are already up and adjusted, while the Italian party follows us on Monday. It is believed that the work of both of these parties will be chiefly spectroscopic. As the exposure of Capt. Abney's plates forms an important part of the English plans, it is intended to take special precaution for securing the photographic rooms and tent from dirt. With the same object in view covers have been prepared for the telescopes, which closely fit them and can be kept, it is fondly hoped, sand-tight. This brings me to say a word about the khamseen. The season this year in Egypt has been extraordinary. There has been much rain and very little khamseen, and now there is a brisk north wind blowing, which generally follows the dust wind. Hence many weather-wise people say that the khamseen is over; if so, of course, all the better. On the other hand, to-night from our sandbank we have witnessed a sunset rendered transcendentally beautiful by clouds over fully one half of the sky. It is possible therefore that if the present weather continues, the sky will not be quite so free from vapour as it is generally in Upper Egypt. To avoid the khamseen, General Stone, who has had the region reconnoitred, has suggested to the English party to occupy an eminence to the north-west of Akmin, a village a little higher up the river than Sohag.

Near Sohag, Sunday

I had got so far at 11 last night, when the time came for closing the mail bag, although we were fast aground, and apparently with less chance than ever of getting off. There were two mail bags, however, made up after all, for the service is so interfered with higher up the Nile that I am still in time on Sunday evening to send a letter which ought to catch the next Brindisi mail, though whether it does or nor is very doubtful, for we have been aground again twice to-day.

So, as we have at last arrived at our station, I will endeavour to give an idea of the proposed arrangements. In the first place, we have found the steamer on which the various parties are to live as the guests of the Khedive moored close to the shore, at a point where it trends north and south, or very nearly so, about half a mile below Sohag. This position, which has been selected by the French party—the first to arrive—is a very admirable one for two reasons. First, the constant wind during the last week has been from the north, and by keeping a staff of people watering the foreshore of the Nile, all dust is obviated. To the north of the place of observation trees, and what looks like grass from a distance, grow close to the margin of the river; so that the dust can only be of nearly local origin; while a long stretch of sandbank to the north, running east and west, is far enough away to deposit its sand in the Nile before it can reach us.

Secondly, the khamseen, if khamseen there is to be, will have to travel a mile and a half along the Nile before it can enter the observatories; and it is thought this amount of water surface will have an important effect in reducing the amount of sand in the air, even in its case also. *Nous verrons.* These considerations have induced the English party to take up ground close to the boat and their French confrères. The hills which look so tempting in the mass are simply impossible as places of observation. With the means at command here it would take a week to get the instruments up, much more in position; while at Akmim, which is only two or three miles away, there does not seem to be any spot more favourable, taking everything into consideration, than the one here.

At five o'clock to-morrow, then, the work will begin, and the next week will be a busy one, for in spite of the fresh breeze and the clouds—for there are very distinct clouds to-day—work on the sand becomes very oppressive in the middle of the day, and there are heavy weights to move, which the observers must move themselves. The scene from the ship is already interesting. To the north two tents and various shelters, to the south one tent. These will increase to six to-morrow. Here and there groups, looking down the bank, stealthily from between the trees. There is a pretty thick grove of acacia trees, which shelter us somewhat from the rays of the setting sun, still fierce in this latitude. Here and there, skirting the grove, a sentinel with fixed bayonet keeping guard. At the extreme south, tents for the military, and a long line of piled arms.

Across the water the scene is novel and beautiful in the extreme. The main Nile, in which the b at is anchored, is here about half a mile wide, but there is an island about two miles long, and a wide stretch of water beyond that. This island forms, with the river, the foreground of the landscape. With an opera-glass we can see the Fellaheen cultivating the ground almost to the water's edge in places, and looking after their crops of maize or their flocks of goats. Here comes a veiled Rachel to the sacred river to fetch water for a house in an indistinct flat-topped village, sheltered in a large group of beautiful palm trees. The arm of the river beyond the island we cannot see, but a background is not lacking. A long line of mountains, we may almost call them, full of geological tracery, are now, as I write, almost blood-red in the light of the setting sun, and are surmounted by that grey purple one always sees to such advantage in Eastern lands—both grey and purple haze in a few hours to give way to the silver dawning of the moon, now terribly dwindling in her visible surface, and reminding the astronomers of the coming seventy seconds in a most forcible manner.

The proceedings at the end of the first day on which the English and French parties found themselves together as guests of the Egyptian Government naturally included some toasts—that of his Highness the Khedive, proposed by M. Trépied, and that of the English and French nations, proposed by Moktah Bey, and responded to by Mr. Norman Lockyer. The arrangements on board are as perfect as those made at the various stations on shore, and one's national pride is a little touched at the idea of what the Government reception would be of a party of Egyptian astronomers coming to England to observe an eclipse of the sun.

ANEMOMETRICAL OBSERVATIONS ON BOARD SHIP[1]

IT is known that the determination of the velocity of the wind in the ocean has always been one of the desiderata of meteorological observations. Maury devoted much attention to this subject, and to determine, at least approximately, the velocity of trade-winds, he was compelled to work on a very unsafe basis—the velocity of ships during different parts of the year—and to put aside all observations made in accordance with the scale of Beaufort as unreliable. But it is obvious that the velocity of a ship depends on so many circumstances quite independent of the wind itself (such as the shape of the ship, the surface of its sails, the disposal of the cargo, and so on), that its velocity is but a very imperfect means of measuring the velocity of wind. Besides, the relation which exists between the force of the wind and the velocity of a ship, under different angles between the direction of both, is a new source of error, as this relation has not yet been established with accuracy, and can be established only by means of anemometric measurements. The necessity of trustworthy measurements of the velocity of wind at sea was so well understood in England that the Royal Society and the British Association established in 1859 two anemometers—one on the Bermuda Islands, and the other at Halifax. But it is known that the force of the wind is usually lessened on continents and islands.

Therefore it was absolutely necessary to make anemometrical observations on board ships, and a few attempts had already been made in this direction. Prof. Piazzi Smith invented an anemometer which might be established on board a ship, and which merited the highest eulogy from Maury, but Lieut. Domojirov does not know if any observations were made with it. Emil Bessel, during the Arctic expedition of the *Polaris*, made a series of observations with an anemometer on board his ship, but he does not explain, neither the methods of observation, nor the corrections he applied to his measurements. In

---

[1] A Domojirov, in the *Izvestia* of the Russian Geographical Society, vol. xviii. 1882, fasc. 1.

1879 Col. Rykatchoff, of the St. Petersburg Central Physical Observatory, established, on board the *Nayezdnik*. an anemometer of his own construction, which was observed during the ocean cruise of the clipper; and the schooner *Nordenskjöld*, which unhappily was lost in 1879 at Yesso Island, had also an anemometer, which was taken afterwards on board the Russian clipper *Djighit* by M. Domojirov. The observations on board of the *Djighit* were carried on with this anemometer (of Casella) put in such an apparatus (like that of the lamps on board of ships), as always maintained it in a vertical position, even during the heaviest seas, when the ship oscillated for 30° on one side, and 35° on the other. The apparatus was put on a 16-foot-long pole, which was pushed out for each observation on the wind-side of the ship, from the boat, and thus exposed to the full force of the wind for ten minutes. The height of the instrument above the sea was 26 feet. The direction of wind was determinated by means of a vane, and its true direction computed from the apparent one, on the principle of the parallelogram of forces, by taking into account the velocity of the ship. When the angle between the direction of the wind and the direction in which the ship goes is known, as well as the seeming velocity of wind (measured by the anemometer), and the velocity of the ship, the true velocity of wind is easily determined by means of simple computations, or of the tables published for that purpose by M. Rykatchoff (*Russian Marine Review*, February, 1880). A series of experiments having been made for ascertaining in how far the calculated figures agree with the true ones, M. Domojirov arrives at the conclusion that these figures are quite reliable; determination having been made during the progress of the ship, she was immediately stopped, and the determination made anew, both results always being quite identical. But the measurements from the side-boat are very tedious and even dangerous during heavy seas, and each observation occupies no less than three men for about twenty minutes. Therefore M. Domojirov proposes to apply electricity to register the rate of the anemometer.

The observations on board the *Djighit* were made five and six times per day from March 23 to May 30, and the complete results, with all elements for calculations, are published in the papers of M. Domojirov. The north-eastern trade-wind, observed on the passage from Japan to the Sandwich Islands and back, had a very regular force of from 5 to 9 metres per second; the south-eastern trade-wind experienced on the passage from the Sunda Islands to the Seyschels, had a velocity of 4 to 9 metres per second, and the south-western winds on the passage from Port Victoria to Aden, had velocities from 12 to 15 metres per second.

It would hardly be necessary to insist on the importance of such observations for meteorology, as well as for practical purposes, and we hope that soon the still prevailing prejudices as to the possibility of anemometrical observations on board ships having disappeared, and more convenient methods of observation having been devised, the anemometer will become on board ships as necessary an instrument as the log and barometer. P. K.

INSTANTANEOUS PHOTOGRAPHY OF BIRDS IN FLIGHT

PROF. E. J. MAREY has lately published in the pages of our contemporary, *La Nature*, an article on a "photographic gun," the illustrations to which, with a somewhat shortened account of the process, we are enabled, through the courtesy of the editor of *La Nature*, to present to our readers. M. Marey's researches on animal locomotion are well known; his experiments carried on by the graphic method were productive of most valuable results, and they corrected and explained many debated points in animal mechanics; but having seen some of the results obtained by Mr. Muybridge, at San Francisco, with photographic pictures taken during an exposure of the 1-500th of a second, he was very desirous to have the same process adapted, so as to admit of its being applied to the taking of birds flying. In September, 1881, on a visit of Mr. Muybridge to Paris, he brought with him some photographs of birds taken on the wing, but these unlike the invaluable series taken by the same gentleman of horses and men, were not the representation of a series of continuous attitudes, but rather represented the bird in the position it happened to be in at a moment of time; whereas, to explain the fall and rise of the wings and the positions of the body, it was, above all things, important to have a series of rapid photographs taken of the same bird over a period during which the whole mechanism was in action, so as to allow of the movements to be afterwards studied at leisure. After deliberating over this subject during the last winter, at last the idea of a photographic gun occurred to him; but the immense quickness with which the movements should succeed one another, in order to bring a series of sensitive surfaces across the lens, at first presented great difficulties in the constructing of the machine. It was necessary to have images taken successively ten or twelve times in one second, in order to

FIG. 1.—The Photographic Gun.

succeed in obtaining the various positions of the wings of a bird at each revolution. As the result of a good deal of thought and labour, an apparatus was constructed about the size of a sporting-piece (Fig. 1), which would take twelve images, in one second, of an object on which the piece was continuously sighted. The time of exposure of each image was about 1-720th of a second.

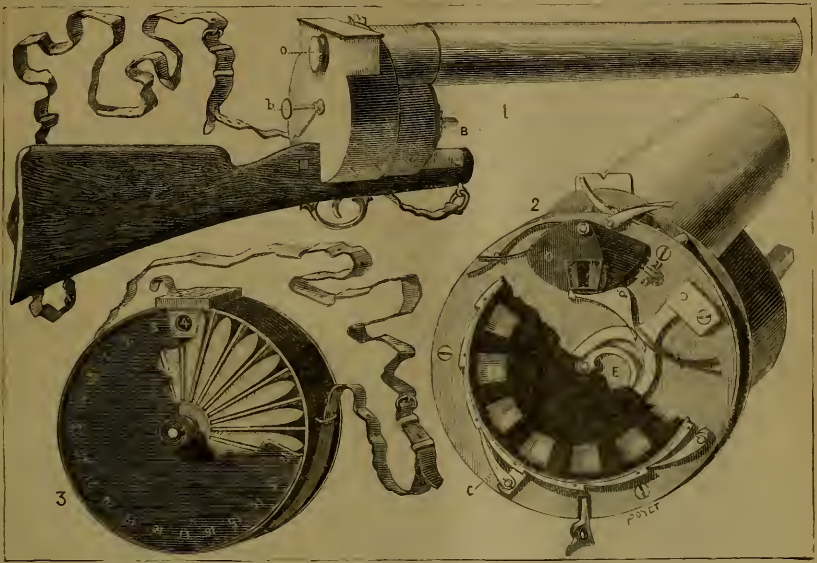

Fig. 2.—Mechanism of Gun. 1, General view; 2, Windowed disc; 3, Box with 25 sensitive plates.

The barrel of the gun is a tube containing a photographic object-glass. Behind this, and solidly mounted on the butt, is a long cylindrical breach, containing clockwork, of which the exterior of the barrel is seen at B, Fig. 2, No. 1. On pressing the trigger the clockwork is set in action, giving to the different parts of the instrument the necessary motion. A central axis, which makes twelve revolutions per second, governs all the pieces of the apparatus. Of these one is a disk of metal pierced with fine openings, which acts as a diaphragm, and only allows the image of the object to be presented twelve times in a second, and each time only for 1-720th of a second. Behind this, and revolving on the same axis, is another disk carrying twelve windows, behind which are the sensitised plates. This windowed disk revolves in such a way as to be slightly arrested in its course twelve times in a second, when the open windows are exposed to the light. The teeth to arrest its movements are seen at C, Fig. 2, No. 2, while the excentric at E, Fig. 2, No. 2, keeps up the regularity of this

Fig. 3.—Sea-gull, flying; heliograph of twelve plates obtained by the process.

Fig. 4.—Sea-gull; beginning of depression of wing.

movement. A cover over all keeps the light out from the rear of the instrument. It will be noted that during the instant of exposure, the sensitised surface is steady, and when the exposure is over, it is at once passed away. Pressure on the button (*b*, Fig. 2, 1) sets the machine in motion. Before applying this instrument to the study of the flight of birds, an experiment was made with it on a black arrow, made to rotate against a white back ground well lit up. The speed of the rotation of the arrow was about 5 metres a second. The marksman, at a distance of 10 metres sighted on the centre of the target, on which the eye could perceive nothing save a confused grey shadow, so quick was the rotation of the arrow: but on the development being completed, twelve images were to be seen, disposed in a circular manner, and each showed not only the arrow, but its shadow, as sharp as if the original had been immovable. Another experiment, equally successful, was made on a pendulum beating seconds. For to be more certain as to the duration of the exposure, M. Marey next adapted to the gun a chronographic apparatus, so that the time intervening between the taking of each picture could be with precision ascertained. After all these preliminary essays, the photography of animals in movement was attempted; and in Fig. 3 there will be seen the photographic representations of a sea-gull, in which the twelve successive attitudes assumed during the space of a single second by this bird during flight are ascertained. On other occasions other successful photographic series of a sea-gull in flight were taken when the bird was seen less in profile. The sea-gull gave exactly three strokes of its wing each second, so in the twelve photographs of each stroke four succeeding stages were reproduced. The wings at first elevated to their greatest, then commence to be lowered; then in the following image they are seen at the lowest point of their course; and in the fourth image are again on the rise. In enlarging these images, figures seen from a good distance were obtainable, but the sharpness of the enlargements left a good deal to be desired; for the negatives were somewhat granular, no doubt owing to some slight fault in the photographic process. The reproduction of these images by the heliographic process gives excellent silhouettes (as seen in Figs. 4 and 5); the originals, when examined under the microscope, showed even the wing-feathers distinctly.

FIG. 5.—Sea-gull; end of depression of wing.

On comparing the indications thus given by the photographic process with those already attained by the graphic process, a confirmation of most of the principal points obtained by the latter were obtained; but otherwise so far, the latter did not seem to add much to our knowledge of the mechanism of flying. However, ere deciding that this is so, numerous observations on different birds flying and in different conditions of flight, during calms and storms, and with and against the wind, must be taken. Attempts were also made to photograph the bat, but its small size, its flight during the dusk, and its capricious method of flying made it a difficult subject; but some of the experiments revealed interesting results. The angle of oscillation of its wings is very extended, especially from below, when the two wings form two vertical planes sensibly parallel.

These extremely interesting researches of M. Marey are only, as it were, in their infancy; he intends pursuing them much further, and his results will be looked for with great interest by all those who study the subject of animal motion.

DR. FRITZ MÜLLER ON SOME DIFFICULT CASES OF MIMICRY[1]

IN his original explanation of the cause of mimicry, Mr. Bates referred to the occurrence of many cases in which species of different genera of Heliconidæ resemble each other quite as closely as the mimicking Leptalides and Papilios resemble species of Ithomia and other Heliconoid butterflies. In these cases both the imitating and the imitated species are protected by distastefulness, and it was not therefore clear how the one could derive any benefit by resembling the other. Accordingly, Mr. Bates did not consider these to be true cases of mimicry, but to be due, either to identical parallel variations of externally similar form, or "to the similar adaptation of all to the same local, probably inorganic, conditions."

Examples of this close resemblance of species of different genera of protected groups have now become very numerous, and they often extend to three or more distinct genera, some species of which imitate each other in most parts of tropical America, each changing in a corresponding manner as we pass from one district to another.

In my Address to the Biological Section of the British Association at Glasgow, in 1876 (reprinted in "Tropical Nature"), I connected these cases with a number of others in which peculiarities of colour or of form appear together in several groups not closely allied, but always among those inhabiting the same locality and as frequently among unprotected (that is, eatable) as among protected groups of butterflies; and I concluded, generally, as Mr. Bates had done, that these curious phenomena were due to "unknown local causes."

Thus the matter rested, till, in 1879, Dr. Fritz Müller published in *Kosmos* a paper on "Ituna and Thyridia; a remarkable case of Mimicry in Butterflies"; and in 1881 a second paper, entitled "Remarkable cases of acquired resemblance among Butterflies," in which he gives a solution of the problem as really a case of mimicry. The first of these papers was translated by Mr. R. Meldola, and communicated to the Entomological Society of London in May, 1879, and the same gentleman has kindly furnished me with a translation of the second paper (the title of which is given below), which discusses the whole question in great detail, and devotes much space to a criticism of my suggested "unknown local causes" as a sufficient explanation of the phenomena. I may at once say that I admit this criticism to be sound; and that Dr. F. Müller's theory appears to me to afford a clue (with some slight modifications) to most of the cases of close individual resemblance of not-nearly-related species of butterflies yet observed. I therefore wish to state, as briefly as possible, the exact nature of the explanation now afforded us, and this is the more necessary because Dr. Müller's theory did not receive much support when brought before the Entomological Society, nor did it then satisfy Mr. Bates, the discoverer of the true meaning and importance of the phenomena of mimicry as interpreted by the doctrine of Natural Selection.

The explanation depends on the assumption, that some at least, if not all, young insectivorous birds learn by experience that the Heliconoid butterflies are distasteful, and in so doing sacrifice a certain number of individuals

---

[1] "Bemerkenswerthe Fälle erworbener Aehnlichkeit bei Schmetterlingen." Von Fritz Müller. (Separat-Abdruck aus "Kosmos," V. Jahrgang, 1881.)

of each distinct species. But if two species, both equally distasteful, closely resemble each other, then the number of individuals sacrificed is divided between them in the proportion of the square of their respective numbers; so that if one species (*a*) is twice as numerous as the other (*b*), then *b* will only lose one-fourth as many individuals as it would do if it were quite unlike *a*; and if it is only one-tenth as numerous then it will benefit in the proportion of 100 to 1. It is an undoubted fact that the species of protected butterflies, like those of other groups, differ greatly in abundance of individuals, some being very rare while others are among the commonest of all butterflies. The proportion of 100 to 1, therefore, is far below the amount of benefit an uncommon species might derive by resembling a common one. The benefit to be derived is thus clear, if the protected species are subject to the danger of attacks by young birds before they learn that such species are uneatable. I agree with Dr. Müller that they are exposed to this danger; and when we consider the great number and variety of insectivorous birds in South America the danger must be considerable, and quite sufficient to render it important for a numerically weak species to reduce it to a minimum, although to a species abounding in individuals it may be of little importance. It has been suggested that young birds have an hereditary instinct enabling them to distinguish uneatable butterflies antecedent to experience; but this seems in the highest degree improbable. It has no doubt been shown by Mr. Darwin that monkeys in captivity have a dread of snakes, and Mr. Jenner Weir believes that birds have an instinctive knowledge of uneatable caterpillars. But even admitting that in these two cases there is an instinctive hereditary aversion, it does not follow that the same will occur with regard to protected butterflies. Snakes form one well-marked group, and it is not alleged that monkeys distinguish between poisonous and harmless snakes; and caterpillars can also be readily divided into the two classes of edible and inedible by their green or brown (protective) colours on the one hand, and their gaudy or conspicuous colouration or hairy bodies on the other. But the protected butterflies have no such general mark of inedibility. Their colours and forms vary greatly, and cannot as a group be readily differentiated from those of other butterflies; and it is not to be accepted without actual proof that a young bird knows instinctively every Heliconoid or Danaoid butterfly in its district, as well as the protected Papilios and moths, almost infinitely varied as they are in colour and marking, among the equally numerous and equally varied butterflies of other groups It therefore seems clear to me that we have here a *vera causa* for the acquisition of true protective mimicry by the less abundant species of inedible butterflies.

There is however yet another cause which may have led to mimicry in these cases, and one which does not appear to have been discussed by Dr. Müller. The fact that the majority of butterflies are edible and are actually eaten by birds and other insectivorous creatures, while a considerable minority are distasteful and are thus protected, renders it pretty certain, *a priori*, that there exist many degrees of distastefulness. Certain species appear to be rejected by all insectivorous creatures, while some, though not eaten by birds, may be devoured by lizards, dragon-flies, or spiders. Some, too, may be eaten by some birds and rejected by others, and no ornithologist will think it strange or improbable that a trogon should have somewhat different tastes from a tyrant-shrike or a swallow. Again, in some species the distastefulness may extend to all the stages of egg, larva, pupa, and perfect insect, while in others it may be confined to one or more of these stages; or special dangers may exist for one species which are absent in the case of another. But it is evident, that, if these differences exist, it will be advantageous for the less protected to mimic the more completely protected species, and the fact of the affinity between the different genera, with perhaps some tendency to revert to a common style of colouration or marking, will afford facilities for the development of this class of mimicry even greater than occur in the case of the distinct and often remote families of completely unprotected butterflies. We need not, therefore, be surprised to find whole series of species of distinct genera of Heliconoid butterflies apparently mimicking each other; for such mimicry is antecedently probable on account of the greater need of protection of some of these species than others, arising either from some species being less distasteful to certain enemies, or less numerous, and therefore likely to suffer to a serious extent by the attacks of inexperienced birds. When these two conditions are combined, as they often would be, we have everything necessary for the production of mimicry.

The explanation now given, so far as it refers to the various degrees of protection, may be extended to explain those cases in which various groups of Nymphalidæ or other families appear to mimic each other; such as Catagramma, Callithea, and Agrias in one series, and Apatura with Heterochroa in another. In my "Tropical Nature" (p 257) I have remarked—"Here, again, neither genus is protected, and the similarity must be due to unknown local causes"; but this is more than we know, and I now think that some of these groups—perhaps Catagramma and Heterochroa—are partially protected, and the advantage of sharing in this partial protection has led species of altogether unprotected and much persecuted groups to gain some protection by mimicking them, whenever their general form, habits, and style of coloration offered a suitable groundwork for variation to act upon.

If these views are correct we shall have the satisfaction of knowing that all cases of mimicry are explicable by one general principle; and it seems strange to me now that I should not have seen how readily the principle is applicable to these abnormal cases. The merit of the discovery is however wholly due to Dr. Fritz Müller; and it is to be hoped that he will complete his work by obtaining, if possible, evidence of its correctness. The chief thing required is an experimental proof of various degrees of inedibility in butterflies, during the different stages of their life-history; and also some observations as to the comparative abundance of the species of protected butterflies which mimic each other. If to this can be added the proof that such groups as Catagramma, which seem to be the objects of mimicry, are partially protected by inedibility, the chief remaining difficulty in the application of the theory of natural selection to all known cases of protective imitation will have been cleared up.

ALFRED R. WALLACE

NOTES

IN reference to the Darwin Memorial, to which we referred last week, the honorary secretaries have issued a circular asking for contributions to the fund. In this memorial it is stated that though the works of Charles Darwin are his best and most enduring memorial, it is felt by his many friends and admirers that these should not be the only one. They are desirous of handing down to posterity the likeness of a man who has done so much for the advancement of natural knowledge. They wish also to establish a fund associated with his name, the proceeds of which will be devoted to the furtherance of biological science A committee has accordingly been formed, of which Mr. T. G. Bonney and Mr. P. Edward Dove are the hon. secretaries. The committee is one of the highest influence, comprising the leading foreign ministers, the two Archbishops, and the best-known names in all ranks and professions.

JOHANN CARL FRIEDRICH ZÖLLNER, whose death we recently announced, was born at Berlin on November 8, 1834.

His first publication of importance was entitled "Grundzüge einer allgemeinen Photometrie des Himmels" (1861), and in 1865 followed the work, which must be considered his principal one, "Photometrische Untersuchungen mit besonderer Rücksicht auf die physische Beschaffenheit der Himmelskörper" (Leipzig, Engelmann). The photometer constructed by Zöllner compares the light of the celestial object observed with an artificial star produced by a constant source of light (the flame of a paraffin lamp kept at a constant height), which can be varied at will by turning two of the three Nicols through which the light from the flame has to pass. A crystal plate allows of variation of colour. With this instrument Zöllner observed both the moon, the principal planets, and the fixed stars, and the last chapter of his "Untersuchungen" contains an interesting attempt to explain all the various phenomena of variable stars, sun-spots, &c., by the gradual cooling of all the celestial bodies. In several later papers in the *Proceedings* (*Berichte*) of the Saxon Society of Sciences these ideas are further developed, particularly with respect to the nature and periodicity of sun-spots. Without knowing it Zöllner here followed in the footsteps of Buffon. Zöllner next directed his attention to spectrum analysis, and on February 6, 1869, he read a paper before the Saxon Society on a method of observing the solar prominences in full sunlight; but Zöllner did not obtain a suitable instrument for carrying out his idea till some months later. His "Reversionsspektroskop" which produces two spectra side by side and in opposite directions, has been utilised by himself and others for determining the rate of rotation of the sun by the shifting of the spectral lines at the opposite limbs. Most of his spectroscopic researches relate, however, to the solar prominences. In 1871 Zöllner published a paper on the nature of comets in the Leipzig *Berichte*, and the following year he republished this paper together with two papers by Olbers and Bessel, and a number of chapters "On the Theory of Comprehension" in his well-known book, "Ueber die Natur der Cometen," which excited much comment at the time, and made him many enemies. About the same time a new chair of "Physikalische Astronomie" was founded at the Leipzig University, to which Zöllner (who had for some years been extraordinary professor) was appointed. His astrophysical activity was at that time at its height, but soon after he turned his attention to spiritualism, which seems to have absorbed all his energy of late years.

It is proposed to hold a meeting of the subscribers to the memorial to the late Prof. Rolleston on Thursday, June 1, at 3 p.m., in the Library of the Royal College of Physicians, for the purpose of determining the form that it shall take.

Mr. J. L. E. Dreyer, assistant at Dunsink Observatory, has been appointed to succeed the late Dr. T. Romney Robinson as director of the Armagh Observatory.

Prof. Haeckel has returned to Jena from his voyage to Ceylon.

There have been great rejoicings at Lucerne this week in connection with the opening of the St. Gothard Tunnel.

With reference to the communication which we published last week, from Mr. T. F. A. Brown, on the cuckoo singing at night, we have received letters from several correspondents, detailing observations similar to those of Mr. Brown. It was not a previously unknown fact that cuckoos call at night, but the fact is probably not so familiar as it might be.

M. Janssen took magnificent photographs of the recent eclipse at the Meudon Observatory, Paris, where his revolver was set into operation to determine the first and the last contact. He also took two series of photographs 90 cent. diameter, one negative, and the other positive by direct exposure, with two large refractors. This is the first time that the whole photographic power of the Meudon Observatory has been set into operation. In the sitting of May 22 of the Academy of Sciences, M. Janssen presented the photographs of the last contact obtained with his revolver during the eclipse, on Daguerreotype plates. He stated that the inspection of the several images proved the contact to have taken place at a later time than that calculated. He presented also a large image, 90 cent. in diameter, obtained with his large refractor, and stated that he was unable to detect any difference in the immediate vicinity of the moon in the representation of faculæ and the minute details of the sun's structure. He considered the fact to be opposed to the existence of a sensible lunar atmosphere, as inferred from the spectroscopic observations of the French astronomers in Egypt.

On May 17, M. de Mahy, the French Minister of Agriculture, presided at the laying of the first stone of the Observatory of Venteux, at an elevation of 1912 metres above the level of the sea. M. Naguet, deputy to the French Lower House and Professor of Chemistry, delivered an eloquent address on the opportunity of establishing mountain observatories, as inaugurated by Leverrier on the top of Puy-de-Dôme (1465 metres), and practised at the Pic du-Midi (2877).

A local observatory has been established at Besançon, in order to determine the exact time by astronomical observations. This city is considered as the headquarters of French watch and clock making.

Mr. C. L. Wragge, F.M.S., has just established a meteorological and climatological station at the Sanitary Depôt, Stafford. Mr. J. B. M'Callum, the borough surveyor, and his brother, Mr. T. M'Callum, have kindly undertaken to observe for Mr. Wragge every morning at nine o'clock (local time). The instruments are all standards, verified at Kew The elements of observation consist of air and earth temperature, moisture, rainfall, direction and force of wind, kind and amount of cloud, hydrometers, and probably ozone.

Griesbach of Gera (Reuss, Germany) announces the issue of Frisch's edition of Kepler's Works (eight vols.) at about one-half the original price.

The June number of the *American Naturalist* will contain a biographical notice of the late Mr. Darwin by Dr. Packard, and the articles will be devoted almost exclusively to the subject of Evolution.

M. W. de Fonvielle writes to us as follows:—"I am in a position to send a few interesting particulars of an aëronautical ascent which was made on May 18 by M. Eloy, in compliance with the programme alluded to in last week's Nature. The ascent was made on the 11th day of a well-defined period during which the prevailing wind was almost without intermission a strong north-easterly breeze which has been detrimental to agriculture. The sky was clear deep blue, and the air cold and dry. A large number of dense small cumuli, dark, well defined, with round edges, were seen carried by with the wind almost without intermission, except during the eclipse, when the weather was magnificent. This period having terminated only on the 20th by a total change of wind, the observations taken may be considered as giving a fair idea of the atmospheric conditions which prevailed during so many days. These clouds were floating at an altitude of more than 2000 metres, and very cold, the thermometer having descended abruptly to −4° and −6° centigrades. When crossing this cloud, the aërial travellers perceived no isolated flakes of snow, but the air seemed illuminated by sudden lights, as if rays travelling from the sun had been reflected by minute icy particles. The balloon having ascended to the upper surface of the clouds, and travelled during more than an hour out of view of the land, the aëronauts were unable to perceive the aureole round the shade of the balloon, which remained visible during the whole of the excursion on the upper face of the clouds. I explain this circumstance by the fact that the cloud was formed by solid water and that the aureole was less easily detected than when it is formed of vapour, being less brilliant, the same relation between these two phenomena existing for luminosity as between halos and rainbows. The aeronauts having remained at an altitude of two to three hundred metres from the clouds, were unable to perceive the coloured rings which were visible to me and M. Brissonet, navigating only at a few metres above similar legions of icy particles. It may have also occurred that our friends were blinded by the light from the sun, which at four o'clock was very powerful, and so detrimental to their eyes, that before entering the clouds they were unable to look fixedly at the earth to ascertain their path. It is the first time that I have heard of aeronauts having experienced the want of coloured spectacles to inspect our planet.

THE new Eddystone Lighthouse, which replaces Smeaton's famous work, built 120 years ago, was opened by the Duke of Edinburgh last Thursday.

UNDER date of Constantinople, May 17, an earthquake is reported to have occurred in the island of Karpathos.

THE first number of a small publication bearing the title of *Studies in Microscopical Science*, and edited by the well-known preparer of microscopic objects, Mr. Arthur C. Cole, F.R.M.S., "assisted by several eminent specialists," has just been published. It consists of a description and lithographed figure of a microscopical slide, which is issued, along with the description, to subscribers. The subject of this first number is yellow fibro-cartilage, and the preparation on the slide is a longitudinal vertical section of the pinna of the cow's ear. It is double stained in logwood and eosin, and is a well-mounted and highly-finished object. The plate is fairly good, though perhaps a little wanting in softness; it represents the section under a magnifying power of 333 diameters. The eight pages of descriptive letterpress contain—1. The name of the object and its etymology. 2. A very good description of the preparation under different powers, and of yellow fibro-cartilage in general, after the action of various reagents; also a few remarks upon its physiology. 3. An account of the different methods of preparation which may be employed, with their respective advantages and drawbacks; and lastly what seems a very complete bibliography of the subject. Altogether this first number has been well carried out, and promises well for the rest of the series. There is no doubt that *if the subjects are judiciously chosen*, this periodical will be a success, as it ought to be of great use to students and amateur workers in science. It is a pity that no list of the proposed subjects is given. It would be a decided advantage to know what the series for the present year will probably be, but beyond the fact that twenty-six histological will alternate with eighteen botanical, and eight petrological preparations, one issued each week, the prospectus tells us nothing.

A CURIOUS fact regarding a dragon-fly (*Æschna cyanea*, Müll.), often met with near Florence, has been observed by Signor Stefanelli. There were several nymphs of the animal in a cistern of water. Some which were near being transformed came out of the water a little way during the night, and, attacking several of the new-born perfect insects which had not yet begun to fly, voraciously devoured them. This singular practice (it is suggested) may explain why one finds such a small number of *Æschna cyanea*, in comparison with the number of nymphs. In raising the larvæ and nymphs of the dragon-flies, the best food, according to Signor Stefanelli, is meat, and especially fish.

THE Queenwood College Mutual Improvement Society seems to be an unusually active one. We have received a very favourable Report for the past term; the work done is very varied, and several of the lectures and papers have been published separately in a neat form.

FROM the Report of the Cardiff Naturalists' Society for the past year we learn that it is in a highly satisfactory condition.

A NEW work, entitled "The Hall Marking of Jewellery Practically Considered," by George E. Gee, author of "The Goldsmith's Handbook," "The Silversmith's Handbook," &c., is announced for immediate publication by Messrs. Crosby Lockwood and Co., London. The work will include an account of the Assay Towns of the United Kingdom, the Stamps at present employed, and will deal fully with the Laws relating to the Standards and the Marks at all the existing Assay Offices, &c. The same publishers also announce a new and enlarged edition of "The Manual of Colours and Dye Wares: their Properties, Applications, Valuation, Impurities, and Sophistications," revised and enlarged by the author, Mr. J. W. Slater.

A REVISED edition of the rules for the International Fisheries Exhibition to be held at South Kensington next year, has been issued. Among the prize essays are the following:—(1) 100*l*. The Natural History of Commercial Sea Fishes of Great Britain and Ireland, with special reference to such parts of their natural history as bear upon their production and commercial use. This would include natural history, habits and localities, fish frequent at different seasons, and artificial propagation. (This will not include the Salmonidæ.) (2) 100*l*. The effect of the existing National and International Laws for the Regulation and Protection of Deep Sea Fisheries, with suggestions for improvements in said laws. (3) 100*l*. On improved facilities for the capture, economic transmission and distribution of sea-fishes. Second-Class Prizes (amount not determined):—(1) On the introduction and acclimatisation of foreign fish. (2) On the propagation of freshwater fish, including Salmonidæ. (3) On oyster culture. (4) On the best means of increasing the supply of mussels and other molluscs (oysters excepted) used either for bait or food.

IN a recent paper called "Le Grain du Glacier" (*Arch. des Sciences*, April 15), Prof. Forel ably investigates the phenomena of glaciers, developing a theory similar to Hugi's and Grad's, and which he would rather designate by *increase of the crystalline grain*, than by *dilatation*. The crystalline grain is found to increase as the glacier descends: from the size of a small nut at the limit of the *névé*, it becomes as big as a hen's egg at the terminal part; Prof. Forel has seen grains at the lower end of the Aletsch and other glaciers, 7 or 8 ctm. (over 3 in.) in the longer diameter. He estimates the volume-increase at about 4½ per cent. annually. Molecular affinity is the force which augments the crystal at the expense of the water which has penetrated the mass, circulating in capillary fissures. For details of the theory, and meeting of objections, we must refer to the original. *Inter alia*, Prof. Forel finds evidence against the view (which is adverse to the dilatation theory), that the central temperature of a glacier remains at zero, invariably and constantly. He considers the mean temperature of a glacier at the end of winter to be somewhat less than seven degrees below zero C.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. F. Foreman; a Collared Peccary (*Dicotyles tajaçu*) from South America, presented by Mr. G. H. Hawtayne, C.M.Z.S., a Mediterranean Seal (*Monachus albiventer*) from the Mediterranean, presented by Mr. M. Yeats Brown; an Oak Dormouse (*Myoxus dryas*) from Russia, presented by Prof. Wrzesniowsky; two Argus Pheasants (*Argus giganteus* ♂ ♂) from Malacca, presented by Major McNair, C.M.G., and Mr. J. M. Vermont; two Common Buzzards (*Buteo vulgaris*) from Scotland, presented by Mr. J. Faed; a Great American Heron (*Ardea herodias*), captured at sea off Cuba, purchased; a Ruddy-headed Goose (*Bernicla rubidiceps*), bred in the Gardens. The following species of Butterflies and Moths have been exhibited in the Insect House during the past week:—Silkmoths: *Samia cecropia*, *Attacus cynthia*, *Attacus pernyi*, *Attacus atlas*, *Attacus roylei*, *Actias selene*, *Actias luna*, *Cricula trifenestrata*; Butterflies: *Papilio machaon*, *Anthocharis cardamines*, *Thais polyxena*, *Melitæa cinxia*; Moths: *Smerinthus ocellatus*, *Chærocampa elpenor*, *Proserpinus œnotheræ*, *Sesia scoliæformis*, *Sesia spheciformis*, *Trochilium apiforme*, *Sciapteron tabaniforme*, *Pygæra bucephala*. Twelve specimens of a leaf insect (*Phyllium scythe*) from eggs transmitted by Mrs. M. A. Meres and Mr. Wood Mason from India, have also emerged.

OUR ASTRONOMICAL COLUMN

THE TRAPEZIUM OF ORION.—Prof. Holden, in an appendix to the Washington observations for 1877, has discussed a long series of measures of the multiple-star Σ 748, made with the 26-inch refractor by Prof. Asaph Hall in 1877 and 1878. It is now known that the nebula in Orion was discovered by Cysat in 1618, thirty-eight years before Huyghens published an account of it, and his discovery is mentioned in his "Mathemcta Astronomica de Cometi Anni, 1618"; Bessel refers to it in his investigation of the elements of the great comet of this year, in the *Berliner Jahrbuch* for 1808. Cysat does not distinctly mention the number of stars, but clearly indicates their locality. Huyghens, in the "Systema Saturnium," 1659, describes his own discovery of the nebula, and refers to "three stars close together," which are shown in an accompanying figure. He saw the fourth star, completing what is now known as the trapezium of Orion on January 8, 1684, and Prof. Holden records that the last observation made by Huyghens was upon this system, on February 4, 1694, and the sketch in his manuscript journal under that date gives the four stars. In Hooke's "Micrographia," published in 1665, is a note (to which the attention of the American astronomer was drawn by Mr. H. B. Wheatley), which would imply that he was aware of the existence of the fourth star (notified by Cassini in his treatise on the comet of 1652), and of the fifth star, the discovery of which is usually attributed to W. Struve. He writes: "In that notable asterism also of the sword of Orion where the ingenious Monsieur Hugens van Zulichem has discovered only three little stars in a cluster, I have, with a 36-foot glass, without any aperture [diaphram] (the breadth of the glass being some three inches and a half), discovered five, and the twinkling of divers others up and down in divers parts of that small milky cloud." Sir John Herschel, in the *Memoirs* of the Royal Astronomical Society, vol. iii. mentions that Sir James South had pointed out to him in the original M.S. journals of the Royal Society a note which runs thus: "September 7, 1664 Mr. Hooke . . . the same relateth to have found those stars in Orion's belt, which M. de Zulichem maketh but three to be five." Prof. Holden made some special experiments in January, 1878, with the 26-inch refractor at Washington, the aperture reduced to 3½ inches, and arrived at the conclusion that if the fifth star were of the same brightness in 1664 as at this time, it would not have been discovered by Hooke; but, on the contrary, Mr. Burnham has brought together a number of cases in which the fifth star has been seen recently with such an aperture. The sixth star was detected by Sir John Herschel in 1830. Of other stars, suspected by several observers, Prof. Holden, during six years' observations of the nebula surrounding the trapezium, has not discovered any trace.

The Washington measures in 1877 were made in a dark field with the wires illuminated by a red-glass lamp; those of 1878 were made with the field illuminated, and with black wires. The mean results of the two years' observations of the four principal stars, after a complete reduction, are as follow, for the epoch 1878·0:—

	Position.	Distance.		Position.	Distance.
	° ′	″		° ′	″

ad ...	342 18·4 ...	16·773	*cd* ...	299 21·0 ...	19·364

The results obtained by South in 1820, W. Struve in 1836, Liaponoff in 1849, O. Struve in 1870, Nobile in 1876, and Jedrzjewicz for 1878, are brought together for comparison in Prof. Holden's paper.

Measures of the fifth and sixth stars in 1877-78, give the positions and distances subjoined, for 1878-0:—

	° ′	″
a and *a*′ ...	121 25·2 ...	3·984
a and *b*′ ...	320 43·3 ...	16·504
b and *b*′ .	352 8·0 ...	4·194

In conclusion, Prof. Holden remarks: "It appears that after making due allowance for the unavoidable, accidental, and systematic errors, the comparison of all our measures on the six stars of this system shows their probable physical association."

THE COMET.—During the last fortnight the increase in the brightness of the present comet appears not to have differed sensibly from that indicated by theory. On May 21 it was hardly below 5·5m.

GEOGRAPHICAL NOTES

AT the Anniversary Meeting of the Royal Geographical Society on Monday, the medals were presented, as we said some time ago they would be, to Dr. Nachtigal and Sir John Kirk. Mr. Francis Galton gave some account of the progress of geographical teaching in schools, which the Society endeavours to promote by holding examinations and the grant of medals, &c. He quoted a passage from the report of the examiner, Prof. H. N. Moseley:—"I have," Prof. Moseley says, "to congratulate the society on the good work effected by its annual award of school medals. As my experience as an examiner in geography increases, the more I am convinced of its pre-eminent fitness as a subject of education, and the more I deplore that it is almost entirely neglected as such in this country. Competent teachers of the subject appear to be scarce indeed, but it is amply apparent from the society's examinations that most valuable results can be produced by really able instructors." This was the fourteenth year in which these examinations had been held, and fifty-six medals—four annually—had been awarded, while altogether ninety-eight boys had obtained honourable mention. Of fifty-two schools invited to compete, forty-one had sent no candidates. Among these the Liverpool School had been distinguished, its scholars having gained medals fifteen times; while Dulwich had obtained eleven medals since 1875, and two in each of the last three years. In the Scotch and Irish schools the boys were younger than in the high schools of this country, and that accounted, perhaps, for the fact that of five Scotch and seven Irish schools invited to compete, only two in each country had accepted the invitation. He regretted that the great schools of Rugby, Shrewsbury, King's College School, and St. Paul's School, London, had not yet sent competitors. The president then reviewed the progress of geography during the past year. He referred to various efforts which were being made to train those who might have opportunities of pursuing geographical research. Sir Allen Young, the president stated, was busy getting ready the whaler *Hope*, which he has hired, for the search for Mr. Leigh Smith and his party.

WE referred some weeks ago to the unusually early date at which ice appeared in the Atlantic this year; the supply has gone on unceasingly since, and the New York correspondent of the *Standard* states that the reports made by ships coming westward read like accounts of Arctic explorations:—One ship passed icebergs almost daily between May 7 and 17, in latitude 43 deg., longitude 37 deg. Many were of immense size, and were visible for forty miles, others were within arm's length of the ship's side. Arctic animals were seen upon them, some living, and others skeletons. The Atlas liner *Ailsa*, from Aspinwall, reports that in the middle of the afternoon of the 7th it was dark, and lights were necessary. Ten waterspouts were observed whirling in dangerous proximity to the ship. They were rendered visible by the lightning. The captain of her Majesty's ship *Tenedos* reports that the ice is nearly solid from Cape Breton to Newfoundland, and that two ocean steamers have been caught in it. The brigantine *Rescue* was completely crushed near Belle Isle. The crew, numbering seventy two, took to the ice, although there was a heavy rolling swell surging among the floes. A perilous passage was made by the steamship *Mastiff*, of Scotland, which has arrived at Montreal She was among the ice for nine days. The crew and passengers, becoming desperate, cut a passage through the ice, which was sometimes twenty feet above the water. Another ship, the *Western Belle*, from Greenock, struck an iceberg off Newfoundland on May 1, and sank instantly with her captain (Frew) and thirteen hands.

HEFT V. of Petermann's *Mittheilungen* contains a long account, by Dr. Wocikof, of his journey in Mexico and Central

America; a paper of much interest by Dr. Konrad Jarz on the ice caves of Frain in Moravia; a short account, from the Russian of Fetisoff, of the Jashil Kul or Kulduk Lake in Central Asia (40° 45′ N., 76° 42′ E.); and some account of the Fiji Islands, to accompany an excellent new map of the group.

BARON NORDENSKJÖLD has published the first volume of the "Scientific Results of the *Vega* Expedition." It covers 800 pages with maps and tables. Besides the papers on the Aurora, of which we have already given an account, there are papers on the Health of the Expedition, the Colour Sense of the Chukchis, on the Botanical Collections, Meteorological Observations, the Invertebrata of the Arctic Seas, and other matters, by the various members of the expedition.

MESSRS. MACMILLAN AND CO. have published a sixpenny edition of Waterton's famous "Wanderings in South America," with the biographical introduction and explanatory index of the Rev. J. G. Wood, and 100 illustrations.

CAPT. BURTON and Commander Cameron have returned to England from their visit to the West Coast of Africa.

THE Geological Society of Stockholm will send a party to Spitzbergen this summer for the geological survey of that island. The two members selected for this object are the well-known geologists, Dr. Nathorst and Baron de Geer, who will leave Drontheim on June 1 in the whaling smack *Bjona* for their destination.

FOOD-PLANT IMPROVEMENT [1]

THE food question may be divided into two parts. 1. Its production (raw material). 2. Its preparation when produced. It is my intention to consider the first part only—food production. This, again, seems naturally to divide itself into: 1. Plant-food. 2. Animal food. And again, I propose to speak mainly of the first alone, alluding only incidentally to animal-food, upon which I will commence by making what remarks I have to make in order to clear the ground for the consideration of *plant*-food, the subject upon which I have been invited to address you. The improvement effected in the production of animal-food by the careful breeding or long repeated selection of sheep, cattle, and swine is so well known as to render it quite unnecessary to occupy much of our time in its consideration; I will only adduce one or two striking illustrations to show the *kind* of change which has been thereby accomplished. There is very strong ground for believing that the celebrated improved breed of shorthorn cattle is descended from a race originally black. Now black seems to have been in the eyes of all the best breeders of it a colour to be got rid of or wiped out, and this most certainly has been effected, for no single instance of it is now to be found. The improvement in the outward form of the animals has been carried almost to the breeders' ideal of perfection. These are external changes. Early in the history of shorthorns the breeders in Yorkshire made the production of milk their chief point, while those in Durham saved for breeding purposes the progeny of those cows only which showed the greatest tendency to lay on meat, and the result is the "Improved Durham," the pride and glory of the modern cattle show, but which are very poor milkers; while the "York" shorthorn is synonymous with a cow specially productive of milk. These are internal changes effected in *animals* by selection. When we turn to plants what do we find? The first thing, and which is apparent to everyone, is that each produces "fruit after its kind." But close observation shows something more than this, viz. that, although each produces "after its kind," no two plants of any kind are absolutely alike. I speak not of monstrosities, of which the characteristics are not heritable, but of that ever present tendency throughout nature to variation, of which the horticulturist has availed himself. These variations, of which we can profit through the great principle of inheritance are generally slight, so much so, indeed, as to be quite inappreciable by the untrained eye or hand, but they are, nevertheless, striking enough to one competent to observe them. I will give a familiar illustration of this. Nothing can well seem more alike to an ordinary person than the sheep composing a well-bred flock, but the shepherd knows them all apart as well as if each had a name. To him they are no more "all just alike" than are the members of his own family. That these differences, apparently so slight, can be practically availed of, the existing improved breeds of sheep prove beyond doubt. I have already said that no two plants are absolutely alike. Of any two, then, one must be (in the direction of the difference between them) superior to the other. This fact, coupled with the principle of inheritance, is the very key-note of all possible plant-improvement. But, it may be asked, do plants offer opportunity of improvement by breeding equal to that presented by animals? Surely much greater. A cow or ewe produces at a birth one (or two) only—a single grain of wheat has produced a plant, the ears upon which contained 8000 grains all capable of reproduction. Now we can plant all these, and of the resultant 8000 plants reserve only the best one of all to perpetuate the race, rejecting every other. Can anything approaching such a choice as this be afforded any breeder of cattle or sheep, no matter how extensive his herd or flock? The advantage on the side of the wheat becomes almost infinite when it is considered that in the case of the above animals three years (instead of one) are required for each reproduction.

Before giving a few examples of results already obtained in cereal development, I will mention analogous improvements obtained in vines and in beetroot cultivated for sugar. Many years ago an old friend from Piedmont, having a relative a vine grower in Italy, carried back with him from here a sufficient knowledge of my system of selection to enable him to explain its principle. Some seven years after, upon my friend again visiting me, he told me that his relative, knowing him to be in London, had written to ask him if he could arrange there for the disposal of his wine, and that he, without reading this letter through, at once replied in the affirmative. This he did, as he knew the small extent of his relative's vineyard—some 12 acres. "You may judge of my astonishment," said this gentleman to me, "when upon reading his letter to the end, I found that he had, without having increased the extent of his vineyard, three times the quantity of wine he formerly produced, and this simply through having followed the plan of selection I had suggested to him." The cultivation of beetroot for sugar is a very important one, and any increase in the percentage of sugar contained in it is of very high value. The following from Toronto, Canada, appeared in the *Gardener's Chronicle and Agricultural Gazette* of March 22, 1873, under the head of "Foreign Correspondence":—"The most vital point, however, of the beetroot grower is the quality of the seed he uses; when beets were first grown for sugar, 5 per cent. of sugar was the amount obtained, now 15 per cent. is obtainable in favourable instances. This has been attained entirely by the improvement of the pedigree principle of the seed. The quality of richness in the root was attained by Vilmorin in the following manner:—Each root is a perfect plant, and therefore, in the examination of each root for the production of seed, the quality of it had to be ascertained. For this purpose, Vilmorin had a set of most delicate instruments made for the determination of specific gravity, and he found that the specific gravity was indicative of the sugar contained. The cups he used were no larger than a lady's thimble, and the saccharometer or measure of specific gravity equally small. The roots were first selected according to the best ordinary rules, then a small portion of each root was punched out of it in such a part as to injure as little as possible its future growth; the pieces were reduced to pulp, and the juice was extracted. All the roots which did not yield juice up to a certain standard were rejected, whilst those which reached the standard were planted for seed; the roots produced from this seed *were found to be constantly increasing in richness*, and a few years of the process produced the great percentage of sugar which is now attained." I may here mention in reference to the foregoing that I had, so long ago as 1860, come to the conclusion that vigour of vegetable growth was identical with the power of supporting animal life, and that specific gravity was the measure of both. The difficulty of determining the specific gravity of a grain of wheat without impairing its vital vigour was, however, found insurmountable.

I will now refer to results obtained in cereals by selection, taking wheat as the illustration. The chief points to attain are vigour of growth, hardiness, productiveness, and quality, and these have become as permanent characteristics of the pedigree cereals as are the good points of a thoroughbred animal, and reproduce themselves as surely. I begin with a report from near Perth, Western Australia, in 1862, nineteen years ago. "The English wheat (Hallett's) sown before I came, produced when drilled 29 bushels per acre; and when dibbled, 35 bushels per acre. The average crops about here are under ten; ours were six; and our neighbours' opposite 4½ bushels per acre. The

---

[1] Paper read by Major Hallett at the Brighton Health Congress.

largest ear produced 113 grains. The greatest number of ears on one 'stool' was 72." And next I give the *last* report received *of the same wheat*, from New Zealand, published in the Otago *Daily Times* of June 3, 1881:—"We have been shown two samples of wheat grown by Mr. M. C. Orbell, at Waikouaitai, and we do not remember to have seen any to compare with them in this country. They are known as Hallett's Pedigree wheat, Hunter's White, and Original Red. The yield exceeded anything ever grown in the district before. Mr. Orbell sowed 1¼ bushels upon one acre, and the yield was 72 bushels (or nine quarters) of good marketable wheat. Many of the plants consisted of over 90 ears, some of which contained as many as 132 grains each. Hallett's Pedigree white Canadian oats, introduced by the same importers, have, we understand, been cultivated by Mr. Shannan, of Conical Hills Station, with the same success as the wheat grown by Mr. Orbell." Thus, after 18 years (not without further selection, but the selection, having been continued annually at Brighton throughout the interval), the *same wheat* is found not only to have maintained, but to have further developed its vigour of growth, producing over "90" ears (instead of 72 ears) upon a plant, with 132 grains (instead of 113) in an ear. In England, 1876, 105 ears on a plant contained more than 8000 grains. (The average number of grains in an ordinary ear is 22 only.) From Essex in the same year as the date of the report first given, a crop of the *same wheat* was reported of 27 quarters on three acres, or nine quarters per acre, exactly the same quantity as that just given as obtained eighteen years later in New Zealand! Can illustration further go that there is no deterioration if only the selection be continued? Here is another experience in another year and country:—M. Tréhonnais, editor of *La Revue Agricole de l'Angleterre*, writes October 9, 1865, from Brussiéres, France—"I am now staying here, a large farm where your wheat is extensively cultivated. The average this last harvest was at the rate of seven quarters to the English acre; the average of the other sorts in the same district did not exceed three quarters per acre."

Thus far as to vigour of growth and productiveness. I will now give examples of the other two points named, hardiness and quality. Report of the Minister of the Interior, Belgium: "I continue to sow the varieties of wheat improved by Hallett, above all the 'Red,' and 'Victoria' white. These varieties are very hardy. During the winter 1875 and 1876 many of our varieties of wheat have been destroyed by frost. The Hallett Red has successfully withstood the frost. It has been the same with the Victoria. On the other hand, the variety 'Galand' has been completely destroyed, not a single plant of it left. We have seen many fields of even our 'little red' variety, very hardy, which have greatly suffered." Lastly, as an example of sustained quality, a report from Linlithgow, Scotland, dated November 23, 1878: "I have again, making now ten years in succession, had the honour of topping the Edinburgh market with your Hunter's white wheat. I sent some of your barley to Australia, and in a few years it spread and gave immense satisfaction." The pedigree cereals having been grown in upwards of forty different countries in Europe, Asia, Africa, America, and Australasia, it is, of course, impossible to give, in such a paper as this, any idea of how widely *extended* has been the success of selection as exemplified in them, but I may mention that, in acknowledgement of that success, the Minister of Agriculture at St. Petersburg placed at my disposal the collection of all the agricultural colleges of Russia; and the Minister for Hungary sent through the Austrian Embassy at Vienna, and published, a most flattering communication showing results obtained by his Government by adopting my system. From Italy, Holland, Denmark, and Sweden, I have received similar acknowledgments. The Government of the United States published my system *in extenso* in the report for 1874 of the Department of Agriculture. The English Government, too, as will presently be seen, did me the honour to appropriate and apply my system in India.

A very practical acknowledgement has been made by less distinguished persons at home. When I commenced my system, now nearly twenty-five years ago, nothing had been done or attempted in the matter of the systematic improvement of food plants. One searches the advertising columns of the newspapers of that day without finding any of those announcements with which they now positively bristle, of seeds of all kinds, "of repeated selection," of "the latest selection," &c. But now many persons and firms, supposed to be of the highest respectability, and among them, as is always the case, some who ridiculed my work at the outset unblushingly try to identify their productions with my own, a sure and certain evidence that the reputation resulting from my system of selection has a very practical value.

In the case of the potato, next to the cereals in importance as a food plant, I have also applied my system, starting every year with a single tuber, the best of the year (proved to have been so by its having been found to produce the best plant), for now fourteen years. My main object here has been absolute freedom from disease, and these potatoes are now descended from a line of single tubers, each the best plant of the year, and absolutely healthy; and concurrently with the endeavour to wipe out all hereditary tendency to disease, I have always kept in full view the point of increasing productiveness. The result may be thus shortly stated. Dividing the first twelve years into three periods, the average number of tubers upon the annual best plant selected was, for the first period of four years, 16; for the second period of four years, 19; for the last period of four years, 27, or nearly double the number produced during the first series of four years. And if, as I might very fairly have done, I had confined the first period to the first three years (instead of four), the last period would have shown an average of 27 tubers against 13 in the first period, or more than double. Here, exactly as with the number of grains in the ear of the cereals, we reach in the last period of a long series of years a standard altogether higher than in the first years of the series, *and this no matter how we divide it into "periods."* In the latter "periods" of a series of years the results vary according to season and circumstances; but (except in a case of disaster) in no year of the last year of a series *do they drop back to the standard of the earliest years!* Can it possibly be conceived that all this is mere chance or accident? Is it not the fair conclusion, rather, that nature offers to us—nay, tempts us with—on every side rewards for intelligent observation, if we will only learn the lessons and avail ourselves of the variations which she presents to us?

I have hitherto spoken of food plants only, of vines, beetroot, cereals, and potatoes, but in a Health Congress such as this, I may be permitted also to refer to plants destined for clothing; of little, if of any, less importance than food to the health of mankind. I will take the cotton plant as an illustration. In the *Times of India*, November 6, 1869, an article headed "Cotton Report" says: "The Cotton Administration Report for the past year concluded with an interesting notice of the experiments made last season and of others which are now in progress in different parts of the Presidency, for growing cotton of an improved quality. To those who remember the conclusions recorded by Mr. Walter Cassels, in 1862, in his work prepared and printed on account of Government, it may seem strange that such experiments are now undertaken at all. These conclusions, drawn from the past history of cotton cultivation in Bombay, were (1) that 'exotic cotton cannot be successfully cultivated on a large scale in Bombay Presidency, except in a limited portion of its southern districts'; (2) that 'Indian cotton may be improved in cleanliness and somewhat reduced in cost, but the general characteristics of the staple will not be materially altered.' Because lacs of rupees had been in a long course of years expended in cotton experiments, and these had resulted in a long list of failures, it seems to have been supposed that the utmost had been tried in vain, and that the question had been finally set at rest." The article, having referred to Mr. Cassel's opinion that the failure of exotic cotton when cultivated on a large scale was due to the violence of the Indian season, continues thus:—"The climate of Hindostan is, we admit, in nearly all that relates to cotton, very different to that of any but the most arid districts in our Northern Deccan collectorates. But it is plainly a fallacy to attribute to climatic influence results for which other causes can be found independent of the climate, and, unlike the climate, quite within our control. One of these causes is indicated in a Minute by the Governor of Bombay, dated January 10, 1869, in which his Excellency, who attaches great importance to the subject as one 'of vital interest to this Presidency,' remarks that 'the experiments that have hitherto been made by the order of Government with a view to improvements in the cultivation of cotton, do not appear to have been hitherto carried out with sufficient persistence or sufficient method. So that, in fact, as remarked in the report before us in the matter of Indian cotton improvement, we are yet but on the threshhold of our experience, but let us hope that the course will now be distinctly mapped, and that we may be saved from the task of beginning our experience again and again. What is still wanted, not only in the North-West Provinces and Upper India, but in the far more favoured cotton fields of our Presidency, is an adequate testing and full authentication of some inexpensive method of treatment or cultivation, which shall be equally applicable to the exotic, hybridised, and good indigenous varieties, and which the ryots themselves will be able to appreciate alike under their present simple methods of tillage, or under any improved system they may eventually be induced to adopt. There is at last, we think, some prospect of this *desideratum* being attained. The minute of his Excellency suggests more than simply a systematic method of operation in future experiments. It describes what is known at home as *Hallett's pedigree system*, which consists in the selection by hand of the finest seed from each successive year's crop, and the annual reproduction of the plant only from such seed; and it enjoins the adoption of this plan in experiments both with exotic and indigenous cotton, as the best means of acclimatising the one and improving the other. The advantage of this system appears so very manifest that the wonder seems to be that it has never yet been tried. A cultivator selecting the finest bolls in his field of cotton, and putting them aside, extracting from them at leisure the seed for his next sowing, is a thing that has never yet been heard of; but the matter is so simple, so reasonable, that we have little doubt that the system will be generally adopted when the ryots come to be acquainted with it, and its advantages are explained to them." The same article then goes on to say: "The pedigree system was begun last year in different parts of the Presidency, but cannot be said to have yet had to any appreciable extent a trial, as it is obvious that the effect of it can only be judged by the character of the produce of successive years. In the experiments now being conducted in accordance with the plan suggested by His Excellency, there is yet another element of success in the efficient character of the agency employed. The Cotton Departments are assisted in the work by four practical horticulturists, Messrs. Shearer, Stormont, Strachan, and Milne, who have been sent out to this country for the purpose by the Secretary of State, who, we believe, selected them from a number of applicants on the recommendation of Dr. Hooker, of the Botanical Gardens at Kew." I wrote to my friend Sir Joseph Hooker, who, in reply, says the men were sent out from Kew in 1869, but that he has no statement of the results beyond a newspaper cutting, stating that their services were highly approved of, adding, "cotton is coming down from the country much better in quality and in much larger quantities." I therefore wrote to the India Office requesting to be furnished with a copy of the Minute above referred to, and with information as to the exact plan adopted and the results obtained. I can only suppose that there is some difficulty in doing this, as, although I stated that these particulars were required for the Congress this day, they have not yet reached me.

Had the Government, when thus appropriating and applying my system, done me the honour to consult me upon it, I should have pointed out that mere horticulturists, however skilful, would not (unaided) be likely to accomplish very much. It appears that in India there are thirty different kinds of cotton grown, in as many separated districts, for the Liverpool market. In each district the kind of cotton grown there is said to be that most suitable, and indeed the only kind that can be cultivated there with advantage. If this be so, then there must be thirty selectors—one in each district—in order to improve to the utmost the cotton most suitable to it. I do not profess any special knowledge of the growth of cotton, but I know something of the growth of wool, and I apprehend that fineness, and length and strength of fibre are qualities equally desirable in both. I have seen a buyer of wool, when blindfolded, tell by the touch the age and sex of the animal from which the fleece in his hand came, and I have tested beyond all possibility of doubt his ability to do this. I am told there are men in Liverpool who have an equal gift in judging cotton, but that such men soon make their fortunes there. But these are exactly the men who are wanted for cotton selectors in India. The available differences of plants are slight, and when out of a number the selection has reduced the competing plants to two or three, the difference is very slight indeed, but still very real. With many different points to take into account, I have occupied weeks in studying the final best two plants. It is evident that if there is anything at all in selection, a selector, ignorant of the one thing needful, may pedigree in the wrong direction, as the first Napoleon did unconsciously when his conscriptions left only those men who were quite impossible for soldiers to be progenitors of the future Frenchmen with the result of the standard in the army having to be lowered by five inches. I must not, I suppose, be surprised if the Government has imperfectly understood my system when such a man as Mr. Darwin, in his "Cross and Self-fertilisation of Plants," can thus write of it:—"Loiseleur-Deslongchamp (Les Céréales) was led by his observations to the extraordinary conclusion that the smaller grains of cereals produced as fine plants as the large. This conclusion is, however, contradicted by Major Hallett's great success in improving wheat by the selection of the finest grains." Here finest evidently means largest; but size of grain is not even an element in my system of selection.

If then we can seize upon these variations in plants, and by means of the principle of inheritance, perpetuate, increase, and accumulate year by year the original variation in the desired direction, what a field does it open to us for increasing this world's plant food! And how vast is this field compared with that presented by the food-producing animals, in mere number probably not equal to the food-plants upon a single English farm; for while these animals supply food for man alone, and for him only in part, plants may be said to almost wholly support both them and man. Vast, indeed, may this field be called, for it includes not only the plants destined for food and clothing, but also every kind of plant which contributes to the welfare and happiness of mankind; surely a field, then, worthy of any man's labour!

Since this paper was read a Minute by His Excellency, Sir Seymour Fitzgerald, the Governor of Bombay, dated January 10, 1868, has been sent to Major Hallett by the direction of the Secretary of State for India, together with reports extending to 1870 only.

"In England I have had opportunities of seeing on my own land, and on the properties of other gentlemen, how much can be effected in the improvement of cereals by a continued attention during successive years to the selection of the best seed only from crops of a common variety. The pedigree wheat, which bears the name of Mr. Hallett, a Sussex gentleman, is, in fact, a new variety which he has produced by the constant selection each year of the finest ears produced on his farm near Brighton, and by his never permitting any seed from small or inferior ears to be sown. None but the best ears selected by hand were set aside the first year for seed; from the produce of these the best were again in the same manner selected by hand, and this course was continued for several successive years; the final result was the introduction of Hallett's Pedigree Wheat, which I have known in my own experience to produce a crop nearly 50 per cent. more in quantity, and 50 per cent. more valuable in quality, than that produced from the best seed that could be purchased in the market, and this in the same field, under exactly the same circumstances, and with the same care taken in the cultivation.

"I believe the same result may probably be obtained if the same process is adopted with our indigenous cotton. At any rate, I desire the experiment to be carefully made, and will take care that funds are placed at the disposal of the Inspector-in-Chief for this purpose. The experiment should be tried not only in different districts but in several parts of each district, and a sufficient breadth should be sown in each case to ensure a fair and satisfactory trial.

The Inspector-in-Chief is, therefore, authorised to make the same experiments as those I have suggested as to the indigenous cotton—with all the exotic varieties he may receive—in the same manner and on the same scale. Even if they are not successful to the extent and in the manner I anticipate, they will serve to show us, if carefully continued for the next three or four years, what are the exotic varieties of cotton which we can with confidence encourage the cultivators in each district to adopt, as being best suited to the particular circumstances of their lands."

The following extract from Administration Report, Cotton Commissioners' Department, for the year 1870-71, was received by Major Hallett on January 9, 1882. Major A. T. Moore, Acting Cotton Commissioner and Inspector-in-Chief, writes under date Bombay, October 31, 1871, on the advantages of "Selection":—

"Taking everything into consideration, I think the fact of the heavier yield—by more than double—being in favour of the 'Pedigree,' goes to show that 'selection,' as desired by His Excellency Sir Seymour Fitzgerald, should be carefully carried out; that the cultivators should be supplied from the Government crops with as much seed as possible, and at the same time, that the necessity for selection should be earnestly pressed on their notice; while the Superintendents themselves, by carefully and steadily pursuing the same plan year by year, by selecting from all their crops, and again selecting from that selection, will be able apparently, if the present results may be relied on, to increase the production and fruitfulness of the plant, and in the course of a few seasons to establish a veritable 'Pedigree Cotton,' as unlike its parent as the 'English thorough-bred,' with his long stride and fine skin, is unlike the stock whence he originally sprang. It remains for me to notice the avidity with which our surplus seed was purchased by the cultivators. Mr. Wilkinson says this seed was sufficient for the requirements of two villages, and that the crop produced was an abundant one. He further adds, 'I was informed by the Patel of one of the villages that this seed had given great satisfaction; yields being reported of 96 lbs. to 150 lbs. cotton per acre, according to the amount of care in cultivation.' This gives an average of 123 lbs., but I will only take 100 lbs. as the *average* product, and even then I find the figures loudly speaking in favour of carefully picked and selected seed.

	Per acre. lbs.
Average yield of our Departmental seed ...	100
Average yield for Kandeish	$82\frac{2}{3}$
Difference in favour of our seed	$17\frac{1}{3}$
	or about 20 per cent.

If only this 20 per cent. could be established as the increased out-turn, by the efforts of our Department, it would bring wealth to thousands, and unspeakable benefit to the Presidency generally. It would represent an increased produce, valued at last year's rates, of Rs. 26,365,979 = £2,636,597 18*s*. 0*d*.; a result and a prize worth striving for, and, it would appear, possible of attainment!"

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The election to the Professorship of Animal Morphology will take place on May 31.

The Moderators and Examiners for the Mathematical Tripos have announced that logarithmic tables will be provided for each of the candidates during the examination.

The mineralogical laboratory will be open to students during July and August.

The proposed enlargement of the space available at the new museums for Practical Morphology and Histology is to be at once proceeded with.

Mr. W. H. Caldwell, B.A., Scholar of Gonville and Caius College, is approved as a Teacher of Comparative Anatomy with reference to certificates for medical study.

Dr. Anningson has been approved as a teacher of Medical Jurisprudence in the Medical School.

The proposal to continue the opening of the Botanic Garden for three hours on Sundays to Members of the Senate accompanied by their friends during the summer months, has met with warm opposition from some who consider that in this case Sunday labour is imposed on others for the selfish pleasures of a few. It has been pointed out that owing to the value of the contents of the garden it must always be watched, and it could not possibly be said that the proposed regulations will impose additional Sunday labour. The voting on this question takes place to-day (25th).

LONDON.—Prof. Ray Lankester has been re-appointed Professor of Zoology and Comparative Anatomy in University College, London.

SCIENTIFIC SERIALS

American Journal of Science, May.—Photographs of the spectrum of the nebula in Orion, by H. Draper.—Mean annual rainfall for different countries of the globe, by A. Woeikoff.—Physiological optics, by W. L. Stevens.—Flood of the Connecticut River valley, from the quaternary glacier, by J. D. Dana.—Brazilian specimens of Martite, by O. A. Derby.—Method of determining the flexure of a telescopic tube for all positions of the instrument, by J. M. Schæberle.—Dykes of micaceous diabase penetrating the bed of zinc ore at Franklin furnace, by B. K. Emerson.—Occurrence of smaltite in Colorado, by M. W. Iles.—Conditions attending the geological descent of some freshwater gill-bearing molluscs, by C. A. White.—Measures of the rings of Saturn in the years 1879, 1880, 1881, and 1882, by E. S. Holden.—Interference-phenomena in a new form of refractometer, by A. A. Michelson.—New minerals, monatite and monite, with a notice of pyroclasite, by C. U. Shepard.—Marine fauna of New England, by A. E. Verrill.

Journal of the Franklin Institute, May.—On the several efficiencies of the steam-engine, and on the condition of maximum economy, by R. H. Thurston.—Ninety miles in sixty minutes, by W. B. Le Van.—Intonation of chime bells, by J. W. Nystrom.—The Mears chlorination process, by W. U. Greene. Action of charcoal on a solution of gold chloride, by G. E. Kœnig.

Bulletin de l'Académie Royale des Sciences de Belgique, No. 3.—On the sensations the author experiences in his eyes, by M. Plateau.—On a claim of priority, introduced in the Academy by M. E. Dewalque, regarding my note on the origin of Devonian limestones of Belgium, by M. Dupont.—On the respiratory effects of excitation of the pneumogastric, by M. Henrijean.—Various products obtained from fresh stocks of peony; new reaction of salicylic acid, by M. Jorissen.—Reports.

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti, vol xv. fasc. vii.—The geology of the Parman Apennines, by A. Del Prato.—The double quadratic transformation of space, &c. (concluded), by F. F. Archieri.—On rational skew curves, by L. Weyr.—On the transformation of the co-ordinates in space, by F. Borletti.

Fasc. viii.—On a formula of Cauchy, concerning the development of functions in infinite products, by P. Cazzaniga.—Whether cemeteries may have an injurious influence on the public health, by L. Gabba.—Remarks on the subject, by C. Zucchi, and reply by L. Gabba.

Atti della R. Accademia dei Lincei, vol. vi., fasc. 10.—On some derivatives of citraconic acid, by Drs. Ciamician and Dennstedt.—Studies on fluoxysalts and fluosalts of molybdenum, by Signors Mauro and Panebianco.—Reports.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 4.—"On the Specific Resistance of Mercury." By Lord Rayleigh, F.R.S., Professor of Experimental Physics in the University of Cambridge, and Mrs. H. Sidgwick.

The observations detailed in the paper were made with the view of re-determining the relation between the B.A. unit and the mercury unit of Siemens, *i.e.* the resistance of a column of mercury at 0°, one metre in length, and one square millim. in section.

According to Siemens' experiments

1 mercury unit = 0·9536 B.A. units,

and according to Matthiessen and Hockin,

1 mercury unit = 0·9619 B.A. units.

The value resulting from our observations agrees pretty closely with that of Siemens. We find—

1 mercury unit = 0·95418 B.A. units.

Four tubes were used to contain the mercury, of lengths varying from 87 to 194 centims. The diameter of the three first tubes was about 1 millim., and that of the fourth about 2 millims. The final numbers obtained from the several fillings of the tubes are as follows:—

Tube I.	0·95386 0·95412 0·95424 0·95436 0·95421	... ... 0·95416
Tube II.	0·95389 0·95414 0·95437 0·95436	... ... 0·95419
Tube III.	0·95424 0·95418 0·95399 0·95425	... ... 0·95416
Tube IV.	0·95440 0·95415	... ... 0·95427

Combining the results of the present paper with our determination of the B.A. unit in absolute measure, we get—

1 mercury unit = $0·94130 \times 10^9$ C.G.S.

Chemical Society, May 18.—Dr. Gilbert, president, in the chair.—The following papers were read:—On the precipitation of the alums by sodic carbonate, by E. J. Mills and R. L. Barr. The authors have determined the quantity of alumina precipitated in one hour from a solution of potash alum containing 1 per cent. of sulphate of alumina by varying quantities of sodium carbonate solution. The precipitation takes place in three stages: in the first no precipitation occurs—at the end of this stage, the ratio is 1 molecule of aluminium sulphate to $\frac{3}{5}$ of a molecule of sodium carbonate; during the second stage precipitation is continuous—at the end of this stage about $\frac{1}{2}$ the alumina is precipitated, the ratio, 1 molecule of the sulphate, to $\frac{3}{2}$ molecule of the carbonate; at the end of the third stage the precipitation is complete, the ratio being 1 molecule of the sulphate to $\frac{12}{5}$ molecule of the carbonate. Similar results were obtained by precipitating potassiochrome alum.—On rotary polarisation by chemical substances under magnetic influence, by W. H. Perkin. The author has determined and compared the power which various organic liquids have of rotating the plane of polarisation, when under the influence of an electro-magnet; and he has calculated the rotary power possessed by the columns of liquids, which would be formed, by the condensation of unit-columns of their vapours, or, in other words, the rotary power possessed by lengths proportional to molecular weight. The numbers thus calculated clearly indicate that the molecular magnetic rotary power increases *pari passu*, with each increment of CH_2.—On the constitution of Amarin and Lophin, by F. R. Japp and H. H. Robinson. By the action of parahydroxy-benzaldehyde upon benzil in presence of ammonia, the authors prepared a substance having the formula of hydroxylophin, which by distillation with zinc dust furnished crystals resembling in all respects the lophin prepared by Laurent, Fownes, &c. Lophin, therefore, belongs to Hübner's anhydrobases, and is an anhydrobenzoyldiamidostilbene.

Geological Society, May 10.—J. W. Hulke, F.R.S., president, in the chair.—Arthur Leech was elected a Fellow, and Prof. L. Rütimeyer a Foreign Member of the Society.—The following communications were read:—On the relations of *Hybocrinus*, *Baerocrinus*, and *Hybocystites*, by P. Herbert Carpenter, M.A. Communicated by Prof. P. Martin Duncan, M.B., F.R.S., V.P.G.S.—On the Madreporaria of the inferior oolite of the neighbourhood of Cheltenham and Gloucester, by R. F. Tomes, F.G.S.—On the exploration of two caves in the neighbourhood of Tenby, by Ernest L. Jones. Communicated by Prof. W. Boyd Dawkins, F.R.S., F.G.S. The caves noticed in this paper were that of Coygan, near Laugharn, partially described by Dr. Hicks in the *Geological Magazine* in 1867, and a cave known as Hoyle's Mouth, reported on to the British Association in 1860 by the Rev. Gilbert N. Smith. Both caves were rock-fissures. The Coygan cave had been a hyæna den, as was shown by the deposits of crushed bones and coprolites trodden down into a solid mass by the passing of the animals. Besides remains of hyæna, it furnished those of horse, mammoth, tichorhine rhinoceros, elk, red deer, roe deer, reindeer, cave bear, cave lion, *Bos primigenius*, wolf, and fox. The presence of hippopotamus was doubtful. Besides these animals, the presence of Palæolithic man in the cave was indicated by some cut bones, and by two flint-flakes evidently chipped by man. In the second cave, Hoyle's Mouth, the hyæna, the cave bear, &c., were wanting, the place of the latter being taken by the common brown bear. In one part, remains of an old hearth were found; and the whole contents of the fissure pointed to a Neolithic date. At one time the cave appears to have been used as a place of sepulture.—Note on the comparative specific gravities of molten and solidified Vesuvian lavas, by H. J. Johnston-Lavis, F.G.S. From some experiments made on Vesuvian lava, Prof. Palmieri, in 1875, expressed the opinion that its specific gravity, when molten, might be as high as 5·0, though when cooled it is only 2·7. The author described the results of experiments made in December, 1881, on some lava flowing across the Atrio del Cavallo. Favourable circumstances enabled him to gain a position above a perfectly molten stream, the surface of which was protected from radiation by the heated walls of a tunnel which the lava had already formed by cooling of the crust. On to this were dropped, from a height of 1½ yard (*a*) light scoria; this floated on the surface until lost to view (the stream could be watched for 150 yards or so); (*b*) fairly solid lava, with some vesicular cavities: this slowly sank, until after some distance it disappeared; (*c*) the most compact lava that could be found, in which, however, were a few small cavities: this sank rapidly, the molten rock welling up round it. The author considered that these experiments demonstrate that the cooled lava is more dense than the molten, and that the apparently contradictory results obtained by Prof. Palmieri were due to the fact that the surface of the stream, by loss of heat, had become viscid, so that the solid material floated, though of greater density. The author concluded by citing other confirmatory evidence of his view.

Entomological Society, May 3.—Mr. H. T. Stainton, F.R.S., president, in the chair.—The president alluded to the interest which the late Mr. C. Darwin, who was one of the original members of the Society, had always shown in entomology.—The Secretary read a communication from the Secretary of the Essex Field Club, relative to the scientific importance of Epping Forest being preserved in its *natural condition* "*unimproved*," and requesting the members to join in a Memorial to the Conservators to this effect, lest it should be converted into a mere park.—Exhibitions: Varieties of *Fidonia atomaria* and *Anchocelis pistacina*, by Mr. W. C. Boyd; a male of *Cryptus titilator*, by Mr. T. R. Billups; a hybrid between *Antheræa Perryi* and *Roylii*, by Mr. W. F. Kirby; and a curious abnormal growth of the flowers of the ash (produced by a gall-mite), by Miss Ormerod. Mr. E. A. Fitch called attention to a woody spherical gall on ash keys, produced by a curmlionideons (?) larva.—Papers read: Further additions to Mr. Mashall's Catalogue of British *Ichneumonidæ*, by Mr. J. B. Bridgman; a continuation of his synopsis of British Hymenoptera, by Mr. E. Saunders; and on the supposed abnormal habits of certain species of *Eurytomidæ*, a group of the Hymenopterous family *Chalcididæ*, by Prof. J. O. Westwood.

Meteorological Society, May 17.—Mr. J. K. Laughton, F.R.A.S., president, in the chair.—Miss W. L. Hall, Mr. E. J. Pearson, Dr. J. R. Somerville, and Mr. W. J. V. Vandenbergh were elected Fellows of the Society.—The following papers were read:—On the diurnal variation of wind and weather in their relation to isobaric lines, by the Hon. Ralph Abercromby, F.M.S. By constructing synoptic charts at different hours of the same day, and by comparing the wind and weather records at the different hours, and examining their relation to mean curves of diurnal variation, the author shows that the mean diurnal increase of the wind's velocity is explained by the fact that for the same gradient there is more wind by day than there is by night. The mean diurnal veering of the wind is explained by the fact that in cyclones the wind is a little more incurved, and in anticyclones a little more outcurved, by night than by day. The mean diurnal increase of the frequency of rain during the day hours is explained by the fact that in any given cyclone the area of rain is larger by day than by night. The diurnal changes of every element are superimposed on the larger general changes, and are independent of each other. Great stress is laid on this point, both as explaining and classifying many meteorological questions, and as simplifying the problem of weather forecasting. The author gives a simple hypothesis, from which it appears that the diurnal veering and increase of rain follow as a natural consequence of the diurnal increase of velocity.—Mechanical conditions of storms, hurricanes, and cyclones, by W. F. Stanley, F.M.S.

Sanitary Institute of Great Britain, May 17.—Annual General Meeting.—Prof. F. S. B. F. Dechaumont, M.D., F.R.S., in the chair.—A favourable report was presented by the council on the progress made by the Institute during the past year. The chairman gave an address, and the officers for the ensuing year were elected, the President being His Grace the Duke of Northumberland, K.G., and the trustees Sir John Lubbock, Bart., D.C.L., F.R.S., Dr. B. W. Richardson, F.R.S., and Thomas Salt.

Institution of Civil Engineers, May 16.—Sir Frederick Bramwell, vice-president, in the chair.—The first paper read was "On the various systems of grinding wheat, and on the machines used in corn-mills," by Mr. W. Proctor Baker.—The second paper was on "Modern Flour-milling in England," by Mr. Henry Simon.—The third paper was on "Roller-mills and milling as practised at Budapest," by Mr. W. B. Harding.

EDINBURGH

Royal Society, May 15.—Prof. Balfour, vice-president, in the chair. Mr. Murray read an account of the explorations which had been carried out by Staff-Commander Tizard and himself in the Faroe Channel during the summer of 1880. In

H.M.S. *Knight Errant* they had taken a series of soundings and dredgings with the view of testing the truth of the theory that a barrier stretched across between the North-West of Scotland and the Faroe bank, separting the cold and warm deep-sea areas which previous exploration had shown to exist in close contiguity to each other. In this they had been quite successful, proving that there was a narrow barrier separating the northern cold area from the southern warm area. From the specimens of rock obtained from the top of this ridge, they concluded that the ridge was in all probability an ancient moraine. The objects, animal and otherwise, brought up from the bottom had been examined carefully by various scientific men, and the paper consisted in great part of their report —sixteen in all.—Mr. E. Sang, in a short notice of the solar eclipse of May 17, laid before the Society calculations which so supplemented for Edinburgh the times and phases given in the *Nautical Almanac* as to make the comparison between calculation and observation more accurate. Should the morning prove favourable for observation, he hoped to be able to lay before the Society the result of the comparison.—Prof. Tait communicated a paper by Mr. A. P. Laurie, on a new secondary cell, with which he had made a long series of experiments. The cell consisted of two copper poles dipping into chloride of zinc, and was charged in the usual manner by running a current through it. Zinc was deposited on the one pole, and cuprous chloride was formed at the other. Even with the small sized cells which were used, the results obtained were tolerably satisfactory. They suffered greatly from loss, however, being in this respect in no way superior to the other known forms of secondary cells.

PARIS

Academy of Sciences, May 15.—M. Jamin in the chair.—The following papers were read :—Observations of small planets with the great meridian instrument of Paris Observatory during the first quarter of 1882, by M. Mouchez.—New note on the project of formation, in Algeria and Tunisia, of a so-called interior sea, by M. Cosson. He brings forward a series of objections to the scheme.—Reply to M. Cosson's note, by M. de Lesseps.—M. Alph. Milne-Edwards presented, in his own name, the second volume of text, and vols ii. and iii. of plates (266 in number) of "L'Histoire Naturelle des Oiseaux de Madagascar." This raises to 400 the number of plates of birds.—Spiraloid drums for cables of equal resistance, by M. Haton de la Goupillière. This relates to extraction from mines. The first part treats of the general properties of every system, of rigorous equilibrium, whatever the form of the cable (cylindrical from end to end, formed of successive cylindrical parts, conical, logarithmic, &c.). In the second part, the general properties arrived at are employed to determine the drum of equilibrium in the case of the logarithmic cable, which represents the exact form of equal resistance. Simple formulæ are furnished for the radii of winding.—Synthesis of several organic compounds by means of electrolysis of water, of acid, alkaline, and alcoholic solutions with electrodes of carbon, by MM. Bartoli and Papasogli. They electrolysed distilled water during about six weeks, using a strong battery (1200 D) the first two days, then 100 Bunsens for ten days, then twenty Bunsens for thirty, the electrodes being carbon. Mixed with the disaggregated carbon was found a dark matter, which they call *mellogen*, because, in oxidation, it produces the acids of the benzocarbonic series. Its other properties are described. Using alkaline solutions (hydrates or carbonates) as electrolytes, the authors got a good deal of mellic acid and very little mellogen ; the reverse being the case where the electrolyte was acid.—On the spherical representation of surfaces, by M. Darboux.—On the conditions of achromatism in phenomena of interference, by M. Hurion. He gives an experimental verification of a principle enumerated by M. Cornu. In a system of interference fringes from heterogeneous light giving a continuous spectrum, there is always an achromatic fringe which plays the part of central fringe, and is found where the most intense radiations present a maximum or minimum difference of phase.—Aperiodic galvanometer of MM. Duprez and d'Arsonval. This is for very weak currents. Between the poles of a horse-shoe magnet set vertically, is a rectangular frame wound with fine wire, connected by two wires, of silver or copper, with a bent support above, and an elastic slip below. These wires, whose tension is regulated by screws, are axial to the frame, to which they also bring the current. The upper wire has a mirror at its lower end ; and within the frame is supported an iron tube to strengthen the magnetic field. The authors indicate a method of graduating galvanometers.—On the length of sparks of the discharge of an electric condenser, by M. Villari. When a condenser is discharged by making it produce one spark or two, the length of the first is not equal to the sum of the lengths of the others, and the sum of lengths of the sparks is not always constant. Small sparks have the effect of elongating another produced at the same time in the circuit ; and this influence grows with the charges of the condenser. It is connected with a sensible diminution of the interior discharge, and increase of the exterior.—Existence of lithine and boric acid in notable proportions in the waters of the Dead Sea, by M. Dieulafait. In a cubic centimetre there is enough lithine to distinctly show, at least a thousand times, the spectrum of that substance. The boric acid can be practically recognised with the product of a single cubic centimetre. These facts (contrary to previous ideas) prove the marine origin of the Dead Sea.—On the laws of solubility of carbonic acid in water at high pressures, by M. Wroblewski. The temperature remaining constant, the coefficient of saturation increases much less quickly than the pressure, while tending to a certain limit. The pressure remaining constant, the coefficient increases when the temperature diminishes.—On the mechanism of putrid fermentation of proteic matters, by MM. Gautier and Etard. The acid fermentation which arises in a few days is an epiphenomenon, not necessary, and not affecting the albuminoid molecules.—On a case of isomerism of bichlorocamphor, by M. Cazeneuve.—On purpurogalline, by MM. de Clermont and Chautard.—On the dimorphism of stannic acid, by MM. Levy and Bourgeois.—On chronic poisoning by arsenic, by MM. Caillot de Poncy and Livon. Cats receiving arsenic in small doses from time to time, eat more, and fatten, for a time, showing every sign of good health ; but by and bye they grow lean, have diarrhæa, lose appetite, and become languid ; and they die in an anæmic and lean state. The authors describe the changes (fatty degeneration) in the lungs, and mesenteric ganglions.—On a disease of early beans in the environs of Algiers, by M. Prillieux. A parasitic champignon produces white wadding-like tufts on the plant.—M. Laussedat said he had seen Mercury with the naked eye on May 11, at 8 p.m.

VIENNA

Imperial Institute of Geology, April 18.—The following papers were read :—C. Doelter, on pyroxenite, a proposal for the classification of the eruptive rocks.—V. Hilber, geological mappings of Zolkiew and Rawa-Ruska (Gallicia).—Th. Fuchs, which deposits are to be considered as of deep-sea origin?

May 2.—T. N. Woldrich, contributions to the fauna of the Istrian breccia.—R. Zuber, geological notes from the Carpathian Mountains of Eastern Gallicia.

CONTENTS

THURSDAY, JUNE 1, 1882

CHARLES DARWIN[1]

III.

THE influence which our great naturalist has exerted upon zoology is unquestionably greater than that which has been exerted by any other individual; and as it depends on his generalisations much more than upon his particular researches, we may best do justice to it by taking a broad view of the effects of Darwinism on zoology, rather than by detailing those numberless facts which have been added to the science by the ever vigilant observations of Darwin. Nevertheless, we may begin our survey by enumerating the more important results of his purely zoological work, not so much because these have been rarely equalled by the work of any other zoologist, as because we may thus give due prominence to the remarkable association of qualities which was presented by Mr. Darwin's mind. This association of qualities was such that he was able fully to appreciate and successfully to cultivate every department and ramification of biological research—whether morphological, physiological, systematic, descriptive, or statistical—and at the same time to rise above the *minutiæ* of these various branches, to take those commanding views of the whole range of nature and of natural knowledge which have produced so enormous a change upon our means of inquiry and our modes of thought. No labourer in the field of science has ever plodded more patiently through masses of small detail; no master-mind on the highest elevation of philosophy has ever grasped more world-transforming truth.

Taking the purely Zoological work in historical order, we have first to consider the observations made during the voyage of the *Beagle*. These, however, are much too numerous and minute to admit of being here detailed. Among the most curious are those relating to the scissor-beak bird, niata cattle, aëronaut spiders, upland geese, sense of sight and smell in vultures; and among the most important are those relating to the geographical distribution of species. The results obtained on the latter head are of peculiar interest, inasmuch as it was owing to them that Mr. Darwin was first led to entertain the idea of evolution. As displaying the dawn of this idea in his mind we may quote a passage or two from his "Voyage of a Naturalist," where these observations relating to distribution are given :—

> "These mountains (the Andes) have existed as a great barrier since the present races of animals have appeared, and therefore, unless we suppose the same species to have been created in two different places, we ought not to expect any closer similarity between the organic beings on the opposite sides of the Andes, than on the opposite shores of the ocean."
>
> "The natural history of these islands (of the Galapagos Archipelago) is eminently curious, and well deserves attention. Most of the organic productions are Aboriginal creations, found nowhere else; there is even a difference between the inhabitants of the different islands; yet all show a marked relationship with those of America, though separated from that continent by an open space of ocean, between 500 and 600 miles in width. The archipelago is a little world within itself, or rather a satellite attached to America, whence it has derived a few stray colonists, and has received the general character of its indigenous productions. Considering the small size of the islands, we feel astonished at the number of their aboriginal beings, and at their confined range. Seeing every height crowned with its crater, and the boundaries of most of the lava-streams still distinct, we are led to believe that within a period, geologically recent, the unbroken ocean was here spread out. Hence, both in space and time, we seem to be brought somewhat near to that fact—that mystery of mysteries—the first appearance of new beings on this earth."

Next in order of time we have to notice the Monograph of the Cirripedia. This immensely elaborate work was published by the Ray Society in two volumes, comprising together over 1000 large octavo pages, and 40 plates. These massive books (which were respectively published in 1851 and 1854) convey the results of several years of devoted inquiry, and are particularly interesting, not only on account of the intrinsic value of the work, but also because they show that Mr. Darwin's powers of research were not less remarkable in the direction of purely anatomical investigation than they were in that of physiological experiment and philosophical generalisation. No one can ever glance through this memoir without perceiving that if it had stood alone it would have placed its author in the very first rank as a morphological investigator. The prodigious number and minute accuracy of his dissections, the exhaustive detail with which he worked out every branch of his subject—sparing no pains in procuring every species that it was possible to procure, in collecting all the known facts relating to the geographical and geological distribution of the group, in tracing all the complicated history of the metamorphoses presented by the individuals of the sundry species, in disentangling the problem of the homologies of these perplexing animals, &c.—all combine to show that had Mr. Darwin chosen to devote himself to a life of purely morphological work, his name would probably have been second to none in that department of biology. We have to thank his native sagacity that such was not his choice. Valuable as without any question are the results of the great anatomical research which we are considering, we cannot peruse these thousand pages of closely written detail without feeling that for a man of Mr. Darwin's exceptional powers even such results are too dearly bought by the expenditure of time required for obtaining them. We cannot, indeed, be sorry that he engaged upon and completed this solid piece of morphological work, because it now stands as a monument to his great ability in this direction of inquiry; but at the same time we feel sincerely glad that the conspicuous success which attended the exercise of such ability in this instance did not betray him into other undertakings of the same kind. Such undertakings may suitably be left to establish the fame of great though lesser men; it would have been a calamity in the history of our race if Charles Darwin had been tempted by his own ability to become a comparative anatomist.

But as we have said—and we repeat it lest there should be any possibility of misstating what we mean—the results which attended this laborious inquiry were of the highest importance to comparative anatomy, and of the highest interest to comparative anatomists. The limits of

---

[1] Continued from p. 75.

this article do not admit of our giving a summary of these results, so we shall only allude to the one which is most important. This is the discovery of the "Complemental Males." The manner in which this discovery was made in its entirety is of interest, as showing the importance of remembering apparently insignificant observations which may happen to be incidentally made during the progress of a research. For Mr. Darwin writes:—

"When first dissecting *Scalpellum vulgare*, I was surprised at the almost constant presence of one or more very minute parasites, on the margins of both scuta, close to the umbones. I carelessly dissected one or two specimens, and concluded that they belonged to some new class or order amongst the articulata, but did not at the time even conjecture that they were cirripeds. Many months afterwards, when I had seen in Ibla that an hermaphrodite could have a complemental male, I remembered that I had been surprised at the small size of the vesiculæ seminales in the hermaphrodite *S. vulgare*, so that I resolved to look with care at these parasites; on doing so I now discovered that they were Cirripedes, for I found that they adhered by cement, and were furnished with prehensile antennæ, which latter, I observed with astonishment, agreed in every minute character, and in size, with those of *S. vulgare*. I also found that these parasites were destitute of a mouth and stomach; that consequently they were short-lived, but that they reached maturity; and that all were males. Subsequently five other species of the genus Scalpellum were found to present more or less closely analogous phenomena. These facts, together with those given under Ibla (and had it not been for this latter genus, I never probably should have struck on the right line in my investigation), appear sufficient to justify me in provisionally considering the truly wonderful parasites of the several species of Scalpellum, as Males and Complemental Males" (vol. i. pp. 292-3).

The remarkable phenomena of sexuality in these animals is summed up thus:—

"The simple fact of the diversity in the sexual relations, displayed within the limits of the genera Ibla and Scalpellum, appears to me eminently curious. We have (1) a female, with a male (or rarely two) permanently attached to her, protected by her, and nourished by any minute animals which may enter her sac; (2) a female, with successive pairs of short-lived males, destitute of mouth and stomach, inhabiting the pouches formed on the under sides of her two valves; (3) an hermaphrodite, with from one or two, up to five or six similar short-lived males without mouth or stomach, attached to one particular spot on each side of the orifice of the capitulum; and (4) hermaphrodites, with occasionally one, two, or three males, capable of seizing and devouring their prey in the ordinary Cirripedal method, attached to two parts of the capitulum, in both cases being protected by the closing of the scuta."

With reference to these Complemental Males (so called "to show that they do not pair with a female, but with a bisexual individual") Mr. Darwin further observes: "Nothing strictly analogous is known in the animal kingdom; but amongst plants, in the Linnean class, Polygamia, closely similar instances abound;" and also that "in the series of facts now given we have one curious illustration more to the many already known, how gradually nature changes from one condition to the other, in this case from bisexuality to unisexuality" (ii. 29).

Lastly, to give only one other quotation from this work, he writes:—

"As I am summing up the singularity of the phenomena here presented, I will allude to the marvellous assemblage of beings seen by me within the sac of an *Ibla quadrivalvis*, namely, an old and young male, both minute, worm-like, destitute of a capitulum, with a great mouth and rudimentary thorax and limbs, attached to each other and to the hermaphrodite, which latter is utterly different in appearance and structure; secondly, the four or five free, boat-shaped larvæ, with their curious prehensile antennæ, two great compound eyes, no mouth, and six natatory legs; and lastly, several hundreds of the larvæ, in their first stage of development, globular, with horn-shaped projections on their carapaces, minute single eyes, filiform antennæ, probosciform mouths, and only three pairs of natatory legs. What diverse beings, with scarcely anything in common, and yet all belonging to the same species!" (i. 293).

Scattered through the "Origin of Species," the "Variation of Plants and Animals under Domestication," and the "Descent of Man," we meet with many purely zoological observations of much interest and importance as such, or apart from their bearing on the general principles and arguments for the illustration or fortification of which they are introduced. In this connection we may particularly allude to the chapters on Variability, Hybridism, and Geographical Distribution—chapters which contain such a large number of new facts, as well as new groupings of old ones, that we cannot undertake to epitomise them in a *résumé* of Mr. Darwin's work so brief as the present. Nor should we forget to mention in the present connection his experimental proof of the manner in which bees make their hexagonal cells, and of the important part played in the economy of nature by earthworms. Moreover, the hypothesis of sexual selection necessitated the collection of a large body of facts relating to the ornamentation of all classes of animals, from insects and crustacea upwards; and whatever we may think about the stability of the hypothesis, there can be no question, from a zoological point of view, concerning the value of this collection as such.

But without waiting to consider further the purely zoological results presented by the work before us, we must turn to consider the effects of this work upon zoological science itself. And here we approach the true magnitude of Darwin as a zoologist. Of very few men in the history of our race can it be said that they not only enlarged science, but changed it—not only added facts to the growing structure of natural knowledge, but profoundly modified the basal conceptions upon which the whole structure rested; and of no one can this be said with more truth than it can be said of Darwin. For although it is the case that the idea of evolution had occurred to other minds—in two or three instances with all the force of full conviction—it is no less certainly the case that the idea proved barren. Why did it prove so? Because it had never before been fertilised by the idea of natural selection. To demonstrate, or to render sufficiently probable by inference the *fact* of evolution (for direct observation of the process is from the nature of the case impossible) required some reasonable suggestion as to the *cause* of evolution, such as is supplied by the theory of natural selection; and when once this suggestion was forthcoming, it mattered little whether it was considered as propounding the only, the chief, or but a subordinate cause; all that was needed to recommend the evidence of evolution to the judgment of science was the discovery of *some* cause which could be reasonably regarded as not incommensurate with *some* of the effects ascribed to it. And, unlike the desperate though most laudable gropings of Lamarck, the simple solution furnished by Darwin was precisely what was required to give a *locus standi* to the evidence of descent.

But we should form a very inadequate estimate of the services rendered to science by Mr. Darwin if we were to stop here. The few general facts out of which the theory of evolution by natural selection is formed—viz. struggle for existence, survival of the fittest, and heredity—were all previously well-known facts; and we may not unreasonably feel astonished that so apparently obvious a combination of them as that which occurred to Mr. Darwin should have occurred to no one else, with the single exception of Mr. Wallace. The fact that it did not do so is most fortunate in two respects—first, because it gave Mr. Darwin the opportunity of pondering upon the subject *ab initio*, and next because it gave the world an opportunity of witnessing the disinterested unselfishness which has been so signally and so consistently displayed by both these English naturalists. But the greatness of Mr. Darwin as the reformer of biology is not to be estimated by the fact that he conceived the idea of natural selection; his claim to everlasting memory rests upon the many years of devoted labour whereby he tested this idea in all conceivable ways—amassing facts from every department of science, balancing evidence with the soundest judgment, shirking no difficulty, and at last astonishing the world as with a revelation by publishing the completed proof of evolution. Indeed, so colossal is Mr. Darwin's greatness in this respect, that we doubt whether there ever was a man so well fitted to undertake the work which he has so successfully accomplished. For this work required not merely vast and varied knowledge of many provinces of science, and the very exceptional powers of judgment which Mr. Darwin possessed, but also the patience to labour for many years at a great generalisation, the honest candour which rendered the author his own best critic, and last, though perhaps not least, the magnanimous simplicity of character which, in rising above all petty and personal feelings, delivered a thought-reversing doctrine to mankind, with as little disturbance as possible of the deeply-rooted sentiments of the age. In the chapter of accidents, therefore, it is a singularly fortunate coincidence that Mr. Darwin was the man to whom the idea of natural selection occurred; for although in a generation or two the truth of evolution might have become more and more forced upon the belief of science, and with it the acceptance of natural selection as an operating cause, in our own generation this could only have been accomplished in the way that it was accomplished; we required one such exceptional mind as that of Darwin to focus the facts, and to show the method.

It seems almost needless to turn from this aspect of our subject to enlarge upon the influence which a general acceptance of the theory of descent has had upon biology. We do not state the case too strongly when we say that this has been the influence which has created organisation out of confusion, brought the dry bones to life, and made all the previously dissociated facts of science stand up as an exceeding great army. Let any one turn to the eloquent prophecy with which the pages of the "Origin of Species" terminate—a prophecy which sets forth in order the transforming effect that the doctrine of evolution would in the future exert upon every department of biology—and he may rejoice to think that Mr. Darwin himself lived to see every word of that prophecy fulfilled. For where is now the "systematist . . . incessantly haunted by the shadowy doubt whether this or that form be a true species"? And has it not proved true that "the other and more general departments of natural history will rise greatly in interest—that the terms used by naturalists, of affinity, relationship, community of type, paternity, morphology, adaptive characters, rudimentary and aborted organs, &c., will cease to be metaphorical, and will have a plain signification?" Do we not indeed begin to feel that "we no longer look at an organic being as a savage looks at a ship, as something wholly beyond his comprehension; and when we regard every production of nature as one which has had a long history, when we contemplate every complete structure and instinct as the summing up of many contrivances, each useful to the possessor, in the same way as any great mechanical invention is the summing up of the labour, the experience, the reason, and even the blunders of numerous workmen, when we thus view each organic being," may we not now all say with Darwin, "How far more interesting—I speak from experience—does the study of natural history become?" And may we not now all see that "a grand and almost untrodden field of inquiry on the laws of variation, on correlation, on the effects of use and disuse, on the direct action of external conditions" *has* been opened up; that our classifications, *have* become "as far as they can be made so, genealogies, and truly give what may be called a place of creation;" that rules of classifying *do* "become simpler when we have a definite object in view;" and that "aberrant species, which may fancifully be called living fossils," actually *are* of service in supplying "a picture of ancient forms of life?" And again, must we not agree that "when we can feel assured that all the individuals of the same species and all the closely-allied species of most genera, have, within a not very remote period, descended from one parent, and have migrated from some one birth-place; and when we better know the many means of migration, then, by the light which geology now throws, and will continue to throw, on former changes of climate and of the level of the land, we shall surely be able to trace in an admirable manner the former migrations of the inhabitants of the whole world?" And who is now able to question that "by comparing the differences between the inhabitants of the sea on the opposite sides of a continent, and of the various inhabitants on that continent in relation to their apparent means of migration, some light can be thrown on ancient geography?" Or, if we turn to "the noble science of geology," do we not see that we are beginning "to gauge with some security the duration of intervals by a comparison of the preceding and succeeding forms of life?" And last, though not least, have we not found this one short sentence so charged with meaning that a new and extensive science, second in importance to none, may be almost said to have grown out of what it states:—"Embryology will often reveal to us the structure, in some degree obscured, of the prototypes?'"

If the progress of science during the last two-and-twenty years has in so astonishing a measure verified the prophecy of the "Origin of Species," surely, in conclusion, we are more than ever constrained to agree with the sentiments expressed by its closing words:—"When I view all beings, not as special creations, but as the lineal descendants of some few beings which lived long before the first bed of the Cambrian system was deposited, they seem to me to become ennobled. . . . There is grandeur in this view of life, with its several powers, having been originally breathed by the Creator into a few forms or into one; and that, whilst this planet has gone cycling on according to the fixed law of gravity, from so simple a beginning endless forms most beautiful and most wonderful have been, and are being evolved."

(*To be continued.*)

ECLIPSE NOTES[1]

III.

THE eclipse of 1882 is now over, and it is not too much to say that the observations have been most successful. Much more work has apparently been done in former eclipses, but it has been of a far more general nature, and, as the old saw has it, *dolus latet in generalibus*. This year the work has put on very much more of a quantitative look, and each observation therefore more or less means a real step in advance. And indeed the time had come when this should be so, for day by day the quantity of laboratory work done which can be more or less compared with eclipse observations is increasing, and in the case of general observations either in one case or the other comparisons are impossible. I have taken many prior occasions of insisting upon this point; but perhaps the reason why this principle has been so generally acted upon on the present occasion has been a capital example set to future eclipse parties. Some days before the eclipse there was a regular Congress of the leaders of the different expeditions and the chief observers, held under the presidency of Mahmoud Pacha, the astronomer at Cairo, and not only was the general plan of observations agreed upon but the necessity of a limited field of inquiry was generally acknowledged; hence at the moment of the eclipse each worker had only a limited part of the spectrum to study, and the instrument to be employed whatever its form, and there were many forms employed, was carefully prepared for this part, and this part only, before totality.

In the way of dispersion, MM. Thollon and Trépied outdistanced all their *confrères*, as each had the most powerful form of Thollon spectroscope yet constructed. The dispersion in this instrument is about the same as that given by a Rutherfurd grating (of 17,000 lines to the inch) in the third order, with this important difference, that the quantity of light is much greater, so that a spectrum can be much better observed. With these spectroscopes, object-glasses of 9 inches aperture, and siderostats of a simple altazimuth focus were employed. All the other spectroscopic arrangements, whether for eye or photography, were mounted on equatorial stands. The instruments employed for exposing the rapid plates, which recent progress in photographic science has placed in the hands of the astronomers, were perhaps the most complicated Thus we had a camera with large lens some 5 feet focus; on this a slitless spectroscope of the Fraunhofer form, similar to that employed in Siam in 1875, but with a prism of greater angle in front of the object-glass then a tele-spectroscopic camera of small dispersion with small image of the sun in the slit, and last of all an ordinary camera of small focus.

Perhaps before I go further it will be convenient to give a collective note agreed upon in a second congress held two hours after the eclipse. This will show the *general* opinion as to the general results.

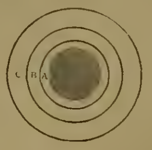
"Unprecedented facilities afforded by Egyptian Government for observation of the eclipse. The plan carried out was agreed upon by the members of the English, French, and Italian expeditions. The accord among the results is very satisfactory. Photographs of the corona and of its complete spectrum were obtained by Schuster on Abney's plates, H and K being the most intense lines. A study of the red end of the spectrum of the corona and prominences was made by Tacchini. A comet which was very near the sun, and a very striking object, was photographed and observed with the naked eye. Bright lines were observed before and after totality of different heights by Lockyer, and with intensities differing from the Fraunhofer lines by Lockyer and Trépied. An absolute determination of the place of the coronal line at 1474, of Kirchhoff's scale, was made by Thollon and Trépied. The absence of dark lines in the corona spectrum was noted by Tacchini and Thollon with very different dispersions. Many bright lines in the violet were observed in the spectrum of corona by Thollon, and were photographed by Schuster. Hydrogen and coronal lines studied in grating spectroscope by Puiseux, and in direct-vision prism by Thollon. Rings observed with grating by Lockyer, first, second and third orders. Continuous spectrum relatively fainter than in 1878, and stronger than in 1871. Intensification of absorption observed in group A at the edge of the moon by Trépied and Thollon.

"LOCKYER, TACCHINI, THOLLON."

Having given the collective note, I may be permitted to refer first to those observations which specially bear upon the matter dwelt upon in these notes—observations touching the bright lines seen before and at the moment of totality.

The importance of this part of the work arises from the following considerations:—If there be a layer of a certain height, by the absorption of which the lines of Fraunhofer are reversed, the lines visible under the stated conditions during eclipses will all be of the same height, and their intensities will all be those of the Fraunhofer lines; if, on the contrary, the reversing layer is a myth, as I believe it to be from a consideration of all the prominence and spot work done up to the present time, the lines will not be all of the same height, and the intensities will widely differ from those of the general spectrum of the sun, for the following reasons:—

As explained in my first batch of notes, it is most probable that the solar spectrum is built up of the absorption of different layers, and not of one, thus—



A, B, C, layers.

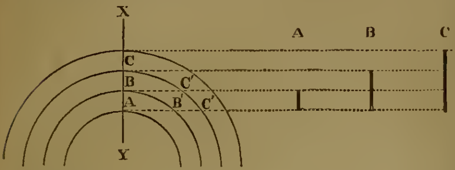
A, layer nearest the sun, and therefore hottest, and

---

[1] Continued from p. 52.

therefore probably best represented in prominence-spectrum. B and C, layers further from the sun, and therefore cooler, and therefore probably best represented in spot-spectrum.

If this be so, when we can see the lines of these layers we shall see something like this—



The lines of A—the hottest layer—will be brightest and shortest.

The lines of B—the next cooler layer—will be less bright and longer, and will also go down to the sun, on account of the part of the layer at B, although it is unrepresented at A, along the section X—Y.

And so on with C.

In an eclipse we have a condition in which the atmospheric light is gradually withdrawn. The lines should appear, therefore, in the order of their lengths; that is, the line which turns out to be longest should be the last to appear, and this is a magnificent proof that the substance which produces the line does not extend down to the sun, for if it did it should be brightest at bottom, and should at first appear as a short line.

Now what were the facts? Dealing with the region between F and *b*, and not all of that, and especially with the three iron lines I have so often mentioned, this was the order of appearance—

May 17, 8.18 a.m., saw F and T_1 very short.

(T_1 meaning the single iron line of the three *wl* 49233 so constantly seen by Tacchini in prominences).

8.19 ... F + T_1 + 4933 short.
8.20 ... F + T_1 + 4933 + *b* long.
8.23 ... F + T_1 + 4933 + *b* + T_2 short.

(T_2 meaning a high temperature iron line at *wl* 50176, constantly seen by Tacchini with 49233).

At this time the darkness sensibly decreased, and then for the first time several long thin lines suddenly burst out.

8.23.30: Single iron line at 49565, and double at 4918 and 49195 and line at 49325, the last three being the longest. Other long lines made their appearance, but their positions were not absolutely determined.

Totality was announced at 8h. 25m. 42s., and it was arranged that I should then change my instrument. I fancy the signal was given a little too soon, for when I went to my $3\frac{3}{4}$ telescope to study the structure of the corona the cross wires were still some distance from the point at which the sun disappeared; but be this as it may, I missed the flash, but this was unimportant, the real work was done. Still this is a point so crucial that we ought not to be satisfied till all these changes, even including the flash, have been photographed on a moving photographic plate, an idea which struck me too late for utilisation during the present eclipse.

Next, as to the structure of the corona. Again the predictions were fulfilled; we were in presence of a repetition of the eclipse of 1871; everything special to that of 1878 had disappeared. There was absolutely no structure near either pole. I was using the same telescope as in 1878, when this feature was so marked, so there can be no mistake on this point. The filamentous character of the streamers, a marked feature in 1871, was however not so decided.

As with the structure so with the ring spectrum. The rings so bright in 1871, so conspicuously absent in 1878, were again visible, but with a Rutherfurd grating they were not so obvious as I at all events expected to find them. As seen at mid-eclipse, 1474 was the faintest ring, and C the brightest.

With regard to the spectrum of the corona as seen with an ordinary tele-spectroscope, arranged to give as much light as possible, I have not so much to say as I had hoped, for the reason that the totality lasted longer than we counted upon. The result of all the preliminary *pourparlers* had been to fix upon sixty-five seconds as the most probable duration of totality, or rather as the duration to be provided for especially from the photographic point of view, since a photograph exposed during totality would be ruined if the sun reappeared before the cap of the camera had been replaced. Sixty-five seconds having elapsed from the announced commencement of totality, I went to the corona spectroscope which I should have gone to ten seconds earlier (but the comet had taken five seconds, and the grating observation had been more uncertain than I had expected) At the moment I made the observation the eclipse was over, but still I noted F, and 1474, and C, bright, and extending right across the field, and a *banded spectrum*, that is to say, not a continuous spectrum certainly, but into maxima and minima, though the minima gave no signs of dark lines. The observation, however, was almost instantaneous, and too much importance must not be attached to it.

Here my notes must close for the present; 104° in the shade is not conducive to writing, even if camels were not growling, and flies teasing, as they can tease in Egypt.

J. NORMAN LOCKYER

Siout, May 21

(*To be continued.*)

BIOLOGY AND AGRICULTURE

RECENT advances in our knowledge of the lowest forms of life have tended to bring into prominence not only their relation to disease but to the ever-increasing importance of the part which they play in our arts and industries. Probably in none of the industrial arts, save those concerned with fermentation, commonly so called, has the progress of this branch of biology shown such remarkable development as in its bearing on the art of agriculture.

It has even been suggested that a *bacterium* is at the bottom of the present state of agricultural depression, and there is a considerable amount of force in this suggestion. The loss of nitrogen from the soil in the form of nitrate is one of the most serious difficulties with which the farmer has to contend; and, as this loss takes place by the washing out of nitrates in the drainage and its diffusion into the subsoil below the reach of the roots of plants, it is necessarily greater in wet seasons such as have been the rule for the last few years.

We believe that Pasteur was the first to suggest, twenty years ago, that the process of nitrification going on in soils and waters might be due to the agency of an organism; but it was not until the last five years that the researches of Schlösing and Müntz and of Warington conclusively showed that this is the case and that the organism is a *bacterium*. This *bacterium* is present in all fertile service soils and under the proper conditions of temperature, moisture, supply of oxygen, and presence of salifiable base is continually converting ammonia and nitrogenous organic matter, which has passed the putrefactive stage, into nitrates. That nitrates are the chief form from which most crops and especially the cereals assimilate their nitrogen is now admitted generally, even by the few physiologists who still cling to the belief that plants can assimilate free atmospheric nitrogen; the very great use of this nitrifying organism is thus apparent. It may be remarked in passing that this Schizomycete is able to effect a change in a mineral substance, ammonia, causing its oxidation into nitric acid, all other known organised ferments being concerned in the transformation of organic bodies, and this is an operation hitherto unsuspected in the life of any Bacteria.

Nitrification takes place in soils most rapidly in the hot months of the year, and as a cereal crop assimilates little or no nitrogen after June, but merely transfers that already taken up and present in the roots, stems and leaves to other organs, it follows that, on a cornfield, in the late summer and the autumn months, nitrates will be formed and, will, in the event of wet weather, be readily washed out of the soil.

Observations made during many years at Rothamsted, and recently published by Messrs. Lawes, Gilbert, and Warington,[1] show the extent to which this loss of nitrates may occur. They find that on land uncropped and unmanured, that is, a bare fallow, during 4 years 1878-1881, nearly forty-two pounds of nitrogen per acre per annum, equal to nearly two and a half hundredweight of ordinary nitrate of soda, was lost by drainage. They also estimate that on land under continuous wheat cropping from ten to twelve pounds of nitrogen per acre per annum was lost by drainage from plots which received no nitrogenous manure. When nitrogen is applied in the manure, considerably larger quantities are lost in the drainage, and this is exclusive of that diffused into the lower layers of soil below the reach of plant roots, and of that which may under certain conditions be lost by deduction to elementary nitrogen.

In an ordinary rotation the loss of nitrogen will be considerably less than in these experiments, for crops will often be growing for months after the cereal crop is removed, and thus conserve the available nitrogen and store it up for future use. It is however obvious, that, with a bare fallow favouring the production of nitrates, followed by a wet season, a very considerable loss of available nitrogen will occur through loss of nitrates, and it becomes a matter for the farmer to consider whether it is to his advantage, for the sake of cleaning his land, to take the risk of this loss and supply the nitrogen at a cost, in ammonia, salts, or Chili saltpetre, of nearly a shilling per pound, or on the other hand, adopt some system of cultivation and cropping by which much of the loss may be obviated. On some soils the growth of an autumn green crop would save most of the nitrates and leave the land in fair condition for a succeeding crop; naturally the decision as to the advisability of such a course must rest in each case with the individual farmer.

The Agricultural mind appears to always require a panacea from the scientific man before it will accept his results as of any use. At a recent meeting of the Farmers' Club it was observed by a leading agriculturist, that, although Mr. Lawes (now Sir J. B. Lawes) had discovered the way in which nitrogen was lost, he had not told the farmer how to retain the goods effects of nitrogenous manures in adverse seasons. The discovery of the manner in which the loss occurs is, however, an immense step in the right direction, and moreover Lawes and his colleagues have clearly shown that with a growing crop on the land the loss is very greatly lessened.

This *bacterium* of nitrification is but one of a great number of the lower forms of life now engaging the attention of scientific men, which are, or ought to be, of immense interest to the scientific pursuit of agriculture. The researches of Pasteur on the life history of *Bacillus* of Anthrax, Aitken and Hamilton's investigations now being conducted into the causes producing braxy and louping ill; and the study of the organisms concerned in the changes which occur during the souring of milk and the ripening of cheese are kindred studies bearing in a direct manner on the daily practice of the farmer. Of no less interest too is the biological work done by Kühn and Liebscher, which has traced the *beet sickness* to the presence of a Nematode, while the investigations into the life history of *Hemileia vastatrix*, the too well-known coffee leaf disease, the *Plasmidiophora*, which is the proximate cause of *anbury* in turnips, and the fungus of potatoe disease, all point to the growing relation between the kindred sciences of biology and agriculture. Illustrations might be multiplied almost indefinitely but these are of sufficient importance to show that the work of the microscopist and biologist has a wide and deep influence, first of all on the practice of agriculture, and through it on the comforts and the pockets of the consumers at large.

THE TRANSIT OF VENUS, 1874

Account of Observations of the Transit of Venus, 1874, *December* 8, *made under the Authority of the British Government*. Edited by Sir George Biddell Airy, K.C.B., Astronomer-Royal.

THIS volume, recently published under the authority of the Treasury, contains the official account of observations of the last transit of Venus, by the five expeditions organised at the public expense and the reduction of the observations.

In an Introduction Sir George Airy briefly recapitulates the various steps taken by himself with the view to the efficient observation of this phenomenon, from his first communication to the Royal Astronomical Society in April, 1857, "On the means which will be available for correcting the measure of the sun's distance in the next

---

[1] *Journal of the Royal Agricultural Society* [2] xvii. and xviii.; and *Journal of Society of Arts*, April 7th, 1882.

twenty-five years." His official correspondence with the Admiralty commenced in October, 1868; the early proceedings were reported to the House of Commons in July, 1869, and after much public discussion a statement on the general plan was made to the House in March, 1873. The collection of an efficient body of observers was then proceeded with, Colonel (then Captain) Tupman, R.M.A., who was one of the first to offer his services, taking an active part, on the recommendation of Sir George Airy, in the arrangements for the expeditions made under the authority of the Admiralty, and it may be stated here that since his return all the observers were placed under his superintendence at the Royal Observatory, for completing their special share in the reductions. He examined every step in the observers' computations, especially all that related to the adjustments of the instruments. "Never perhaps," says Sir George, "was such an enormous mass of calculations so severely criticised, and where necessary, repeated." In the latter part of 1880, the calculations with portions of introduction for each station, were handed over to Sir George Airy, by Captain Tupman, who was about to leave the country, and the remainder of the work was performed under the immediate guidance of the Astronomer-Royal, who states that it had occupied all the hours, not engaged on routine business, on which he could usually have reckoned for other matters of science.

The volume is divided into five parts, referring to as many expeditions for the observation of the transit, with an appendix. Part I. treats of the expedition to the Sandwich Islands, and the observations at Honolulu, Kailua, and Waimea; II. the expedition to Egypt (Mokattam Hills, near Cairo and Suez); III. that to Rodriguez, and the observations at Point Venus, Point Coton, and Hermitage Islet; IV. that to Kerguelen Island, and observations at Observatory Bay, Supply Bay, and Thumb Peak; and Part V. details operations in New Zealand. The observations and reductions in the expedition to the Sandwich Islands are printed at much length, but particulars relating to the other expeditions were presented on the scale which Sir George Airy had proposed in an address to the Royal Astronomical Society in March, 1875. It is hardly necessary to say that the actual observations of the transit are given *in extenso*, with full descriptions of the determinations of longitude, whether by telegraph, runs with chronometers, or lunar observations with the transit or alt-azimuth, to which last method Sir George Airy had called early attention, as one which it might be essential to apply in certain cases. The reduction of the observations is carried to the formation of the equations of condition, from which the parallax, &c., have to be determined. Sir G. Airy says he has "endeavoured to give the equations in the shape that will admit of combination in the easiest way for the computer's further operations—(whether he may desire to use the Calculus of Probabilities for the whole, or to make any special selection of combinations)—when he shall have decided on the recorded phase of contact of limbs which he thinks best to adopt."

The Appendix contains some tabular details and an account of photographic observations of the transit. The photographs are preserved at the Royal Observatory, and Sir G. Airy considers it possible that some astronomer may deem them worthy of rediscussion, though he does not anticipate that any great improvement can be made in measuring them.

This important volume, which extends to over 500 pages, is printed for Her Majesty's Stationery Office.

OUR BOOK SHELF

Worked Examination Questions in Plane Geometrical Drawing. By F. E. Hulme, F.L.S., F.S.A. (London: Longmans.)

THE Art Master at Marlborough College has gathered together in this book 300 problems, chiefly from papers set at the examinations for entrance to the military colleges. He gives fully worked out solutions to two-thirds of the questions, leaving the student to exercise himself unaided with the remainder. The figures embodying the solutions seem to have been very carefully prepared, and are clearly printed, and each plate is furnished with a blank fly-leaf, making reference easy.

A fair knowledge of geometry is assumed, but to certain of the questions notes are appended on special points as they arise, such as might not have been dealt with in the text-book or course that the student has worked through. These notes are very good, and not too long; the author's experience enabling him to anticipate difficulties and to give warning against pitfalls. Especially is the attention of the student drawn to constructions which, though they do not involve much head knowledge, yet require great care to ensure accuracy, and are thus severe tests of neatness and power in the use of instruments. In view of the growing importance of graphical methods of obtaining numerical results, the acquisition of this sort of hand-skill is becoming every day more desirable.

This book will be a welcome addition to the appliances of all teachers of the subject, for it will help to fill a wide gap; still the author might have made it more generally useful by a more judicious arrangement of his materials. The current text-books resemble treatises on arithmetic with very few examples: this volume furnishes an admirable collection of miscellaneous examples, but they are neither graduated nor classified; and they are too numerous for use by ordinary students *after* going through a systematic course of instruction in the subject. Teachers will know how to use the materials here provided whilst developing the subject, but their labour would be lightened, and the book made more serviceable for private students, by a classified table of contents or index to the problems. A. R. W.

Contributions to the History of the Development of the Human Race. By Lazarus Geiger. Translated from the second German edition by Daniel Asher, Ph.D. (Trübner and Co.)

THE firm of Trübner and Co. has done well in admitting this translation as a member of its *Philosophical Series*. The work is a thoughtful contribution by an able linguist to the science of anthropology as elucidated by the study of language. It is full of interesting facts and suggestive ideas concerning each of the following subjects, which form the headings of the six chapters of which the work consists:—The importance of language in the development of the race, the earliest history of the race as elucidated by language, the colour-sense of primitive times, the origin of writing, the discovery of fire, and the primitive home of the Indo-Europeans.

The Brain and its Functions. By J. Luys. International Scientific Series, vol. xxxvii. (London: Kegan Paul and Co., 1881.)

WE consider this a disappointing book, whether we regard it from a physiological or a psychological point of view.

It adds nothing, either to our previous knowledge of facts, or to our previous conceptions with regard to them, and so is of no use to scientific readers; while the manner in which it treats its subject is so dreary that we fear it is no less ill adapted to the requirements of popular readers. We regret this failure the more because the author, as is well known, is so hard a worker, both in cerebral morphology and morbid psychology, that in writing this book he deserved a success which he has failed to achieve. Having said this much it seems needless to enter on any detailed criticism. We have forced ourselves to read the work from end to end, but cannot advise any one else to follow our example.

Ideality in the Physical Science. By Benjamin Peirce. (Boston: Little, Brown and Co., 1881.)

THIS work is a series of six lectures published posthumously by the author's son. The lectures are of a purely popular character, and their object throughout is to maintain that science is, so to speak, an intellectual handmaiden to Christianity. The arguments, or rather illustrations, are all drawn from the domain of physics and astronomy, of which the writer was himself so distinguished a cultivator, and every page glows with the fervour of a deeply religious mind. Indeed, we may question whether there is not rather too much of this, even in view of the emotional effects which it seems to be the main object of the speaker to produce. The intellectual or argumentative object throughout is to show that the "ideality in the physical sciences" points to ideation in the source of the physical universe, or, to quote the concluding paragraph: "Judge the tree by its fruit. Is this magnificent display of ideality a human delusion, or is it a divine record? The heavens and the earth have spoken to declare the glory of God. It is not a tale told by an idiot, signifying nothing. It is the power of an infinite imagination, signifying IMMORTALITY."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Mr. Charles Darwin's Letters

WILL you allow me to mention that I am collecting my father's letters with a view to a biography. I shall be much obliged to any of my father's friends and correspondents who may have letters from him, if they will kindly allow me to see and make copies of them. I need hardly add that no letter shall be published without the full consent of its owner.

Down, Beckenham, May 25 FRANCIS DARWIN

Comet (*a*) 1882

THE following observations of Comet (*a*) 1882 have been made with the Transit-Circle of the Radcliffe Observatory, Oxford, when passing *sub-polo*:—

	1882.	G.M.T. h. m. s.	Observed R.A. h. m. s.	Observed N.P.D. (uncorrected for parallax). ° ′ ″	Observer.
(*a*)	May 12,	8 57 20·13	0 14 22 90	15 32 53·4	R.
(*b*)	13,	9 18 33·31	0 39 36·12	15 54 2·9	W.
(*c*)	15,	9 57 21·31	1 26 23·60	17 8 33·8	R.
(*d*)	16,	10 14 15·71	1 47 17·34	18 0 13·7	W.
(*e*)	17,	10 29 20·28	2 6 20·93	19 0 10·5	R.
(*f*)	18,	10 42 34·30	2 23 33·69	20 7 31·7	W.
(*g*)	19,	10 54 4·86	2 39 2·69	21 21 18·8	R.
(*h*)	20,	11 3 59·82	2 52 55·84	22 40 44·3	W.
(*i*)	21,	11 12 28	3 5 (22)	24 5 (18)	R.
(*k*)	22,	11 19 38·70	3 16 30·40	25 33 (54)	R.

Observers' notes:—

(*a*), (*b*) Very faint; but observations fair.

(*c*) Very faint at times; observation fair on the whole.

(*d*) Nucleus sometimes showed as a bright point, but generally not so well defined, and would scarcely stand any illumination of field. Observation, though difficult, very fair.

(*e*) Observation good.

(*f*) Observation considered very good. Nucleus very sharp at times.

(*g*) Difficult, but observation considered fairly good. Nucleus faint at times.

(*h*) Faint. Observation good.

(*i*) Observation only approximate. Sky cloudy.

(*k*) R.A. good. N.P.D. very rough, from a single bisection when extremely faint.

General Notes:—In the telescope, the light of the head on the night of May 18, the nucleus being better defined than on any other night when the observations were made by me, was certainly not brighter than an eighth magnitude star (W.).

Brightness = Eight in star-magnitude (R.).

Observers—W. = Mr. Wickham.
R. = Mr. Robinson.

Sea-shore Alluvion—Calshot and Hurst Beaches

WESTWARD of Brighton; Shoreham Harbour, Portsmouth, Southampton, and the Solent roadstead, all derive protection from shingle moles thrown up to windward of their entrances, the most remarkable of which, Calshot and Hurst Points, have each one of Henry VIII.'s stone castles at their extremities. The first incloses a large tidal estuary (Owers Lake) at the entrance to Southampton water, and forms a pier covering the entrance to that fine natural harbour from the south-west.

The condition of this spit is not much altered since Leland's time, A.D. 1539; it terminates in a horn, which forms the lake, and the outfalls of the Beaulieu and Lymington Rivers westward have similar windward moles on a modified scale.

Hurst Point is two miles in length in a north-west and south east direction, formed of rounded siliceous pebbles on an argillaceous base, which last terminates in a nearly perpendicular submarine cliff 200 feet in height; this physical peculiarity of position has been described by Webster and other writers; it has for centuries acted as a breakwater to the Solent and the small natural harbours eastward of it on the Hampshire coast, but has also limited their capacity by promoting a rapid deposition of silt along their foreshores. In the storm of November, 1824, its position was, and remained for some time, considerably altered, as has been described by Lyell. Still, however, the maps in the Cottonian and Burleigh collections all show the peculiar horn-like termination due to the indraught into the Solent, and the general outline of the spit much as at present, which doubtless has preserved its main features for centuries, subject, however, to local disturbance and variation. Half a mile landward of the lighthouses the beach curves eastward, and forks into three or four gradations of "fulls," showing modern variations and additions to the extremity locally termed the "Point of the Deep," a quarter of a mile long, and running nearly at right angles to the main mole; two smaller spits called "Rabbit Point" and "Shooting Points" (a double formation), tail out from the main spit, within or landward of the extremity.

Parallel to the entrance to the Solent, a bank of shingle three to four miles in length, with about six feet water over it at low water of spring tides, varying in level with the weather, easterly winds banking it up, stretching from the extremity of Hurst Point, south-westward to opposite the ledge called the "Bridge," off the "Needles" rocks, leaves the small entrance channel (the "Needles" Channel) intervening.

Hurst Beach presents many characteristics peculiar to the Chesil, Calshot, and other similar formations such as a low, flat shore to leeward or eastward, and a highly-inclined beach seaward, with a tendency to curve round north-eastward, and ultimately to inclose a tidal mere or lake; the elevation and size of the pebbles increase towards the summit and termination, and in places patches of sand and shingle conglomerate of an early date crop out through the shifting modern "fulls."

The degradation of the cliffs to the westward has been very great, and they are much serrated and water-worn, with frequent slips in the upper strata of sand and gravel on a clay base, and in the neighbourhood of Hordle huge masses of fallen cliff alternate with hollow chines. At Barton also the loss is great, averaging over certain periods one yard per annum, and the whole frontage of Christchurch Bay is similarly affected.

The shingle immediately westward of Hurst becomes smaller, as is universally the case with these spits. Hurst Beach in effect, with alternating withdrawals and renewals, due to change of wind, represents by its height and the size of its pebbles the general leeward accumulating drift.

General observation leads to the conclusion that littoral shingle travels mainly along the shore, as in all cases the coarse pebbles are succeeded by fine shingle, and this ultimately, by sand, silt, or clay; but that spits of shingle grow out into deep water, creating a base for themselves the numerous nesses on our coasts amply show; but before arriving on the shore that shingle does travel at very considerable depths is shown by such cases as the above-mentioned submarine shingle bank west of the Needles passage and the "Boulders" off Selsea Bill.

Here the "Park Anchorage" eastward of the Bill is the traditional site of the bishop's see, and hydrographic authorities cited in the English Channel Pilot describe the gravel bottom as rough and thinly covering a strong clay. J. R. REDMAN

Difficult Cases of Mimicry

IN the very interesting communication by Mr. Wallace, in NATURE, *ante* p. 86, on some difficult cases of mimicry, there is one statement which apparently challenges comment.

Mr. Wallace states that although it has been so suggested, it is highly improbable that young birds have a hereditary instinct enabling them to distinguish uneatable butterflies antecedent to experience. Mr. Wallace has not alluded to the very thorough and careful experiments made by the late Mr. Dougl. A. Spalding on this point. It is unnecessary to refer to the results obtained by Mr. Spalding in proving the inherited acquisition of ideas and experience in young chickens, it will at least suffice to repeat the observations made by him, on the actions of a young turkey which he had adopted—"When chirping within the uncracked shell." Now this young turkey, not only on the tenth day of its life, exhibited the most intense terror at the sound of a hawk's voice which was confined in a cupboard but also proved its *inherited* knowledge of uneatable insects.

"When a week old my turkey came on a bee right in its path—the first, I believe, it had ever seen. It gave the danger chirp, stood for a few seconds with outstretched neck and marked expression of fear, then turned off in another direction. On this hint I made a vast number of experiments with chickens and bees. In the great majority of instances the chickens gave evidence of instinctive fear of these sting-bearing insects, but the results were not uniform, and perhaps the most accurate general statement I can give is, that they were uncertain, shy and suspicious."

If domesticated fowls and turkeys exhibit such inherited "instinct," may we not postulate a much greater excess of the same in purely insectivorous birds in a state of nature. And if this is so, it will be unnecessary to explain away, what appears to be one of the most philosophical considerations in the doctrine of "mimicry." W. L. DISTANT

Deaf-Mutes

J'APPRENDS seulement aujourd'hui par M. Graham Bell que *La Nature* à bien voulu mentionner mes communications à l'Académie des Sciences sur l'accent des sourds muets. Je regrette que les *Comptes Rendus* n'aient pas reproduit mes communications *in extenso* et que M. le Secrétaire perpétuel se soit borné à en faire une analyse incompléte. Je prends donc la liberté de vous adresser ces quelques lignes afin que vos lecteurs sachent au juste la portée de ma communication.

J'ai dit que nous sommes frappés de la ressemblance des visages et quelquefois aussi des mains parce que se sont les seules parties du corps, qui ne soient pas couvertes par les vêtements, mais qu'évidemment la ressemblance s'etend à toutes les parties du corps. J'ajoute même que la ressemblance ne s'arrête pas aux traits extérieurs, on doit la retrouver entre les organes. Pourquoi les organes de la voix feraient-ils seuls exception à la règle générale?

M. le sénateur Robin et M. Milne-Edwards, de l'Institut, à qui on ne saurait refuser la compétence en ces matières, nous disaient qu'il ne comprenaient pas qu'on pût faire des objections sérieuses au fait que j'ai signalé touchant la transmission héréditaire de l'accent; que la voix, avec ses diverses propriétés, hauteur, intensité, timbre, accent, est une manifestation des organes vocaux au même titre que toutes les manifestations dont notre corps est le siége. Rien ne se produit au dehors qui n'ait sa cause ou son siége au dedans; c'est dans la constitution intime de notre corps qu'il faut chercher la raison de tous les phénomènes externes. Ainsi s'expliquent les transmissions par voie d'hérédité, soit des aptitudes comme celles pour les mathématiques, les arts graphiques, etc.; soit des affections maladives comme la goutte, le cancer, la folie, etc.; soit des monstruosités comme les doigts surnuméraires, le bec-de lièvre, etc. Pourquoi dans les ressemblances, les organes vocaux seraient-ils exceptés?

Il faut chercher la ressemblance dans la cellule; sans doute, il n'est pas facile de la saisir, mais nous n'osons pas dire, que c'est chose impossible. Une longue expérience est nécessaire pour arriver à saiser des nuances imperceptibles au grand nombre. Ne sait-on-pas qu'un berger reconnait et distingue chaque mouton de son troupeau, tandis que pour nous tous les moutons sont les mêmes à fort peu près.

Ne serait-il pas possible, d'ailleurs, qu'il y eût moins de nuances d'accent chez les sourds-muets et les entendants-parlants americains que chez les Français du Nord et du Midi, de l'Est et de l'Ouest. La voix de nos chers Alsaciens est teintée de sons germaniques, tandis que celle de nos Provençaux a acquis une sonorité et un timbre particuliers qui lui viennent sans doute du long séjour des Romains dans le Midi. Peut-être nous est-il plus facile de constater ces nuances dans la voix chez les sourds-muets de notre pays.

Voici un nouveau fait très curieux sur lequel j'appelle votre attention.

Nanterre (Seine) FELIX HÉMENT

Caution to Solar Observers

IN the interest of solar observers I send you a caution. A first-class sample of black glass was set with a bit of white paper behind it, and exposed for an instant to the focus of a 7-inch lens. The paper was charred where an eye would be placed. A longer exposure of a few seconds made the glass burst asunder.

J. F. CAMPBELL

Niddry Lodge, Kensington, London, W.

Aurora Borealis

WHAT was, probably, the termination of the aurora seen at Worcester and Dublin on May 14 was observed here, by me, between midnight and 1 a.m. of the morning of the 18th. At that time, and for some time after, I saw along the north-west horizon a strong, green, auroral glow. The evening of the 14th was bitterly cold; the sunset clouds threatened snow, wind, light north-north-east light, cloudy. At dawn, the sky was cloudless and wonderfully clear. The 15th was warm and pleasant.

Glasgow, May 24 S. MAITLAND BAIRD GLENNILL

ON THE MUTUAL RELATIONS OF CARBON AND IRON IN STEEL[1]

IN this paper the author sets himself to prove the following four propositions concerning steel: (1) the carbon of steel is (primarily) in a state of simple absorption in the iron; (2) the hardening of steel is due to a metamorphic change in the condition of the carbon, which then assumes a crystalline form closely analogous to the diameter; (3) the varying temper of steel results from the dissociation of this crystalline carbon, at varying but low temperatures; (4) the real strength of steel does not vary to any material degree with a varying content of carbon—that is, *ceteris paribus*, steel is not increased in tensile strength by an increased percentage of carbon.

With regard to No. 1, the author rejects the idea that carbon in steel can be in chemical combination. The only possible hypothesis would be that it is found as a carbide of iron dissolved in excess of iron; and this no modern author holds. It may be alleged in its support that hydrocarbon gas is evolved on dissolving steel in hydrochloric acid; but the great variation in the results and the fact that more or less carbon is at the same time deposited, forbid us to suppose that we have here a definite chemical decomposition. The Eggerty colour test, again, which was supposed to be founded on the same theory, has been in great measure abandoned on account of its inaccuracy. The

---

[1] Abstract of paper by Mr. George Woodcock, read before the Iron and Steel Institute.

phenomena of the conversion of iron into steel in the cementation process all point to the conclusion that the carbon is simply absorbed, as the varying rate of impregnation with variations of temperature, the gradual change from the outside to the inside, and the large deposition of free carbon from such steel, if dissolved in hydrochloric acid, or chloride of copper, or cold dilute nitric acid.

As to No. 2, the author adopts the theory of Jullien, that the hardening of steel is due to the crystallisation of the so-called combined carbon (really absorbed) in a form resembling the diamond. He observes that cemented steel only becomes hard when heated and quenched, and that the fracture then shows innumerable small crystals, which, under the microscope, present physical features very much like small diamonds. These crystals do not appear in wrought iron, increase in number as the proportion of carbon increases, and as the hardening increases, and are more numerous at the outside of the piece, where the hardness is also less. They are therefore crystallised carbon, in other words, diamond. Estimations of carbon in the different layers of a piece of hardened steel have always shown that the actual proportions, as formed by combustion, are the same throughout, but that, as examined by the colour test, they increase gradually from the outside to the inside. This shows that some change has taken place in the carbon. The author's theory is that at a red heat the molecules of iron are expanded and partially separated; that in this state the absorbed carbon is partially dissociated from the iron, and upon the steel being suddenly quenched, the carbon is not re-absorbed, but takes up a small amount of hydrogen, and is fixed in the state of diamond. It is known that hydrogen is present in the diamond, and also in steel, and it is submitted that it forms the active agent in reducing the carbon from the amorphous to the crystalline form. On analysing this hardened steel, it is supposed that the crystalline carbon goes off in all cases as gas; so that less "combined carbon will remain to be shown by the colour tests or deposited on solution in hydrochloric acid. It must follow from this view that carbon is the acting hardener of steel, and that the idea of other elements, as phosphorus hardening steel is a delusion. In support of this it is observed that phosphorus does not harden wrought iron and that probably the real effect of phosphorus and silicen is to cause dissociation of carbon, thus producing a larger extent of crystallisation and a harder metal. Thus it is found that the higher the proportion of phosphorus, the greater will be the difference between the carbon, as shown by the colour test, and as fixed by analysis. Again, English Bessemer or Siemens steel will require 20 per cent. less carbon to make it work and harden equally well with best Swedish steel; the explanation being that the phosphorus in the former assists the dissociation and crystallisation. To this effect of phosphorus many of the mysterious failures of steel may probably be traced.

With regard to No. 3, the author regards the variations of tempering as due solely to the completeness, or otherwise, of the decomposition of the crystalline carbon in the hardened steel. He observes that carbon and iron have no action on each other at the heat at which tempering is effected; while, even at such temperatures, the abstraction of hydrogen from carbon, in the presence of iron, cannot be deemed impossible. The tempering of steel by simply quenching it in hot water or oil, may thus be explained; the outer layers may be supposed to be hardened at first in the ordinary way, but then, as the interior heat does not pass away so rapidly, it has time to act on the crystalline carbon, and partly to dissociate it again, thus producing something between hardened and unhardened steel—in other words, tempered steel. The crystallised carbon in the hardened steel is supposed to be diffused in a state of molecular disaggregation, and to be less intimately united with the iron than before hardening.

As to No. 4, the startling statement that the ultimate strength of steel is very little dependent on its amount of carbon, is explained to refer to the strength as calculated upon the fractured area, not the original area. It is, therefore, equivalent to saying that the contraction of the fractured area in iron or steel is proportional to the diameter of ultimate strength. The author finds that this is the case, both in the various published tables of tensile strength of steel, and in his own experiments. Hence he holds that the contraction of area should be taken as the proper measure of ductility (as is usual on the Continent), and not the elongation. He looks upon hard steel as a metal of a certain strength, having diffused through its mass a greater or less number of particles of a very hard and rigid substance. Hence, as ductility means the power of contracting in area, and extending in length by molecular flow, the ductility will be less as flow is more difficult; and flow will be more difficult as there are more of the rigid crystals in the mass. The apparent strength per unit of original area is thus increased; but the strength per unit of fractured area is usually diminished, probably because the hard sharp crystals tend to cut the metal between them, and produce a sort of tearing action. For these reasons the use of ductile and mild steel, in structures of every kind, is much to be preferred to that of a brittle material, though of a higher apparent tenacity.

A CHAPTER IN THE HISTORY OF CONIFERÆ

THE ABIETINEÆ

THE most recent classification of the *Abietineæ*, and the one that will probably be chiefly adhered to, at least in England, is published in the "Genera Plantarum" of Bentham and Hooker, 1880. In it *Pinus*, *Cedrus*, *Picea*, *Tsuga*, *Pseudotsuga*, *Abies*, and *Larix*, are recognised as separate genera. The tribe comprises the cedars, larches, firs, pines, and contains some 150 species, and is almost exclusively confined to northern and north temperate regions. The genera are all cone-bearing, and with few exceptions produce winged samaroid seeds. No definite remains are known of earlier age than Jurassic, but with the Wealden and Cretaceous they become plentiful, and already in the Neocomian and Gault the ancestors of several existing genera were completely differentiated.

Pinus, Linn.—The cones in this genus vary from the size of a walnut to a length of 19 inches, or possibly even more. The scales are woody and persistent, and closed until the seeds are ripened, when they gape widely. The seeds are in pairs under each scale, and, with few exceptions, winged. The leaves are acicular, and in some cases very long, and are sheathed in bundles of two, three, or five. Nearly all classifications are mainly founded on the number of leaves that occur in a fasciculus, but this character is rejected in the "Genera Plantarum" as inconstant. Two natural divisions are, however admitted—*Pinaster* and *Strobus*.

The former and larger division is distinguished by the scales being very closely adpressed before shedding the seeds, and by their quadrate, umbonate, or elongate, conical heads. The *Strobus* section is comparatively small, and has elongated, often pointed cones, with hard and rigid, yet scarcely woody, loosely imbricated scales, thicker centrally than at the margins, and terminating in a minute or obsolete umbo. Cones of *P. strobus* and *P. excelsa*, representing this section, may be picked up in most botanical gardens, while the *Pinaster* section comprises all the pines commonly grown in plantations.

Besides the "Genera Plantarum," many excellent accounts of the tribe have recently been published. Among these are Gordon's "Pinetum" (1880), Veitch's "Manual of the Coniferæ" (1881), Dr. Maxwell Masters' "Coniferæ of Japan" (*Linn. Trans.* 1881), and an exquisitely illustrated essay on the "Coniferous Forests of the Sierra Nevada," in *Scribner's Magazine*, also in 1881.

Of the *Pinaster* division seventy-seven fossil species were enumerated by Schimper; none, however, are definitely assigned to the group from deposits older than the Eocene of Aix, and most are from the upper Miocene, and even later deposits. The oldest forms are from Solenhofen, and the Gault of Hainault is said to contain connecting-links between the two sections.

Of the *Strobus* division twenty species are enumerated, the oldest being from the Komeschichten of Greenland; but there are a number of additional species which cannot well be grouped in either section.

In England no cones are known that can be referred to Pinus, as now restricted, from rocks older than the Purbeck, but their number gradually increases until the close of the Tertiaries.

Seven species of pine are known from our British Eocenes. They are enumerated here for the first time :—

P. Prestwichii, sp. nov. mihi	Woolwich and Reading Beds.
P. macrocephalus, (Lind. and Hutton)	
P. ovata, (id.)	
P. Dixoni, Bowerbank	Bracklesham to Bembridge.
P. Bowerbankii, Can.	London Clay to Bracklesham.
P. Plutoni, Baily	Eocene of Antrim.
P. Graingeri, id.	

I am not sure that the two latter may not be identical with species already described abroad, but they seem distinct from the other British species.

It will be remarked that all the English species are from marine or estuarine deposits, and it is a singular fact that no trace whatever of leaves or fruit of the Abietineæ have been found in those plant beds of freshwater origin in England, which have recently yielded such exceedingly rich floras. It is equally strange that all our Eocene cones from the London clay and strata beneath have been imbedded before shedding their seed, while those from the Middle and Upper Eocenes are gaping and seedless. If inference upon such slender ground were permissible, it would seem as if those that were imbedded during the cooler Lower Eocene period had grown near to where they were imbedded, and their leaves may yet be found in our little-known Lower Eocene floras, while those that were imbedded during the hottest Eocene periods had drifted a long way. The well-ascertained absence of pine foliage during the Middle Eocene in England, and the constantly-decayed condition of the cones, are the data upon which this view may be grounded. Farther north, at Antrim, as we should anticipate, the cones seem more perfect.

It appears desirable to test the relative length of time that ripe and unripe pine cones, seeds and foliage will float, especially in sea-water, and the length of time required to reduce them to the decayed condition of the Barton and Bracklesham specimens, and it is to be hoped that some one possessing facilities, will undertake experiments.

It will also be interesting to trace out why cones so frequently fall in a closed unripe condition. A Bournemouth resident writes to me that it takes three years for the cone to come to perfection, and that if it remains on the tree all that time, the scales open wide as it hangs, beginning at the base, and making a plainly audible crackling noise as they separate. This occurs chiefly on sunny summer days. The seeds being liberated, either fall or are picked out by tom-tits.

CEDRUS.—Only four species, or varieties according to some, are known—the Himalayan, Lebanon, Atlas, and Cyprus cedars. The cones are globose and erect on the upper side of the branches. The scales are thin, leathery, and closely pressed together, and persist for some time after the seeds are shed. The cones break up on the trees, and fall piecemeal, the scales falling separately, except near the apex, where they remain together as a rosette. This habit may account for the absence of fossil cedars in the Tertiaries, the older forms from the Greensand of Shanklin and Maidstone having possibly possessed a different habit.

PICEA has twelve to twenty-four species. The leaves are solitary, acicular, and more or less in two rows, while the cones somewhat resemble those of the cedar. They inhabit temperate regions throughout the northern hemisphere, almost to the confines of vegetation. Two Gault forms from Hainault are doubtfully referred to the genus, while fossil species are met with in Iceland and Greenland, the Wetterau, the amber-beds, and a few other Miocene localities.

TSUGA possesses five species. The leaves are not very different to those of Picea, and the cones are like those of Cedrus, but pendent and terminal, persisting for several years, and with scales more loosely imbricated and persistent. They inhabit Japan, the Himalayas, and North America, and have been found fossil in the same beds as Picea. *Pinus Crameri*, Heer, related to Tsuga, is the most widely-spread fossil in the Arctic Cretaceous.

PSEUDOTSUGA has only one species, inhabiting from Mexico to Oregon.

ABIES contains eighteen species. The scales are leathery, loosely imbricated, and fall with the seeds and the leaves, as in Tsuga. It extends over the northern temperate regions of both hemispheres, chiefly in mountainous districts. It is known from the Wealden, and even Jurassic, and from Greenland, Iceland, and in European Miocenes.

LARIX possesses seven to ten species. The cones are small, with leathery persistent scales, and fall in clusters with the dead branches. The leaves are linear, solitary, or in bundles, and deciduous in all but one species. The larch extends over the colder regions of Europe, Asia, and America. But four fossil forms have been noticed—three from the Miocene of Francfort, and one from Austria.

The Abietineæ in the existing state in northern regions of Europe, Asia, and America, outnumber the broad-leaved trees by ten to one, for pine-barrens in North America stretch 300 to 500 miles uninterruptedly, and, in the Old World, form a nearly continuous belt from Scandinavia to the east coast of Asia.

Some grow to gigantic size. Sections from two American species of Abies, two of Picea, and one of Pinus, have been exhibited, and officially stated to have been cut from trees considerably over 300 feet in height. In the Himalayas, the cedar and *Pinus excelsa* exceed 200 feet, and other species almost rival these, and even in Europe the heights of several species have been stated at from 120 to 180 feet. The greatest longevity ascribed to any of the Abietineæ belongs to the cedars, which have been estimated at from 600 to 900 years old.

Many of the species are exceptionally hardy, and pass the Arctic circle, and the larch in Siberia extends, as a trailing shrub, to latitude 52°. In Mexico, pines grow at an elevation of nearly 13,000 feet, and in Central Asia, of 10,000 feet.

The economic value of the Abietineæ surpasses that of all other forest-trees, and they supply a very large proportion of the timber in use. Their wood is valuable for all purposes, and some of it is of immense durability, while the money value of that imported into England alone is 9,000,000*l*. per annum, exclusive of other products, such as pitch and tar, which reach nearly another million. The nuts of some species of pine are used as food, and the bark, woody fibre, and secretions are more or less utilised in different countries, and for most varied purposes. Only one species of the whole family is indigenous to England, *Pinus Sylvestris*, the common Scotch pine. the larch and the spruce having been introduced, though both were, I believe, indigenous here in the Pliocene age.

J. STARKIE GARDNER

THE BRUSSELS CHRONOGRAPH

ON November 18, 1880, a description was given in NATURE of certain great galvanic chronographs which were then being constructed by Messrs. E. Dent and Co., of the Strand and Royal Exchange, London. The second of these instruments—that for the Royal Observatory of Brussels—has now been completed. The arrangements for pricking upon the chronograph barrel are much improved, and as they overcome a serious constructive difficulty, we propose to give some account of them.

It will be remembered that the main feature in the chronographs referred to was a cylinder (or barrel) 12 in. in diameter, and 2 ft. 6 in. long. That cylinder, which was covered with paper, rotated once in two minutes Beneath it (see Fig. 1) was a pricker placed in electrical connection with the standard clock, and alongside another pricker placed in electrical communication with an observer at any of the instruments. At every second of the standard clock, the clock pricker rose and punctured the paper. Meanwhile, as the cylinder rotated, the carriage, K, on which the prickers were mounted slowly, travelled along the length of the cylinder; and this motion of K, combined with the rotation of the cylinder, caused the succession of clock pricks to arrange themselves around the cylinder in the form of a spiral. The time of any observation was reckoned by comparing the puncture of the observation pricker with the two adjacent clock pricks. The distance between each successive turn of the spiral of clock pricks was $\frac{3}{20}$ inches, and it was within this space (which was limited by the consideration of the size of the cylinder, and the number of hours of observation it should contain) that the two prickers worked.

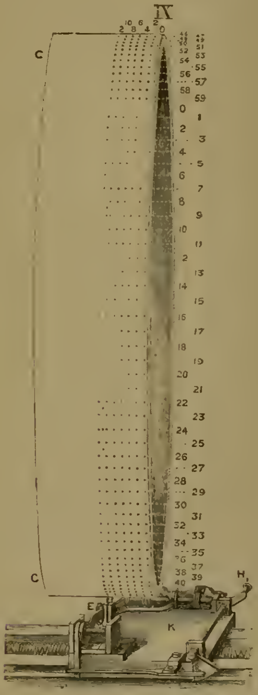

FIG. 1.

In the Brussels chronograph, by the directions of M. Houzeau, the Belgian Astronomer-Royal, provision had to be made for *three* observation prickers, in addition to the clock-pricker. The space available for the prickers to work in was only ⅛ in, and it was obviously impossible to place them side by side. The difficulty was surmounted by arranging them in the form of a fan, so that they should converge into the space, which then became amply sufficient for the disposition of the punctures.

N_1, N_2, N_3, N_4 (see Fig. 2), are the prickers. As may be seen, they take the form of pins with very large heads. Each is mounted in a sheath, S S. Each sheath is jointed (see side section), and swings about an axis A A. It is kept to its bearing by a spring. This arrangement allows the pricker to swing forward a little as it enters the moving paper. It corresponds to the action of the old form of pricker shown in Fig. 3. The pricker, however, that we are describing has an important advantage.

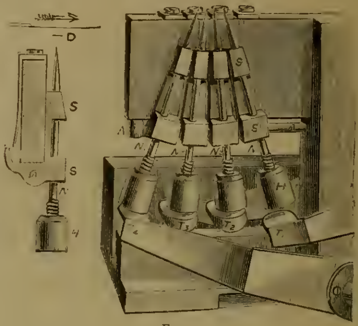

FIG. 2.

It might happen that an observer on pressing down the electric button which worked the pricker, would keep his finger on it. In that case, with the old form, the pricker would be kept against the paper, and would very likely cause damage. But in the new case nothing of the kind would happen, for each pricker, N_1, N_2, N_3, N_4, is *projected* by the blow of its corresponding striker, T_1, T_2, T_3, T_4, and travelling beyond the reach of the striker, pierces the paper by its own momentum only. On falling back, should the striker, T, be still kept raised, the pricker will rest upon it, but its point will be free of the cylinder, and at some distance, D, below it. The strikers, T_1, &c., are worked by electro-magnets: the spiral spring shown just above the head of each pricker, is compressed when the pricker is projected between the head and sheath, and assists in the disengagement of the pricker from the paper. The punctures of the prickers are very marked and distinct.

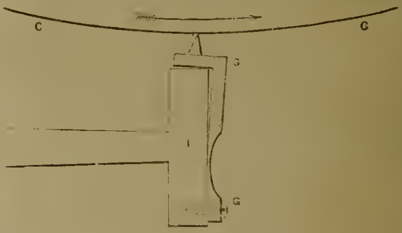

FIG. 3.

A NON-ELECTRIC INCANDESCENT LAMP

A BRIGHT light, easily obtained and sufficient for projections, has frequently been regarded as a *desideratum*, where it has been impracticable to procure either the electric or the lime-light. The French Minister of Public Instruction lately appointed a special commission to indicate the apparatus most suitable for projection in primary schools; and it appeared that while there was no lack of simple arrangements for the projection proper, the problem of easy production of an adequate luminous source was hardly solved.

Dr. Regnard has lately conceived the idea of getting a bright light by burning on platinum gauze a mixture of air and petroleum vapour. The intense heat which results raises the platinum to bright incandescence, giving a light equal to about half the lime-light.

The apparatus (described in *La Nature*, to which we are indebted for the accompanying figure) is very simple. There is an ordinary Bunsen burner, terminated by a small cage of platinum wire. The mixture of air and petroleum vapour is admitted below, in place of the gas; it is produced by a familiar method, and the current is generated by means of a pair of bellows or a Richardson "pear." With a ventilator or "trompe," several of the lamps may be maintained in action at once, for lighting halls, workshops, &c., where there is no gas. The aspect is that of electric incandescent lamps. In this case, it is well to augment the volume of the carbonator, so that the supply of petroleum vapour is abundant. To send all the light in one direction, the Bunsen burner may be fitted with a bent trumpet-shaped nozzle closed with platinum gauze. One has merely to regulate, with the ring of the burner, the admission of the mixture of air and vapour, to have, whenever the current is produced, an extremely bright light.

Regnard's Incandescent Lamp.

With a large loaded bag of air under the table the lamp may be kept in action for several hours, without requiring attention.

The apparatus should be useful to medical men in examination of the larynx, ear, &c.

The expenditure is very small, only a few centimes an hour, with maximum action.

OBSERVATIONS OF THE SOLAR ECLIPSE OF 1882, *MAY* 16, *MADE AT THE RADCLIFFE OBSERVATORY, OXFORD*

THE weather was very favourable, the sky being quite clear.

Remarks.—(*a*) The first contact was detected as the merest trace of an indentation on the sun's limb, and the time recorded is considered precise. (*b*) Limbs very steady; the time noted may be a very little late. (*c*) The recorded time of last contact considered accurate, as the moon's limb was followed steadily till the last. The tremor of the sun's limb did not very materially affect the definition. (*d*) Just before contact limbs slightly tremulous; observation considered fairly good. (*e*) Observation good. (*f*) If anything a fraction of a second too soon.

(*g*) This mountain was the highest peak of a ridge of mountains which were conspicuous on the moon's limb.

E. J. STONE

CHEMICAL LECTURE EXPERIMENTS

SEVERAL interesting and instructive experiments have been described of late in the chemical journals: we propose to give a short account of the more important.

I.—PHYSICO-CHEMICAL EXPERIMENTS

A. *Mixing of Gases by Diffusion.*—That gases do not mix very rapidly by diffusion alone, may be illustrated by placing a strip of white paper moistened with lead acetate solution inside a tall glass stoppered cylinder, so that when the cylinder is inverted the paper extends from the bottom (which now forms the uppermost end) not more than one-third of the total length of the cylinder. A little sulphuretted hydrogen water is placed in the hollow stopper of the cylinder, and the stopper is inserted loosely into its place. After ten to fifteen minutes the production of brown lead sulphide on the white paper shows that the sulphuretted hydrogen gas has risen two-thirds of the height of the cylinder. Paper moistened with starch and potassium iodide, and chlorine water, may respectively replace the lead acetate paper and the sulphuretted hydrogen water (C. von Than, *Berichte*, xii. 1414).

B. *Liquefaction of Gases by Increasing Pressure or Lowering Temperature.*—Ethylic chloride, which boils at 12°, is easily liquefied. A Hofmann's lecture eudiometer, with one limb about 100 cm. and the other 50 cm. in length, serves as apparatus. The eudiometer is filled with mercury; ethylic chloride gas is led into the shorter limb through the upper stopcock, while the mercury flows out by the other stopcock; when the smaller limb is partly filled with gas, the mercury is adjusted to the same level in both limbs, the gas is liquefied by pouring ether over the shorter limb, and any air which has entered with the gas is allowed to escape by opening the upper stopcock for a moment. The liquid ethylic chloride is gasified by running out as much as possible of the mercury in the larger limb, and so reducing the pressure. If the temperature is lowered—by pouring ether on to the outside of the shorter limb—or if the pressure is increased—by pouring mercury into the longer limb, equal to an extra half atmosphere of pressure—the ethylic chloride becomes liquid (Hofmann, *Berichte*, xii. 1124).

C. *Absorption of Heat Accompanying Change from Liquid to Gaseous Form.*—A test tube, partly filled with water, is placed in a small glass cylinder containing ether sufficient to completely cover that part of the tube in which there is water. A brisk stream of dry air is driven through the ether, which rapidly evaporates; in a few minutes the water in the tube is completely frozen (Hofmann, *Berichte*, xii. 1125).

D. *Thermal Changes Attending Solution of Salts in Water.*—A small flask of about 100 cc. capacity is fitted with a cork carrying a glass tube, 3-4 mm. diameter, bent twice at right angles; the larger limb of the tube is about 70 cm. in length, and passes through a cork nearly to the bottom of a wide-mouthed bottle, of about 40 cc. capacity, containing coloured water. A straight piece of similar tubing of about the same length passes through a second hole in the cork, and also reaches nearly to the bottom of the wide-mouthed bottle. The salt under examination is placed in the flask, water is added, and the cork is inserted. If heat is evolved during solution, the coloured water rises in the straight glass tube, which is open at the upper end; if heat is absorbed during solution, the water rises in the tube connected with the small flask (Rosenfeld, *Berichte*, xiii. 1475).

II.—EXPERIMENTS ILLUSTRATIVE OF CHEMICAL ACTION IN GENERAL

A. *Conservation of Mass.*—Two small glass tubes, about 15 cm. long by 2 cm. wide, are sealed and rounded off at one end and drawn out at the other to tubes about 3 mm. diameter. About two centigrams of freshly heated charcoal is dropped into one tube, the air is replaced by dry oxygen, which is led in by a capillary tube passing through the narrow opening, and the tube is sealed. The other tube is also sealed at a point such that the weights of the two tubes are equal. The tubes are placed on the opposite pans of a balance, and the balance is shown to be in equilibrium: that tube which contains charcoal is heated by a small gas-flame, the charcoal burns brilliantly, and by carefully shaking the tube is all, or almost all, consumed. When the tube is cold it is replaced on the balance pan, on releasing the beam it is found that no change has occurred in the mass of matter in the tube, although the form of the matter has undergone most marked change. Sulphur, or a very small quantity of gun-cotton, may be employed in place of charcoal in this experiment (C. von Than, *Berichte*, xii. 1413).

B. *The Individual Substances taking part in a Chemical Change Gain or Lose Weight.*—To demonstrate that a substance increases in weight during oxidation, &c., or loses weight during reduction, &c., a piece of copper-wire, about 10 cm. long by 1 mm. thick, is fused into the upper end of a glass hydrometer: the wire carries a little glass cup (the bottom part of a test tube serves admirably) on its upper end, on which lies a piece of platinum foil. The hydrometer is placed in water contained in a cylinder. Such a quantity of finely divided iron as suffices to sink the hydrometer, so that the wire is just wetted, is placed on the platinum foil; the foil is removed, heated till the iron is oxidised, allowed to cool, and replaced on its support: the hydrometer sinks considerably in the water. To illustrate loss of weight on reduction, a little cylinder of copper oxide, made by mixing the substance with gum and drying, may be employed. Before the reduction is commenced, nearly the whole of the wire supporting the platinum foil ought to be immersed in the water (Rosenfeld, *Berichte*, xiv. 2102).

C. *Influence of Mass, Time, etc., on a Chemical Change.*—The influence of *time*, *temperature*, and *mass*, as also the meaning of the phrase *reverse action*, may be qualitatively illustrated as follows:—Three beakers are arranged on white surfaces and with white backgrounds; in beaker (1) is placed about 100 cc. of cold water, in (2) the same quantity of water at 90°–100°, and in (3) about 500 cc. of cold water. A few drops of a solution of bismuth iodide in concentrated hydriodic acid is poured into each beaker; brown bismuth iodide is precipitated in the first beaker, red bismuth oxyiodide in the second, and the same salt, but in smaller quantity, in the third. On standing for a little time, the brown iodide is slowly changed into red oxyiodide; but on adding a little concentrated hydriodic acid, the reverse change—viz. from oxyiodide to iodide—takes place (Muir, *Chem. Soc. Journ. Trans.*, 1882, 6).

The influence of mass and time on a chemical change may be quantitatively exhibited by arranging a series of similar glass cylinders filled with water, and inverted in glass basins: a stoppered retort of about 100 cc. capacity is supported close to each cylinder. The retorts are carefully cleaned, and 50 cc. of pure sulphuric acid, regularly diminishing in concentration by a fixed amount, is placed in each. Sheet zinc is cut into squares of equal sizes, which are rolled into slit cylinders (by bending round a glass rod), cleansed in soda solution, then washed, immersed in strong sulphuric acid, again rapidly washed in a stream of water, and dropped into the retorts, which are then stoppered. The hydrogen which is evolved is collected as long as the areas of the zinc remain visibly constant. The upper surfaces of the water in the cylinders exhibit, in the form of a curve, the influence of the mass of sulphuric acid on the change under consideration. As the evolution of hydrogen may be stopped at any moment by withdrawing the stopper of a retort, the experiment may be arranged to show the influence of time on the change (Mills, *Chem. Soc. Journ. Trans.*, 1880, 454).

III.—EXPERIMENTS ILLUSTRATIVE OF COMBUSTION PHENOMENA

A. *Burning Oxygen in Sulphur Vapour.*—A two-necked balloon is fitted with corks, each carrying a tube, one of which passes towards the bottom of the balloon, and has its tip slightly bent upwards, the other, beginning flush with the inner surface of the cork, passes downwards into a cylinder containing water. The first of these tubes communicates, by means of a long piece of caoutchouc tubing, with a supply of dry oxygen. About 40 to 50 grams of dry sulphur are placed in the balloon, and heated till the vessel is quite filled with reddish vapours, the oxygen delivery tube being meanwhile withdrawn. Oxygen is allowed to flow from the delivery tube in a stream sufficiently rapid to cause a glowing chip of wood held 2 to 3 millims. from the end of the tube to burst into flame; a small piece of charcoal is attached by platinum wire to the tip of the oxygen delivery tube; the charcoal is ignited, and the cork carrying the tube which delivers oxygen is inserted into the neck of the balloon. The oxygen is soon seen burning in the vapour of sulphur which fills the vessel; the product of combustion, viz. sulphur dioxide, is led by the second tube into the water in the cylinder, the presence of sulphurous acid in which is easily exhibited (C. von Tham, *loc. cit.*).

B. *Burning Sulphuretted Hydrogen in Vapour of Nitric Acid.*—60 to 80 c.c. of concentrated nitric acid (sp. gr. 1·53) are placed in a flask of 500 c.c. capacity. A rapid stream of sulphuretted hydrogen is passed, through water, into the acid, whereupon red fumes are copiously produced. The delivery tube is slowly raised from the surface of the acid towards the neck of the flask; at a certain distance from the acid the sulphuretted hydrogen takes fire and burns with a blue flame; the upper part of the flask becomes filled with white fumes of sulpuric acid, the lower part with red fumes of oxides of nitrogen, little or no sulphur separating (Kessel, *Berichte*, xii. 2305).

C. *Burning Ammonia in Oxygen.*—A wide-mouthed flask is fitted with a cork, which carries a tube passing nearly to the bottom of the flask, and also a large straight drying tube, which contains solid caustic soda and is closed at its upper end by a cork carrying a little piece of tubing drawn out to an opening about 2 mm. in diameter. A quantity of strong ammonia liquor is placed in the flask and heated nearly to boiling, the lamp is withdrawn, and the cork with its tube inserted. A stream of oxygen is passed into the hot liquor, and the dry ammonia, mixed with oxygen, is ignited as it issues from the caustic soda tube. As the amount of ammonia diminishes, the flame becomes smaller, but very hot; a piece of platinum wire may be melted, or a lime cylinder may be caused to give out much light, by holding it just above the central zone of the flame (Rosenfeld, *Berichte*, xiv. 2104, and xv. 169.)

D. *To show that Water is produced by Burning Hydrogen in Oxygen.*—A small platinum flask (as is figured in Roscoe and Schorlemmer's "Chemistry," I., p. 339) is furnished with a good cork carrying two tubes of ordinary pipe-clay, which reach towards the bottom of the flask: one of these tubes communicates by caoutchouc tubing with a supply of dry hydrogen, the other with a supply of dry oxygen. The exit-tube of the flask is attached to a piece of glass tubing which connects with a glass worm condenser, underneath which a beaker is placed. Dry hydrogen is passed into the flask until the air is completely replaced from the entire apparatus: while this is being done, the caoutchouc tubing which connects the clay tube with the oxygen supply is securely clamped just above its junction with the clay pipe, to prevent hydrogen from diffusing backwards into the oxygen tubes, and so forming an explosive mixture. When the air is all driven out of the apparatus, the platinum flask is heated to redness, dry oxygen is passed into it, and the lamp is withdrawn. By properly regulating the streams of oxygen and hydrogen, so much heat is produced that the flask becomes nearly white hot; water is quickly formed and trickles, and after a little, flows in a continuous stream through the glass worm into [the beaker beneath (Hofmann, *Berichte*, xii. 1122).

E. *Unburning of Water-gas by Iron and by Magnesium.*—3-4 grams very finely divided iron (*Ferrum alcoholisatum*) are placed in a small piece of hard glass tubing about 12 cm. long and 14 mm. diameter. One end of this tube is connected with a flask containing hot water, the other with an ordinary gas exit-tube and small pneumatic trough. The iron is heated, the water brought to, and just maintained at the boiling-point, and the end of the delivery-tube is plunged under the water in the trough. Hydrogen is obtained in a rapid stream. As thus arranged the decomposition of water-gas by iron is readily shown without the use of a furnace or porcelain tube.

A similar apparatus serves to show the decomposition of water-gas by magnesium; a piece of magnesium-ribbon about 60 cm. long is folded on itself so as to form a bundle about 1 cm. in length, which is placed in the glass tube; the water is kept nearly boiling; the magnesium is heated until it begins to melt and burn at the edges, at this moment the water is rapidly boiled (and the exit-tube is plunged under the water in the trough), when the magnesium is found to burn vividly in the steam and hydrogen to be evolved in quantity (Rosenfeld, *Berichte*, 15, 160.

M. M. P. M.

NOTES

WE are glad to learn that one of the evening (Friday, August 25) discourses at the Southampton meeting of the British Association will be given by Sir William Thomson, and that the subject will be "Tides." Prof. Moseley's discourse on "Pelagic Life" will be given on Monday evening, August 28.

THE honour of Companion of the Order of St. Michael and St. George has been conferred upon Mr. W. T. Thiselton Dyer, F.R.S., Assistant Director of the Royal Botanical Gardens, Kew, for services rendered to Colonial Governments.

THE FRENCH Minister of Public Instruction has again appointed a Commission to direct the deep sea exploration of the Atlantic in the *Travailleur* in July and August next; the investigation will include the ocean bed along the coasts of Spain, Portugal, and Morocco. The members of the Commission are MM. A. Milne-Edwards, L. Vaillant, E. Perrier, Marion, Folin, and P. Fischer.

A FLORENCE correspondent writes:—"On Sunday, May 21, the students and professors of the Faculties of Science and Medicine of Florence assembled to celebrate the memory of Charles Darwin. The large aula of the "Istituto" was crowded with auditors, and many had to be content with standing-room in the corridor outside. An address was read by the representative of the students, and an eloquent study of the genius and character of the great man of science by Prof. Mantegazza. I was struck by the note of religious solemnity that marked the proceedings." Similar testimonies of the high veneration in which the name of Darwin is held abroad come to us from other parts of Italy, as well as France, Germany, Norway, and Russia.

WE lately noticed the death of Mr. T. Donovan, lecturer on physiology and other scientific subjects at the Working Men's College and at the Birkbeck Institution. We learn that he has left a widow and two children, whose position has excited the sympathy of some of those who know the value of the work he did, and that a committee has been formed to collect a fund for their assistance. Mr. R. B. Litchfield, Bursar of the Working Men's College, whose address is 4, Bryanston Street, Portman Square, W., is Treasurer of the Fund.

MESSRS. HACHETTE AND CO. have just published two "map-size" chromo-lithographic plates of the "Phylloxera de la Vigne," one of which illustrates the habits of the insect, whereas the other represents it in its varied stages and conditions. They are especially suitable for the lecture-room, and their distribution in some of our colonies might serve to nip unnecessary panic in the bud. All the figures are enormously enlarged, and highly (perhaps a little *too* highly) coloured, with full explanatory text.

MISS ORMEROD'S "Reports of Observations on Injurious Insects during the year 1881" (W. Swan Sonnenschein and Co.) is far more bulky than its predecessors. This is mainly due to a lengthy and valuable series of reports on the Turnip Fly, which we commend to the notice of all who are likely to be directly influenced by this pest. Other old friends (?) receive their usual share of attention. Miss Ormerod was recently appointed honorary consulting entomologist to the Royal Agricultural Society.

THE following is the programme of the Davis Lectures on zoological subjects which will be given in the lecture-room in the Zoological Society's Gardens, in the Regent's Park, on Thursdays at 5 p.m., commencing June 8:—June 8, Armadillos, living and extinct, by Prof. Flower, LL.D., F.R.S.; June 15, the British Lion, by Prof. Boyd Dawkins, F.R.S.; June 22, Crocodiles, by Prof. Parker, F.R.S.; June 29, British Snakes and Lizards, by Prof. Mivart, F.R.S.; July 6, Frogs and Toads, by W. A. Forbes, B.A.; July 13, Insects and their Metamorphoses, by Prof. Martin Duncan, F.R.S.; July 20, Foreign Zoological Gardens, by P. L. Sclater, M.A., F.R.S.

WE are glad to notice that the Principal of the Royal Agricultural College at Cirencester has supplemented the teaching of biology in that institution, by establishing a thoroughly equipped and efficient biological laboratory. One of the largest and best lighted rooms in the college has been devoted to this purpose, and under the direction of Prof. Harker, has been furnished with dissecting tables and apparatus suited to modern requirements for the effective teaching of the subject. A number of microscopes have been provided; and practical demonstrations in the laboratory now form a necessary part of the course. The students are afforded every opportunity of acquainting themselves with the methods of microscopic manipulation. A special collection of types and a reference library in biology are to form part of the new institution. In view of the growing importance of biology in relation to agriculture, we think this is a wise step in the interests of the student.

ACCORDING to the *Golos* correspondent at Singapore, M. Miklukho Maclay was at that place on April 10, on his return from Australia and on his way home. But his visit home is to be short, as he expects soon to return to Australia, where he has left his large collections. His health is very bad in consequence of continuous fever and neuralgia, and notwithstanding his being only thirty-seven years old, he looks an old man. His twelve years' travel, accompanied with all possible privations, has broken his health. It is to be feared therefore that the publication of the results of his journeys and the description of his extensive collection will be considerably delayed.

IN the Scandinavian Exhibition now being held at South Kensington, there is a very fine and complete collection of objects in prehistoric archæology.

WE have received the second part of the "Descriptions of new Indian Insects from the Collections of the late Mr. W. S. Atkinson," by Mr. Frederic Moore (published by the Asiatic Society of Bengal). The remarks that have already appeared in NATURE, concerning the first part, apply equally to this, and we defer a longer notice until the completion of the work.

"HUMAN MORPHOLOGY" is the title of a work in three volumes, by Mr. H. A. Reeves of the London Hospital, the first volume of which Messrs. Smith, Elder, and Co. will immediately publish.

THE Göttingen Royal Society of Sciences have announced the following subject for prize competition (Beneke-foundation): Comprehensive researches are desired on the microscopical, that is, the anatomical and micro-chemical structure of vegetable protoplasm. The two prizes offered are about 85*l*. and 34*l*. respectively. Papers, written in German, Latin, French, or English, to be sent in in the usual way, before August 31, 1884. The prize award takes place on March 11, 1885.

THE Ben Nevis and Fort-William meteorological observations will be recommenced to-day by Mr. Clement L. Wragge, under the auspices of the Scottish Meteorological Society. A new fixed station is to be established near the lake, about 1,840 feet above the sea, the observations made at which, together with additional observations by means of travelling instruments at certain fixed hours and places to be taken during the ascent and descent, will the better enable atmospheric disturbances existing in the stratum of air between the summit of Ben Nevis and Fort-William to be observed, and discussed with some fulness. The hours of observation at Fort-William will be 5 a.m., 6 a.m., 7 a.m., 8 a.m., 8.30 a.m., 9 a.m., 9.30 a.m., 10 a.m., 10.30 a.m., 11 a.m., 11.30 a.m., noon, 1 p.m., 2 p.m., 3 p.m., 6 p.m., and 9 p.m. The observations to be taken on the journey to Ben Nevis will be 6 a.m. on the peat moss, 7 a.m. at the lake, 8 a.m. about 300 feet, and 8.30 a.m. at Buchan's Well. On the summit of Ben Nevis, Mr. Wragge will observe at 9 a.m. 9.30 a.m., 10 a.m., 10.30 a.m., and 11 a.m. During the descent, or homeward journey, the observations will be at Buchan's Well at 11.30 a.m., about 300 feet at noon, at the lake at 1 p.m., and on the peat moss at 2 p.m. Thus all these observations will be simultaneous with those taken at the low level station at Fort-William. Specially constructed thermometers to record the temperature by clockwork on the top of Ben Nevis at 9 p.m. have been most kindly placed at Mr. Wragge's disposal by Messrs. Negretti and Zambra, London. The indications of these instruments at that hour on the Ben will be of especial value to meteorologists, since the means of temperature and humidity at 9 a.m. and 9 p.m., the observing hours adopted by the English and Scottish Meteorological Societies, will thus be obtained for the top of the Ben. Mr. John Browning, of the Strand, London, has kindly presented a rain band spectroscope, to be used in the Ben Nevis investigations, from the use of which, in the hands of Mr. Wragge, valuable observations bearing on weather forecasting may be expected. Dr. R. Angus Smith, F.R.S., Manchester, has generously undertaken to supply apparatus for measurement of the actinism of the sun's rays and of daylight; and it has further been arranged that a very complete system of ozone observations at the foot, on the slopes and top of the Ben shall be carried out. The ordinary observations on Ben Nevis, at Fort-William, and at intermediate points will be of atmospheric pressure, temperature of the air, earth, lochs, and wells, direction and force of wind, kind, and amount of cloud, movements of the various strata of cloud, rainfall, ozone, and optical phemena. Additional rain gauges will be fixed on the summit of Ben Nevis to ascertain if the rainfall is the same with various winds at different points of the plateau, particularly from near the edge of the tremendous cliffs inward over the plateau. The work of arranging and opening the stations has already been commenced, and Mr. Wragge will doubtless have the entire system in full working order by 9 a.m., June 1, as stated above.

WE learn from *Naturen* that the authorities at Washington have availed themselves of the presence in the capital of Herr L. Stejneger, of Christiania, to secure the services of this eminent

Norwegian naturalist to conduct a scientific mission to Kamchatka. At two days' notice, Herr Stejneger started, on March 22, well supplied by the U.S. Signal Service Department with all the instruments and appliances necessary for carrying out his instructions which emanate conjointly from the Smithsonian and the U.S. Meteorological Institutions. A year and a half has been suggested as the term of his mission, but in this, as in other matters, he is left to follow his own judgment in regard to the best way of attaining the objects it is proposed to secure. These are: (1) the erection of a meteorological station, of the first class if possible, on the coast of Kamchatka, and one of the second or third class on Behring Island, and at Petropawlovsk, for each of which he is to make arrangements that will secure their permanent efficiency after his departure; (2) in the capacity of a member of the U.S. Fish Commission, to draw up a report of the fishing-grounds, more especially with reference to the condition of the cod-fisheries; (3) to collect, for the national museum the largest attainable number of the remains of the now extinct Rhytina, or Arctic sea-cow, good skins of *Phoca leonina*, *Otaria ursina*, and other sea-animals, together with a few skeletons and a large number of the crania of these and other marine mammals, and of the local birds and fishes. Herr Stejneger promises to keep the readers of *Naturen* acquainted with the success that may attend him in the prosecution of his various and arduous labours.

WE are glad to observe that the telegraph is making rapid way in China. The Shanghai-Tientsin line has been working now for a few months, and a line is being constructed in the south between Canton and Hongkong—a distance of about 100 miles. The first section is to connect Canton, which is practically the commercial capital of China, with the frontier of British Kowloon, situated opposite the town of Victoria. After some consideration it has been decided that a land-line is preferable to a submarine cable, as it will be more economical, and the latter also would seriously interfere with the enormous junk traffic and fishing operations in the estuary of the Canton River. It is interesting to remark that this line is purely a private undertaking of a company of Chinese merchants in Canton, who, doubtless, want to be on a level with their brethren in the north, in rapidity of communication with the markets of the world. The line, as above stated, will for the the present terminate on the confines of British territory. It seems hardly credible—but the fact is stated in the Hongkong journals—that opposition is made by the British authorities to the further construction of the line, and especially to the cable across the harbour necessary to connect Kowloon with Hongkong, unless it is constructed by a British company.

WE regret to see that the project of a meteorological observatory in Hongkong, which we have already described in NATURE, is still "under consideration." Major Palmer's very complete scheme, on which we commented at the time, was in the hands of the Colonial Office six months ago, but nothing has since been done, and there seems to be grounds for the fear that a work of much importance, local as well as general, for which funds are amply provided by the colonial authorities, will be postponed so long that the officer to whose knowledge and ability the scheme is chiefly due will have left the colony. It will be difficult and may be impossible to find a well-qualified substitute in a small community such as that of Hongkong.

THE Aëronautical Society of Great Britain propose to hold next year an exhibition similar to the one held in the year 1868 at the Crystal Palace, with the object of ascertaining the position of the science of aëronautics, and with the view of affording an opportunity to inventors to embody and exhibit the results of their labours. Several prizes will be offered, and an exhibit of balloons and all the appliances connected therewith will be invited; also of any methods for propelling a balloon or any gas vessel, influencing its direction, prolonging its life, improving its utility, &c. The Council will be glad to have an intimation addressed to the secretary, from members or others, that they are likely to exhibit, or to assist in raising the funds which will be necessary to carry out the project.

IT has been decided by the Chancellor of the Upsala University to purchase the botanical collection belonging to the famous Swedish botanist, the late Prof. Elias Fries, for a sum of 1250*l.*; the collection, however, does not include a Scandinavian Phanerogam herbarium, a collection of mosses and algæ, as well as some other objects, which have been purchased by some one, who desires to be unknown, and presented to the Botanical Museum in Upsala.

THE Swedish Diet has voted a sum of about 300*l.* towards a geological expedition to Spitzbergen in the summer of 1883, which amount will be placed at the disposal of the Academy of Science in Stockholm; it is, however, stipulated that all objects collected shall be presented to the National Museum.

INTELLIGENCE from the island of Fayal, one of the Azores, states that a violent earthquake occurred there on May 3. The shocks continued during an hour, in which time churches, public buildings, and several houses were destroyed.

AFTER efforts to domesticate several species of wild ducks in America, capturing them young, or raising them from the eggs, Mr. Lindon says (Buffalo Soc. Nat. Sci.) that none adapted themselves thoroughly to the barnyard state except the mallard, dusky duck, and Canada goose, whose progeny prospered well, and attained a greater weight and size than the ordinary domesticated stock. Some of them betrays a tendency to revert in plumage, to their original condition, but the majority have been completely metamorphosed into the ordinary barnyard fowl. No hybrids from any two different wild species, which bred only within the inclosure, were ever obtained, except from crosses between the mallard and dusky duck. The mallard has been supposed to be the originator of the common tamed ducks, but the dusky duck is now pronounced to be fully as domesticable.

IN view of the vagueness of expression "rainy day" in meteorology, Prof. Schmeltz has lately devised an apparatus to register the actual duration of rain. (He was not aware of M. Redier's apparatus for this purpose). From a description in the *Journal de Physique* (May), we learn that a long band of Morse paper sensitised for rain is used. The paper is dipped in a solution of sulphate of iron, dried carefully, and coated with tannic acid, or pulverised ferrocyanide of potassium, mixed with powdered resin for better adherence. The strip is stretched between rollers, one of which is actuated by means of an endless chain from a toothed wheel on the axle of the minute hand of a common clock. It passes under a funnel in the top of a wooden case, which is open below and is fixed outside a window. By means of guide rollers it receives double inclination (longitudinal and transverse), and the rain in excess does not sensibly spread beyond the part passing under the funnel. The length which the rollers transfer during a whole day is divided into twenty-four equal parts, each corresponding, on an average, to an hour. When no rain has fallen during the day, the paper strip used may be utilised again, being easily wound on the delivering roller. This simple and cheap apparatus is said to act admirably.

A WELL-ARRANGED and instructive Popular Handbook to the Natural History Collection in the Museum of the Yorkshire Philosophical Society, has been issued by the keeper, Mr. Walter Keeping.

THE Council of the Society of Telegraph Engineers and of Electricians have determined that the Society shall offer three premiums annually for the best original papers sent in to the Society on Telegraphic or Electrical Subjects during the Session by any person not being a m.mber of the Council of the Society. The 1st Premium will be called the Society's Premium, value 10*l.*; 2nd, the Paris Electrical Exhibition Premium, value 5*l.*; 3rd, the Fahie Premium, value 5*l.* The Premiums will consist of books or scientific apparatus. The first Premium will be awarded in 1883 for the best papers sent in between this date and the end of May next.

DR. F. A. FOREL, of Morges, informs us that the supposed lacustrine canoe referred to in NATURE, vol. xxvi. p. 67, was really a simple trough made out of a log, for the reception of spring water.

THE additions to the Zoological Society's Gardens during the past week include a Spotted Cavy (*Cœlogenys paca*) from South America, presented by Mr. V. Gibbs; a Red Brocket (*Cariacus rufus* ♂) from Trinidad, presented by Mr. H. Sandbach; a Black-breasted Sparrow (*Passer diffusus* ♂), a White-throated Seed Eater (*Crithaga albogularis*) from South Africa, presented by Mr. J. Abrahams; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Capt. E. C. B. Walker; three Midwife Toads (*Alytes obstetricans*), fourteen Alpine Newts (*Triton alpestris*) from Belgium, presented by M. G. A. Boulenger; a Lesser White-nosed Monkey (*Cercopithecus petaurista* ♀) from West Africa, a Jackass Penguin (*Spheniscus magellanicus*) from the Falkland Islands, two Cape Crowned Cranes (*Balearica chrysopelargus*) from South Africa, a Flamingo (*Phœnicopterus antiquorum*) from North Africa, two Bernicle Geese (*Bernicla leucopsis*), two White-fronted Geese (*Anser albifrons*), a Ruddy Sheldrake (*Tadorna rutila*), a Herring Gull (*Larus argentatus*), European, a Bordeaux Snake (*Coronella girondica*), South European, deposited; a Koala (*Phascolarctos cinereus*) from Australia, two Javan Peafowls (*Pavo spicifer* ♂ ♀) from Java, purchased; a Collared Fruit Bat (*Cynonycteris collaris*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE COMET.—The following orbit of the present comet has been calculated by Mr. Hind, from observations at Harvard College, U.S., on March 19, Josephstadt (Vienna) on April 19, and one by Prof. Millosevich, at the Collegio Romano, Rome, on May 21; parallax and aberration were taken into account:—

Perihelion passage, June 10·52442 Greenwich M.T.

	°	′	″	
Longitude of perihelion	53	55	18·0	From M. Eq., 1882·0.
,, ascending node...	204	53	56·9	
Inclination...	73	46	39·8	
Log. of perihelion distance ...	8·782864			

Motion—direct.

From these elements we find the positions near perihelion passage thus—

	d.	h.	R.A. °	R.A. ′	Decl. °	Decl. ′	Distance from Sun's centre. In R.A. ′	″	In Decl. ′	″	Intensity of Light.
June	10	0	74	58·4	+23	41·9	−3	33	+0	40	82·6
	10	6	75	50·8	+22	34·5	−2	56	−0	29	104·5
	10	18	78	0·2	+20	29·2	−1	18	−2	36	105·2
	11	0	79	16·1	+19	40·4	−0	17	−3	26	87·6

The intensity of light on May 21 has been taken as unity. The comet was then judged to have the brightness of a star of 5·6m. On May 18 Mr. G. Knott estimated it a little higher than 6·0, which fairly accords. Whence theory would raise it to over an average first magnitude at perihelion. With due precautions which will occur to most observers who have large refractors, it is now seen to be by no means improbable that the comet may be observed in full daylight, on June 10 and 11. Still it may be well to remark that as compared with the first comet of 1847, observed at noon, close to the sun, on March 30, by Mr. Hind, with a 7-inch refractor, stopped down to about 3 inches, the theoretical intensity of light at perihelion is not quite half as great; thus calling the brightness unity when the comet was first glimpsed with the naked eye, the brightness of the present comet at perihelion will be 186, while that of the comet of 1847 was 408.

By the above orbit the comet traverses the plane of the ecliptic at the ascending node 0·038 within the earth's track.

DOUBLE STARS.—No. 6 of "Publications of the Cincinnati Observatory" has been issued. It contains micrometrical measures of double stars made with the 11-inch refractor in 1879–80, consisting partly of observations preliminary to the formation of a general catalogue of known double stars situated between the equator and 30° south declination, and partly of observations of objects which Mr. Burnham has found to need re-observing. The cases of notable differences from previous measures are collected in the introduction. Mr. Ormond Stone is doing excellent work with his refractor, which appears to have been much improved since the object-glass was re-figured by Messrs. Alvan Clark and Son.

THE VARIABLE STAR U GEMINORUM.—Mr. G. Knott, writing from Cuckfield on May 29, states that he had caught a maximum of this apparently capricious variable on May 27 or 28; on both nights it was about 9·9 m. This, compared with the previous maximum noted by the same observer on February 28, gives a period of eighty-eight days.

Prof. Schönfeld finds that a star R.A. 16h. 13m. 36s., Decl. −7° 21′·0 for 1855 is variable.

A star in R.A. 19h. 17m. 33s., Decl. −21° 32′·3 for 1850, must be variable to a great extent—6·5 to 9·0 at least.

TEMPERATURE REGULATORS

BEFORE proceeding to the consideration of some of the means adopted for controlling temperature, more or less perfectly, it will be as well to notice two instruments, because although they are in reality only indicators, yet the latter is always referred to as a regulator.

Hall's aërometer[1] consists of a glass bulb 4½ c.i. in capacity, attached to a long tube whose capacity is 1 c.i. This tube is inserted into another of nearly equal length, and supported on a stand. The first tube admits of being sustained within the second at any given height by means of a spring. The outer tube is charged with mercury or water, according to circumstances, and the bulb and inner tube are arranged to contain, at the normal pressure and temperature, 5 c.i. of air. Any changes, therefore, in the atmospheric conditions will affect the level in the inner tube, and can be allowed for accordingly.

Doyere's regulator[2] (1848), which is on the same principle, consists of a glass bulb, to the bottom of which a fine tube is attached. This tube is bent, then carried upwards for a certain distance, is then bent again to form an inverted U-tube, the extremity is again bent upwards, and terminates in an open bulb. The lower bulb and the quill-tube are partly filled with water, the surface of which in the tube indicates by its change of position the alterations in the volume of the air contained in the bulb. The principle on which Fresenius' cast-iron drying-disk is constructed is the same which long ago led to the use of sand-baths, for it is obvious that if a large mass must be warmed before the heat can reach the substance, a rapid rise in temperature is impossible. The number of substances which can be conveniently dried at the temperature of boiling water, and the number of chemical operations which require that temperature, have led to the construction of every variety of water-bath and water-oven. With a temperature not much above the boiling point of water, the increase may be obtained by using solutions of various salts; but with these the evils of bumping and crystallisation are so great that Sprengel (1869)[3] replaced the water in a water-oven by sulphuric acid having a specific gravity of 1·55, and for that purpose constructed a leaden one of the following description: The outside case of the double-walled air-bath is a 6½-inch cube, the inside a 5-inch cube. The worm, made of about 30 feet of leaden piping of ⅜-inch diameter, is 15 inches high and 4 inches wide. The coils of the worm are kept apart from each other ⅛ inch by means of solder, and the worm is kept in its upright position by two iron supports soldered to the sides of the air-bath.

Laspeyres[4] (1874), using the same liquid, constructed two pieces of apparatus. One was a glass flask so arranged that

the substance could be heated in a test-tube; and the other consisted of a platinum vessel so constructed that the substance could be inserted into a horizontal tube.

Although Laspeyres in the article just quoted argues most conclusively that an absolutely constant temperature cannot be maintained by controlling the gas-supply, and Jac. Myers concludes his considerations on the subject by saying, "For so long must we give up the hope of being able to regulate these temperatures at pleasure," yet the subject of temperature-regulators is one to which so many have at various times turned their attention, that a comparison of the different methods is not without interest. Most of the instruments constructed may be classified under one or another of the following heads, viz., as modified:—

Air thermometers, with mercury or other fluid arranged to control supply of gas:—(*a*) in which the mercury employed becomes more or less heated while in use; (*b*) in which the mercury or other fluid does not become heated.

Mercurial thermometers (*a*) acting directly on gas-supply; (*b*) acting on gas-supply through the intervention of electric arrangements.

Vapour-tension thermometers.

Air Thermometers (*a*).—Kemp's regulator (1852) consists of a glass tube, at one end of which an elongated bulb is blown; the part of the tube near the bulb is then bent so that the open end of the tube and the bulb are parallel.[1] Sufficient mercury is then introduced to partly fill the bulb, the remainder being occupied by air. To the open end of the tube is cemented a brass cap, which is provided at the side with the gas inlet tube, and in the centre with a stuffing box, through which the brass outlet tube slides. The temperature is adjusted by moving this tube up or down as the case may be.

Bunsen's modification made the apparatus more compact, but not so simple or easy of construction.[2] It consists of a glass cylinder whose lower part is closed, and serves as air-vessel which communicates with the upper portion by a tube reaching nearly to the bottom. In the upper portion is inserted a wide glass tube which is provided with a side-tube, and which dips into the mercury. Fastened to the upper end of this tube is the gas-supply tube, which is rather shorter, and which has a fine opening in it. The position of these tubes is adjusted by the screw-thread in a brass cap, which works on a corresponding thread in the supply tube. The two parts of the apparatus are held together by a spring (in the newer patterns this is replaced by a pin working in a groove).

His low-temperature regulator has a much larger air-chamber, so as to increase its sensitiveness.[3] It is also provided with a side-tube fitted with a stopcock, so that mercury may be added or drawn off at pleasure. Guthrie[4] (1868) constructed a regulator on Kemp's principle, but attached the top of the vertical tube to the bottom of an U-tube which the gas had to traverse, so that the mercury on rising checked the flow. The adjustment consisted of a side tube (bent at a right angle) attached to the vertical tube; in that tube a glass rod could be raised or depressed, being held in its position by passing through a perforated cork. Müncke's[5] (1876) is very similar to Bunsen's, but the brass cap and fittings are entirely dispensed with, as the gas-supply pipe works stiffly through a perforated cork which fits the top of the tube.

Air Thermometers (*b*).—Schorer[6] (1870) used for an air-vessel a test tube 60 mm. × 14 mm., fitted with an india-rubber cork, and connected by a narrow tube with one limb of an U-tube, partly filled with mercury, the other limb being fitted with the control arrangement of Bunsen's pattern.

Clowes[7] (1871) constructed an apparatus on the same principle, but added a small outlet tube at the bottom of the U-tube, so that by means of an india-rubber tube, which is closed by a screw clip, the mercury level in the U-tube may be adjusted. In his apparatus the gas exit consisted of a glass tube passing through a perforated cork.

Jeannel[8] (1872) used a metallic air-vessel of 300-400 c.c. capacity, communicating, as in Schorer's, with an U-tube (charged, however, with glycerine instead of mercury). The pressure of the air in the vessel is regulated by means of an india-rubber ball, which is fitted (by means of a T-piece and stopcock) to the connecting tube. The flow of gas is controlled by means of a float in the other limb of the U-tube, which approaches or recedes from the end of the gas-delivery tube. The float is held steady by a guide needle, which is fixed to the upper extremity by means of sealing-wax. He mentions Steling's regulator, but gives no reference.

Martenson[1] (1872) used an air-chamber 14 c.m. long × 2 c.m. diam., and connected it by means of a fine tube with a modified U-tube charged with mercury. The rough adjustment is made by a fine opening in the narrow tube, which is closed by slipping an india-rubber tube over it, and the final adjustment is made by means of the gas-delivery tube, which works air-tight through a cork. A side branch to the U-tube serves as a by-pass.

J. Myers[2] (1872).—In this apparatus the air-vessel consists of four tubes 15 c.m. long × 2 c.m. diam. connected together by small tubes, and which then communicate with a regulator similar to that which Schlösing uses.

Cresti[3] (1878) employs a glass apparatus consisting of a horizontal air-vessel 15 c.m. long × 2 c.m. diam.; to this is attached at right angles a glass regulator of the Bunsen-Kemp pattern, the communication between the two being made by a capillary tube which enters the upper part of the air-chamber of the regulator. It is however a form of regulator which would require to be well screened from draughts, as so much of it is exposed.

Mercurial Thermometers (*a*).—Carmichael's[4] (1870) arrangement consists of a tube 40 cm. long by 6 mm. diameter, closed at one end, so that when filled with mercury it forms an elongated thermometer. This is bent according to the bath in which it is immersed, but is so arranged that the open end is vertical; near this end is affixed a side tube of 2 mm. diameter. This tube, after bending upwards, bifurcates. Into the open end of the larger tube a cork is fitted, through a hole in which a glass rod slides. This rod serves as a regulator to adjust the level of the mercury in the side tube.

In Hannay's[5] (1874) arrangement the principle is the same as in the preceding, except that the adjustment is effected by means of a piston in the side tube, which is graduated, while the main tube is bifurcated. It is open however to the objection that the gas has to pass over heated mercury.

Schlösing[6] (1870) used a very fine tube of considerable length (suitably bent) as the mercury reservoir, and led the open end of it into one of the horizontal arms of a T-piece. The other horizontal arm carried the inlet-pipe of the gas, which passed to the burner through the vertical arm. The escape of the mercury from the reservoir was prevented by a piece of sheet india-rubber, which was tied over the end of the tube. As the mercury expanded it forced this elastic cap to assume a globular form, and thus checked the supply of gas. The quantity of mercury in the reservoir was adjusted by means of a side-tube provided with a stop-cock (Fig. 4). The outer tube of Fig. 1 is replaced by a four-branched bulb which contains the extremities of the reservoir and of the gas entrance tube; but these are separated by a small wooden disk with a handle attached, which is fixed in the upper branch, and which rests lightly on the india-rubber sheet. The diameter of the gas tube no longer depends on that of the india-rubber; it can be larger, and the opening gaining in circumference can be diminished to become so narrow that the slightest movement of the disk closes it. Total extinction of the flame is prevented by a small radial groove on the disk.

Reichert[7] (1872) constructed his regulator by expanding the top of the thermometer tube so as to form an elongated bulb. In the top of this bulb was fixed the gas-inlet tube, which nearly reached the lower extremity of the bulb. A side tube served as gas exit. The adjustment was effected by means of a screw which worked in a cap cemented on to a side tube in the stem of the thermometer.

Milne-Edwards[8] (1872) describes a regulator similar to Reichert's, but does not specify what shape or description of bulb he employs.

Schäfer's[9] (1874) is essentially the same as the preceding, except that the inlet tube is a small steel tube with slit at lower extremity.

Page[1] (1876).—The regulating arrangement is the following: A piece of glass tube about seven-sixteenths of an inch diameter and 1½ inch long is fitted at one end with a short round cork; through the centre of this cork a hole is bored, so that the stem of the thermometer just fits in it; the other end of this glass tube is closed by a short tightly-fitting india-rubber cork, which is pierced by a fine brad-awl through its centre. Into the hole thus formed is forced a piece of fine glass tubing three inches long and small enough to fit loosely inside the stem of the thermometer. The gas enters by this fine tube.

Fletcher[2] (1876) stated that he had for some time used a similar regulator, but that the thermometer had an iron bulb capable of containing two or three pounds of mercury. He also reversed the direction of the gas.

Mercurial Thermometers (*b*).—Scheibler[3] (1865) devised the following arrangement. In the bath or chamber which is being heated is placed an electric thermometer; this communicates with an electro-magnet which is inclosed in a small metallic chamber through which the gas for the burner has to pass. When by a rise in temperature the circuit is closed, the hinged armature of the magnet is brought into contact with the opening of the gas inlet-tube, and is not liberated until a fall in the temperature breaks the circuit.

O. Zabel[4] (1867) placed in communication with an electric thermometer a contrivance which consisted of two electro-magnets acting on a hinged metallic screen. The completion of the circuit by a rise in temperature placed the screen over the flame, and thus checked the heat.

J. Maistre[5] (1866) recommended an electric thermometer connected with an electro-magnet, the armature of which could remove the gas-burner from under the bath, or which could be connected by means of a lever with the gas-supply tap.

Springmühl[6] (1871) arranged an electro-magnet with a hinged armature, so that on the completion of the circuit a weight attached to a lever closed the gas-tap, which was not opened until the release of the armature liberated a spring which acted in the opposite direction.

Vapour-tension Thermometers.—Appold's[7] consists of a glass tube having a bulb at each end. The tube is filled, as also about half of each bulb, with mercury; the lower bulb containing ether to the depth of half an inch, which floats on the mercury. The tube is secured to a plate of boxwood, supported on knife-edges, on which it turns freely. At the end of the plate, underneath the higher bulb, is a lever, which controls the supply-valve of a gas-stove or the damper of a furnace. With a rise in the temperature the increased tension of the ether-vapour drives more mercury into the upper bulb; this end then falls. With a diminished temperature the reverse action takes place.

Andreae's[8] (1878) is like Kemp's and various others, on the principle of an U-tube with one limb closed. It is, however, rendered more sensitive by the introduction of a certain quantity of a volatile liquid into the air space. It must be borne in mind that the liquid must be selected according to the temperature required, as it is obvious that the regulator cannot be used in any case where it has to be heated beyond the boiling-point of the liquid.

Benoit[9] (1879) constructed an apparatus in which he regulated the temperature by adjusting the pressure on the volatile liquid contained in the bulb. The following is the arrangement:—A small reservoir, which can be shaped to suit the oven or bath in which it is placed, holds the volatile liquid. This is connected by means of a tube from the bottom, to which is attached an india-rubber tube, to a regulator of the same pattern as that used by Reichert. The regulator is fixed on a board which can be raised or lowered, and is provided with two side tubes for adding or drawing off mercury at will.

By-pass.—Since it is obvious that in cases where the quantity of gas required to pass through the regulator is large, any perceptible increase in the pressure or the supply from the main must be accompanied by a rise in the temperature of the bath, it is advisable therefore to adjust the by-pass tap so that as small a quantity as possible shall have to pass through the regulator. Here, however, experience must decide how wide a margin must be left to the control of the regulator, for in some districts the difference between the day and evening pressures is so great that adjustment becomes a matter of great difficulty. In some laboratories, especially when near a suburban gas-works, the day pressure is so low and the evening pressure is so high that unless a pressure regulator be interposed between the main and the temperature regulator, the by-pass cannot be used.

Bunsen's[1] thermostat is the vessel in which he maintains a constant temperature, and which is used by him in his vapour density method. It consists of a sheet-copper cylinder, from which at seven places equally distant from each other project pairs of copper rods 7-8 mm. thick, which are riveted and brazed into it. These rods are heated by gas flames, and the temperature is adjusted by moving the burners to or from the cylinder; but in order to maintain it as constant as possible, the apparatus must be carefully screened and the heights of the flames kept nearly equal by means of a gas-regulator, and the flames must reach a height sufficient to keep both the copper rods in the middle part of the flame, and not to have the upper rod heated only by the extreme point of the flame.

Hipp's[2] (1868) regulator, which is described by Hirsch (and is therefore sometimes referred to as Hirsch's), consists of a bent compound metallic strap, *steel* on the outside and brass on the *inside*. The ends thus approach with a falling temperature. The one end is fixed securely inside the air-bath, and the free end communicates by means of a fine copper wire with a regulating screw which connects it with a bent rod carrying the gas-control valve.

Flow of Liquid.—Dupré and Page[3] (1869). The water-bath contains a coil of metal-tube like an ordinary condenser. The lower end of this coil is connected with a second and smaller worm, which is contained in a small water-bath. The latter is heated by a lamp and kept gently boiling. The lower end of this second worm is bent upwards and terminates in a long funnel. Any water poured into this funnel will pass first through the worm surrounded by boiling water, and be thus heated, and then through the tube in the water-bath containing the specific-gravity bottle. By regulating the flow of water the temperature of this water-bath can be raised quickly, or kept constant at any desired point.

Stricker and Burdon-Sanderson[4] (1870).—In this apparatus, which is especially arranged for heating the stage of a microscope, the temperature is adjusted by regulating the flow of boiling water, through the hollow stage, by means of a compression clamp. As the water in the small boiler is kept at a constant level by means of an overflow, the supply when once adjusted remains uniform.

The exceedingly accurate method of maintaining a constant temperature by controlling the pressure under which a liquid in an outer casing is made to boil, is one that depends so essentially on pressure that its consideration must be reserved for the paper on Pressure-regulators.

J. T. BROWN

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The establishment of the Waynflete Professorship of Physiology was provided for by the late University Commission, it being arranged that the emoluments of the post should be paid out of the funds of Magdalen College, to which college the Professor is to be attached as a Fellow. Magdalen College had already shown interest in the development of physiology, and has for some years past maintained a physiological laboratory, in which Mr. Yule, Fellow of the College, has given courses of instruction in Practical Physiology, open to all members of the University, and his lectures have been attended by all candidates for honours in physiology, such instruction not having been available elsewhere in Oxford. Since the passing of the new statutes, the Linacre Professorship has become confined to Human and Comparative Anatomy, and there has been no University representative of physiology. The want of a Professor of Physiology has lately been very strongly felt, especially as the number of candidates in the subject has much increased. It is understood that Magdalen College, acting on the representations of the University to that effect, has determined to apply such surplus funds as are avail-

able at once to the foundation of the professorship, and it is expected that an election to the post will therefore take place shortly. All praise is due to the college for having thus promptly acted in the best interests of science in the University, and given this professorship precedence amongst several other schemes which might have been carried out by it first instead. The Profesor is required by the Statutes to give instruction in Human and Comparative Physiology, with histology.

CAMBRIDGE.—The annual report of the Museums and Lecture Rooms Syndicate at Cambridge has contained in past years no more valuable record of work than that lately issued. Taking first the department of experimental physics, we learn that sixty-two students were attending the practical classes in the Lent term, doing work which few of the candidates for the mathematical or natural sciences triposes ever did at Cambridge before the establishment of the Cavendish Laboratory. The pupils in mechanism in Prof. Stuart's workshop have numbered thirty-six during the past winter. In chemistry the increase in the students has considerably exceeded the accommodation available in the University laboratory, notwithstanding the existence of several college laboratories. Professors Liveing and Dewar plead strongly for further provision as regards both buildings and appliances, such as may bear comparison with those of Zurich and Bonn; they believe that to delay building until other departments can be adequately dealt with will be most detrimental to the present flourishing prospects of chemistry. A new register of the specimens in the mineralogical museum is completed; but the want of additional apparatus is seriously felt. Prof. Hughes records the use of the Arts School as a lecture-room, and the arrangement for additional class and work-rooms in the Woodwardian museum. The accessibility of the collections, and the determinations being kept up to date, attract many geologists who wish to pursue special investigations. Among the additions to the collections are 700 species of Pliocene shells from Tuscany, casts of vertebrates from Lausanne Miocene, 270 species of Miocene shells from the Vienna basin; Upper greensand corals from Devonshire, many Cretaceous specimens from the neighbourhood of Cambridge, 450 specimens from Neocomian of Saint Croix, Switzerland, and casts of *Hesperornis regalis*, Marsh, from Kansas; several hundred specimens from Portland Sands, Swindon, Wilts, collected by Mr. H. Keeping, the curator of the museum; numerous specimens of rocks and building-stones.

Turning, now, to the biological departments, the Woodward and Hepburn collections of shells have been carefully examined and catalogued by the curator, Mr. A. H. Cooke. The report gives notes upon the principal families of mollusca, as represented in the museum, with indications of gaps in the series; it should be widely circulated in the interest of the museum itself, as many old University students must have it in their power to supply deficiencies at a slight cost of trouble to themselves. Mr. Salvin reports that his catalogue of the Strickland collection of birds is complete, making an octavo volume of 653 pages. The species in the collection number 3125. Mrs. Strickland has presented a further portion of the valuable library of her late husband to the museum. In Amphibia and Reptilia the collection is still relatively poor. A beautiful skeleton of Menopoma has been prepared by W. Robinson, one of the assistants in the museum, and a considerable number of skeletons and skins of representative genera in these groups has been added. Among the mammalian acquisitions should be mentioned the skeleton of a male giraffe purchased from the Zoological Society; a skeleton of a mare, presented by Mr. R. Pryor, of Trinity College; skeletons of a ringed seal, a bladder-nosed seal, and a Polar bear, all carefully killed and preserved, so that the bones were neither injured nor missing, as is too often the case. A complete skeleton of an Indian elephant has been given by Sir John Phear, and a less perfect skeleton of an individual of the same species, sent from Calcutta through the kind exertions of Sir Joseph Fayrer. English additions of interest continue to be made, such as a male badger, an adult male otter from Norwich, and a female wild cat from Sutherlandshire.

The average number of students working at physiology practically is now over 100. Mr. Balfour's classes in practical morphology have very nearly attained the same numbers. More demonstrators are seriously needed. Mr. Vines has been assigned a small room for practical botany, but the advanced students can only do their work by the course being repeated two or three times, since only ten students can work at once. Elementary students are at present unprovided with any space for practical study.

Prof. Paget, in reporting on the department of medicine, strongly urges the speedy appointment of a Professor of Pathology, and the provision of a Pathological Laboratory. The Museum of Human Anatomy has been enriched by sixteen models of the brain and other models, prepared by the late Mr. Joseph Towne, modeller to Guy's Hospital, presented through Mr. T. Bryant.

One further note should be made, calling attention to the magnificent presents made to the Philosophical Library, on its transfer to the new room, and being made available for all students in the museums, by Mr. J. W. Clark, Prof. Humphry, Mr. F. M. Balfour, Prof. Babington, Prof. Newton, and others. Mr. Clark's gift is of priceless value to the science school, including as it does several hundreds of volumes of the most valued and superb editions of zoological and anatomical works.

The Hopkins Prize for the best original memoir, invention, or discovery in connection with mathematics physical or mathematics experimental science that may have been published during the three years immediately preceding, has been awarded to Lord Rayleigh, M.A., F.R.S., of Trinity College, Professor of Experimental Physics in the University, for his various important papers connected with the theory of vibrations, and particularly for his paper on "The Theory of Resonance."

Prof. Humphry announces practical classes in histology by the Demonstrator, Mr. Hill, and in osteology by Mr. Wheny, during July and August.

The Cavendish Laboratory will be open to students obtaining permission from the Professor during July and August, and the Professor or one of the Demonstrators will attend daily.

It has been decided to confer the Honorary Degree of LL.D. on Prof. J. P. Cooke, the eminent Professor of Chemistry in Harvard College, U.S.

The opening of the Botanic Garden during three hours on Sundays to members of the Senate and friends accompanying them has been confirmed by 88 to 76 votes.

MR. H. S. HELE SHAW has been appointed Professor of Engineering at University College, Bristol, vice Dr. J. T. Main, elected Assistant Professor of Mechanics at the Normal College of Science and Royal School of Mines, South Kensington. Mr. Sidney Young, D.Sc. London, succeeds Mr. W. L. Goodwin as Chemical Lecturer and Demonstrator, the latter having obtained the professorship of Sackville College, New Brunswick, Canada.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 11.—"On the Organisation of the Fossil Plants of the Coal-measures," part xii. By Prof. W. C. Williamson, F.R.S.

At the recent meeting of the British Association at York, Messrs. Cash and Hick read a memoir, since published in part iv. of vol. vii. of the *Proceedings* of the Yorkshire Geological and Polytechnic Society, in which they described a stem from the Halifax Carboniferous deposits characterised by a form of bark hitherto unobserved in those rocks. To this plant they gave the name of *Myriophylloides Williamsonis*. It was characterised by having a large cellular medulla, surrounded by a thin vascular zone composed of short radiating lamellæ. This, in turn, was invested by a cylinder of cortical parenchyma from which radiated a number of thin cellular laminæ, like the spokes of a wheel, separating large lacunæ. Each lamina generally consisted of a single series of cells. At their peripheral end, these laminæ merged in a thick, large-celled, cortical parenchyma. The generic name, Myriophylloides, was given to the plant because of the resemblance between sections of its cortical tissues and those of the recent Myriophyllum. Two reasons induced the author to object to this name (NATURE, December 8, 1881, p. 124), and to propose the substitution of that of Helophyton. Such substitution, however, was rendered unnecessary by the discovery, by Mr. Spencer, of Halifax, of some additional specimens which indicate that the supposed new plant was merely the corticated state of the Astromyelon, described by the author in his Memoir, part xi. (*Phil. Trans.*, 1878). These specimens showed that the plant was more complex than had been supposed, different ramifications of it having each their individual peculiarities.

In some of the new specimens the vasculo-medullary axes present no differences from those of the Astromyelon already described. The radiating lines of cells separating the laminæ prove to be transverse sections of elongated vertical laminæ composed of cells with a mural arrangement, and which separate large vertical lacunæ of varying lengths; a type of cortical tissue clearly indicating a plant of aquatic habits. So far as this bark is concerned, all the ramifications of the plant display similar features, but several of the specimens exhibit important variations in the structure of the vasculo-medullary axis. In them the central cellular medulla is replaced by an axial vascular bundle, which has little, or in some examples apparently no, cellular element intermingled with the vascular portions. In some examples this axial bundle is invested by the thick exogenous zone seen in Astromyelon. In others that zone is wholly wanting. Yet there appears to be no reason for doubting that these are but varied states of the same plant which branched freely, the differentiated branches having, doubtless, some morphological significances, as yet incapable of being explained. That the plant was a Phanerogam allied to Myriophyllum, is most improbable. It has several features of resemblance to the Cryptogamic Marsileæ, from which it does not differ more widely than the fossil Lepidodendra do from the living Lycopodiaceæ.

The author describes a new specimen of *Psaronius Renaultii*, found by Mr. Wild, of Ashton-under-Lyne. Those previously described, consisted almost entirely of fragments of the bark and its ærial rootlets. The present specimen contains a perfect C-shaped fibro-vascular bundle and a portion of a second one, resembling some of those described by Corda, and which leave no room for doubting that our British Coal-measures contain at least one arborescent fern, equal in magnitude to those obtained from the deposits at Autun.

In his Memoir, Parts IX. and X., the author described, under the provisional generic name of Zygosporites, some small spherical bodies with furcate peripheral projections. Similar bodies had been met with in France, and were regarded by some of the French palœontologists as true Carboniferous representatives of the Desmidiaceæ. The author was unable to accept this conclusion, deeming it much more probable that they would prove to be spores of a different kind. Mr. Spencer exhibited the specimen now described at the York meeting. It is a true sporangium, containing a cluster of these Zygosporites. Though they undoubtedly bear a close superficial resemblance to the zygospores of the Desmidiæ, their inclosure within a common sporangium demonstrates them to be something very different. There is now no doubt but that they are the spores of the strobilus, described by the author in his Memoir, Part V., under the name of *Volkmannia Dawsoni*. Hence the genus Zygosporites may be cancelled.

Another interesting specimen found by Mr. Wild, is a young Calamite, with a more curiously differentiated bark than any that has hitherto been discovered. The structure of the vascular cylinder and of the innermost layer of the bark, differs in no essential respect from those previously described; but the outermost portion displays an entirely new feature. It consists of a narrow zone of small longitudinal prosenchymatous bundles, each one having a triangular transverse section, the apex of each section being directed inwards, whilst their contiguous bases are in contact with what appears to be a thin epidermal layer. As in every previously discovered Calamite in which the cortex is preserved, the peripheral surface of this specimen is perfectly smooth or "entire." It displays no trace of the longitudinal ridges and furrows seen in nearly all the traditional representations of Calamites figured in our text-books.

It has long been seen that the medullary cells of the Lepidodendra, as well as the vessels of their non-exogenous medullary sheaths, steadily increased in number as these two organs increased in size correlatively with the corresponding general growth of the plants. But the way in which that increase was brought about has continued to be a mystery. The author now describes a Lepidodendron of the type of *L. Harcourtii* in which nearly every medullary cell is subdivided into two or more younger cells, showing that, when originally entombed, the pith was an extremely active form of meristem, though the branch itself had attained to a diameter of at least two inches. The numerous small young cells are of irregular form. Their development by further growth into a *regular* parenchyma would inevitably necessitate a corresponding increase in the diameter of the branch as a whole; and it must have been from these newly-formed cells that the medullary cylinder obtained the element out of which to construct the additional vessels, the increase of which has been shown to be the invariable accompaniment of the growth of the branch. As might be expected, the growth of the vascular cylinder, or medullary sheath, could only have been a centripetal one.

A new form of Halonia from Arran is described. Instead of its central portion consisting, as in previously-described examples, of the usual Lepidodendroid medulla surrounded by a vascular cylinder, it consists of a solid axis of vessels, resembling in this respect all the very young Lepidodendroid twigs previously described from the same locality. Many recently obtained specimens of Lepidodendroid branches sustain the author's previous observations that all examples from Arran having less than a certain diameter, have the solid axial bundle, whilst all above that diameter have a cylindrical vascular bundle inclosing a cellular medulla. The first type commences with the smallest twigs, and is found increasing gradually up to the diameter referred to. The second type begins where the other ends, and increases in diameter until attaining the dimensions of the largest stems, in none of which does the solid bundle reappear. Halonial branches have not hitherto been described attached to the branches of any true Lepidodendron, though in 1871 (Memoir, Part II.), the author gave reasons, based upon organisation, for insisting that Halonia was a fruit-bearing branch of a Lepidodendroid tree. This conclusion was sustained by Mr. Carruthers in 1873 in his description of a branch belonging to a Lepidophloios. The author now figures a magnificent example, from the museum of the Leeds Philosophical Society, of a dichotomous branch of a true Lepidodendron of the type of *L. elegans* and *L. selaginoides*. In this specimen every one of the several terminal branches bears the characteristic Halonial tubercles. The leaf scars of these latter branches have the rhomboid form, once deemed characteristic of the genus Bergeria, whilst those of the lower part of the specimen are elongated as in *L. elegans*, &c. These differences are not due to their appearance in separate cortical layers of the branch, but to the more rapid growth in length of its lower part compared with its transverse growth.

The author throws some additional light upon the structure of Sporocarpum ornatum, described in Memoir, Part X., as also upon the nature of the development of the double leaf-bundles seen in transverse sections of the British Dadoxylons, described in Memoir IX. After a prolonged but vain search for a structure similar to the latter amongst the twigs of the recent Conifers, the author has at length found it in the young twigs of the *Salisburia adiantifolia*. Sections of these twigs made immediately below their terminal buds exhibit this germinal arrangement in the most exact manner. Pairs of foliar bundles are given off from the thin, exogenous Xylem zone which encloses the medulla, whilst at the same points the continuity of the Xylem ring is interrupted, as was also the case with the Dadoxylons, by an extension of the medullary cells into the primitive cortex. Sections of the petiolar bases of the leaf-scales of the bud show that these bundles enter each petiole in parallel pairs, subsequently sub-dividing and ramifying in the Adiantiform leaf. This curious resemblance between Salisburia and Dadoxylon, accompanied as it is by other resemblances in the structure of the wood, bark, and medulla, suggest the probability that our British Dadoxylon was a Carboniferous plant of Salisburian type, of which Trigonocarpum may well have been the fruit. If so, the further possibility suggests itself that this plant may have been the ancestral form whence sprang the Baieras of the Oolites, and, through them, the true Salisburias of Cretaceous and of recent times.

Linnean Society, May 4.—Sir J. Lubbock, Bart., F.R.S., president, in the chair.—Dr. Cuthbert C. Gibbes was elected a Fellow.—The Council and Fellows passed a resolution of sympathy with the family of the late Mr. Chas. Darwin.—The Rev. R. P. Murray called attention to specimens of *Carex montana* obtained at Heathfield, Sussex, corroborating Mr. Roper's late rediscovery of the plant in that county.—Mr. J. Murison exhibited dried examples of *Helipterum eximium* from the Cape, of *Ixodia achilleoides* from South Australia, and of jungle cotton from Nagpoor.—A paper was read, on a collection of algæ from the Himalayas, described by Prof. G. Dickie.—A communication was made, referring to new varieties of the sugar-cane produced by planting in apposition, as asserted by experiments of the Baron de Villa Franca and Dr. Glass of Rio de Janeiro. In correspondence which had passed between the authors and Mr. Chas. Darwin, the latter had expressed doubts as to whether two varieties could affect the character of the buds produced by either, it appearing more probable to him that the so-called new variety was due to bud-variation. The Baron de Villa Franca thereupon forwarded a document signed by eight distinguished Brazilians, testifying to the fact that valuable varieties have been raised by the process in question. Dr. Glass furthermore describes in detail his early but fruitless attempts to graft two varieties of the sugar-cane, though he succeeded with another monocotyledon, viz. *Dracæna*.—Mr. S. Grieve gave a notice of the discovery of remains of the Great Auk (*Alca impennis*) on the Island of Oronsay, Argyllshire. Wing and leg-bones were obtained, along with a various assortment of remnants of the Guillemot, Red Deer, Otter, Seal, and other mammals, mingled with fish-bones and shells. These were dug out of a large mound, which, the author believes, must in early times have been occupied by man. The exceeding rarity of the Garefowl remains in Britain gives a special interest to the record of their being found in these western Scottish Isles.—Then followed the reading of notes on some Cape orchids, by Mr. Harry Bolus, wherein several new species were described, and details given in elucidation of particular structural points in the flowers of certain forms, accompanied by a full list of the Cape orchids named by previous writers.—A note was read, on the dimorphic florets of *Catananche lutea*, by Mr. B. D. Jackson, which was followed by a paper on the clasping organs auxiliary to the generative parts in certain Lepidoptera, by P. H. Gosse. After some general remarks the latter author mentioned his mode of manipulation, and proceeded to a description of the organs in question, finally dealing with the modification of the apparatus as investigated in a very considerable number of species.

Zoological Society, May 16.—Osbert Salvin, F.R.S., vice-president, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of April, 1882, and called special attention to the following birds, all of which were said to be new to the collection:—(1) a male Rifle-bird (*Ptilorhis paradisea*), in immature and worn plumage, changing very slowly into the adult dress, but apparently in good health; (2) a pair of Black-headed Tragopans (*Ceriornis melanocephala*); (3) four Rüppell's Parrots (*Pœocephalus rueppelli*), from Western Africa; (4) a Western Black Cockatoo (*Calyptorhynchus naso*), conspicuously differing from the eastern *C. banksi* in its smaller size; (5) a male Cabot's Tragopan (*Ceriornis caboti*), making a fine addition to the gallinaceous series; and (6) two of the recently described Uvæan Parrakeet (*Nymphicus uvæensis*).—There was exhibited, on behalf of Mr. Henry Stevenson, a specimen of the Dusky Petrel (*Puffinus obscurus*), which had been picked up dead in the neighbourhood of Bungay, Norfolk, in 1858.—A communication was read from the Rev. O. P. Cambridge on some new genera and species of *Araneidea*. Of the sixteen species described, two were from Caffraria, one from St. Helena, two from Ceylon, and the remaining eleven from the Amazons.—Mr. W. A. Forbes called attention to a peculiarity recently observed in a young male specimen of *Pithecia satanas*, in which the third and fourth digits of both hands were completely "webbed."—Mr. W. A. Forbes also read a paper on certain points in the anatomy of the Todies (*Todus*), and on the affinities of that group. He dissented from the views of most previous authors as to the close affinities of these birds to the *Momotidæ*, considering that they must form a group by themselves, to be called *Todiformes*, of value equivalent to the *Pici-*, *Passeri-*, and *Cypséli formes* of Garrod. There were many grounds for supposing that *Todus* is a very ancient form, more nearly representing the ancestors of the whole group of Anomalogonatous birds than any other living form.—A communication was read from Mr. Roland Trimen, F.Z.S., containing a description of an apparently undescribed Sun-Bird obtained in the province of Mossamedes, South-western Africa, which he proposed to name *Cinnyris erikssoni*, after its discoverer Mr. Abel W. Eriksson.—Mr. P. L. Sclater read some notes on a species of Duck (*Anas gibberifrons*), examples of which had recently bred in the Society's Gardens.—Mr. W. E. Forbes gave an account of some points in the anatomy of a rare Australian Duck *Biziura lobata*) from examples that had recently died in the Society's Menagerie.

Physical Society, May 20.—Prof. Fuller in the chair.—Prof. W. Chandler Roberts, F.R.S. communicated the results he had obtained in repeating the experiments of M. W. Spring, Professor at the University of Liége, on the union of finely-divided particles of metal by pressure. M. Spring had shown that at a pressure varying from 5000 to 7500 atmospheres, metallic filings may be united into coherent discs. Thus at a pressure of 6000 atmospheres bismuth filings may be united into a disc which has a crystalline fracture and a density which is identical with that of the metal cooled from the molten state. Zinc again, also a very crystalline metal, will weld into a disc at a pressure of 7000 atmospheres, and the metal will even "flow" into cracks between the die and the collar surrounding it, just as in the experiments of M. Tresca, lead "flowed" under similar circumstances. Prof. Roberts had repeated and confirmed many of the experiments of M. Spring, whose more recent results are of special interest, as he has shown that if filings of bismuth, lead, and cadmium be *mixed* in suitable proportions, such, for instance, as in Wood's alloy; and if the mixture be submitted to a pressure of 7500 atmospheres, an *alloy* is obtained which will actually fuse at 70° C. the true fusing point of Wood's alloy being 63° C. Prof. Roberts showed to the Society an alloy he had prepared which melted below 100° C., although of the constituent metals the lowest melting-point is 230° C., and he pointed out the great interest both to the physicist and metallurgist of M. Spring's results.—Mr. Walter Baily then showed mathematically that the repulsion between the magnet and revolving copper disc in the experiment shown by Prof. Guthrie at the last meeting of the Society ought to vary as the square of the velocity of rotation of the disc, a result which Prof. Guthrie had found.—Mr. Lecky gave the results of tests of Mr. Bennet's cell (described at the last meeting) made by Prof. Guthrie. The electromotive force was 1·14 volts; the internal resistance 0·8 ohms, but both quantities vary under certain conditions. Prof. Macleod also gave the results of tests made by him. These show that the cell rose in E.M.F. from 1·005 volts on changing to 1·213 volts after standing three days. The internal resistance was then 1·007 ohms. Both quantities varied under different conditions of working.—Mr. C. V. Boys then exhibited an improved form of his vibratory meter for measuring electric currents, and specially designed for electric lighting purposes. He has applied to the form formerly shown to the Society, the contact-making device employed in Hipp's electric clocks, which, though imperfectly adaptable to the clocks, is perfectly adaptable to the meter. The force is proportional to the displacement. No sliding contacts are employed. Mr. Boys also explained some other plans for current meters, one of which he believes to be the final form for practice, and which, besides being remarkably simple in construction, is free from the objection of being tampered with by means of extraneous magnets. In reply to Prof. Foster he stated that self-induction does not disturb their action.

PARIS

Academy of Sciences, May 22.—M. Jamin in the chair.—The following papers were read:—Note on the application of a theory of Poncelet to approximate calculation of the arcs of plane curves, by M. Resal.—Researches on the absorption of gases by platinum, by M. Berthelot. He investigates the liberation of heat in absorption of hydrogen and oxygen by platina in different states. It is shown that the state of porous bodies changes continually while they absorb gases.—Action of oxygenated water on organic substances and fermentations, by MM. Bert and Regnard. *Inter alia*, dilute oxygenated water stops fermentations due to living organisms, and putrefaction of all substances which do not decompose it; it does not act on diastasic fermentations. It is rapidly destroyed (under 70°) by collagenous azotised matters, by musculine, blood fibrine, and azotised vegetable matters; but not by fats, amylaceous matters, soluble ferments, egg albumen, caseine, peptones, creatine, creatinine, or urea.—Reply to objections made by M. de Lesseps in the last *séance*, by M. Cosson.—A new scientific cruise of the *Travailleur* in the Atlantic, in July and August, as far as Madeira and the Canaries, was announced by M. Alph. Milne-Edwards.—M. Demontzey was elected Correspondent in Rural Economy, in room of the late M. Pierre.—On the measurement of carbonic acid contained in the atmosphere, by M. Mascart. He describes a method based on direct measurement of the diminution of pressure of a mass of air at constant volume and temperature, when the CO_2 is removed. Travellers may take about 500 cc. of air in glass tubes sealed at a lamp, and afterwards analyse at leisure.—Quantity of carbonic acid contained in the air at Colèves, near Nyon (Switzerland), altitude 430 m., by M. Risler. The general average for three years is 3·035 vols in 10,000.—Inoculability of tuberculosis by respiration of consumptives, by M. Giboux. In these experiments air expired by animals in phthisis was introduced twice a day for 105 days into a wooden case containing young rabbits, the grated apertures of the case being closed for two hours. Tubercles appeared in the rabbits' lungs. Other rabbits in a similar case, and similarly treated, except that the infected air was passed through carbolised wadding, showed no organic alteration.—Researches of pathological physiology on respiration, by MM. Grehant and Quinquaud. In the case of bronchial, pulmonary or pleural alterations, even in fever, the exhalation of carbonic acid is considerably diminished. The lesion, apparently, does not act by barring the elimination of CO_2, so that this accumulates in the blood, but by interfering with general nutrition at the various points where CO_2 if formed.—On the persistence of effects of preventive inoculation against symptomatic *charbon*, and on the transmission of immunity of the mother to her product in the bovine species, by MM. Arloing, Cornevin, and Thomas. The persistence of immunity for seventeen months has thus far been verified.—Observations serving in the study of phylloxera, by M. Lichtenstein.—Telegram from Cairo about the solar eclipse.—On the observations of the telescopic comet at the Imperial Observatory of Rio de Janeiro, by M, Cruls.—On a new case of formation of the dark ligament, and its utility for observation of the transit of Venus, by M. André. This was observed, during the recent eclipse, by MM. Gonessiot and Marchand, where the moon's disc came on three sun-spots. The ligament is much less dark than in the case of the transit. Here the laws of diffraction can alone explain it.—On a class of invariants relative to linear equations, by M Poincaré.—On uniform functions affected by sections, by M. Picard.—On the chemical work produced by the battery, by M. Tommasi.—On the employment of rotating discs, for the study of colour-sensations; relative intensity of colours, by M. Rosenstiehl.—Influence of introduction of the interior sea on the *régime* of Artesian sheets of water in the region of the Chotts, by M. Dru. These Artesian sheets would not be destroyed, but the general *régime* of waters in the country would be improved and protected.—Sulphhydrate of sulphide of nickel, by M. Baubigny.—Action of alkaline sulphides on proto-sulphide of tin, by M. Ditte.—Researches on cuproso-cupric sulphites, by M. Etard.—Basic salts of protoxide of manganese, by M. Gourgeu.—On the addition of hypochlorous acid to monochlorinated chloride of allyl, by M. Henry.—The odd eye of Crustaceans, by M. Hartog. It is composed of three simple eyes, anterior to the brain, with optic rods reversed, receiving the conductive fibres of the optic nerve on their external border, and having the pigment layer confounded in one mass. A similar structure is found in Chætognatha and in some Planaria. To this primitive and ancestral group of Turbellaria, the eyes of Crustacea and Chætognatha may probably be referred.—Researches on flagelliferous Infusorians, by M. Kunstler.—On a bed of tertiary mammalia at Aubignas (Andèche), by M. Torecarpel.—Influence of ethylic alcohol, and of essence of absinthe on the motor functions of the brain, and on those of the muscles of the life of relation, by M. Danillo. The influence of alcohol (in strong doses) referred to is similar to that of other anæsthetics (ether, chloral, morphine). Five periods are distinguished in the case of essence of absinthe, a tonic, a clonic, a choreïform, a period of delirium, and one of resolution. Thus the poisoning is like that from strychnine, in which, however, the period of delirium is absent.

VIENNA

Imperial Academy of Sciences, April 20.—L. I. Fitzinger in the chair.—The following papers were read:—Fr. Brauer, on the *segment mediare* of Latreille.—R. Maly, on the ratio of bases and acids in blood-serum and other animal fluids; a contribution to the theory of secretion.—Fr. Emich, on the behaviour of ox-bile to Huefner's reaction, and on some properties of glycocholic acid.—T. Mauthner, on the optic-rotatory power of tyrosine and cystine.—G. Becka, on the orbit of the planet Ino (No. 173).—E. Suess, on Fr. Bassani's work, "Discrizione dei pisci fossili di Lesina."—T. V. Rohon, on the origin of the nervus acusticus in Petromyzon.—F. T. Paulsen, on the path of the air-stream in the nasal cavity of man.—O. Simony, on a series of new mathematical principles derived from experience.

May 4.—L. I. Fitzinger in the chair.—The following papers were read:—C. Doelter, on the mechanical separation of minerals.—G. Gruss, on the orbit of the "Loreley" (165).—O. Seeliger, on the history of development of the Ascidia.—S. Lustgarten, on test for zodoform, naphthol, and chloroform in animal liquids and tissues.—A. Wassmuth, on the specific heat of strongly magnetised iron and on the mechanical equivalent of a diminution of the magnetism by heat.—T. V. Tanovsky and H. v. Perger, a sealed packet containing a paper on a new reaction of the azo-bodies.—A Brezina, report on some new and little-known meteorites (part iv.)—Z. A. Skraup, synthetical experiments on the chinolin series (part iii.).—R. Wegscheider, on the derivates and constitution of opianic and hemipinic acid.—A. Boehm, on the tertiary fossils of the Isle of Madura.

BERLIN

Physiological Society, May 19.—Prof. du Bois-Reymond, president.—Dr. Rabt Rückard spoke about the development of the brain in fishes, and about the import of its so-called lobi optici. He especially combated the view that the part covering these lobes is a part of the cerebrum; he is, on morphological, histiological, and embryological grounds, rather of the opinion that this portion of the brain belongs to the middle brain, and that it is an homologue to the corpora quadrigemina in the brain of the higher orders of animals. He endeavoured to establish this view by the history of the development of the brain in fishes, which he made a minute study of in the trout.—Prof. Hirschberg laid before the Society the results of his dioptric measurements of the eyes of fishes and amphibia (pikes and frogs), as a further contribution to the comparative dioptrics of the eye. According to his measurements, the cornea in the pike has a large radius of curvature which exceeds the length of the optic axis; consequently, these animals are very myopic in the air; when, however, the eye was ophthalmometrically examined under water, the distance of distinct image formation was much greater. The eye in fishes (both those of the pike and roach were examined) behaves quite differently in air and in water. This fact is a contradiction of Herr Rateau's statements, who also found the seeing distance of fishes almost the same in both media. The eye of the frog also behaves differently in water from what it does in air; the radius of curvature of its cornea is much smaller in proportion to the length of the optic axis, and its myopia in air is much less than in fishes. It is remarkable, that in the case of the eyes of both the frog and the pike, neither a solution of atropine nor of eserine produced any alteration in the distance of the formation of images; it is hence probable that the accommodation of the eye, if it occur at all in these animals, takes place by some other mechanism than that which affects it in the higher vertebra.

ANTS, BEES, AND WASPS

Ants, Bees, and Wasps; a Record of Observations on the Social Hymenoptera. By Sir John Lubbock, Bart., M.P., F.R.S., D.C.L., LL.D., Pres. B.A. and L.S., &c. International Scientific Series, Vol. XL. (London: Kegan Paul, Trench, and Co., 1882.).

SIR JOHN LUBBOCK has done well to gather all the results of his serially published observations on the social hymenoptera in one treatise, and to bring out the treatise in the International Scientific Series. On the one hand the extensive and important research on which he has for so many years been engaged is thus presented to the naturalist no longer in the form of scattered papers, and on the other hand the International Scientific Series, both on account of its popularity at home, and of its well-organised machinery for securing rapid translations abroad, is the most suitable place for publishing results which are in so eminent a degree of interest to general readers.

Looking to the investigations as a whole, or in the connected form in which they are now presented, we think that they deserve to be considered the most scientifically methodical, as well as in many respects the most scientifically fruitful, which have hitherto been prosecuted in the region of comparative psychology. In saying this we do not forget the investigations of Reaumur, Huber, Forel, Darwin, Moggridge, McCook, Morgan, or Spalding—all of whom we regard as holding more substantial claims to recognition in this respect than many others who might be mentioned in the same connection. But when we compare the researches of Sir John Lubbock with those of any other comparative psychologist, we find that he has the merit of showing, if not the greatest appreciation of scientific method, at least the greatest determination in applying such method to the questions with which comparative psychology has to deal. Darwin and Spalding are the only other men who in this department of science have shown an adequate estimate of the importance of experiment as distinguished from observation; but neither Darwin nor Spalding had time to experiment in psychology on a large scale—the former having had so many other lines of inductive and deductive research to attend to, and the latter having died so young. Thus it is that when we compare the investigations of Sir John Lubbock with those of other workers in the field of animal psychology, we must assign to him the first place among these workers as a scientific observer.

For the most part the volume before us is a reprint of the papers read before the Linnean Society, with only as much re-casting as is rendered necessary to give a systematic form to the book. A few coloured plates, however, are added, as well as a brief account of some of the chief facts recorded by other observers of ants. The latter, indeed, is slender, and is not even attempted in the case of bees; so that the essay is strictly, as its title proclaims, "A record of observations on the social hymenoptera"; it is not an account of all that we know concerning the psychology of these animals. As the essay is sure to attain a wide popularity, it is perhaps to be regretted that its author did not take the opportunity of disseminating complete information upon so interesting a subject, together with the "record" of his own "observations." But this is a matter on which opinions are likely to differ, and there can be no doubt that within the scope laid down by its title, the work is admirably arranged.

We shall now proceed briefly to enumerate the principal results which this record of observations sets forth.

The longevity of ants has been found to be much greater than was formerly supposed, for while previous observers were for the most part of the opinion that these insects die off every year, Sir John says:—

> "I have now (December, 1881) two queens which have lived with me since the year 1874. They must therefore be at least seven years old, and seem still quite strong and well. I have also some workers which I have had in my nests since 1875."

The following facts and opinions on questions of morphology may be quoted;—

> "I must regard the ancestral ant as having possessed a sting, and consider that the rudimentary condition of that of Formica is due to atrophy, perhaps through disuse."

Some species have the power of ejecting their poison to a considerable distance—as much as eighteen inches—and this power might have led to the sting falling into disuse, especially if the poison is, as it appears to be, "so intensified in virulence as to act through the skin."

> "The question arises whether the different kinds of workers are produced from different eggs. I am disposed to agree with Westwood in the opinion 'that the inhabitants of the nest have the instinct so to modify the circumstances producing this state of imperfection, that some neuters shall exhibit characters at variance with those of the common kind.'"
>
> "Among bees and wasps the workers are occasionally fertile; but so far as our observations go, it is a curious fact that their eggs never produce females, either queens or workers, but always males. . . . It became therefore an interesting question whether the same is the case among ants, and my nests have supplied me with some facts bearing on the question."

These facts consist of numerous cases of fertile eggs having been laid by workers, and in every case with the result of producing a male insect.

With regard to psychology, we have only space to allude briefly to the more important results.

Experiments showed that certain individual ants in a community "are told off as foragers, and that during winter, when little food is required,' two or three are sufficient to provide it."

Observations concerning sympathy and affection went to show, that while in most cases such feelings seemed to be entirely absent, in some cases they seemed to be certainly present. This was so in an instance observed last year, of a "poor ant lying on her back, and quite unable to move." Her companions moved her tenderly, for whenever Sir John "tried uncovering the nest where she was, the other ants soon carried her into the shaded part," and when they left the nest for an airing, they carried the invalid with them.

It was previously known that all the ants in the same nest recognise one another as friends. Sir John tried chloroforming and intoxicating certain individuals, to see whether this would prevent their being so recognised.

The chloroformed ants were treated by their companions as dead, but the intoxicated ones were recognised and taken into the hive, while intoxicated strangers were rejected. The manner in which recognition is effected has long been a standing puzzle to observers, and although Sir John Lubbock has not shown "how it is done," he has at least shown very conclusively how it is *not* done. Previous hypotheses supposed the faculty to depend on recognising personal appearance, personal scent, or on there being some pass-signal understood by all the members of a hive, and not known to members of other hives. But Sir John has found that the recognition is effected when the pupæ are hatched out away from their native hive, and even when the eggs are developed in one half of a divided hive, and the matured insects then returned to the other half. He also found that the memory of companions or nest-mates extends over at least a year and nine months.

Regarding the power of communication, the experiments went to show a strange uncertainty, though they agree with previous observations in establishing the main fact that such a power exists. Thus, for instance, when a dead fly was pinned down so that the ant which found it could not drag it towards the nest, she returned to the nest and procured assistance. This experiment was repeated, with small variation, a great number of times, and certainly proves a power of communication at least to the extent of "follow me." Moreover, by an ingenious device with three parallel tape bridges extending from a nest to three similar glasses, one empty, another holding a few larvæ, and the third filled with many larvæ, Sir John was able to show the interesting fact that ants can give definite information to one another as to locality, without requiring merely to lead the way. For he took two ants and placed one of them to the glass with many larvæ, and the other to that with a few. Each of them took a larva, carried it to the nest along the respective tapes, returned for another, and so on. After each journey he put another larva in the glass with a few larvæ to replace the one which was taken away. Every new ant which came to either of the glasses was imprisoned till the end of the experiment. Such being the conditions, it was observed that no ants went along the tape bridge to the empty glass, 104 ants went to the glass with a few larvæ, and 304 to the glass with the many larvæ. Thus it seems that the two original (marked) ants were able to tell their companions, not only where larvæ were to be found, but even where the largest store was to be met with.

Concerning the powers of special sense, a large number of experiments proved that ants are able to appreciate colour, and when their nests are covered with slips of stained glass, analysis of some of these experiments showed that there had congregated "under the red 890, under the green 544, under the yellow 495, and under the violet only 5." Other experiments showed that red light was the same to them as darkness, or, at least, that about the same proportion of ants congregated under red glass as congregated under a slip of porcelain. With reference to the parts of the spectrum invisible to our eyes, other experiments proved "that the limits of vision of ants at the red end of the spectrum are approximately the same as ours, that they are not sensitive to the ultra-red rays; but, on the other hand, that they are very sensitive to the ultra-violet rays." A layer of sulphate of quinine or of bisulphide of carbon had the effect, as might be supposed from the latter statement, of rendering the ultra-violet rays invisible, or less obnoxious to the ants. Conversely, a saturated solution of chrome alum, and chromium chloride in a layer so thick that in the darkness beneath it the ants could not be seen, had the effect of inducing the ants to escape from its luminosity to their eyes, and to go beneath the bisulphide of carbon; so that, "though to our eyes the bisulphide of carbon is absolutely transparent, while the chrome alum and chromium chloride are very dark, to the ants, on the contrary, the former appears to intercept more light than a layer of the latter."

A number of elaborate experiments on the sense of hearing produced only negative results, though from other considerations (chiefly anatomical) Sir John concludes, "On the whole, though the subject is still involved in doubt, I am disposed to think that ants perceive sounds which we cannot hear." Experiments on the sense of smell showed that the estimate previously formed by naturalists of its excellence was not exaggerated.

A number of experiments on the general intelligence of ants in overcoming difficulties of various kinds which Sir John devised for them, went to indicate a poverty of resources scarcely to have been expected; but it must be remembered that this only shows that there are ants and ants, for other trustworthy observers give wonderful accounts of the high intelligence of certain foreign species. On the subject of way-finding, there are also many interesting observations, which show that sight is not of nearly so much service as smell, although it is of much use in giving them their general "sense of direction;" for they observe the direction in which light is shining, guide themselves accordingly, and lose themselves if turned partly round on a rotating table in the dark.

We must not leave these chapters on ants without referring to one on the relation of these insects to plants, and another on their relation to animals. It is of importance to many species of plants that they should not be visited by ants, as the presence of these insects would tend to keep away bees, &c., which are required to fertilise the flowers. Consequently, these species of plants present a great variety of contrivances to exclude the ants, such as water-traps, slippery surfaces, narrow passages, sharply-curved stalks, hairs, viscid secretions, &c. Instances of such contrivances are given, and the general conclusion is stated that "though ants have not influenced the present condition of the vegetable kingdom to the same extent as bees, they have also had a very considerable effect upon it in various ways." Concerning the relation of ants to other animals, the most interesting addition to our knowledge which Sir John has made is that of *Lasius flavus* farming the eggs of aphides. For "here are aphides, not living in the ants' nests, but outside, on the leaf-stalks of plants. The eggs are laid early in October on the food-plant of the insect. They are of no direct use to the ants, yet they are not left where they are laid, exposed to the severity of the weather and to innumerable dangers, but brought into their nests by the ants, and tended by them with the utmost care through the long winter months until the following March, when the young ones are brought out and again placed on the young shoots of the daisy. . . . Our ants may not perhaps lay up food for the winter (like the harvesters), but they do more, for they keep during six months the eggs which will enable them to procure food during the following summer, a case of prudence unexampled in the animal kingdom."

Only one chapter of the book is devoted to bees, and one other to wasps. These, however, are very interesting, as the following *résumé* will show:—

Numerous observations went to prove "that bees do not bring their friends to share any treasure they have discovered so invariably as might be assumed from the statements of previous writers;" and also that in general bees are rather stupid in finding their way to honey out of rooms, &c. Their affection and sympathy is even less developed than in ants, so that Sir John doubts "whether they are in the least fond of one another." Their special senses are much the same as those of ants, hearing being to all appearance absent, while smell and sight are well developed, the latter enabling the insects to distinguish differences of colour on coloured surfaces. They prefer blue.

All these remarks apply to the experiments on wasps no less than to those on bees, except that they are somewhat more clever in finding their way, and show less preference for certain colours. One individual wasp was tamed, used to perch upon the hand, "apparently expecting to be fed," and even allowed herself to be stroked without any appearance of alarm.

We have now said as much as our space permits to recommend this work to all who take an interest in one of the most interesting branches of natural history. We can only find two points on which to offer criticism. Over a hundred pages are occupied with appendices, conveying minute details of the observations and experiments mentioned in the previous part of the work. These details appear to us unnecessary in a popular book, and we think that the space filled by them might have been more profitably devoted to a well compressed abstract of the observations of other naturalists upon the psychology of the hymenoptera.

The second point, which seems to us fairly open to criticism, is that concerning the author's views on the philosophy of vision. He discusses the theories of vision by simple and compound eyes of insects, and says, "The prevailing opinion of entomologists now is that each facet receives the impression of one pencil of rays; so that, in fact, the image formed by a compound eye is a sort of mosaic," and proceeds to observe that this theory "presents great difficulties," because "those ants which have very few facets must have an extremely imperfect vision," and also because the ants have simple eyes as well as compound, so that, according to the theory, the former cast reversed images, and the latter direct—a consideration which leads Sir John to remark, "that the same animal should see some things directly, and others reversed, and yet obtain definite conceptions of the outer world, would certainly be very remarkable."

Now, as regards the first objection, the perfection or imperfection of the vision would not necessarily be determined by the *number* of the facets any more than by their *size*. If a given area or eye-space is throughout a receptive surface, it need make no difference whether the area is composed of a few facets or of many; the perfection or imperfection of the apparatus as an eye would in either case depend on the distinctness or definition with which a pencil of rays is admitted into each facet, whether the pencil itself be wide or narrow.

And, as regards the second objection, we can see no real difficulty in supposing that the same animal should with some of its eyes see direct images and with others reversed images, without any confusion resulting to its mental perceptions. Let us first consider the case of reversed images. Sir John Lubbock says that we "see everything really reversed, though long practice has given us the right impression." But this statement is not quite correct. We do not really *see* things reversed, for the mind is not a perpendicular object in space standing behind the retina in the manner that a photographer stands behind his camera. To the mind there is no up or down in the retina, except in so far as the retina is in relation to the external world, and this relation can only be determined, not by sight, but by touch. And if only this relation is *constant*, it can make no difference to the mind whether the images are direct, reversed, or thrown at any angle with reference to the horizon; in any case the correlation between sight and touch would be equally easy to establish, and we should always *see* things, not in the position in which they are *thrown upon* the retina, but in that which they occupy *with reference to* the retina. Thus it really requires no more "practice" correctly to interpret inverted images than it does similarly to interpret upright images, and therefore the fact that some eyes of an ant are supposed to throw direct images, while others are supposed to throw reversed, is not any real objection to the theory which Sir John Lubbock is considering.

We give these criticisms as the only ones we have found it possible to make, and heartily wish so interesting a book the success which it deserves.

GEORGE J. ROMANES

OUR BOOK SHELF

The Great Giant Arithmos, a Most Elementary Arithmetic. By Mary Steadman Aldis. (London: Macmillan, 1881.)

"THERE are still mothers who wish to retain some portion of that influence which nature intended them to have in the training of their children, and who refuse to abandon it wholly either to the schoolmaster or the state. To such as these this little book is offered as a help in laying the foundations of one of the most important branches of instruction." In fifty-eight chapters the tender student is led pleasantly, clearly, and thoroughly, from the very simplest notions which lie at the threshold of arithmetic till he (or she), having solved many of the giant's easy riddles, is in a very good position to find out for himself some of the harder ones. We should say that the child who has had this course carefully laid before it, will have had its interest maintained throughout without flagging, for the mode of presenting the subject is such as to excite attention without causing fatigue. The lessons are all short, the questions pointed, and such as to draw out what knowledge has been acquired. Very little more is done than to explain the elementary operations of numeration, addition, subtraction, multiplication, and division. Towards the close a glance is given at some of the giant's more recondite mysteries, as of parts or fractions of things. Much useful, if elementary, information is conveyed in small doses as the child is able to receive it, but there is nothing childish in the matter or the manner. We should say that the best way to use the book would be for the parent (or governess) to master each lesson well beforehand, so that there should be little or no reference to the book during lesson-time, except, perhaps, for the purpose of looking at the illustrative drawings. We feel sure that when the "good bye" is reached there will be few to call Arithmos unkind names and say "he is a horrid, cross old thing," and that "they hate him, and wish such a giant had never been made."

A Treatise on Elementary Trigonometry. By the Rev. J. B. Lock. (Macmillan, 1882.)
Introduction to Plane Trigonometry. By the Rev. T. G. Vyvyan. (Deighton, Bell, and Co., 1882.)

BOTH these works are elementary: their scope is in the main limited by the requirements of the Previous Examination at Cambridge, and of the Entrance Examinations for the army. Mr. Lock's is by far the fuller work, and is well adapted for a student who has not constantly at hand the assistance of a private tutor; in fact, such a reader, if of fair intelligence, might be independent of extraneous aid, if he have previously grounded himself carefully in geometry and elementary algebra. The work contains a very large collection of good (and not too hard) examples. The only fault—if we must grumble—is that there is too much, we think, for ordinary school teaching. As Mr. Vyvyan remarks, "in all public schools but a few hours a week can be given to mathematics by the generality of boys," and trigonometry has to take, in general, a very small portion of that limited time. But Mr. Lock is to be congratulated, when so many "Trigonometries" are in the field, on having produced so good a book, for he has not merely availed himself of the labours of his predecessors, but by his treatment of a well-worn subject has invested the study of it with interest. The figures are numerous, and are drawn so that the salient features arrest the eye at once.

Mr. Vyvyan's work also is well adapted to the end he has in view. He aims at producing a book which may fairly be mastered by any schoolboy of average ability, whose sole desire in studying this branch (or any other branch of mathematics) is to satisfy the University examiners in an early stage of residence, that so he may be free to read other subjects, and bid farewell to mathematics.

The matter is clearly, though somewhat concisely put, and is sufficient in quantity for Mr. Vyvyan's purpose, which is not to bring out a book that will render a schoolboy or other junior student independent of the assistance of a master—this he considers to be an impossible task. We ourselves have found that very much explanation is required by the generality of pupils. There is a sufficient collection and variety of exercises.

We cannot say that either text-book will supersede all other text-books, but each merits, and will no doubt secure a very fair circulation in schools. Mr. Lock's being the fuller, is likely to be the more generally acceptable.

An Elementary Treatise on Conic Sections. By Charles Smith, M.A. (London: Macmillan, 1882.)

A THOROUGHLY excellent elementary treatise. For a long time we have been exercised in mind when asked to recommend a book on Conics. To all its predecessors, with their varying shades of goodness and badness, we had some objection or other to urge. Mr. Smith has just met our want; his book is right up to the time, and is admirably adapted for the preparation of pupils for college scholarships; for students at the university it is a fitting introduction to that as yet unapproached work, Salmon's treatise on these curves. The text is excellent, full in alternative proofs, and suggestive in its methods; the numerous worked-out exercises, in addition to those collected at the close of the several chapters, render the reader independent of any other work. We think the title-page should state that it is an "analytical" treatise on conics.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Darwin Memorial

THE note in NATURE, vol. xxvi. p. 87, on the Darwin memorial, says that there is to be a fund associated with the name of the great naturalist, which shall be devoted to the furtherance of biological science. Probably most biologists would agree that one of the best plans for effecting this object would be one, the idea of which originated with Mr. Sydney Hickson, of Downing College, Cambridge, who is at present on the staff of the Oxford Biological Laboratory. This plan is to establish out of the fund a marine zoological station somewhere on the English coast, that of Devonshire, for example. Mr. Hickson has advocated this course in a letter to the *Times*, where he pointed out that Italy, Austria, and France have zoological stations, while we have none, a fact which is one of the many signs that the teachings of Darwin have aroused more enthusiasm and activity abroad than at home. If you would give publicity to this suggestion it would be certain to come under the notice of the Memorial Committee and of biologists generally. J. T. CUNNINGHAM

Cottons, Romford, May 27

Comet *a* 1882

OWING to recent bad weather, the only opportunity we have had here of observing the spectrum of the comet was on June 4. Unfortunately our view was obstructed by clouds just as it grew dusk, but at 11.30 I managed to obtain a glimpse for a few moments. The nucleus gave a very bright continuous spectrum, with a marked increase of luminosity and widening of the spectrum in the yellow. I could see no lines or bands. I was not able to make any further observations, as the comet was on the point of disappearing behind a tree. A. PERCY SMITH

Temple Observatory, Rugby, June 6

THIS comet was distinctly visible to the naked eye, at 11 p.m. on Sunday, June 4, in the north-west, about 5° to 10° above the horizon (being in a hilly country, I could not estimate it correctly), with a bright nucleus, and a tail about $1\frac{1}{2}°$ in length. The sky had been overcast and stormy all day, but cleared up before midnight. I observed it from a hill-side about 400 feet above sea-level. F. T. MOTT

Leicester

Meteors

ABSENCE from home on business connected with the Transit of Venus Expeditions prevented me sending you earlier notice of a very brilliant meteor, which was seen here and at several distant stations.

On May 4, at 9h. 31m. p.m., Mr. Rooney, one of the assistants of the Observatory, saw a large fire-ball of a light purple tint. It was first observed near the star Arcturus, and then it moved towards the Great Bear, passing between δ and ϵ Ursæ. It burst just under α Ursæ, when its train changed in colour from a purple tint into a brilliant red. It was visible for about five seconds, and lit up the whole garden.

Another assistant, Mr. Cullen, saw the same body from a place not far distant, and his account agreed well with the above.

A note from a friend at Clitheroe informs me that the meteor was seen in that town by several persons, and was as brilliant as the full moon.

Another observer, writing from Prestwich to the *Manchester Examiner and Times*, describes it as having moved from S.S.E. to N.N.W., passing a few degrees to the east of the zenith, and exploding and then vanishing at an angle (altitude) of 40° to 45°.

At Tarporley it was visible for thirty seconds, moving from E. to N.N.W.

The same fire-ball was also seen in Cheshire.

Stonyhurst Observatory, Whalley, May 31 S. J. PERRY

ON May 16, about 11 p.m., I saw a meteor that was, I think, the most terrific, as well as the grandest, I have ever happened to see. I reached my house about ten minutes afterwards, and at once wrote down, substantially, the following unvarnished account of the phenomenon. It may have been witnessed and recorded by some one elsewhere. If so, the observer may like to compare my record of it with his own:—I was walking westward, and I was about two miles south-west of Woodstock (as the crow flies). Suddenly my attention was drawn upward by a brilliant light. I then saw a meteor high up in the western sky, and a little south of the Great Bear. It was descending at an angle of 50°. Its speed was so moderate, that I got a good observation of it. Its seeming size was, I think, quite half that of the full moon. It appearance was such as I never saw before: it struck me as being like a transparent lantern, or, rather, pail, full of burning matter. Its base was a sharply-defined broad cone. It looked as though let down from above by an unseen string, rather than falling. It seemed to be very near me. A flickering reddish flame rose, fitfully, straight up from the horizontal surface of its yellow-hued fiery mass. It vanished, without my seeing any scattering of sparks, when it was about half way between the Pointers and the horizon.

JOHN HOSKYNS-ABRAHALL

Combe Vicarage, near Woodstock, May 27

Earth-Tremors in Japan

AN article on earth-tremors, which appeared in the *Times* last November, seems to have attracted considerable attention in Japan, and a few facts respecting the work which has been attempted in the investigation of microseismic disturbances in this country, may possibly be of interest. In the *Transactions* of the Seismological Society of Japan we have already had three communications on this subject. Prof. H. M. Paul told us how, when searching for a site for the United States Naval Observatory at Washington, by watching the reflection of the image of a star in a vessel of mercury with a telescope, he was easily enabled to detect earth-tremors produced by a railway train at the distance of a mile.

Major H. S. Palmer, R.E., of Hong Kong, gave us an account of how, by digging a trench large enough to contain himself and his instruments when seeking for a station from which to make observations on the Transit of Venus, he practically escaped from earth-tremors which emanated from a railway line about 400 yards distant. As there are strong reasons for believing that many of the earthquakes which are felt in Yedo are produced by the faulting of the rocks, it was natural to assume that before the actual breakage took place there might be a crackling or gradual giving way which would be indicated to us by preceding earth-tremors.

In order to determine the presence of these earth-tremors, at the end of 1879 I commenced a series of experiments with a variety of apparatus, amongst which were microphones and sets of pendulum apparatus, very similar in general arrangement, but, unfortunately, not in refinement of construction, to the arrangements now being used in the Cavendish Laboratory.

The microphones were screwed on to the heads of stakes driven in the ground, at the bottom of boxed-in pits. In order to be certain that the records which these microphones gave were not due to local actions, such as birds or insects, two distinct sets of apparatus were used, one being in the middle of the lawn in the front of my house, and the other in a pit at the back of the house. The sensitiveness of these may be learnt from the fact that if a small pebble was dropped on the grass within six feet of the pit, a distinct sound was heard in the telephone, and a swing produced in the needle of the galvanometer placed in connection with these microphones. A person running or walking in the neighbourhood of the pits, had each of his steps so definitely recorded, that a Japanese neighbour, Mr. Masato, who assisted me in the experiments, caused the swinging needle of his galvanometer to close an electric circuit and ring a bell, which, it is needless to say, would alarm a household. In this contrivance we have a hint as to how earth-tremors may be employed as thief-detectors.

The pendulum apparatus, one of which consisted of a 20 lb. bob of lead at the end of 20 feet of pianoforte wire provided with small galvanometer mirrors, and bifilar suspensions were also used in pairs. With this apparatus a motion of the bob relatively to the earth was magnified 1000 times, that is to say, if the spot of light which was reflected from the mirror moved a distance equal to the thickness of a sixpence, this indicated there had been a relative motion of the bob to the extent of 1000th part of that amount.

The great evil which every one has to contend with in Japan when working with delicate apparatus are the actual earthquakes, which stop or alter the rate of ordinary clocks.

Another evil which had to be contended with was the wind, which shook the house in which my pendulums were supported, and I imagine the ground by the motion of some neighbouring trees. A shower of rain also was not without its effects upon the microphones. After many months of tiresome observation, and eliminating all motions which by any possibility have been produced by local influence, the general result obtained was that there were movements to be detected every day and sometimes many times per day.

Although these observations, which I found required more attention than a private observer was enabled to give to them, have been discontinued, I sincerely hope they may be again taken up. My reason for this is that in a country like Japan, where earthquakes are in some part or other phenomena of everyday occurrence, we have excellent opportunities of determining whether any connection exists between earthquakes and earth-tremors. The idea that earth-tremors may be the forerunners of earthquakes is by no means novel, and that earth-tremors actually exist was demonstrated some years ago in Florence by Timoleo Bartelli, who made microscopic observations of the pointer of a pendulum, which, to free from local surface action, he suspended in a cell. The localities which I should recommend for the observations of earth-tremors would be as near as possible to some earthquake centre. The localisation of these centres, however, is a matter of some difficulty. The difficulty arises from the fact that *good* time observations on earthquakes have, so far as I am aware, never yet been obtained; and farther, although we are able with our seismographs to write down the direction in which the earthquakes shake us backwards and forwards, these directions by no means always tell us the direction in which an earthquake came, an east and west motion having sometimes been proved to have travelled broadside on up from the south.

A great assistance to the interpretation of the various records which an earthquake gives us on our seismographs is what I may call a barricade of post-cards. At the present moment Yedo is barricaded, all the towns around for a distance of one hundred miles being provided with post-cards. Every one of them is posted with a statement of the shocks which have been felt.

For the months of October and November it was found from the records of the post cards that nearly all the shocks came from the north and passed Yedo to the south-west. When coming in contact with a high range of mountains, they were suddenly stopped, as was inferred from the fact that the towns beyond this range did not perceive that an earthquake had occurred. This fact having been obtained, the barricade of post-cards has been extended to towns lying still farther north. The result of this has been that several earthquake origins have, so to speak, been surrounded or coralled, whilst others have been traced as far as the seashore. For the latter shocks earthquake hunting with post-cards has had to cease, and we have solely to rely upon our instruments. Having obtained our earthquake centres, at one or more of these our tremor instruments might be erected, and it would soon be known whether an observation of earth-tremors would tell us about the coming of an earthquake as the cracklings of a bending do about its approaching breakage. To render these experiments more complete, and to determine the existence of a terrain tide, a gravitimeter might be established. I mention this because if terrain tides exist, and they are sufficiently great from a geological point of view, it would seem that they might be more pronounced and therefore easier to measure in a country like Japan, resting in a heated and perhaps plastic bed, than in a country like England, where volcanic activity has so long ceased, and the rocks are, comparatively speaking, 'cold and rigid, if an instrument sufficiently delicate to detect differences in the force of gravity in consequence of our being lifted farther from the centre of the earth every time by the terrain tide as it passed between our feet, could be established in conjunction with the experiments on earth-tremors. Limulus

CONCERNING the systematic place of Limulus, I should like to draw attention to a habit which has, as far as I know, never been alluded to in discussions, viz. the manner of casting its skin, mentioned by me in Deformation of Insects (*Mem. Compar. Zoology*). Limulus splits the skin exactly around the front margin of the head. Among Crustacea the Decapods at least split the skin around the hind margin of the carapace. Insects split the skin in the longitudinal middle line of the occiput and thorax, with the later addition of a transversal split on the head. I have seen cast skins of Scorpio, Pseudoscorpions, Hydrachna, and Arachnids, but they are not now at hand for a sure verification. As far as I remember all of them split the skin in the middle line of the anterior parts. At least I do not remember to have seen any transversal anterior split. H. A. HAGEN

The Utilisation of Ants in Horticulture

DR. C. J. MACGOWAN has sent me from Han Chow, Province of Hainan, China, a little paper on the "Utilisation of Ants as Insect Destroyers in China." It seems that in many parts of the province of Canton the orange trees are injured by certain worms, and to rid themselves from these pests, the inhabitants import ants from the neighbouring hills. The hill-people throughout the summer and winter find the nests of two species of ants, red and yellow, suspended from the branches of various trees. The "orange ant breeders" are provided with pig or goat bladders baited inside with lard. The orifices of these they apply to the entrance of the bag-like nests, when the ants enter the bladders, and, as Dr. Macgowan expresses it, "become a marketable commodity at the orangeries." The trees are colonised by placing the ants on their upper branches, and bamboo rods are stretched between the different trees, so as to give the ants easy access to the whole orchard. This remedy has been in constant use at least since 1640, and probably dates from a much earlier period. This is certainly a new way of utilising ants, which as a rule are deservedly considered a nuisance by the horticulturist. I should like to learn from any entomological reader of NATURE whether the facts communicated have before been known in Europe, and, if so, whether the species of ant has been determined. C. V. RILEY

Washington, D.C.

Aurora Australis

APRIL 17.—Evening very dark; air close and sultry; thermometer at 65. About 6.35 p.m. noticed a broad sheath of dull osy red in the south, stretching upwards towards the zenith; from outh-east to south was spread a bright greenish-yellow glare, ufficiently luminous to enable us to read the figures of a lady's small watch. Shortly afterwards, the sky from east-by-south to south-south-west was illumined with a ruddy glow deepening to dark red; at the most easterly point of the auroral light were broad pulsating streamers of great brilliancy; these extended to south-east-by-east. Could not detect the slightest sound from aurora. Weather continued fine. April 20.—This evening there was a wide-spread glare of auroral light, with greater range, but of far less brilliancy than marked the grand display on the 17th. Weather fine and clear. T. H. POTTS

Ohinitaki, N.Z., April 21

"Cuprous Chloride Cell"

As the account given of my cuprous chloride cell in your report (NATURE, vol. xxvi. p. 96) of the Proceedings of the Royal Society of Edinburgh is rather misleading, I hope I may be excused if I make a few remarks on the subject. It is there stated that my cells suffered greatly from loss. This is not a correct statement. There are two ways in which the work expended in charging a secondary battery is lost. When a secondary battery is being charged, the E.M.F. between the terminals of the battery is higher than the normal E.M.F. of the battery with open terminals, work being expended in heating the cells. When the charged cells are used to supply a current, the E.M.F. between the terminals is lower than the normal E.M.F. with open terminals, work being again spent in heating the cells. This source of loss is unavoidable, and is in practice very serious. I need only refer to the recent experiments in Paris with Faure accumulators, which were, I think, reported in NATURE. The second source of loss is the local action in the cell. This depends upon the chemistry of the cell. I have found the estimation of loss from this cause a difficult matter, but I think I am justified in saying that the loss from this cause in my cell is very small, when it is properly constructed. In fact, when used as a primary, its advantage is that it does not suffer from diffusion and consequent local action as all double-fluid cells do. I think it deserves a trial as a primary battery on this account. It is necessary to protect the cuprous chloride from air, covering it with water being quite sufficient. If this is done it should be a very durable form of cell A. P. LAURIE

King's College, Cambridge

[The statement that the cells suffered greatly from loss is in our report coupled with an additional statement which implies that other secondary cells have the same fault; so that Mr. Laurie is in no worse predicament than other inventors of secondary batteries. Unless Mr. Laurie's cell is in this respect superior to others, the report can hardly be regarded as misleading.—ED.]

Physico-chemical Lecture Experiments

A VERY striking lecture experiment, which I have never seen performed or described, and which illustrates the reaction, by double elective affinity, of *dry solids*, is the trituration together in a mortar of corrosive sublimate and iodide of potassium. The result is a brilliant scarlet coloration of iodide of mercury. If a large crystal of the one is rubbed on a crystal of the other, a scarlet precipitate (if the word may be so applied) is formed at every point of contact. From the brilliancy of the colour the experiment may be readily seen by a large number of spectators.

June 5 LEIGH CLIFFORD

CUPS AND CIRCLES

AN important addition to the literature of "Cups and Circles" and Cup-marked Stones,[1] has just been issued as part of the fifth volume of "Contributions to North American Ethnology," printed by the Department of the Interior in their series of the publications of the U.S. Geographical and Geological Survey of the Rocky Mountain Region. The literature of the subject as regards the Old World is already extensive, and the object of Mr. Rau's work is to collect and systematise the existing information regarding the "cup and ring cuttings" that have been observed on rocks and boulders in Europe and India, and to add to this systematised knowledge an account of those that are now known in America.

The first monograph on these archaic forms of sculpturings on rocks and stones was that of A. E. Holmberg, on the Lapidary Sculpturings of Scandinavia ("Skandinavien's Hällristningar," Stockholm, 1848), but though copiously illustrated, it remained in a great measure a sealed book, from its being written in Swedish; and it was not till the publication of Mr. Tate's memoir on "The Ancient British Sculptured Rocks of Northumberland and the Eastern Border" (Alnwick, 1865); the exhaustive essay on the same subject by the late Prof. Sir James Y. Simpson, entitled "Archaic Sculpturings of Cups, Circles, &c., upon Stones and Rocks in Scotland, England, and other Countries" (Edinburgh, 1867); and the larger work, prepared under the direction of the late Algernon Duke of Northumberland, entitled "Incised Markings on Stone found in the County of Northumberland, Argyle, and other Places, from Drawings made in the Years 1863 and 1864" (London, 1869) that the attention of archæologists generally was awakened to the

---

[1] "Observations on Cup-shaped and other Lapidarian Sculptures in the Old World, and in America." By Charles Rau. (Washington, 1881.)

subject. Since that time a host of enthusiastic observers has arisen over Europe, and innumerable examples of "cups and circles" have been discovered and described. It is difficult to account for the fascination that allures men to the study and pursuit of these "pitted stones." They are neither beautiful, nor intrinsically valuable. They are often earth-fast boulders, too large for transport, and unsuitable for "collections." But there is an element of mystery about them, and the mysterious is often more attractive than the beautiful or the useful. They pique the curiosity of the ordinary observer by the obvious suggestion that they have a story to tell if they could be made to speak; and they whet the ardour of the scientific investigator by the equally obvious suggestions that they are the products of a definite human purpose, which may be discoverable from an examination and comparison of their special characteristics. Probably no series of archæological remains has been more carefully examined, more minutely described, or more copiously illustrated, and if the accumulation of such a mass of detailed information regarding their typical forms and characteristics over wide areas should ultimately fail in determining the nature of the purpose or purposes for which they were produced it cannot fail to add largely to the extent and precision of our knowledge of an essentially obscure subject.

It is certainly a matter of great interest, whatever may prove to be its general significance, that "cup-stones" and "pitted stones," which are in many cases analogous to those in the Eastern Hemisphere, are found in the United States and other parts of the Western Continent. Perhaps the most remarkakable of those found in the United States is one at Ironton, in Lawrence County, Ohio, which was first brought to the notice of European archæologists by Prof. Daniel Wilson, in the *Proceedings* of the Society of Antiquaries of Scotland for June, 1875. It is a boulder of grey sandstone 3 feet long, 2 feet 7 inches wide, and a foot and a half high, weighing between 1000 and 1200 pounds. The surface of the stone is pitted all over by about 116 cups, whose average diameter is 1½ inches and their depth about ½ inch, and on one side of the block there are several grooves 4 or 5 inches long, shallow and circularly hollowed in the bottom, so that "a cylindrical stone applied in the direction of its length would have produced the grooves, and its end by rotation the cup-shaped cavities." Another cupped boulder of granite occurs at Niantic, in New London County, Connecticut. It has only six cups, varying from about 2 inches to 3⅛ inches diameter, and from ¼ inch to almost 1 inch in depth. Mr. Rau does not notice a still more remarkable boulder of granite in Forsyth County, Georgia, 9 feet long, 4½ feet high, and 3 feet wide, of which Prof. Wilson has given a figure. Along one side of the boulder is a row of cups, eighteen in number, connected by an incised line or gutter, while the face of the boulder is covered with markings of single or double concentric circles, surrounding small cups in the centre. In some cases two of these circles are connected by a straight gutter. Two very large boulders on the bank of the Ohio, a few miles below Manchester, in Adams County, have been seen by Dr. Hill, but are not more precisely described than that they are of sandstone, the one having twenty-nine and the other thirty-seven cups. A large cupped boulder at Orizaba, in Mexico, has been figured in Lord Kingsborough's "Mexican Antiquities." Two boulders of sandstone in an old Indian town in Santa Barbara County, California, are covered with conical-shaped excavations and cup-shaped depressions. The largest is 25 feet long and 10 feet wide, and shows twenty-five excavations from 6 inches to 26 inches diameter at the surface, and 5 to 16 inches deep. In one instance a groove is cut between two of the basins.

"Cup-stones" or "pitted stones" of small size are also frequently found in the United States. The first of these that has been noticed as obtained from the Indian Mounds in Ohio, was described and figured in "The Ancient Mounds of the Mississippi Valley," by Squier and Davis (Washington, 1848), and is now in the Blackmore Museum, Salisbury. It is a small block of sandstone, 6 inches by 8 inches, weighing between thirty and forty pounds, and presenting on its surface three detached cups—two confluent, one half-finished, and several which are apparently just commenced. They are slightly oval in shape, about 1½ inches in greatest diameter, and seven-eighths of an inch in depth. Still smaller stones, often water-rolled greywacke pebbles, with one or more cup-shaped indentations on their flattish sides are extremely common. The cavities are rough and irregular, and the explanation given of their purpose is that they were probably used by the Indians for cracking hickory nuts. Another variety of "cup-stone" with regularly rounded and well-smoothed cups is regarded as paint-mortars. But while some of the larger boulders with basin-like cavities, such as those from Santa Barbara County, California, may have been used as mortars for triturating grain, it is obvious that such an explanation cannot apply to the boulders with smaller cups, or to those cases in which the cups are hollowed in the perpendicular surfaces of stones and rocks.

Such cups, often surrounded by concentric rings, or by broken rings with a gutter passing from the central cup outwards through the part where the rings are interrupted, are found abundantly in the British Islands, and in France, Switzerland, Germany, and Scandinavia. They are sculptured on rocks, boulders, on monolithic and on megalithic monuments, on the stones of dolmens and cists, and on stones built into the walls of underground dwellings. Thus they occur in close connection with the habitations and the graves of prehistoric man in central and north-western Europe. In a few cases in Scandinavia they occur on sepulchral structures that are assigned to the Stone Age, but their associations, so far as these are determinable, are chiefly with the Bronze Age. In Britain, and especially in Scotland, their associations are largely with the Iron Age, and the Age of Bronze; but few, if any well-authenticated instances of their occurrence in association with the typical objects of the Age of Stone are upon record. On the other hand small, portable cupped stones have been found in cists and grave-mounds which are attributed to the Stone and Bronze Ages, both in Great Britain and Ireland. In Brittany the large stones of the dolmens are frequently sculptured with a variety of rude figures, among which cups and circles not unfrequently occur.

Perhaps the most remarkable examples in Scotland are the rock-sculptures at Achnabreac in Argyleshire, described and figured in Prof. Simpson's work, and a rock-surface on the shore of Loch Tay, recently described by Mr. J. Romilly Allen. Prof. Simpson described nearly a hundred examples of rock and stone surfaces thus sculptured, but this number has been more than doubled during the last year by two observers, Mr. William Jolly and Mr. Romilly Allen, the former working in the northern, and the latter in the central, districts of Scotland. In England the most curious examples are those on the moor at Ilkley, in Yorkshire, described in the *Journal* of the British Archæological Association (1879), by Mr. Romilly Allen. In Ireland the most striking groups are those on the stones of the great chambered cairn at New Grange, in the valley of the Boyne, and those associated with the remarkable cairns in the Lough Crew Hills, described by the late Eugene Conwell.

Many theories have been advanced with reference to the presumable purpose of such "cups and circles." It has been suggested that their purpose was useful, that it was ornamental, that it was commemorative, and that it was religious. The utilitarian theory is disposed of by their position in situations where use of any kind is almost impossible. The ornamental theory is negatived by the fact that they occur so often in situations in which they cannot be seen, as for instance on the under sides of cist-covers. The commemorative theory admits of much being said in its favour, but fails to suit all the circumstances of the case. The theory that they fulfilled some purpose in relation to the religious observances of prehistoric man is perhaps the most plausible that has yet been suggested, and has the following arguments in its favour.

If this early system of sculpturing these enigmatic markings on rocks and stones originally had reference to a common idea connected with the religious observances of prehistoric times, the existence of some traces of this connection might reasonably be looked for in the superstitions of the area in which it was formerly prevalent. This, in point of fact, is found to be the case. In many parts of Sweden, these cup-marked boulders are known as *elf-stenar*, and are still believed by the common people to possess curative powers. They say prayers, and make vows at them, anoint the cups with fat (usually hog's lard), place offerings of pins and small copper coins in them, and when they are sick, they make small dolls or images of rags, to be laid in them. These facts are stated in the *Manadsblad* of the Swedish Academy of Science. Miss Mestorf, as quoted by Mr. Rau, is more explicit:—

"The elfs are the souls of the dead; they frequently dwell in or below stones, and stand in various relations to the living. If their quiet is disturbed, or their dwelling-place desecrated, or if due respect is not paid to them, they will revenge themselves by afflicting the perpetrators with diseases or other misfortunes. For this reason, people take care to secure the favour of the 'little ones' by sacrifices, or to pacify them when offended. Their claims are very modest: a little butter or grease, a copper coin, a flower, or ribbon, will satisfy them. If they have inflicted disease, some object worn by the sick person, such as a pin, or button, will reconcile them. A Swedish proprietor of an estate in Uppland, who had caused an elf-stone to be transported to his park, found, a few days afterwards, small sacrificial gifts lying in the cups. In the Stockholm Museum are preserved rag dolls, which had been found upon an elf-stone."

These superstitious practices are connected with actual cup-stones of prehistoric times, but there are others, for the practice of which cups have been made in modern times. In the *Proceedings* of the Berlin Anthropological Society for June, 1875, Dr. Veckenstedt called attention to the existence of cup-markings on the walls of the church of Cottbus, in Brandenburg. Since then, they have been discovered on the walls of churches in more than twenty different localities in Prussia, and also in Germany and Switzerland, and even in Sweden. They are usually on the southern side of the churches, near an entrance, and not beyond the height of a man's arm. According to some accounts, in Germany at least, the cups were believed to possess healing virtues, chiefly for charming away fevers, and in some instances these modern cups in the church walls have been anointed with grease, like the cups in the prehistoric *elf-stenar* of Sweden. In Posen a tradition refers to the cups on the church-walls as the work of damned souls who ground them out in the night-time.

The existence of this superstitious veneration for prehistoric cup-stones, and the continuance of the custom of forming cups (on the walls of Christian churches) for curative purposes, pre-supposes the religious character of the original system of which these twin superstitions are apparently direct survivals. No evidence exists within the area occupied by the prehistoric cup-stones of Europe by which the precise form of the natural religion with which they were connected can be determined. But a religion exists in whose observances cups and circles are still made on rocks and stones. It does not exist in Europe, and there is no direct evidence that it ever existed within the European area, but it exists in the area which was the home of the Aryan race.

In the district of Nagpur, in India, Mr. Rivett-Carnac found a group of grave-mounds surrounded by stone-circles. The mounds contained burials after cremation, accompanied by urns and implements of iron. The circles round the mound are from 20 to 56 feet in diameter, are mostly formed of trap-boulders, but each circle has a few stones larger and more regularly-shaped than the rest, and on these stones he found sculpturings of cups and circles, which he recognises as analogous to the cups and circles of the European area. He has also found in Kumaon, close to the temple of Chandeshwar, a rock-surface, on which, in a space 14 feet by 12 he counted more than 200 cups, varying from an inch and a half to six inches diameter, and from half an inch to an inch in depth. These cups are occasionally surrounded by rings and connected by grooves, but the usual form is that of a simple cup. All these markings, whether on the rocks or on the stones of sepulchral circles, are old, so old that the natives attribute them to the giants. But in the temple itself the conventional symbols of Siva, as Mahadeva (The Generator), were in some cases represented by rough slabs with a cup and circle, or concentric circles with a radiating gutter rudely incised. The resemblance of these symbols to the European cup and ring cuttings is not so close as their resemblance to some of the sculpturings on Bald Friar Rock, on the Lower Susquehana in Maryland. Mere resemblance of form, however important it may be in a tentative classification of things whose relations are unknown, is quite insufficient if not irrelevant as evidence of identity of purpose or significance. Symbols that are absolutely similar in form may have had widely different meanings and applications in different places, at different times. Mr. Rau observes that no one who has examined Mr. Rivett-Carnac's papers in the *Journal* of the Asiatic Society of Bengal (1879) can help admitting the striking resemblance between the cup and ring cuttings of India and Great Britain; and he is probably right in his inference that the close connection between cups and rings implies that both belong to one system of primitive sculpture, the single cup being merely the simpler form. The argument in favour of both forms being symbols of the *cultus* of the reciprocal principles of nature rests solely on the ground of a similarity of form which does not amount to identity. Even though an absolute identity had been established between the ancient and modern sculpturings, their identity of significance would still remain to be proved.

It appears from this extended survey of the phenomena of cup and ring cuttings on rocks and boulders that more progress towards the elucidation of the subject is to be made by the study of their differences and diversities than by the mere observation of general similarities of form and circumstances. It seems probable that there are some, such as the portable varieties, which had a utilitarian purpose. It is not improbable that others of larger size on boulders, such as the block under the entrance to the tumulus of New Grange, may have been merely ornamental; and there are considerations which forbid the absolute exclusion of the supposition that others may have been commemorative, or in some sense possessed of a religious connection and significance. But none of these conclusions can be reached by mere force of argument. If the problem is ever to be solved, its solution will be reached by research, by comparison of the phenomena of different areas, and investigation of the inferences deducible from them. With regard to the American forms, Mr. Rau observes that as the cups on the Cincinnati boulder are perfectly similar to those on many stones in the Old World, it is probable that they owe their origin to the same motives. If these motives arose from some religious conception, we might feel inclined to trace the origin of American cup-cutting to Asia. But if, on the other hand, the cups were designed for a practical purpose, the custom of excavating them may have sprung up in America, as well as elsewhere.

THE ECLIPSE EXPEDITION

THE following letter from its Special Correspondent with the English Eclipse Expedition, appeared in the *Daily News* of Tuesday :—

Sohag, May 19

Still at Sohag! but how different is the place now from what it was when I first sighted it—as it seems, years ago. Then the solitary steamer and the tents of the French party were hardly sufficient to break the shore line as we looked at it, alas for too long a time, from the place of our last *ensablement*. But now the steamer is lost in a fleet of dahabeeahs, and the line of tents and shelters has been extended for some distance towards the town; but tents are coming down, the hot sand is being strewed with boxes, and in 24 hours nothing will be left but some brick piers, which the next high tide will make short work with. Yes, something will be left. Sohag will have taken its place in scientific history by the side of many other out-of-the-world places, which seem to be chiefly affected by eclipses, and its memory may still puzzle the dryasdusts of the future.

As the 17th approached the excitement of almost everybody visibly increased, and as the energy waned the tension waxed. A little wind eddy of fearful violence, which produced a small sand-storm on the land, and almost a waterspout as it tore its way out of sight across the Nile, after hurling down one of the French tents and driving the dahabeeah occupied by the English party from its moorings, was almost a relief; and a further variety was introduced into the monotony of heat and work by the arrival of the dahabeeahs and the final visit of the Governor-General to the astronomers and his new visitors, Aly Pacha Cherif (son of Cherif Pacha, Minister of Mohamet Aly); Osman Pacha Galeb, Governor-General of Assiout; Mahmoud Pacha, director of the Cairo Observatory; Mohamed Bey-el-Kakim, and others being among them. On this occasion the Governor-General Aly Pacha Riza was accompanied by Teidrous Effendi, chief judge, and Mohamet Effendi Kamil, one of the judges of his province, and his aide-de-camp Moustafa Effendi Sirry. The commandant of the garrison of Sohag was also in attendance. Moktah Bey, as usual, acted as interpreter, and the final arrangements for the eventful day were made. First among these the military guard had to be largely strengthened, for not only is a very pardonable curiosity a thing to be utterly suppressed during eclipses, but a whisper had gone abroad that the False Prophet of the Soudan had included the eclipsers in his anathemas, and even one fanatic in the camp at Sohag might give a deal of trouble. And at last the 17th came, ushered in by the finest morning we had had—(clouds had been terribly persistent for several previous days at the time the eclipse was to happen)—and when the observers turned out at dawn to put the final touches to their preparations the local excitement had begun to show itself. On the hill, under palm trees, between us and Sohag there was already a great crowd, which rapidly increased; but a cordon of sentries round the camp kept everything quiet within.

And now for the actual work. In an eclipse there are four critical points: the first, second, third, and fourth contacts, so called—the first when the moon makes its appearance on the sun, the second when its first totality obscures it, the third when the sun again reappears, and the fourth when the sun is quite clear of the moon again. It is of course with the totality—that is, the time that the sun as we know it is invisible between the second and third contacts—that the physical astronomer has almost exclusively to do, but as some of the phenomena are visible slightly before totality the time has to be carefully watched. During totality this has to be done in the most steady manner, and the observer upon whom this duty falls has a most responsible task. In the English Observatory, to which I shall now confine myself, this fell upon Mr. Buchanan; and as the arrangement adopted this time was new, I will describe it. It was devised by Mr. Lockyer as the result of his Indian experience, when the timekeeper found it so difficult to keep the time and to observe the eclipse, which he had come 600 miles to see, that he resolutely turned his back upon the sun lest he should fail in his self-imposed task and so disturb the work of others. What one wants to know at any moment during an eclipse is for how many seconds the phenomenon is yet to be visible and when each ten seconds of the totality have flown away, as each observer has generally more than one thing to do, and the announcement of the timekeeper is the signal for changing his instrument. On this occasion a clock used for testing gas meters was employed, with a seconds pendulum set going at the moment of totality, and with a large dial marked 65, 60, 50, 40, and so on to 0; 65 being the number of seconds which it was thought would leave a safe interval for covering the lenses of all the cameras before the actual termination of the eclipse. The plan answered admirably. Mr. Buchanan sang out the times shown on the dial, and sketched the eclipse with perfect ease.

While the land was darkening and the sky and the Nile were beginning to put on those indescribable hues round which so much of the terror of eclipses is centred, and while the whispers on the hill at Sohag were beginning to surge into a sound—half roar, half moan—some eight minutes before totality, Mr. Lockyer announced the appearance of bright lines, indicating that our atmosphere was already dimly illuminated enough to permit of the atmosphere of the sun being seen through it, and it was easy to see by the rapid pencilling on a copy of Angström's map, which was arranged on a stand under the eye-piece of his spectroscope that observations in earnest had commenced. This went on, the image of the retreating cusp of the sun being carefully kept on the slit of the spectroscope, by Mr. Lawrence until Dr. Schuster, as had been arranged, announced the instant of totality. At this signal Mr. Buchanan said, "65 seconds," Mr. Lockyer left the spectroscope to study the structure of the corona with the telescope, and Dr. Schuster uncovered all the lenses of his camera—all four of them arranged on a single stand—and to all, except the observers, the sun's atmosphere shone out in all its splendour and majesty, and the roar increased on the hill. In the telescope the verdict was that the solar conditions of 1871 were again present; and at the signal "40 seconds more," the information to be gathered by the naked eye and the grating was to be sought by one observer, while the photographic plates had to be changed by another. At this moment the silence in the observatory was broken by shouts calling attention to a strange object among the fainter exterior details of the corona itself, which were more suspected than seen. There, one solar diameter to the right and one solar diameter long, was an exquisitely formed comet, complete with nucleus and tail, sweeping in a beautiful curve, in brilliancy almost, if not quite, equalling that of the very corona itself—a real photometer, in fact, of which we have not yet heard the last. As in the naked eye view there was a struggle with the comet, so with the grating there was a struggle of another kind. A prism or a diffraction grating used without lenses forms what is called a slitless spectroscope. The coronal ring is really used as a circular slit, and according to the substances present in the solar atmosphere we shall have rings or no rings; and if rings are seen, then their presence in certain definite positions will tell us what substances are present. Now, in 1871 rings were seen, and they were very bright. In 1878 no ring whatever was seen. The question to be decided, then, was, Did this year's eclipse resemble in this respect the eclipse of 1871 or 1878? The result of the inquiry was that there were rings, but that they took time to see. This indicated a solar condition more resembling that presented in 1871 than in 1878, but stopping short of it.

Owing to these difficulties, hardly had Mr. Lockyer time to pass back to the telescope by means of which the spectrum of the corona was to be studied, when the clock showed that sixty-five seconds had elapsed, and Mr. Buchanan's "over" filled all with regret that the phenomenon, so rare and beautiful, and full of such precious knowledge, which each was doing his "level best" to secure, should be so ephemeral. So the caps were put on the cameras by Dr. Schuster and his assistant, Mr. Woods, lest the precious records which it was hoped might have been secured should be spoiled by the first beam of the reappearing sun. It turned out, however, that so admirably had the eclipse been calculated, and so exactly had the French party hit upon the central line, that the totality really lasted 7 seconds more, that is, the full 72 seconds. The spectrum of the corona, therefore, was studied for a second or two under, perhaps, better conditions than had ever been present before, excepting during the memorable observation of Janssen in 1871. There were the red and green and blue lines stretching right across a wide field of view, and although no obvious dark lines were seen in the momentary glimpse, it was obvious that the spectrum was not truly a continuous one. There were variations of intensity here and there, and not the equal toning generally observed. So then ended the totality in one of the observatories. Dr. Schuster and his assistants at once proceeded to the extemporised dark room on board the steamer to develop the photographs, while those members of all the parties who had made telescopic or spectroscopic observations retired to the solitude of their tents to write down their results while they were still fresh in their minds.

Later on in the day there was a conference, at which the collective note, which I have already telegraphed to you, was drawn up and signed on behalf of the several expeditions. The observations were thought then, and are thought now, to have been a splendid success. The photographic results obtained by Capt. Abney's rapid plates have secured permanent records of the highest value, which largely increase our knowledge of the sun's atmosphere. They connect the spectrum of the sun with that of the stars in a most unmistakable manner; and, taken in connection with the observations of Lockyer and Trépied on the bright lines visible before totality—observations predicted a year ago in the teeth of received opinion—show that those who would explain solar phenomena in the light of terrestrial chemistry have their work cut out for them. But on this and on some other matters I may have something to say in a subsequent letter.

The Cairo Correspondent of the *Daily News* telegraphs on Monday:—

By order of the British Government, Sir E. Malet has officially thanked the Khedive for the great attention and services rendered to the Eclipse Expedition. The Khedive has returned a complimentary answer. No other Consul has yet thanked his Highness.

AURORÆ IN GREENLAND[1]

SINCE the publication of the researches on Auroræ by Baron Nordenskjöld, the study of this enigmatical phenomenon has acquired still more attraction for the student of the physics of the globe. We are glad, therefore, to notice the appearance of a new work on "Auroræ," published by the Danish Meteorological Institute, being a discussion, by M. Sophus Tromholt, of the fifteen years' observations (1865-1880) made by M. S. Kleinschmidt at Godthaab in Greenland.

The auroræ at Godthaab are seen, of course, almost exclusively in the southern part of the sky. "I do not remember," M. Kleinschmidt says, "to have seen during these last twenty-five years, more than a few times, any aurora in the north; the middle point of the aurora-arc is usually situated between due south and south-south-east, with small oscillations on both sides of this middle point. In all colonised parts of the western coast of Greenland, the auroræ are always seen towards the south; but it seems to me that at the southern extremity of this country, I have observed more intense auroræ extending throughout the whole of the sky." This observation fully confirms the conclusions of Baron Nordenskjöld, as will be seen from his map, which we reproduced (NATURE, vol. xxv. p. 371). Godthaab being situated in 64° 11′ N. lat., that is, in the third region of Nordenskjöld, the exterior circle of the glory must appear as a bow in the south, and the common, or interior one, as a luminous arc in the magnetic north, or, rather, as a light spread throughout the sky. Indeed, northern auroræ were seen at Godthaab only during twenty-five days, out of fifteen years, and their number was but forty in the morning hours, and sixteen in the evening. At Jacobshavn (69° 13′ N. lat.) 50 per cent. of all auroræ are seen towards the south east, 26 per cent. towards the east, and only 9·5 per cent. appear in that part of the sky which is comprised between north-west and north-east. At Upernivik (72° 47′ N. lat.) the disproportion is still greater, 74 per cent. of auroræ appearing between south-east and south, 14·5 towards the east, and only 4·8 per cent. between north and west. As to the frequency of the quiet arc-aurora (the "glory" of Nordenskjöld), as compared with that of the brilliant ray-auroræ, it is difficult to judge by the abstracts of observations published by M. Tromholt, inasmuch as the observer seems not to have attached great importance to this difference; but it results from what he says that the most frequent shape is that of a luminous arc "whose rays are diffused so that the luminous mass seems to be homogenous." The rays are often only pulsations in the arc itself. As to the fascinating and brilliant ray-auroræ, they are by far less frequent than the former; however—in accordance with Nordenskjöld's theory—they are not uncommon in this latitude. The height of the middle point of the arc is usually from 5° to 10° above the horizon. Feeble light, very much like twilight, is not uncommon, as well as a similar light spread throughout the sky. M. Kleinschmidt has also observed auroræ in the shape of "an immense column of smoke," consisting of more or less defined rays: "it nearly always appears in the same position, starting from a point between north-east and east-north-east, whence it crosses the zenith and reaches an opposite point of the horizon." The same was observed in the "common arc" by Nordenskjöld (NATURE, vol. xxv. p. 369, Fig. 5).

The number of auroræ extending beyond the zenith, or appearing in the northern part of the sky being anything but numerous, it is only with caution that we may admit the conclusion arrived at by M. Tromholt as to a periodicity in the oscillations of the "auroral belt;" but it is worthy of notice that his conclusion is the same as that arrived at by Weyprecht, namely, that "the auroral belt advances towards the south about the autumnal equinox, then moves towards the north, and reaches its most northern position about the winter solstice; thence it again moves towards the south, and occupies its most southern position about the spring equinox; after that it again returns towards the north." If confirmed by more extensive observations, this result would imply an

---

oscillation of Nordenskjöld's "glory" in dependence on the seasons. Another, diurnal oscillation, according to which the auroral belt would slowly advance towards the north (for Godthaab) during the night, seems very probable. It would explain—M. Tromholt says—the greater intensity of auroræ towards midnight, as well as the greater frequency of northern auroræ among those which were observed at Godthaab during the morning; but this last phenomenon, of course, might depend also upon some diurnal variation of the intensity of the "common arc." In any case, these conclusions are to be considered as provisory ones, and must be submitted to the further test of observations carried on at points more favourably situated than Godthaab for the study of these oscillations. Such is also the opinion of M. Tromholt himself.

Of course, the fifteen years' observations at Godthaab do not include a period of time sufficiently long for enabling us to deduce from them the laws of periodicity of auroræ. But still they allow of several interesting conclusions which may serve as a guidance for further researches. Thus, it appears from them—contrary to what was said as to the auroræ being more frequent during the most cloudy days—that the number of observed auroræ is directly proportionate to the brightness of the sky. This dependence appears not only for different years or months, but also for separate days. If all the days when auroræ were observed are classified according to their brightness, which is expressed by the figures 1 to 4, and the brightness compared with the average number of auroræ observed during the days thus classified, we see that while the quantity of clouds was 1·6, 1·7, 1·8, 1·8 ... 3·2, 3·3, 3·4, and 3·5, the average corresponding number of auroræ was 7·0, 7·0, 5·0, 5·0 ... 2·9, 2·7, 3·5, and 1·5, the decrease being altogether very regular, so as to leave little doubt as to the accuracy of the law.

The following data have some bearing on the 11⅑ years' period of auroræ which was deduced from observations in more southern latitudes, and which is considered as depending upon the amount of solar spots. Reckoning the years from August to May, so as to comprise in each year all autumn, winter, and spring auroræ (during the bright nights of the summer they are not observable), the yearly number of auroræ during the years 1865-66 to 1879-80 is given by M. Tromholt as follows:—97, 112, 65, 84, 45, 61, 32, 47, 73, 97, 97, 104, 69, 100, and 75, that is, rather irregular. Nevertheless, it is easy to perceive in these figures a certain periodicity with three maxima corresponding to the years 1866-67, 1876-77, and 1878-79. By introducing a correction which depends upon the brightness of the sky, and reducing the observed number of auroræ to an average cloudiness, M. Tromholt finds another series which is more in accordance with the number of solar spots as given by Wolf. Both series for the years 1865-66 to 1879-80 (August to May), appear as follows:—

Number of auroræ, with correction for brightness of sky

86·2, 91·3, 67·4, 80·9, 51·7, 56·5, 32·0, 46·0, 78·4, 97·0, 95·0, 102·0, 73·0, 85·2, 83·3

Number of solar spots

23·5, 6·1, 18·3, 60·1, 107·0, 133·5, 98·6, 89·4, 51·7, 32·1, 11·6, 13·5, 6·8, 2·2, 16·3

It would seem from these two series, that instead of being proportionate to the number of solar spots, the number of auroræ is rather *inversely* proportionate to this number, the two maxima of auroræ corresponding with the two minima of solar spots, and the minimum of auroræ arriving one year later than the maximum of solar spots. The same appears still better from the observations at Stykkisholm in Iceland, which run through the years 1846-47 to 1872-73. Both curves for this place (auroræ and solar spots), although showing several irregularities, nevertheless display a marked connection between the two phenomena; both inflexions of the auroræ curve towards a maximum correspond very well with the minima of solar spots, and *vice versâ*. The result for Godthaab and Stykkisholm is thus the inverse of what was found in more southern latitudes; and, to explain this contradiction, the author admits that the "auroral belt" is subject in its oscillations to a period of about eleven years, during which it advances more towards the north at the time when the number of solar spots reaches a minimum, and returns back towards the south during the maximum period of solar spots.

As to the number of auroræ observed respectively during the evening and during the morning, the observations at Godthaab fully confirm the fact already noticed at other places, namely, that auroræ are more frequent during evening hours. But it still remains to investigate in how far this difference depends upon the hours of observation, the observer usually taking notice of nearly all auroræ which appear before midnight, and not noticing those which appear during the first six hours after midnight.

Such are the questions discussed in M. Trombolt's memoir. As will be seen, they are rather indicated than definitely solved; but we must be thankful to the author for having raised them, and express a hope that the observations of auroræ which are now made to such an extent in Norway and Greenland, may be extended to the polar parts of Siberia and North America; we earnestly hope that the Meteorological Commission of the Russian Geographical Society, which already has done so much useful work, will soon extend its network of observations over this new field, which becomes every day more and more important.

P. K.

ILLUSTRATIONS OF NEW OR RARE ANIMALS IN THE ZOOLOGICAL SOCIETY'S LIVING COLLECTION[1]

VIII.

20. THE MULE DEER (*Cariacus macrotis*).—While the Virginian Deer (*Cariacus virginianus*) is widely distributed all over the continent of North America, it is necessary to go far to the west before we arrive within the limits of the range of the two other species of the same group—the Mule Deer (*C. macrotis*), and the Black-tail (*C. columbianus*). Of these western deer, the latter, of which the Zoological Society had living specimens some years ago,[2] is confined to a narrow strip of land along the Pacific coast. But the Mule Deer has a larger distribution, being found on both sides of the Rocky Mountains, and extending eastwards of the main range, far into the prairies of Missouri.

The Mule Deer was discovered by Lewis and Clarke during their expedition to the Rocky Mountains in 1804, on the Missouri River, in about 42° N.L., and was so named from the excessive development of the ears, which at once distinguishes it from its fellows. Its most natural home is the mountainous region which flanks the main range of North America on both sides, though, as already stated, it extends hundreds of miles into the great plains drained by the Mississippi and its affluents. It is also met with in Oregon and British Columbia, though rather superseded in numbers in this quarter by the Black-tailed Deer.

The antlers of the Mule Deer, which, as in most other deer, are borne only by the male, are of the same peculiar type as those of the Virginian Deer. All the normal tines have a posterior projection, and the beam, after casting off the basal snagg, curves gradually forward and inward, until the extremities remotely approach one another. The tines thus stand mostly upright when the head is carried in its usual position, but when the head

---

[1] Continued from vol. xxv. p. 610.

[2] See Wolf and Sclater "Zoological Sketches," vol. i. pl. 20, for figures of the Deer.

is bowed in battle, the tines become nearly horizontal, and offer formidable weapons of offence. Five points is about the usual number carried by the adult male, though six or seven are not uncommon, and heads are said to have been obtained with even eleven and twelve tines.

FIG. 20.—The Mule Deer.

The size of the Mule Deer is rather larger than that of the Virginian, and it is also more strongly built. Individuals are said to attain a weight of 250 pounds, but this is the extreme size. The most marked characteristic of the species, however, is certainly the long, broad, and thick ears, which are well covered with hair on both sides, and somewhat resemble those of a donkey or mule.

FIG. 21.—The Chilian Deer

For their living examples of this fine animal, Fig. 20 (the first, it is believed, ever received in Europe), the Zoological Society are indebted to one of their Corresponding Members, Dr. John Dean Caton, of Ottawa, Illinois, U.S.A., author of an excellent volume on the Antelope and deer of North America.[1] Males of the species were

---

[1] "The Antelope and Deer of North America," by John Dean Caton, LL.D. New York: Hurd and Houghton, 1877 1 vol. 8vo.

safely imported some years ago, but it is only a few months since that Dr. Caton, after several previous unsuccessful attempts, succeeded in supplementing his gift by transmitting to England an adult female. There is now therefore for the first time some prospect that the Mule Deer may be added to the list of acclimatised species propagating its young in this country.

21. The Chilian Deer (*Furcifer chilensis*).—The Chilian Deer also belongs to the American group of the Cervidæ, but has some special peculiarities, and together with an allied form—the Andean Deer (*Furcifer antisiensis*)—constitutes a small and distinct section of the American Deer, remarkable for the simple character of the bifurcated antlers.

The Chilian Deer is generally known to the natives of Chili as the "Guemul," and, though but slightly deviating from the ordinary deer in general appearance, has been strangely misunderstood by some of the older authors. Molina, in his work on the Natural History of Chili, classed it as a horse (!) under the name *Equus bisulcus*, while Hamilton Smith has referred it to the Llamas, and other authors to the Camels! Gay, in his "Fauna Chilena," published in 1847, first gave a clear account of this animal, and figured the female in the accompanying "Atlas," from a specimen in the Museum of Santiago. Gay tells us it is rare in Chili, being only met with in the Cordilleras of the southern provinces. Mr. E. C. Reed, who sent a skin and skull of the "Huemul" for exhibition before the Zoological Society in 1875,[1] tells us that several specimens of it have of late years been procured by the Chilian vessels engaged in exploring the Chonos Archipelago, and that it extends throughout Patagonia down to Sandy Point, in the Straits of Magellan.

The Chilian Deer is of about the size of a large roedeer, but much stouter and thicker in its limbs. The antlers of the male, as will be seen by the illustration (Fig. 21), are very simple in character, consisting of a well-developed beam provided with a single anterior snag or brow antler, which curves rapidly upwards, and attains nearly an equal length with the beam itself.

FIG. 22.—The Radiated Ground-Cuckoo.

The example of this rare deer in the Zoological Society's collection was received from the Jardin d'Acclimatation of Paris in December last, and is believed to be the only individual of the species ever brought alive to Europe.

22. The Radiated Ground-Cuckoo (*Carpococcyx radiatus*).—To the minds of most people the name cuckoo conveys only the idea of a tree-loving bird of strong flight, that utters a well-known cry and drops its eggs in other birds' nests. But the Cuckoo family (Cuculidæ) of naturalists is an extensive group, containing many birds which not only have neither cuckoo-like call nor parasitic habits, but differ greatly from our familiar summer visitor both in structure and in manner of life. No better instance can be given of this truth than the very remarkable bird which we now figure (Fig. 23) from an example living in the Zoological Society's "Insect House." Though a "cuckoo" in all the essential points of its conformation, it is a purely terrestrial bird with a pair of long and strong legs, and in its general gait and actions much more nearly resembles a pheasant or a rail than the ordinary cuckoo of this country, with which it claims relationship.

The Radiated Ground-Cuckoo was first made known to science in 1832, by Temminck, who described and figured it in one of the *livraisons* of his "Planches Coloriées," published in that year from a specimen in the Leyden Museum. This, he tells us, was received from M. Diard, a well-known Dutch collector, who had obtained it at the settlement of Pontianak, in Western Borneo. A ticket attached to the foot of the bird called attention to its singular structure and habits, and contained the remark that it differs from the Malkoha Cuckoos (*Phænicophai*) also found in the same district, in keeping constantly on the ground in search of worms, and in avoiding danger by rapid running, whereas the Malkohas are always met with flying about amongst the trees in search of insects.

---

[1] See *Proc. Zool. Soc.*, 1875, p. 44.

Our great countryman, Mr. Wallace, who, we believe, met with this ground-cuckoo in Sarawak, also speaks of its terrestrial habits, and states that its mode of life resembles that of the pheasants of the genus *Euplocamus*. Little else appears to have been recorded respecting this cuckoo, which is certainly one of the most peculiar forms of bird-life that have of late years been exhibited in the Zoological Society's aviaries.

On examining the specimen in question, which, when it first arrived, had only a half-grown tail, but is now in excellent plumage, it will be at once observed that the naked space round the eye has been incorrectly coloured in Temminck's figure of this species. Instead of being of a red colour as there represented, it is of a nearly uniform pale green, as is likewise the bill. Few non-professional ornithologists, indeed, would recognise a cuckoo in the pheasant-like ground-loving bird with large bright bill, which is labelled in the Zoological Society's Gardens "The Radiated Ground-Cuckoo."

MR. STROH'S VIBRATORY EXPERIMENTS

A CENTRE of attraction at the recent Paris Electrical Exhibition was the Norwegian section, in which Prof. Bjerknes of Christiania exhibited his remarkable experiments with little drums or tambours vibrating under water, and attracting or repelling each other according as the phase of the pulsations was like or unlike. An account of his results was published in NATURE, vol. xxiv. p. 361, and the analogy between them and the well-known effects of magnetism was there drawn attention to. The field opened up by Prof. Bjerknes has been entered by Mr. Augustus Stroh, a well-known member of the Society of Telegraph Engineers and of Electricians, who recently delivered a lecture on his researches. Mr. Stroh has gone over the experiments of Dr. Bjerknes in air as a medium for propagating the pulsations of the drums instead of water, and has advanced beyond his predecessor in further experiments on the same line. The beauty of the apparatus and methods devised by him, and the exquisite skill with which he manipulated them, elicited the unanimous admiration of his hearers.

The drums employed by Mr. Stroh were small shells of wood having their mouths covered by an elastic membrane and their rears communicating with a flexible pipe, through which the pulsating air was communicated to the membrane, so that it could cause the latter to bulge out or collapse at every wave of air. The source of the vibrations was a vibrating reed, against which the air was forced by a small hand-bellows shaped like an accordion. By employing a flexible forked tube with arms of equal length, each fitted with a drum at the end, the vibratory air-blast from the reed could be conveyed to the drums so as to set them vibrating in like phase; and when one of the drums was mounted on a vertical axis, and free to rotate round it like the pole of a balanced magnetic needle, the approach of the other drum to it resulted in an attraction between them which was very pronounced. In this case the drums were vibrating in like phase, that is to say, they both bulged out and bulged in simultaneously. The mechanical explanation of the attraction is that there is a rarefaction of the air between the drums produced by the simultaneous advance and recession of the membranes toward each other. This rarefaction occasions a difference of pressure between the front and backs of the drums, causing them to move towards each other.

When, however, the vibrations are in opposite phase, that is to say, when one drum bulges out while the other bulges in, there is a repulsion between the drums corresponding to a condensation of air in the space between them. This condition of things is ingeniously obtained by means of an electromagnetic air-pump or bellows devised by Mr. Stroh. It consists of an iron armature placed between the poles of two double electromagnets, and free to move alternately towards either electromagnet. This to-and-fro motion of the armature is kept up by making and breaking the battery circuit in the coils of the electromagnets alternately. The armature carries a cross-arm or lever-rod fixed at right angles to its axis, and the ends of the rod are attached to two leather diaphragms, which act as partitions across the interior of two boxes. Each of these two boxes communicates with the external air by two pipes or orifices, one on each side of the leather partition. Now when this diaphragm or partition stretching across the box oscillates, air is expelled from one compartment of the box, and at the same time air rushes into the other through the orifices provided. It follows that if the orifices communicate with two drums one drum will collapse whilst the other is inflated. Now the oscillations of the armature keep the diaphragm oscillating, and hence the two drums communicating with opposite compartments of the air-chamber are kept vibrating in unlike phase. By employing two such air-boxes or pumps Mr. Stroh is able at a moment's notice to change the vibrations of the two drums from like to opposite phase by simply connecting the drums to the two expelling compartments of the two boxes, or one to an expelling and the other to an indrawing compartment of the box. The same device of a pivoted drum served in this case also to show that when the drums were vibrating in unlike phase there was repulsion between them.

In the science of magnetism we are taught that like poles repel and unlike poles attract; but in the experiments we are considering it is the drums in like phase which attract and those in unlike phase which repel. Mr. Stroh does not attempt to theorise upon his results; but if the analogy with magnetism hold good our ideas of what constitute like poles in a magnet will suffer a considerable change.

The aërial analogy for the attraction which always takes place between a piece of soft iron and a magnetic pole, whether it be a north or a south pole, was illustrated by Mr. Stroh in holding quiescent or non-vibrating bodies, such as his hand, or a piece of cardboard, near to either drum. The result was always an attraction of the drum towards the passive surface presented, whatever the phase of the drum. This attraction was prettily shown by means of a small round disk of paper attached to the end of a delicate lever pivoted on an upright stand like a magnetic needle.

The dying oscillations of the pole of a magnetic needle, when brought to rest in front of a disturbing magnet, were further illustrated by Mr. Stroh, in presenting the free drum a little apart from the pivoted one, and observing the latter shift round and oscillate before the other, until it came to rest face to face with it. This of course happened when the two drums were vibrating in like phase. When they vibrated in opposite phase, the pivoted drum moved away from the free one, and came to rest further off.

Until this point Mr. Stroh had been occupied with repeating Dr. Bjerknes' experiments in air; but beyond this he makes a new departure on his own account. The object of his further experiments was to ascertain what goes on in the air between the vibrating drums; and by inclosing a pair of the drums in an air chamber communicating with a capillary tube containing a column of spirits of wine to act on a pressure guage he showed that when the vibrations were of like phase, the spirit fell, indicating that the air was expelled from between the drums, and on the contrary, when the vibrations were of unlike phase, the spirit rose in the tube, indicating that air had been drawn into the space between the drums, and the pressure thereby raised.

The most valuable part of Mr. Stroh's results was now arrived at. By a series of test experiments he demonstrated that the lines of pressure in the air between the two drums are practically identical in direction with those which Faraday revealed to us in the magnetic field by means of iron filings. These were investigated by exploring the field between the drums with a small taper flame and noting the direction of the blast, as well as with a small windmill mounted on a stand, but the action of both these explorers requires a still atmosphere, and therefore could not be shown to a large audience. Mr. Stroh however, had devised a means of showing the movements of the air by models of the drums vibrating in glycerine traversed by the electric light which threw an image of the drums upon a screen. The membranes of the drums were oscillated in this case by working a crank and pulley, and four star-like water-wheels were pivoted between them in such a manner that when the drums were vibrated the wheels revolved under the streaming of the glycerine caused by the vibrations of the drums. Aniline blue placed in the glycerine at the middle of the surfaces of the drums also indicates the stream lines of the fluid to an audience. Starting from the middle, the glycerine separating into two trails, curved outwards into a kind of volute. This happened at both membranes, so that the space between was filled up by four such curves having a diamond space between them. This effect was produced by unlike phase, and closely resembled the arrangement of lines seen when two like magnetic poles are opposed to each other. On the other hand, the stream lines produced by vibrations in like phase were much less complex, and resembled the lines of force crossing over between two unlike magnetic poles.

NOTES

AT a meeting of the subscribers to the Memorial to the late Prof. Rolleston, held at the Royal College of Physicians on Thursday, June 1 last, it was resolved that the fund subscribed for the above object, which amounts to a little over 1100*l*., should be paid to the University of Oxford, as trustees, for the purpose of founding a prize, to be known as the Rolleston Prize, to be awarded every two years to the author of the best memoir embodying the results of original research on any branch of the following subjects:—Animal and Vegetable Morphology, Physiology and Pathology, and Anthropology. The prize, which will amount to about 70*l*. on each occasion, is to be open to all members of the Universities of Oxford and Cambridge who have not exceeded in standing ten years from the date of their matriculation. The adoption of the report of the executive committee was moved by Prof. Acland. Sir James Paget, Mr. Douglas Galton, and other distinguished men of science were present. A vote of thanks to the chairman, Dr. A. B. Shepherd, who has been most active in the furtherance of the objects of the Memorial, and also to the secretaries, Messrs. W. M. Moullin, M.D., C. T. Acland, M.A., A. P. Thomas, M.A., and E. B. Poulton, M.A., was carried.

CAPT. DOUGLAS GALTON, R.E., C.B., F.R.S., has accepted the Presidentship of the forthcoming Congress at Newcastle of the Sanitary Institute of Great Britain.

M. DUMAS, Perpetual Secretary of the Academy of Sciences, Paris, has, we understand, requested Dr. Siemens to allow a translation of his paper on the Conservation of Solar Energy to appear under M. Dumas' authority in the *Annales de Chimie et Physique*.

THE Committee for the arrangement of the Electric Exhibition in Vienna have resolved to delay the opening of the Exhibition till 1883.

THE fifth annual meeting of the Midland Union of Natural History Societies takes place at Nottingham on June 15. The programme includes a *conversazione* on the 15th and various excursions on the 16th.

THE Jubilee Exhibition of the Royal Cornwall Polytechnic Society and the Fine and Industrial Arts, will be opened at the Polytechnic Hall, Falmouth, on Tuesday, September 5, 1882. The Exhibition will be on an extensive scale, and the Committee have determined to make it representative of the progress of the past half century in science and art, mining enterprise, naval architecture, and fishing, meteorology, photography, natural history, and statistics, as well as the fine arts pure and applied, more especially in connection with the county of Cornwall. The Exhibition will be attended by men eminent in science, who will come to Falmouth after the British Association Meeting at Southampton, several of whom will deliver lectures at the jubilee. Electricity and the electric light will be a special feature of the Exhibition. The Exhibition itself will occupy the Polytechnic Hall and the Volunteer Drill Hall, and will be open for double the ordinary period. Excursions on a large scale will also be organised for exploring the sea coast, the scientific and archæological interests, and the natural beauties of the neighbourhood. In order to ensure success the Committee with confidence solicit the aid of all Cornishmen. They estimate that 600*l*. will be required to carry out the object in view.

A YOUNG Finnish lady, Miss Irene Åström, passed the examination for a candidate of philosophy at the University of Helsingfors, on May 24, with great honours. The young lady was subsequently, through a deputation of ladies, presented with a gold watch and chain, at a festive meeting given in her honour at the Æsthetic Club, Hesperia.

AT the expense of Herr Oscar Dickson, of Gothenburg, a promising young Swedish entomologist, Herr A. S. Mortenson, will, during the summer, study the entomology of the islands of Gotland and Öland in the Baltic.

IT ought to be mentioned, to the credit of our namesake, *Naturen*, that its recent numbers contain an unusually large proportion of original matter of more than local interest. To the April number, Hr. J. B. Barth, Director of Forests, has contributed an exhaustive and highly interesting memoir on forest economy generally, and on the biology of the Norwegian pine, *Abies excelsa*, specially. He treats at great length of the physical influence exerted by this tree, in rendering the earth around it more adaptable for its own rapid diffusion, as well as for that of other plants, and he regards it as of later development than the common fir, *Pinus sylvestris*, which, it appears, it is destined to some extent to supersede. The same number contains an amusing, but not uninstructive paper by Hr. Uhrbrand, on the appearance of will-o'-the-wisps (Norw. *Lygtemænd*) and their chemical or meteorological character, and a short notice by Hr. Reusch, of the conglomerates near Christiania. The May number gives a summary of Vogt's recent reports of the mines and minerals of Norway, from which it would appear, that while no sanguine hopes can be entertained of the continued yields of the once prolific Norwegian silver mines, the newly opened copper, nickel, and apatite works promise to become the most remunerative of the otherwise unimportant sources of national industry. The same number records the most interesting results of Hr. Tromholt's comparisons of the various meteorological observations made in Greenland, chiefly by officers of the Danish navy. From these it is shown, that while the auroral manifestations exhibit in Greenland the same periodicity of intensity as elsewhere, their minima and maxima do not correspond with those of the solar spots, the minima of the aurora coinciding with the maxima of the spots, and *vice versâ*. It also appears, that the arch of the aurora is most frequently seen at the south of the magnetic pole, and only in exceptional cases in the north, and that mostly at the winter solstice, when the southern manifestations generally are of rare occurrence, their greatest frequency coinciding with the equinoxes.

THE tide of travel, with insects, as with men, seems naturally to be from east to west. With the noted exception of the grape phylloxera and the Colorado potato beetle (as Miss Murthly points out in a paper to the St. Louis Academy), Europe has not received from America any considerable pest, while innumerable noxious species have crossed the Atlantic from Europe. There is a comparative scarcity, too, of Asiatic insect species on the western seaboard of America, notwithstanding frequent ocean traffic. Spite of great arid plains and lofty mountains, nearly all the insects of Eastern American States, including those from Europe, have found their way to the fields, orchards, and vineyards of the Pacific States. One of the latest insect-invaders from Europe is the cabbage or rape-butterfly (*Pieris rapæ*, Schrank). It appeared about twelve years ago in some northern seaports, and its range now extends from far north in Canada to the south of Georgia. It attacks every cruciferous garden vegetable, but in the flower garden curiously rejects plants of that family in favour of mignonette. Miss Murthly has noted a large amount of premature emergence from the chrysalis, and consequent death; indicating imperfect adjustment of the insect to the climate of its new habitat. In Europe the insect is mainly kept in check by numerous parasites. For several years in America none such came to the aid of the disheartened gardener, but some have now appeared, the most important being a small, metallic green fly, which, though identical with the most destructive European parasite, is proved to be indigenous on both sides of the Atlantic. It lays its eggs in or upon the skin of the mature caterpillar, and from these come small maggots, which live on the fatty tissues of their victim, but do not touch its vital organs till the chrysalis state is reached.

THE mines opened a short time since in China in the province of Chihli, with the special support and patronage of Li Hung Chang, have recently become the subject of much adventitious interest in Europe. The working of these mines was wholly a native enterprise; foreign machinery was imported in large quantities, and up to a month or two ago all seemed going on well. A canal between the mines and Tientsin was nearly completed, and it was calculated that 250 tons of fine coal could be forwarded daily to the latter port. Five thousand tons were, it was said, ready at the pit's mouth for conveyance as soon as the canal was opened. It was believed that, with sufficient transport, one thousand tons a day could be raised for many years from the present pits, while it was said that fifty collieries of an equal size to the present one could be opened in or near Kaiping. The information, therefore, telegraphed by Reuter's agent in Shanghai that the further working of the mines had been peremptorily stopped by the Government, came with a shock to many interested in progress in China. It was stated that a censor in a memorial to the throne complained that the long galleries in the mines, and the smoke of the foreign machinery, disturbed the earth dragon, who in his turn disturbed the spirit of the Empress, who died some months ago, and who was buried about a hundred miles off. The irate spirit of the departed lady promptly took vengeance by afflicting the denizens of the palace in Peking with measles. The latter were, the censor is reported to have said, distinctly traceable to the Kaiping mines, which interfered with the *fêng-shui*. The conclusion was obvious: the mines must be stopped. Such was the story told by the Tientsin correspondent of a Shanghai newspaper. The process by which a suggestion that the mines should be stopped grew in the excited minds of the residents of Shanghai into the certainty that they were actually stopped—and thus to Reuter's telegram—is not an unfamiliar one. The latest information from the East enables us to say that the mines are still working as usual, and there is not the slightest evidence that there is or has been any intention of interfering with them. It is even denied that such a memorial as that mentioned above has had any existence except in the imagination of a *gobemouche* at Tientsin. However this may be, it must be confessed that the petition has a Chinese ring about it, and that the method of argument is one sufficiently familiar to readers of the *Peking Gazette*. The mines are fortunately within Li Hung Chang's jurisdiction, and while they enjoy his encouragement it is unlikely that *fêng-shui* or other superstition will be allowed to interfere with them.

THE Chinese Customs authorities have, we observed, declined to assist the Chamber of Commerce of Shanghai in making a series of meteorological observations along the coast of China. We have already described the project in these columns. The reason of this refusal is unknown; but it is generally believed that Sir Robert Hart, the Inspector-General of Chinese Customs, intends establishing a special meteorological bureau in connection with his department. If Sir Robert can obtain the assistance of one of the very few men in the East competent for such a task, he may add one more to the many good services which the organisation over which he presides has done to China.

A SHARP earthquake shock, at first undulatory, then vertical, lasting seven seconds, was felt at Naples on Tuesday Morning at 6·47. The instruments on Mount Vesuvius gave warning. The centre of the disturbance proves to have been at Isernia, in the Abruzzi, according to the telegrams received since.

A *conversazione* in connection with the Royal Colonial Institute will be held at the South Kensington Museum on the evening of June 23.

THE Scientific Publishing Company announce that they have in the press "Photometry and Gas Analysis," by J. T. Brown, F.C.S., divided into three sections—Standards, in two chapters, Photometers, in eight chapters, and Gas Analysis, in two chapters. The Company also announce the publishing in handy form of the "Minutes of Evidence on Electric Lighting Bill, 1882," with text of the bill and a commentary upon the whole.

WE have received a sensible and interesting lecture on the Relations of Science to Modern Life, by the Rev. Dr. H. C. Potter, delivered before the New York Academy of Sciences; it is published by Putnam and Sons of New York.

WE have on our table the following books:—British Freshwater Algæ, II., Mr. C. Cooke (Williams and Norgate); Transactions of the Brighton Health Congress (J. Beal and Co., Brighton); Capital and Population, Fredk. B. Hawley (Appleton, New York); Hydrographical Surveying, Capt. W. G. L. Wharton (Murray); Logic for Children, A. J. Ellis, F.R.S. (C F. Hodgson); First Lessons in Geology, A. S. Packard (Providence, U.S.); Diagrams to First Lessons in Geology, A. S. Packard (Providence, U.S.); Anales de la Officina Meteorologica, vol. ii., B. A. Gould (Buenos Aires); Scientific Transactions of the Royal Dublin Society, vol. ii. series ii.; The Great Diamond Fields of the World, Edw. W. Streeter (Bell and Sons); A Flight to Mexico, J. J. Aubertin (Kegan Paul); Geological Survey of Canada, Report of Progress for 1879–80 (Dawson Brothers, Montreal); New Indian Lepidopterous Insects, F. Moore (Asiatic Society); Regenwaarkemingen in Nederlandsch Indie, 1881 (Batavia); Lohrmann's Mondcharten, J. A. Barth of Leipzig; The Land of the Bey, T. Wemyss Reid (Low and Co.); Catalogue of Fossil Foraminifera in the British Museum; Die Seefischerei an der Westkisten Schwedens, Gerhards. Yhlen (Norstedt und Soner, Stockholm); Botanicon Sinicum, E. Bretschneider (M. D. Trubner and Co.); Tabular View of the Geological Systems, Dr. Clement (Swan Sonnenschein); Report on Injurious Insects, E. A. Omerod (Swan Sonnenschein); Bibliographie Generale de l'Astronomie, vol. ii. (Brussels); Proceedings American Association, 2 parts; Colliery Ventilation, Alan Bagot (Kegan Paul); Report U.S. Geographical Surveys, vol. vii. Archæology (Washington); Report of the Metropolitan Board of Works, 1881; Botanical Atlas, parts 1 and 2, D. M'Alpine (W. and A. K. Johnston); Ancient Water Lines, D. Milne Home (Edinburgh, Douglas); Laboratory Guide, A. H. Church (Van Voorst); Wolf's Naturwissenschaftlich-Mathematisches Vade-Mecum; Madeira, its Scenery and how to see it, Ellen M. Taylor (Stanford); The Foundations of Mechanics, W. F. Browne (Griffin and Co.); Land Nationalisation, A. R. Wallace (Trübner and Co.).

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus erythræus*) from India, presented by Capt. E. B. Stephens, R.N.; a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by Miss R. M. Stanley; two Striped Hyænas (*Hyæna striata*) from India, presented by Mr. N. H. Beyts; a Cape Zorilla (*Ictonyx zorilla*) from Cape Colony, presented by Capt. Farmer, s.s. *Pretoria*; a Three-striped Paradoxure (*Paradoxurus trivirgatus*) from India, presented by Mr. R. A. Sterndale; a Puma (*Felis concolor*) from America, presented by Capt. J. Jellicoe, R.M. s.s. *Moselle*; an American Tantalus (*Tantalus loculator*) from Columbia, presented by Mr. H. B. Whitmarsh, R.M. s.s. *Moselle*; a Java Sparrow (*Padda oryzivora*) from Java, presented by Miss M. North; a Landrail (*Crex pratensis*), British, presented by Mr. A. Battiscombe; a White Pelican (*Pelecanus onocrotalus*) from North Africa, presented by Mr. C. G. Bolau; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, an Emu (*Dromæus novæhollandiæ*) from Australia, four Summer Ducks (*Aix sponsa*) from North America, three Brant Geese (*Bernicla brenta*), two Common Wigeons (*Mareca penelope*), a Common Buzzard (*Buteo vulgaris*), European, deposited; two Great Anteaters (*Myrmecophaga jubata*) from South America, a Negro Tamarin (*Midas ursulus*) from Guiana, a Purple Heron (*Ardea purpurea*) from Java, a Blue-crowned Hanging Parrakeet (*Loriculus galgulus*) from Malacca, two Rose-breasted Grosbeaks (*Hedymeles ludovicianus*) from North America, a Bell's Cinixys (*Cinixys belliana*) from Angola, purchased; a Red Deer (*Cervus elaphus*), born in the Gardens; two Herring Gulls (*Larus argentatus*), two Impeyan Pheasants (*Lophophorus impeyanus*), four Horned Tragopans (*Ceriornis satyra*), two Peacock Pheasants (*Polyplectron chinquis*), bred in the Gardens. The following species of insects have emerged in the Insect House during the past week—Silk Moths: *Actias selene*, *Attacus mylitta*, *Attacus cynthia*, *Telea polyphemus*; Butterflies: *Limenitis sibylla*, *Argynnis paphia*, *Lycæna iolas*; Moths: *Chærocampa elpenor*, *Sphinx pinastri*, *Sesia spheciformis*, *Sciapteron tabaniforme*, *Callimorpha dominula*.

OUR ASTRONOMICAL COLUMN

THE COMET (1882 *a*).—In a circular issued from Lord Crawford's Observatory on May 29, Dr. Copeland remarks that the spectrum of the nucleus of the present comet deserved the closest attention, as it showed "a sharp bright line coincident with D, as well as strong traces of other bright lines, resembling in appearance those seen in the spectra of γ Cassiopeiæ and allied stars." For some weeks the head had exhibited white light, which might be inherent in the comet or the reflected light of the sun; on May 28 the nucleus began to throw out yellow rays, which on June 1 were also given out by parts of the tail immediately behind the head. Of γ Cassiopeiæ, Secchi writing in 1877, says: "Le plus remarquable de ces étoiles exceptionelles est γ de Cassiopée, qui présente les raies spectrales de l'hydrogène, non pas noires, par renversement, mais directement brillantes, curiosité unique jusqu'ici dans tout le ciel. Il n'y a que β de la Lyre qui ait quelquefois les raies brillantes, et encore pas toujours, parce qu'elle est variable"; and he further writes of β Lyræ, "Elle nous a montré une fois, au maximum d'éclat, les raies brillantes de l'hydrogène, comme γ de Cassiopée, chose que nous n'avons plus vue ensuite, bien que nous l'ayons souvent cherchée."

The Radcliffe meridian observation of the comet on May 20, communicated by Mr. Stone last week, shows that the place calculated from the orbit we then published required only the following small corrections:—$\Delta\alpha . \cos\delta = -1''·8$ $\Delta\delta = +4''·0$.

The Kiel observation on May 31 indicates corrections of +4″ in R.A., and −19″ in declination.

The positions given last week for June 10 and 11 are not likely to require material correction. In seeking for the comet in daylight on those dates, care should be taken to focus accurately (for this purpose Mercury or Venus may be available), and a pretty long "dew-cap" or a cardboard tube should be fitted to take off the direct sunlight from the object-glass. At so short a distance from the sun, it will of course be necessary to use a dark glass, but it may be well that the illumination of the field should not be diminished much beyond that which the eye will readily bear. More than one astronomer considered he had missed seeing the first comet of 1847 in daylight on March 30, by using too dark a glass; this was the opinion of Dawes, who could not otherwise explain his want of success.

On August 9 the comet situated near the star 16 Virginis will have the same theoretical intensity of light as at the first Harvard College observations on March 19, setting in London about 1h. 50m. after the sun. On July 5, when not far from Regulus, the intensity of light is equal to that on May 6.

THE TRANSIT OF MERCURY, 1881, NOVEMBER 8.—This phenomenon was fully observed at Sydney, by Mr. H. C. Russell and seven assistants. The mean results are as follows, in Sydney, M.T.:—

	h.	m.	s.	
First contact—external	8	21	57·53	a.m.
,, —internal	8	23	40·65	a.m.
Last contact—internal	1	40	25·16	p.m.
,, —external	1	42	9·22	p.m.

If we calculate with Leverrier's Tables of the Sun and Mercury, and adopt his diameters, the above observations show differences for the internal contacts of +22·9s. and +26·2s. respectively.

THE SMALL PLANETS.—The number of known members in this group is now 225, the last one having been discovered by Palisa at Vienna on April 19. It appears to belong to the more distant division of the group, the period of revolution exceeding six years.

THE CORDOBA ZONES.—We have received vol. ii. of "Resultados del Observatorio Nacional Argentino en Córdoba," containing the observations of stars in zones, made during the year 1872, and shall give an early account of this important work, for which astronomy is indebted to Dr. Gould's untiring energy and zeal, and the enlightened liberality of the Argentine Government in promoting the interests of science.

CHEMICAL NOTES

IN the Chemical Section of the Meeting of Bohemian Naturalists in Prague, on May 27, B. Brauner (Fellow of The Owens College) communicated a paper on the atomic weight of didymium. The author's former determinations gave the number 146·6, but after further purification he finds now didymium to be 145·4. Both samples were entirely free from any known earth metal. Assuming that both numbers are true, the author remarks that the only explanation which can be given, is that "didymium" is a mixture of two (or more) bodies, one, whose atomic weight is *smaller* than 145·4, and a second, whose atomic weight is greater than 146·6. Thus it is clear that the chemistry of didymium becomes as complicated as that of "erbium," which was thought to be a simple earth, and later on was split up into the following earths, viz. real (1) erbia, (2) terbia, (3) scandia, (4) ytterbia, (4) thullia, and (6) holmia. The evidence, that the mineral cerite contains other earth metals besides cerium, lanthanum, and didymium, has been given by the author some time ago (*Monatshefte* iii. 1) when he found that the *spark-spectrum* of the portions *intermediate* between lanthanum and didymium, as well as of those between didymium and cerium, contains *new lines*, not belonging to any known cerite metal. The author is pursuing his researches in the laboratories of the Owens College.

ZIMMERMAN, who recently determined the densities of gaseous uranium tetrachloride, and bromide, has obtained pure metallic uranium, and made measurements of its specific heat, which completely confirm the number 240 as the atomic weight of this metal (*Berichte*, 15, 847).

J. W. Brühl, from the results of determinations of molecular refractions of many carbon compounds, concluded that the atomic refraction of carbon varies according as the atoms of carbon are tetravalent, divalent, or monovalent (singly, doubly, or trebly "linked"), in the molecule under consideration. In calculating molecular refractions, Brühl used the empirical expression $\frac{n - 1}{d} \cdot M$; Landolt has recently re-calculated the ratios of many molecular refractions by the use of the formula $\frac{n^2 - 1}{(n^2 + 2)d} \cdot M$, deduced by Lorenz from the theory of light; his results entirely confirm those arrived at by Brühl by the use of the empirical expression stated above

In their researches on ozone, MM. Chappuis and Hautefeuille have made use of the spectroscope to trace the progress of the chemical change which occurs when oxygen, or a mixture of oxygen and nitrogen, is subjected to the action of the electric discharge. They find that ozone is characterised by a distinct absorptive spectrum, the prominent bands in which are two in number situated in the neighbourhood of D. The same bands are promineut in the absorptive spectrum of liquid ozone.

MM. Chappuis and Hautefeuille also find that the amount of ozoue produced by the action of the electric discharge on a mixture of oxygen and nitrogen increases to a maximum, then decreases to a minimum, then again increases, and so on; by the aid of the spectroscopic method they trace this oscillation to the formation and decomposition of an oxide of nitrogen not hitherto observed, which they propose to call pernitric oxide (*acide pernitrique*) (*Compt. rend.*, xciv. 858 and 1111).

The *Journal* of the Society of Chemical Industry, the fourth number of which is now before us, promises to be of very great service to all who are interested in chemical manufactures. The present number of the journal contains papers read before the Society on "Smoke Abatement," "The Chemical Technology of Jute Fibre," "The loss of Sulphuric Acid in the Manufacture of Salt Cake," &c. Notes on the more important recent technical applications of chemistry and chemical physics, and very useful classified abstracts of recent patents complete the number.

In the last number of the *Berichte* of the German Chemical Society (xv. 1161) HH. v. Meyer and H. Goldschmidt describe an apparatus by means of which the specific gravities of gases may be determined at very high temperatures. The apparatus consists of a cylindrical porcelain tube 500 or 600 mm. in length, capacity about 100 c.c., furnished with a capillary tube of about 200 c.c. long at each end. The apparatus is heated, the air is driven out by an inert gas, *e.g.* by nitrogen, the gas whose specific gravity is required is allowed to enter the apparatus, and the weight of this gas is determined by driving it out, by means of an inert gas, into some liquid by which it is completely absorbed. The temperature may be calculated from the ratio between the volume of air contained in the apparatus under the conditions of the experiment and the volume contained at the ordinary temperature of the room. By the use of this apparatus the authors have determined that the density of cyanogen is normal (*i.e.* corresponds with the formula C_2N_2) between 100° and 800°, but that at 1200° this gas is decomposed with evolution of nitrogen.

PHYSICAL NOTES

A new method of comparing the brightness of different coloured lights has been proposed by Herr Brücke (*Wien. Ber.*, 84). He finds that objects cease to be visible at a greater visual angle, the more they differ from the background on which they are seen, only in colour and not in brightness. If a board be set up, which is black at one end and white at the other, with successive shades of grey between (a brightness-table), one may determine the brightness, *e.g.* of a coloured paper, by placing a piece of it before different parts of the board, and noting the place where, with shortest interval, it becomes invisible. This relation of brightness, in red and blue, varies much with the strength of illumination, so that each determination becomes invalid, where the illumination is considerably altered. Herr Brücke believes such a table might be useful in the colourless reproduction of paintings (drawings, copper-plate engravings, &c.). Further, he constructs a photometer, in which, instead of the brightness-table, he employs a variable illumination of the object to be distinguished from it.

The specific gravity of liquid steel has been determined by Herr Alexjeff, by a method proposed by Herr Petruschewsky (*J. d. Russ. Chem. Phys. Ber.*, 12). A porcelain tube, open at both ends, was connected at one end with a forcing pump and a manometer, while the other end was immersed in liquid steel to a given depth (the tube vertical). On pumping, bubbles appeared at the latter end; and the indication of the manometer at that moment, compared with the depth of immersion, served for determination of the relative density of the steel and the liquid (naphtha) used in the manometer. The specific gravity of liquid steel was thus found to be 8·05, and so, greater than that of solid steel.

According to Herr Antolik (*Wied. Ann.*, 3) very regular and pure Lichtenberg figures are obtained on spherical glass vessels filled with warm water at about 60° C. The surface can be made at will electrically positive or negative (which is not the case with ebonite or resin). Wires are inserted which are furnished with balls at their upper end. If positive electricity be introduced, electricity of that kind becomes free at the surface, and on dusting with Villarsy's mixture, a quite homogeneous sulphur layer is produced. Very regular discs appear on drawing sparks with the knuckles. A number of interesting effects are described by the author.

Prof. H. M. Paul has communicated to the Seismological Society of Japan some notes on the effect of railway trains in transmitting vibrations through the ground. A box holding about twenty pounds of mercury thickened by amalgamation with tin, was placed upon a heavy plank screwed to the top of a post sunk 4½ feet into the ground. Images reflected in the surface of the mercury were observed by a telescope, as in meridian observations. An express train passing at a distance of one-third of a mile, set the surface of the mercury in confused vibration for two or three minutes. Other observations were made at stations at somewhat greater distances. The experimenter also found that a one-horse vehicle passing along a gravelled road 400 or 500 feet distant, caused a temporary agitation of the mercury whenever the wheels struck a small stone.

An extremely valuable series of notes on physiological optics, from the pen of W. Le Conte Stevens, has lately appeared in the *American Journal of Science*: most of these relate to stereoscopic vision and the theory of the stereoscope. They are both too valuable and too full of matter to render full justice possible in a brief note.

A new form of refractometer, producing interference-bands and rings between two pencils of light which have traversed paths at right angles to each other, is described by Mr. A. A. Michelson in the *American Journal of Science*. In the path of a ray from a lamp, a piece of plane-parallel glass is interposed at 45°. The two pencils respectively reflected and refracted are then returned along their own paths by mirrors normal to each; and these returning rays unite at the point whence they parted, giving a resultant ray at right angles to the former path. The theory of this refractometer is deduced by Mr. Michelson, who devised this apparatus for use in his experiments to test the hypothesis of a relative velocity between the earth and the luminiferous æther.

M. Violle finds the temperature of fusion of zinc free from lead, cadmium, arsenic, and other impurities to be 929·6° (C.); the value previously found by Edm. Becquerel was 932°; that given by Sainte-Claire Deville and Troost being 1040°.

The rapidly-reversed currents generated in an ordinary Bell telephone do not sensibly affect the needle of a galvanometer even when the loudest tones are being sung into the instrument. Nevertheless M Chardonnet has made the curious and interesting observation that during the short period while the note is increasing or diminishing in intensity, a deviation of the needle is observed. The explanation advanced is that during the rise or fall in intensity the alternate currents are no longer of equal strength, the odd semi-oscillations being either greater or less in amplitude than the even semi-oscillations during the period of rise or fall.

Some interesting new pieces of acoustical apparatus have been recently described by Herr Hartmann (*Wied. Beibl.* No. 3). The *motorophone* shows the change of rotatory motion into sounding motion, and the dependence of the qualities of the tone on the nature of the motion. A rapidly-rotated shaft has an adjustable eccentric with jointed rod, which at each rotation pulls a large drum-skin to and fro. A bell-mouth strengthens and concentrates the tones. The velocity of rotation determines the pitch; the eccentricity the strength of the tones. The *phonomotor* acts on the opposite principle, rotatory motion being got from vibration. In the *electromagnetophone* a piece of sheet-iron under an electro magnet has a point dipping in mercury; a current passing through the coils and the point becomes readily intermittent, and the membrane sounds. The *electromagnetic membrane-siren* is similar, but a solid sliding contact takes the place of the mercury, and a driving-wheel gives rapid interruption. Again, a tuning-fork is supported so as to be capable of rotation before a resonance-case. According to position it gives a strong resonance or a weak interference tone, the latter slightly higher. On rotating, the former becomes lower, the latter higher, and the dissonance ever greater. A *resonance-interference-pipe* is formed by connecting a caoutchouc tube with the nodes of an open pipe. If the tube be shortened by pressure at different parts, the tone of the pipe is raised or lowered through resonance-interference, is extinguished, or lets only the first overtone be heard. These instruments are made by G. F. Weigle, in Stuttgart.

CONTINUING his researches on "adsorption," or condensation of gases on surfaces of solids, Herr Kayser (*Wied. Ann.* No. 4) has studied the influence of the adsorbing material. The pressure was determined, which occurred in the glass vessel when given volumes of gas had been in contact with the solid material. The gases were carbonic acid, sulphurous acid, and ammonia, and these were adsorbed in the empty glass vessel, by coarse glass powder, and by turnings of brass and wrought iron. The metal-turnings were quite clean and unoxidised, and before each experiment they were heated *in vacuo* to about 300°, to remove gas. It was found that pressure was greatest, and so adsorption least, in the empty vessel. The order of increasing adsorption was, in general: empty vessel, iron, brass, and glass powder. By the empty vessel, SO_2 was least condensed, CO_2 and NH_3 about equally. Also, on the metallic surfaces, SO_2 always gave greater pressure than NH_3; between CO_2 and SO_2 there was hardly any difference. By the glass surfaces, on the other hand, CO_2 was comparatively little condensed, NH_3 considerably, and SO_2 to a large extent.

THE behaviour of mercury when polarised in contact with dilute sulphuric acid (as in Lippmann's well-known experiments), and with other acids and salt solutions, has been studied by Herr König at the instance of Prof. Helmholtz (*Wied. Ann.*, No. 5). The surface-tension, it is shown, reaches a maximum at a mean state of polarisation different for different liquids; the values diminishing on either side, as one removes from this, and both with positive and negative charges. Prof. Helmholtz offers some comments by way of theory on the phenomena.

FROM experiments at Würzburg (*Wied. Ann.*, No. 5), Mr. William Hallock infers the correctness of the view that the changes of electromotive force of the Smee element are due to action of polarisation. The electromotive force of polarisation is by no means independent (he affirms) of the nature of the electrodes, and it considerably exceeds that necessary for visible decomposition. The polarisation cannot be calculated from the heat phenomena.

To find whether the two coefficients used in equations of motion of incompressible liquids—one of viscosity, the other of variable adherence of the liquid to the walls—are independent of velocity, M. Elie (*Journ. de Phys.*, May) rotates a solid sphere within another filled with liquid, and hung bifilarly. The smaller sphere (0·04 m. diameter) is supported by a metallic wire passing through an aperture in the larger (0·12 m.) between the suspending wires to the vertical axis of an electric rotatory apparatus. During rotation (2 to 10 turns in a second) the hollow sphere is displaced to an amount indicated by a reflected light spot, and stops when the moment of the bifilar suspension balances that due to friction. In all the experiments with water, the reactions due to friction were found to increase more rapidly than the velocity; the ratio increased a third when the velocity was doubled; hence it appears that the viscosity or adherence, or both together, increase with the velocity.

THE name of *rheolyser* has been given by Prof. Wartmann to an apparatus (described in the *Archives des Sciences* for May) whereby the intensity of a derived electric current may be rapidly varied from zero to a maximum, and which indicates exactly the relation of those variations. A graduated metallic ring round a tripod-supported column encloses a thick disc of glass or ebonite, resting on the six radii of the ring. In the upper surface of the disc is a circular trough of mercury receiving two copper electrodes at the bottom, at a semicircle of interval. A cross-bar on the top of the column, on which it turns as axis, acts as a movable Wheatstone-bridge; it has two terminal verniers, and two screws dipping in the mercury; these latter are insulated, but communicate, through central binding screws, with a mirror galvanometer. The intensity of the derived current varies according as the bridge is displaced.

GEOGRAPHICAL NOTES

THE last work by Dr. E. Regel, on the Flora of Central Asia, which has recently appeared in the "Acta Horti Petropolitani" (vol. vii.), gives to Prof. Rehring, of Berlin, the opportunity of discussing the relations between the present flora and fauna of the North-eastern Asiatic Steppes, and the Post-glacial flora and fauna of Middle Europe. Prof. Regel, on the ground of his researches in Asia, arrived at the conclusion that out of the species which inhabited Central Asia during post-glacial times, very few have migrated towards north-western Asia and to Europe, and that the species now inhabiting this part of Asia have probably immigrated from Europe. The same was the conclusion arrived at several years ago by Dr. Rehring, when he and Dr. Liebe discovered in the Diluvium of Germany (at Westregeln and at Gera), a steppe-fauna much akin to the West Siberian (*Dipus jaculus*, *Arctomys bobac*, *Spermophilus altaicus*, *Lagomys pusillus*, *Equus caballus*, &c.), which facts led him to the inference that in post-glacial times middle Germany enjoyed a steppe vegetation and climate. The same steppe fauna has since been discovered at many other places in Germany, so that it may be said that the German diluvium encloses an unmistakable steppe fauna. Dr. Rehring discovers in Dr. Regel's work new proofs in favour of his theory of migration of the diluvial fauna from Europe to Asia, in opposition to the theory of the late Dr. Brandt, who considered North-western Asia as the true fatherland of the European diluvial fauna. We may observe that Dr. Rehring's theory would imply the migration of the German steppe fauna, not only to North-western Siberia, but also to Eastern Siberia, during the post-glacial period, which would involve several important difficulties. We believe that a true theory of the migrations of post-glacial faunas can be established only by taking into account the history of the glacial period in Asia, which history has never investigated.

DISCUSSING the character of the Glacial period on the Caucasus, M. Moushketoff points out (*Izvestia*, vol. xviii. fasc. 2), those features which are common to the former glaciers of the Caucasus, and those of the Zerafshan in Central Asia. He observes the present comparatively small extent of glaciers and snow-fields in both countries. The area now covered with perpetual snow on the Caucasus is very small (250 square kilometres) compared with the extent of the same regions in the Alps (more than 3000 square kilometres). The same relations—M. Moushketoff says—must have existed to some extent between both countries during the Glacial period, because of the greater dryness of climate on the Caucasus, and still more in Central Asia, in comparison with Western Europe. He concludes, in accordance with M. Abich and many others, that the ancient glaciers of the Caucasus had a far greater extension than the present ones (for instance, those of the Elbrouz reached, at least, down to 5200 feet, and the Baskan glacier united into one single mass all the present small glaciers which do not now descend lower than 6600 to 8600 feet). Nevertheless the glaciation was not so general as in Western Europe. This conclusion only must be provisional, the traces of the Glacial period having not yet been the subject of a thorough exploration, either on Caucasus or in Turkestan, whilst the obliteration of these traces has been far more complete in both these countries than in Europe. Taken in its widest sense, the supposition that the glaciation has been less intense in Middle Asia than in Europe seems very probable, and has been arrived at also by other explorers of Turkestan and Siberia.

BESIDES the Annual Address of the President, Lord Aberdare, reviewing the geographical progress of the year, the June number of the *Proceedings* of the Royal Geographical Society contains Mr. O'Donovan's paper on Merv; M. de Gorloff's account of his journey in the Atlas and the Northern part of the Algerian Sahara; the Rev. Thos. Wakefield's fourth journey to the Southern Galla country; and Capt. Paiva de Andrada's Zambesi Expedition, 1881. We learn that the Search Expedition for Mr. Leigh Smith is now organised, and will be commanded by Sir Allen Young. The expedition will leave this month.

FROM a letter of Consul H. E. O'Neill in the June number of the Geographical Society's *Proceedings*, it would seem that the "snow-clad Irati" spoken of by Messrs. Maples and Goldfinch as reported to exist in the country south-east of Lake Nyassa, is probably a delusion. Mr. O'Neill was close to the mountain, which he estimates at not more than between 5000 to 6000 feet above the sea.

MISS ELLEN M. TAYLOR has compiled a very useful guide-book to Madeira, under the title of "Madeira: its Scenery, and How to See It" (Stanford). She gives the very kind of information intending visitors are likely to want, and the possession of which will save them much trouble. While Miss Taylor draws largely on existing authorities, she also gives the results of her own experience. Her list of trees, flowers, ferns, and seaweeds will be useful to the amateur naturalist.

THE first paper in the June number of *Petermann's Mittheilungen* is on M. Charnay's expedition to the ruins in Central America, by Herr Fred. Kofler. Dr. Hermann J. Klein has an article of much interest on "Some Volcanic Formations in the Moon," in which he suggests that the lunar surface ought to be carefully examined by geologists, in order to discover the exact condition of things as compared with terrestrial geology. There is a short account of Oschanin's exploration of Karategin in 1878, and a very useful paper by Herr B. Hassenstein, on the geographical and cartographical literature of the Indo-Chinese border-lands, with a map of the Tibetan and Indo-Chinese border-region.

THE last number of the *Izvestia* of the Russian Geographical Society (vol. xviii. fasc 2), contains a good many valuable papers. We notice among them the preliminary report on the geological exploration of the former beds of the Amu-daria, by A. E. Hedroitz; a paper by M. Mousketoff on his geological exploration of the Caucasus; a description of an excursion to Seraks, by P. M. Lessar, with a map of the route between Askabad and Seraks; a notice by A. Regel of his journey to the Karategin and Darvaz, dated Kala-i-Khumb, with a map; on the sands of Ferghana, by M. W. Malakhoff, and a variety of small notices. We are glad to learn that the *Izvestia* will have a special department, "Polar News," devoted to all that concerns the exploration of Polar regions; it will be under the direction of Baron Wrangel.

WE learn from the *Izvestia* of the Russian Geographical Society that Dr. A. E. Regel has returned from his journey to Karategin and Darvaz to Samarkand, and is preparing for a new journey to the Pamir.

PROF. NORDENSKJÖLD has telegraphed to the Mayors of Tromsö, Hammerfest, and Vardö, on behalf of Herr Oscar Dickson, of Gothenburg, asking them to acquaint skippers leaving for the Arctic Sea, with the rewards offered by Herr Dickson for the Discovery of the *Eira*, viz. 225*l*. to be paid to the one who may first relieve Mr. Leigh Smith or any of his companions; 140*l*. to the one who may first discover and give information in writing of the crew of the *Eira*, of a later date than November 1 last, 56*l*. for the first information, by telegraph, addressed to Herr Oscar Dickson, that any one of the crew of the *Eira* has been found, or a letter from either of a later date than that of November 1 last.

THE German Antarctic expedition, consisting of Dr. Schrader and six companions, have sailed by the Hamburg mail steamer for Monte Video, thence by Imperial corvette to the island of South Georgia, to establish a scientific station for meteorological observations. They will remain twelve months.

AT the last meeting (May 30) of the Russian Geographical Society, the Secretary said that a telegram received from Irkutsk announces the possibility of establishing seven new meteorological stations in the far north, namely, at Verkhoyansk, Orlensk, Witimsk, Olekminsk, Kirensk, Nokhtuisk, and Preobrajensk, besides the station already established at the mouth of the Lena. The necessary instruments will be forwarded immediately by the Central Meteorological Observatory. At the same meeting, M. Rykatcheff made a communication on tides in the atmosphere. He proved the correctness of the theory of Laplace with regard to atmospherical tides by the discussion of a very great number of anemometrical observations.

PROF. LENSTRÖM, Secretary of the Meteorological Commission of the Society of Science in Finland, anxious that Finland may participate in the Circumpolar observations, has offered to erect a station at Sodankylä (67° 20′ N., 26° 40′ E.), which proposition has been accepted by the President of the International Congress, Dr. H. Wild, of St. Petersburg.

THE ROYAL OBSERVATORY

THE annual visitation of the Royal Observatory took place on Saturday, when the Astronomer-Royal, Mr. W. H. M. Christie, presented his report.

"The Report," Mr. Christie states, "here presented, refers to the period of twelve months, ending May 20, 1882, a fixed date being taken, conveniently near to the visitation day. Sir G. B. Airy resigned his office on August 15, 1880, and a portion of the observations here referred to were made under his superintendence. There seems to be no occasion to separate these from the remainder, as the course of observation which Sir G. B. Airy has carried out for so many years has been continued without essential alteration in its main features."

Of the Transit of Venus instruments the Report states, two transits, three altazimuths, five 6-inch equatoreals, two photoheliograph mountings, nine clocks, and one Transit of Venus model have been sent to Mr. Stone at Oxford for use in the forthcoming Transit of Venus, and three transits, an altazimuth, a photoheliograph, and two clocks are at the Cape of Good Hope, where they will be available for the Transit of Venus.

A series of pendulum observations was made in the record room last autumn by Major Herschel, R.E.

After giving details as to the usual astronomical observations, the altazimuth, and other matters, Mr. Christie goes on to speak of the spectroscopic and photographic observations:—

"During the twelve months ending May 20, 1882, the sun's chromosphere has been examined with the half-prism spectroscope on 36 days, and on every occasion prominences were seen. On one day a detailed examination of the whole spectrum of the chromosphere was made at 24 points on the sun's limb. Several prominences have shown great changes in the course of two or three minutes, and large displacements or contortions of the bright lines, indicating very rapid motions of approach or recession have been noted. In particular, a prominence examined on May 13, 1882, was observed to rise through a space of about 30′ in less than two minutes, being at the rate of about 110 miles a second, whilst the C line showed a displacement towards the red gradually increasing from $1\frac{1}{4}$ to 11·4 tenth metres, corresponding to a motion of recession increasing in two minutes from 36 to 330 miles a second. Thirteen sun-spots have been examined on 20 days with reference to the broadening of the lines in their spectra. The strong black lines or bands in the part of the spectrum between *b* and F, first noticed in the spectrum of a spot on November 27, 1880, have been generally observed to be present in the spectra of spots during the last twelve months, besides several fine lines in the same region of the spectrum to which there is nothing corresponding in the solar spectrum. For the determination of motions of stars in the line of sight, 177 measures have been made of the displacement of the F line in the spectra of 41 stars, 68 of the b_1 line in 19 stars, and 9 of the b_4 line in 5 stars. Of the 61 stars observed, 15 had not previously been examined, and the total number of stars of which the motions have been spectroscopically determined, is now 106. In the case of three of the stars observed in the last year, a dispersive power equivalent to that given by sixteen prisms of 60° has been used. A comparison of the successive determinations of the motion of Sirius indicates a progressive diminution from about 22 miles a second in 1877 and 1878, to about 7 miles a second or less this year, and as other stars do not show anything similar, it appears likely that the change is due to the orbital motion of Sirius. Further observations will, however, be required to settle the point. The spectrum of Comet *b* 1881, was examined on six nights, that of Comet *e* 1881, on three nights, and that of Comet *a* 1882, on three nights. The spectra of the first two objects showed the usual cometary bands corresponding to those of the first spectrum of carbon, and a continuous spectrum from the nucleus and brighter portions of the head. Comet *a* 1882, has hitherto shown only a continuous spectrum with two irregular ill-defined maxima of light. The observations of this comet are being continued."

In the year ending May 20, 1882, photographs of the sun have been taken on 200 days, and of these 352 have been selected for preservation. Since the end of last August photographs have been taken on Sundays as well as on week days. There were only 2 days out of 200 on which the sun's disk was observed to be free from spots. There has been a large increase in the number and size of spots and faculæ, the mean of the daily areas for each in 1881 being nearly double of the corresponding quantities for 1880, and the increase is still continuing, though with well-marked fluctuations. A very remarkable outbreak of spots occurred in April last.

With regard to magnetical observations the report states that no important change has been made in the three magnetometers with which the changes in the magnetic declination, horizontal force, and vertical force are continuously recorded by photography.

"The large temperature correction for the vertical force magnet has made it impracticable to discuss satisfactorily the diurnal inequality of vertical force and its dependence on solar activity, notwithstanding the great care taken to keep the magnetic basement at as nearly uniform a temperature as possible. After giving details as to rearrangements of the earth-current apparatus, the report states that "on four days during the year, viz., September 12 and 13 and April 16 and 19, magnetic storms have occurred. Those of April were of more marked character than any that have taken place since the great storms of the year 1872, and it is a significant fact that exceptionally large spots made their appearance on the sun shortly before, viz., on April 11 and 17. Smaller magnetic movements are now also much more frequent, the traces exhibiting a marked contrast to their general appearance some two or three years ago. In regard to the long period variation of about 11 years, we are able now to say definitely that the minimum as regards diurnal range of declination occurred at the commencement of 1879, whilst as regards diurnal range of horizontal force, it occurred unmistakeably earlier, about August, 1878. Since the epochs mentioned, each element has, with small fluctuations, continued regularly to increase again in magnitude, the daily range of declination having increased from 6′·59 at the beginning of 1879 to 9′·15 in 1881, and that of horizontal force from ·00110 (in parts of the whole H.F.) in 1878 to ·00181 in 1881. We have frequent applications from mining surveyors for the values of the magnetic elements, and recently the wish has been expressed that information as to the diurnal inequality and particulars of magnetic storms observed here should be communicated from time to time to the *Colliery Guardian* newspaper, in order that mining surveys may be carried out with due allowance for the diurnal and other motions of the magnetic needle."

Under the heading of Meteorology, the Report states that "the mean temperature of the year 1881 was 48°·7, being 0°·6 lower than the average of the preceding 40 years. The highest air temperature was 97°·1 on July 15, and the lowest 12°·7 on January 17. The mean temperature was below the average, 6°·7 in January and 4°·8 in October, and above the average, 5°·9 in November. In other months the temperature in general differed little from the average. On four days in July the temperature rose above 90°. The mean daily motion of the air in 1881 was 291 miles, being 12 miles greater than the average. In January and September the mean daily motion was 70 miles and 72 miles below the average respectively. In April, August, and November it was 70 miles, 60 miles, and 71 miles above the average respectively. The greatest daily motion was 999 miles on October 14, the day of the great storm, and the least, 59 miles on May 25. A velocity of 61 miles an hour was recorded on October 14, and one of 58 miles an hour on April 29, these being both greater than any recorded in previous years. The greatest pressure was 53 lbs. on the square foot on October 14; pressures of 46, 47, and 48 lbs. were also registered during the same gale. On April 29 a pressure of 49½ lbs. was recorded at a time when the hourly velocity was 50 miles; the pressures corresponding to the maximum velocity of 58 miles an hour were not registered, the cord of the pressure pencil having slipped off the pulley."

"The volume of Greenwich Observations for 1879 was printed and distributed last autumn, and the volume for 1880 was passed for press in the middle of April. The copies are now in the binder's hands. As regards the volume for 1881, the transits are printed to May 19, meridian zenith distances to April 27, azimuths with the altazimuth to March 31, and zenith distances to June 2."

"The number of chronometers now being tested at the Observatory is 214, 168 of which (120 box-chronometers, 23 pocket-chronometers, and 25 deck-watches) belong to the Government, and are being rated after repair previous to being issued to the navy. The remaining 46 are placed here for the annual competitive trial, and of these 18 are fitted with Airy's supplementary compensation. In addition to the above, 6 chronometers have been placed on trial for the Mauritius Observatory, and 5 chronometers have been tested for the Japanese Government.

"There has been only one case of accidental failure in the automatic drop of the Greenwich time-ball. On four days the ball was not raised, on account of the violence of the wind. The Deal ball has been dropped automatically at 1h. on every day throughout the year, with the exception of 15 days, on which there was either failure in the telegraphic connection, or interruption from telegraph signals continuing up to 1h., and of one day when the current was too weak to release the trigger without the attendant's assistance. On 3 days, high winds made it imprudent to raise the ball. The Westminster clock has continued to perform well, its errors having been under 1s. on 40 per cent. of the days of observation, between 1s. and 2s. on 44 per cent., between 2s. and 3s. on 14 per cent., and between 3s. and 4s. on 2 per cent. Time-signals, originating in the Observatory, are distributed at 10 a.m. and 1 p.m. to all parts of the country by the Post Office telegraphs."

Mr. Christie concludes his Report by referring to some new arrangements for calculations and observations, which will greatly economise the time and labour of the staff. The staff, indeed, seems inadequate to the constantly increasing work. With reference to spectroscopic observation, for example, Mr. Christie says:—"With only one assistant available for observations, we can barely do half of the work which we have undertaken in deference to a widely-expressed wish, and we are continually forced to make a choice between observations with conflicting claims on our attention. As regards solar photography, the value of our results would be very greatly increased if the gaps in the Greenwich series were filled up by the help of the photographs taken in India and elsewhere under the auspices of the Solar Physics Committee, so that the areas and positions of sun-spots and faculæ should be given for every day. I am in communication with the Committee on this matter, and am in hopes that the saving of labour recently effected in our photographic reductions will enable us to undertake the work with our existing staff."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The honorary degree of D.C.L. will be conferred at the approaching Encænia upon the following among other distinguished persons:—Baron Nordenskjöld, Dr. Allen Thomson, and M. Pasteur.

CAMBRIDGE.—The election of a Professor of Animal Morphology took place on May 31, when Mr. Francis Maitland Balfour, M.A., F.R.S., Fellow of Trinity College, was by an unanimous vote of the members of the electoral roll selected to fill the newly-established chair. The professorship was established by a grace of the Senate passed on May 11 by virtue of the provisions of the University Statute for the establishment of additional professors. The stipend attached to the chair is 300*l*. per annum, and it is provided the professorship shall terminate with the tenure of office of the professor first elected unless the University shall decide that the professorship shall be continued. The Council of the Senate in their report recommending the foundation of the professorship laid stress on the fact that the teaching of biology in Cambridge had lately been most successful and had rapidly developed. The classes are now so large that the accommodation provided a few years ago had already become insufficient. It was well known that one branch of this teaching—viz. that of animal morphology, had been created in Cambridge by the efforts of Mr. F. M. Balfour, and that it had grown to its present importance through his ability as a teacher and his scientific reputation. The service to the interests of Natural Science thus rendered by Mr. Balfour having been so far generously given without any adequate academical recognition, the benefit of its continuance was entirely unsecured to the University, and the progress of the department under Mr. Balfour's direction remained liable to sudden check. Upon this representation the Senate unanimously concurred in the report of the Council and established the professorship.

EDINBURGH.—Dr. James Geikie, F.R.S., has been appointed to the Murchison Chair of Geology and Mineralogy in succession to Prof. Archibald Geikie, Director of the Geological Survey. Dr. Geikie will not enter upon the duties of his class till November next.

DR. P. PHILLIPS BEDSON, F.C.S., Demonstrator and assistant Lecturer on Chemistry in the Victoria University, Owens College, has been elected to the Professorship of Chemistry in the Durham University College of Physical Science, Newcastle-on-Tyne.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 25.—"On the Cause of the Light Border frequently noticed in Photographs just outside the Outline of a Dark Body seen against the Sky; with some Introductory Remarks on Phosphorescence." By Prof. G. G. Stokes, Sec. R.S.

An observation I made the other day with solar phosphori, though not involving anything new in principle, suggested to me an explanation of the above phenomenon which seems to me very likely to be the true one. On inquiring from Capt. Abney whether it had already been explained, he wrote: "The usual explanation of the phenomenon you describe is that the silver solution on the part of the plate on which the dark objects fall has nowhere to deposit, and hence the metallic silver is deposited to the nearest part strongly acted upon by light." As this explanation seems to me to involve some difficulties, I venture to offer another.

1. I will first mention the suggestive experiment, which is not wholly uninteresting on its own account, as affording a pretty illustration of what is already known, and furnishing an easy and rapid mode of determining in a rough way the character of the absorption of media for rays of low refrangibility.

The sun's light is reflected horizontally into a darkened room, and passed through a lens,[1] of considerable aperture for its focal length. A phosphorus is taken, suppose sulphide of calcium giving out a deep blue light,[2] and a position chosen for it which may be varied at pleasure, but which I will suppose to be nearer to the lens than its principal focus, at a place where a section of the pencil passing through the lens by a plane perpendicular to its axis shows the caustic surface well developed. A screen is then placed to intercept the pencil passing through the lens, and the phosphorus is exposed to sunlight or diffuse daylight, so as to be uniformly luminous, and is then placed in position; the screen is then removed for a very short time and then replaced, and the effect on the phosphorus is observed.

Under the circumstances described there is seen a circular disk of blue light, much brighter than the general ground, where the excitement of the phosphorus has been refreshed. This is separated by a dark halo from the general ground, which shines by virtue of the original excitement, not having been touched by the rays which came through the lens.

2. The halo is due to the action of the less refrangible rays, which, as is well known, discharge the phosphorescence. Their first effect, as is also known, is, however, to cause the phosphorus to give out light; and if the exposure were very brief, or else the intensity of the discharging rays were sufficiently reduced, the part where they acted was seen to glow with a greenish light, which faded much more rapidly than the deep blue, so that after a short time it became relatively dark.

3. This change of colour of the phosphorescent light can hardly fail to have been noticed, but I have not seen mention of it. In this respect the effect of the admission of the discharging rays is quite different from that of warming the phosphorus, which, as is known, causes the phosphorus to be brighter for a time, and then to cease phosphorescing till it is excited afresh. The difference is one which it seems important to bear in mind in relation to theory. Warming the phosphorus seems to set the molecules more free to execute vibrations of the same character as those produced by the action of the rays of high refrangibility. But the action of the discharging rays changes the character of the molecular vibrations, converting them into others having on the whole a lower refrangibility, and being much less lasting.

4. Accordingly when the phosphorus is acted on simultaneously by light containing rays of various refrangibilities, the tint of the resulting phosphorescence, and its more or less lasting character, depend materially upon the proportion between the exciting and discharging rays emanating from the source of light. Thus daylight gives a bluer and more lasting phosphorescence than gaslight or lamplight. I took a tablet which had been exposed to the evening light, and had got rather faint, and, covering half of it with a book, I exposed the other half to gaslight. On carrying it into the dark, the freshly exposed half was seen to be much the brighter, the light being, however, whitish, but after some considerable time the unexposed half was the brighter of the two.

Again, on exposing a tablet, in one part covered with a glass vessel containing a solution of ammonio-sulphate of copper, to the radiation from a gas flame, the covered part was seen to be decidedly bluer than the rest, the phosphorescence of which was whitish. The former part, usually brighter at first than the rest, was sure to be so after a very little time. The reason of this is plain after what precedes.

A solution of chromate of potash is particularly well suited for a ray filter when the object is to discharge the phosphorescence of sulphide of calcium. When it stops the exciting rays, it is transparent for nearly the whole of the discharging rays. The phosphorescence is accordingly a good deal more quickly discharged under such a solution than under red glass, which, along with the exciting rays, absorbs also a much larger proportion than the chromate of the discharging rays.

5. I will mention only one instance of the application of this arrangement to the study of absorption. On placing before excited sulphide of calcium a plate of ebonite given me by Mr. Preece as a specimen of the transparent kind for certain rays of low refrangibility, and then removing the intercepting screen from the lens, the transmission of a radiation through the ebonite was immediately shown by the production of the greenish light above-mentioned. Of course, after a sufficient time the part acted on became dark.

6. I will mention two more observations, as leading on to the explanation of the photographic phenomenon which I have to suggest.

In a dark room, an image of the flame of a paraffin lamp was thrown by a lens on to a phosphorescent tablet. On intercepting the incident rays after no great exposure of the tablet, the place of the image was naturally seen to be luminous, with a bluish light. On forming in a similar manner an image of an aperture in the window shutter, illuminated by the light of an overcast sky reflected horizontally by a looking-glass outside, this image of course was luminous; it was brighter than the other. On now allowing both lights to act simultaneously on the tablet, the image of the flame being arranged to fall in the middle of the larger image of the aperture, and after a suitable exposure cutting off both lights simultaneously, the place of the image of the aperture on which the image of the lamp had fallen was seen to be *less* luminous than the remainder, which had been excited by daylight alone. The reason is plain. The proportion of rays of lower to rays of higher refrangibility is much greater in lamplight than in the light of the sky; so that the addition of the lamplight did more harm by the action of the discharging rays which it contained on the phosphorescence produced by the daylight, than it could do good by its own contribution to the phosphorescence.

7. The other observation was as follows:—The same tablet was laid horizontally on a lawn on a bright day towards evening, when the sun was moderately low, and a pole was stuck in the grass in front of it, so as to cast a shadow on the tablet. After a brief exposure, the tablet was covered with a dark cloth, and carried into a dark room for examination.

It was found that the place of the *shadow* was *brighter* than the general ground, and also a deeper blue. For a short distance on both sides of the shadow the phosphorescenco was a little feebler than at a greater distance.

This shows that, though the direct rays of the sun by themselves alone would have strongly excited the phosphorus, yet

---

[1] The lens actually used was one of crown glass which I happened to have; a lens of flint glass would have been better, as giving more separation of the caustic surfaces for the different colours.

[2] The experiments were actually made, partly with a tablet painted with Balmain's luminous paint, partly with sulphide of calcium and other phosphori in powder.

acting along with the diffused light from all parts of the sky, they did more harm than good. They behaved, in fact, like the rays from the lamp in the experiment of Section 6. The slightly inferior luminosity of the parts to some little distance on both sides of that on which the shadow fell, shows that the loss of the diffuse light corresponding to the portion of the sky cut off by the pole was quite sensible when that portion lay very near the sun.

All this falls in very well with what we know of the nature of the direct sunlight and the light from the sky. In passing through the atmosphere, the direct rays of the sun get obstructed by very minute particles of dust, globules of water forming a haze too tenuous to be noticed, &c. The veil is virtually coarser for blue than for red light, so that in the unimpeded light the proportion of the rays of low to those of high refrangibility goes on continually increasing, the effect by the time the rays reach the earth increasing as the sun gets lower, and has accordingly a greater stretch of air to get through. Of the light falling upon the obstructing particles, a portion might be absorbed in the case of particles of very opaque substances, but usually there would be little loss this way, and the greater part would be diffused by reflection and diffraction. This diffused light, in which there is a predominance of the rays of higher refrangibility, would naturally be strongest in directions not very far from that of the direct light; and the loss accordingly of a portion of it where it is strongest, in consequence of interception by the pole in front of the tablet, accounts for the fact that the borders of the place of the shadow were seen to be a little less luminous that the parts at a distance.

8. The observations on phosphorescence just described have now prepared the way for the explanation I have to suggest of the photographic phenomenon.

It is known, that with certain preparations, if a plate be exposed for a very short time to diffuse daylight, and be then exposed to a pure spectrum in a dark room, on subsequently developing the image it is found, that while the more refrangible rays have acted positively, that is, in the manner of light in general, a certain portion of the less refrangible have acted in an opposite way, having undone the action of the diffuse daylight to which the plate was exposed in the first instance.

It appears then that in photography, as in phosphorescence, there may in certain cases be an antagonistic action between the more and less refrangible rays, so that it stands to reason that the withdrawal of the latter might promote the effect of the former.

Now the objective of a photographic camera is ordinarily chemically corrected; that is to say, the minimnm focal length is made to lie, not in the brightest part of the spectrum, as in a telescope, but in the part which has strongest chemical action. What this is, depends more or less on the particular substance acted on; but taking the preparations most usually employed, it may be said to lie about the indigo or violet. Such an objective would be much under-corrected for the red, which accordingly would be much out of focus, and the ultra-red still more so.

When such a camera is directed to a uniform bright object, such as a portion of overcast sky, the proportion of the rays of different refrangibilities to one another is just the same as if all the colours were in focus together; but it is otherwise near the edge of a dark object on a light ground. As regards the rays in focus, there is a sharp transition from light to dark; but as regards rays out of focus, the transition from light to dark, though rapid, is continuous. It is, of course, more nearly abrupt the more nearly the rays are in focus. Just at the outline of the object there would be half illumination as regards the rays out of focus. On receding from the outline on the bright side, the illumination would go on increasing, until on getting to a distance equal to the radius of the circle of diffusion (from being out of focus) of the particular colour under consideration, the full intensity would be reached. Suppose, now, that on the sensitive plate the rays of low refrangibility tend to oppose the action of those of high refrangibility, or say act negatively, then just outside the outline the active rays, being sharply in focus, are in full force, but the negative rays have not yet acquired their full intensity. At an equal distance from the outline on the dark side, the positive rays are absent, and the negative rays have nothing to oppose, and therefore simply do nothing.

9. I am well aware that this explanation has need of being confronted with experiment. But not being myself used to photographic manipulation, I was unwilling to spend time in attempting to do what could so much better be done by others. I will, therefore, merely indicate briefly what the theory would lead us to expect.

We might expect, therefore, that the formation of the fringe of extra brightness would depend :—

(1) Very materially upon the chemical preparation employed. Those which most strongly exhibit the negative effect on exposure to a spectrum after a brief exposure to diffuse light might be expected to show it most strongly.

(2) Upon the character of the light. If the light of the bright ground be somewhat yellowish, indicating a deficiency in the more refrangible rays, the antagonistic effect would seem likely to be more strongly developed, and, therefore, the phenomenon might be expected to be more pronounced.

(3) To a certain extent on the correction of the objective of the camera. An objective which was strictly chemically corrected might be expected to show the effect better thaa one in which the chemical and optical foci were made to coincide, and much better than one which was corrected for the visual rays.

It is needless to say that on any theory the light must not be too bright, or the exposure too long; for we cannot have the exhibition (in the positive) of a brighter border to a ground which is white already.

P.S.—Before presenting the above paper to the Royal Society I submitted it to Capt. Abney, as one of the highest authorities in scientific photography, asking whether he knew of anything to disprove the suggested explanation. He replied that he thought the explanation a possible one, encouraged me to present the paper, and kindly expressed the intention of submitting the question to the test of experiment.

Linnean Society, May 24.—Auniversary Meeting.—Sir John Lubbock, Bart., F.R.S., president, in the chair.—Mr. H. T. Stainton, on behalf of the Audit Committee, read the statement of receipts and payments for the year, and the Treasurer, Mr. Frank Crisp, followed with a detailed explanation of the various items, showing that the Society was in a very sound financial condition; besides investments of about 4000*l.*, the balance at bankers' being 649*l.* 2*s.* 5*d.* Afterwards the secretary, Mr. B. D. Jackson, read his annual report. Since the last auniversary, fifteen Fellows of the Society, 2 Foreign Members, and 1 Associate, had died, and 7 Fellows had withdrawn; while 40 new Fellows had been elected. Between purchase, exchange, and donations, 383 vols. and 348 separate parts had been added to the Library.—The President then delivered his anniversary address, commenting generally on the events of the past year with especial reference to their bearing upon the Society; he also made allusions to the removal of the Botanical Department of the British Museum to South Kensington, and to the additions of Miss North's oil paintings, &c., to Kew Gardens; this was followed by reports on the various botanical and zoological publications published during the last twelvemonth. The obituary notices of deceased Fellows was read by the Secretary, the Society having to deplore the loss of Charles Darwin, Professor Rolleston, Sir C. Wyville Thomson, and their late treasurer, Mr. Frederick Currey, who had been in office above twenty years. The scrutineers having examined the ballot, then reported that Mr. H. W. Bates. T. S. Cobbold, Prof. P. M. Duncan, E. M. Holmes, and Sir J. D. Hooker had been elected into the Council, in the room of Prof. Allman, Rev. J. M. Crombie, W. S. Dallas, A. Grote, and Prof. Lankester, who retired; and for officers, Sir J. Lubbock as president, Frank Crisp as treasurer, and B. D. Jackson and G. J. Romanes.

MANCHESTER

Literary and Philosophical Society, March 13.—Alfred Brothers, F.R.A.S., in the chair.—Mr. Marcus M. Hartog, F.L.S., made a communication upon water-fleas.—On *Cypræa guttata* (Gmel.), by J. Cosmo Melvill, F.L.S.—Lepidoptera of the Shetland Islands, by Hastings C. Dent, C.E.—Notes on the Giant Dragon's-blood tree at Orotava, by Mr. John Plant, F.G.S.—Mr. R. D. Darbishire, B.A., F.G.S., exhibited a fine series of Ceylonese land and freshwater shells, procured through the instrumentality of Mr. M. M. Hartog, F.L.S.

April 17.—Annual Meeting.—Mr. Boyd remarked upon the discovery of the egg-cases of *Pediculis capitis* in the crevices in an African chief's head stool in the possession of a friend of his.—Mr. Plant stated that he had endeavoured to obtain larger specimens of the Dreissena noted at the last meeting, but without success.—Dr. Alcock concluded his notes on frog tadpoles by describing the three remaining periods into which their life-history may be divided.

Berlin

Physical Society, May 12.—Prof. Du Bois-Reymond in the chair.—Dr. Herz spoke on hardness. The methods hitherto used to determine the hardness of bodies have all been merely comparative estimates, *e.g.* in mineralogy it has been stated by what other substances the material in question is scratched, and what it can scratch, and so its position in the scale of hardness is shown to be between these others. Or it has been ascertained by some physicists to what depth in the substance a steel cone is pressed by a given force, and this depth gives a measure of the hardness. Herr Herz has sought a more absolute method; and he has confined himself, on account of the complexity of the question, to consideration of isotropic elastic substances. In these the hardness may be determined by the pressure which must be exerted on a round surface, to exceed, by the deformation produced, the limit of elasticity. In the case of plate-glass, *e.g.* it was found by experiment, that at a pressure of 136 kg. per square mm., the limit was passed, and a circular crack was produced; 136, accordingly, expresses the degree of hardness of the glass. Every isotropic body which has exceeded its limit of elasticity under greater or less pressure, is, respectively, harder or less hard. The advantage of this method lies in the fact that no second substance is needed, but only two balls or lenses of the substance examined.—Prof. Christiani then showed, as samples of a new method of preservation a series of organic bodies coated galvanoplastically; a mulberry leaf, a crab, a butterfly, a beetle, the brain of a rabbit, a rosebud, and other objects, were silver-, gold-, or copper-plated, and showed all details of their outer form, down to the finest shadings, very well preserved. As to the process (which is patented by the inventor), it was stated that the objects to be preserved, being put, living or dead, into a solution of silver nitrate in alcohol, then dried, and treated with sulphuretted and phosphuretted hydrogen, form good conductors, which, brought in the usual way into the galvanoplastic bath, can be coated with any desired thickness of a metallic deposit.

Gottingen

Royal Society of Sciences, January 7.—Contribution to the theory of surfaces, with special reference to minimal surfaces, by A. Enneper.

February 4.—Report on the Polyclinic for ear diseases, by K. Burkner.—Completion of Steiner's elementary geometrical proofs of the proposition that the circle has a greater surface-content than any other plane figure of equal circumference, by F. Edler.

March 4.—On functions which remain unchanged by linear substitutions, by L. Fuchs.—Measurement of the earth's magnetic horizontal intensity by means of bifilar suspension of a magnet, by F. Kohlrausch.—Contribution to the theory of surfaces, &c. (continued), by A. Enneper.—On cryolith, pachnolith, and thomsonolith, by C. Klein.—Communications on Giordano Bruno, by P. de Lagarde.—Report on Beneke prize.

Paris

Academy of Sciences, May 29.—M. Blanchard in the chair.—The following papers were read:—Separation of gallium, by M. Lecoq de Boisbaudran.—On the cycle of reasoning; its use for formulating and strengthening the fundamental hypotheses and propositions of all science; application to mechanics, by M. Ledieu. The cycle includes four operations: (1) observation and, if necessary, experimentation *a priori*; (2) induction; (3) deduction; (4) experimentation and, at least, observation *a posteriori*. A fundamental hypothesis or law is more or less rational when, on submitting it to the cycle, one can more or less close this cycle. The author illustrates this.—Report on a memoir of M. Bouquet de la Grye entitled, "Study on Waves of Long Period in the Phenomena of Tides." In this memoir the author extends the work of Laplace. It is also proved, *inter alia*, that the greatest elevation of the water at Brest occurs, not with west but with south winds. The density of the water is found to explain the unexpected fact revealed by Bourdaloue, that the mean level of the ocean at Brest is higher by 1·02 m. than that of the Mediterranean at Marseilles. From 1834 to 1878 the mean level of the ocean has sunk, at Brest, or the ground has risen (the fact subsists, after allowing for variation of temperature and saltness). The relative rise of ground has been about 1 mm. a year.—Measurement of the volume of blood contained in the system of a live mammal, by MM. Gréhant and Quinquaud. The method used depends on carbonic oxide giving an oxycarbonised hæmoglobin, a more fixed combination than oxygenated hæmoglobin (the carbonic oxide being substituted for the oxygen volume for volume). An animal is made to breathe gas containing a known amount of CO. The volume of CO remaining is noted, say, in a quarter of an hour, and this gives the amount fixed. On the other hand, the blood is analysed to find the CO fixed in a given volume. In this way it was found that the total weight of blood is between 1-12th and 1-13th of the body-weight. In the normal state there are no great variations.—Obervations to serve in the study of phylloxera, by M. Boiteau.—On a proposition relative to linear equations, by M. Darboux.—Demonstration of a theorem relative to the function $E(x)$, by M. Bouniakowski.—Two means of having π in the game of head or tail, by M. Barbier.—On a mode of transformation of figures in space, by M. Vanecek.—On a potential with four variables, which renders almost intuitive the integration of the equation of sound, and the demonstration of the formula of Poisson concerning the inverse potential with three variables, by M. Boussinesq.—On the actinic transparence of optical glasses, by M. de Chardonnet. A species of glass only allows passage (even with thin plates, and with long exposure) to wave-lengths exceeding a certain minimum, characteristic of the material. Another characteristic is the thickness beyond which elective absorption diminishes no further. With these limits, the shortening of the spectrum seems sensibly proportional to the thickness of the medium. The actinic absorption (measuring the shortening of the spectrum in the scale of wave-lengths) for a given optical system is comprised between the absorption of the least transparent glass and the sum of proportional shortenings due to all the glasses of the apparatus.—Action of sulphydrate of ammonia on sulphide of tin, by M. Ditte.—Influence of the tension of sulphuretted hydrogen in presence of a neutral solution of sulphate of nickel, by M. Baubigny.—On the transformations of cuproso-cupric sulphites, by M. Étard.—Determination of glycerine in fatty matters, by M. David. He saponifies 100 gr. of tallow with baryta.—On the ligneous formations produced in the pith of cuttings, by M. Prillieux.—On the true situation of the mouth of the Shiré, and on the canal of communication connecting this river with the Zambesi, by M. Guyot. Correcting the notion that the Shiré, after entering the lake of Lydia, resumes its course and joins the Zambesi near the foot of Chamouara, he represents that the lake is really connected with the Zambesi by a canal called Zio-Zio; running first W.S.W. to E.N.E., then nearly east, which conveys water *from* the Zambesi and is a larger feeder of the lake than the Shiré (the latter at its entrance into the lake is only about 670 feet wide and 3 to 4 feet deep, with little current).

CHARLES DARWIN[1]

IV.

IN attempting to estimate the influence which Mr. Darwin's writings have exerted on the progress of botanical science, a little consideration will show that we must discriminate between the indirect effect which his views have had on botanical research generally, and the direct results of his own contributions. No doubt in a sense the former will seem in the retrospect to overshadow the latter. For in his later writings Mr. Darwin was content to devote himself to the consideration of problems—with an insight and patience essentially his own—which, in a limited field, brought his theoretical views to a detailed test, and so may ultimately seem to be somewhat merged in them. It is wonderful enough that so great a master in biological science should, at an advanced age, have been content to work with all the fervour and assiduity of youth at phenomena of vegetable life apparently minute and of the most special kind. But to him they were not minute, but instinct with a significance that the professed botanical world had for the most part missed seeing in them failing the point of view which Mr. Darwin himself supplied. It is not too much to say that each of his botanical investigations, taken on its own merits, would alone have made the reputation of any ordinary botanist.

Mr. Darwin's attitude towards botany, as indeed to biological studies generally, it should always be remembered was in his early life essentially that of a naturalist of the school of Linnæus and Humboldt—a point of view unfortunately now perhaps a little out of fashion. Nature in all its aspects spoke to his feelings with a voice that was living and direct. The writer of these lines can well remember the impression which it made upon him to hear Mr. Darwin gently complain that some of this warm enthusiasm for nature, as it presents itself unanalysed to ordinary healthy vision, seemed to be a little dulled in the younger naturalists of the day, who were apt to be somewhat cramped by the limits of their work-rooms. The pages of the "Journal of Researches" show no such restraint, but abound with passages in which Mr. Darwin's ever unstudied and simple language is carried by the force of warm impression and a perfect joy in nature to a level of singular beauty. One passage may be quoted as an illustration: it is from the description of Bahia in Chapter xxi.:—

"When quietly walking along the shady pathways, and admiring each successive view, I wished to find language to express my ideas. Epithet after epithet was found too weak to convey to those who have not visited the intertropical regions, the sensation of delight which the mind experiences. I have said that the plants in a hothouse fail to communicate a just idea of the vegetation, yet I must recur to it. The land is one great wild, untidy, luxuriant hothouse, made by Nature for herself, but taken possession of by man, who has studded it with gay houses and formal gardens. How great would be the desire in every admirer of nature to behold, if such were possible, the scenery of another planet! Yet to every person in Europe, it may be truly said, that at the distance of only a few degrees from his native soil, the glories of another world are opened to him. In my last walk I stopped again and again to gaze on these beauties, and endeavoured to fix in my mind for ever, an impression which at the time I knew sooner or later must fail. The form of the orange-tree, the cocoa-nut, the palm, the mango, the tree-fern, the banana, will remain clear and separate; but the thousand beauties which unite these into one perfect scene must fade away; yet they will leave, like a tale heard in childhood, a picture full of indistinct, but most beautiful figures."

A spirit such as this, penetrating an intelligence such as Mr. Darwin's, would not content itself with the superficial interest of form and colour. These, in his eyes, were the outward and visible signs of the inner *arcana*. The fascination of sense which the former imposed upon him but stimulated his desire to unveil the latter. In the Galapagos we are not then surprised to find him ardently absorbed in the problems which the extraordinary distribution of the plants, no less than of other organisms, presented:—

"I indiscriminately collected everything in flower on the different islands, and fortunately kept my collections separate."

After tabulating the results which they yielded after systematic determination, he proceeds:

"Hence we have the truly wonderful fact, that in James Island, of the thirty-eight Galapageian plants, or those found in no other part of the world, thirty are exclusively confined to this one island; and in Albemarle Island, of the twenty-six aboriginal Galapageian plants, twenty-two are confined to this one island, that is, only four are known to grow on the other islands of the Archipelago; and so on, as shown in the above table, with the plants from Chatham and Charles Island."

It is impossible in reading the Origin of Species not to perceive how deeply Mr. Darwin had been impressed by the problems presented by such singularities of plant distribution as he met with in the Galapagos. And of such problems up to the time of its publication no intelligible explanation had seemed possible. Sir Joseph Hooker had indeed prepared the ground by bringing into prominence, in numerous important papers, the no less striking phenomena which were presented when the vegetation of large areas came to be analysed and compared. No one therefore could estimate more justly what Mr. Darwin did for those who worked in this field. How the whole matter stood after the publication of the Origin of Species cannot be better estimated than from the summary of the position contained in Sir Joseph Hooker's recent address to the Geographical Section of the meeting of the British Association at York.

"Before the publication of the doctrine of the origin of species by variation and natural selection, all reasoning on their distribution was in subordination to the idea that these were permanent and special creations; just as, before it was shown that species were often older than the islands and mountains they inhabited, naturalists had to make their theories accord with the idea that all migration took place under existing conditions of land and sea. Hitherto the modes of dispersion of species, genera, and families had been traced, but the origin of representative species, genera, and families, remained an enigma; these could be explained only by the supposition that the localities where they occurred presented conditions so similar that they favoured the creation of similar organisms which failed to account for representation occurring in

---

[1] Continued from p. 100.

the far more numerous cases where there is no discoverable similarity of physical conditions, and of their not occurring in places where the conditions are similar. Now under the theory of modification of species after migration and isolation, their representation in distant localities is only a question of time, and changed physical conditions. In fact, as Mr. Darwin well sums up, all the leading facts of distribution are clearly explicable under this theory; such as the multiplication of new forms, the importance of barriers in forming and separating zoological and botanical provinces; the concentration of related species in the same area; the linking together under different latitudes of the inhabitants of the plains and mountains, of the forests, marshes, and deserts, and the linking of these with the extinct beings which formerly inhabited the same areas; and the fact of different forms of life occurring in areas having nearly the same physical conditions."

If Mr. Darwin had done no more than this in the botanical field he would have left an indelible mark on the progress of botanical science. But the consideration of the various questions which the problem of the Origin of Species presented led him into other inquiries in which the results were scarcely less important. The key-note of a whole series of his writings is struck by the words with which the eighth chapter of the Origin of Species commences:—

"The view generally entertained by naturalists is that species, when intercrossed, have been specially endowed with the quality of sterility, in order to prevent the confusion of all organic forms."

The examination of this principle necessarily obliged him to make a profound study of the conditions and limits of sterility. The results embodied in his well-known papers on dimorphic and trimorphic plants afforded an absolutely conclusive proof that sterility was not inseparably tied up with specific divergence. But the question is handled in the most judicial way, and when the reader of the chapter on hybridism arrives at the concluding words in which Mr. Darwin declares that on this ground "there is no fundamental distinction between species and varieties," he finds himself in much the same intellectual position as is produced by the Q.E.D. at the end of a geometrical demonstration.

It was characteristic of Mr. Darwin's method to follow up on its own account, as completely as possible, when opportunity presented, any side issue which had been raised apparently incidentally in other discussions. Indeed it was never possible to guess what amount of evidence Mr. Darwin had in reserve behind the few words which marked a mere step in an argument. It was this practice of bringing out from time to time the contents of his unseen treasure-house which affords some insight into the scientific energy of his later years, at first sight so inexplicably prolific. Many of his works published during that period may be properly regarded in the light of excursuses on particular points of his great theory. The researches on the sexual phenomena of heterostyled plants, alluded to above, which were communicated to the Linnean Society in a series of papers ranging over the years 1862-8, ultimately found their complete development in the volume "On the Different Forms of Flowers or Plants of the same Species," published in 1877. In the same way, the statement in the Origin of Species, that "the crossing of forms only slightly differentiated, favours the vigour and fertility of their offspring," finds its complete expansion in "The Effects of Cross and Self-Fertilisation in the Vegetable Kingdom," published in 1876.

The "Origin of Species" in the form in which it has become a classic in scientific literature was originally only intended as a preliminary *précis* of a vast accumulation of facts and arguments which the author had collected. It was intended to be but the precursor of a series of works in which all the evidence was to be methodically set out and discussed. Of this vast undertaking only one, the "Variation of Plants and Animals under Domestication" was ever actually published. Apart from its primary purpose it produced a profound impression, especially on botanists. This was partly due to the undeniable force of the argument from analogy stated in a sentence in the introduction:—"Man may be said to have been trying an experiment on a gigantic scale; and it is an experiment which nature, during the long lapse of time has incessantly tried." But it was still more due to the unexpected use of the vast body of apparently trivial facts and observations which Mr. Darwin with astonishing industry had disinterred from weekly journals and ephemeral publications of all sorts and unexpectedly forced into his service. Like Molière's Monsieur Jourdain, who was delighted to find that he had been unwittingly talking prose all his life, horticulturists who had unconsciously moulded plants almost at their will at the impulse of taste or profit were at once amazed and charmed to find that they had been doing scientific work and helping to establish a great theory. The criticism of practical men, at once most tenacious and difficult to meet, was disarmed; these found themselves hoist with their own petard. Nor was this all. The exclusive province of science was in biological phenomena for ever broken down; every one whose avocations in life had to do with the rearing or use of living things, found himself a party to the "experiment on a gigantic scale," which had been going on ever since the human race withdrew for their own ends plants or animals from the feral and brought them into the domesticated state.

Mr. Darwin with characteristic modesty had probably underrated the effect which the "Origin of Species" would have as an argumentative statement of his views. It probably ultimately seemed to him unnecessary to submit to the labour of methodising the vast accumulations which he had doubtless made for the second and third instalments of the detailed exposition of the evidence which he had promised. As was hinted at the commencement of this article, his attention was rather drawn away from the study of evidence already at the disposal of those who cared to digest and weigh it to the exploration of the field of nature with the new and penetrating instrument of research which he had forged. Something too must be credited to the intense delight which he felt in investigating the phenomena of living things. But he doubtless saw that the work to be done was to show how morphological and physiological complexity found its explanation from the principle of natural selection. This is the idea which is ever dominant. Thus he concludes his work on climbing plants:—"It has often been vaguely asserted that plants are distinguished from animals by not having the powers of movement. It should rather be said that plants acquire and display this power only when it is of some advantage to them; this being of comparatively rare occurrence, as they are affixed to the ground, and food is brought to them by the air and rain." The diversity of the power of movement in plants naturally engaged his attention, and the last but one of his works—in some respects perhaps the most remarkable of them—was devoted to showing that these could be regarded as derived from a single fundamental property. "All the parts or organs of every plant while they continue to grow . . . are continually circumnutating." Whether this masterly conception of the unity of what has hitherto seemed a chaos of unrelated phenomena will be sustained time alone will show. But no one can doubt the importance of what Mr. Darwin has done in showing that for the future the phenomena of plant movement can and indeed must be studied from a single point of view.

Along another line of work Mr. Darwin occupied himself with showing what aid could be given by the principle of natural selection in explaining the extraordinary variety of detail in plant morphology. The fact that cross-fertilisation was an advantage, was the key with which, as indicated in the pages of the "Origin of Species," the bizarre complexities of orchid flowers could be unlocked. The detailed facts were set out in a well-known work, and the principle is now generally accepted with regard to flowers generally. The work on insectivorous plants gave the results of an exploration similar in its object and bringing under one common physiological point of view a variety of the most diverse and most remarkable modifications of leaf-form.

In the beginning of this article the attempt has already been made to do justice to the mark Mr. Darwin has left on the modern study of geographical botany (and that implies a corresponding influence on physio-palæontology). To measure the influence which he has had on any other branches of botany, it is sufficient to quote again from the "Origin of Species":—"The structure of each part of each species, for whatever purpose used, will be the sum of the many inherited changes, through which that species has passed during its successive adaptations to changed habits and conditions of life." These words may almost be said to be the key-note of Sachs's well-known text-book, which is regarded as the most authoritative modern exposition of the facts and principles of plant-structure and function. And there is probably not a botanical class-room or work-room in the civilised world, where they are not the animating principle of both instruction and research.

Notwithstanding the extent and variety of his botanical work, Mr. Darwin always disclaimed any right to be regarded as a botanist. He turned his attention to plants doubtless because they were convenient objects for studying organic phenomena in their least complicated forms; and this point of view, which if one may use the expression without disrespect, had something of the amateur about it, was in itself of the greatest importance. For, from not being, till he took up any point, familiar with the literature bearing on it, his mind was absolutely free from any prepossession. He was never afraid of his facts or of framing any hypothesis, however startling, which seemed to explain them. However much weight he attributed to inheritance as a factor in organic phenomena, tradition went for nothing in studying them. In any one else such an attitude would have produced much work that was crude and rash. But Mr. Darwin—if one may venture on language which will strike no one who had conversed with him as overstrained—seemed by gentle persuasion to have penetrated the reserve of nature which baffles smaller men. In other words, his long experience had given him a kind of instinctive insight into the method of attack of any biological problem, however unfamiliar to him, and he rigidly controlled the fertility of his mind in hypothetical explanations by the no less fertility of ingeniously-devised experiment. Whatever he touched he was sure to draw from it something that it had never before yielded, and he was wholly free from that familiarity which comes to the professed student in every branch of science, and blinds the mental eye to the significance of things which are overlooked because always in view.

The simplicity of Mr. Darwin's character pervaded his whole method of work. Alphonse de Candolle visited him in 1880 and felt the impression of this. "He was not one of those who would construct a palace to lodge a laboratory. I sought out the greenhouse in which so many admirable experiments had been made on hybrids. It contained nothing but a vine." There was no affectation in this. Mr. Darwin provided himself with every resource which the methods of the day or the mechanical ingenuity of his sons could supply, and when it had served its purpose it was discarded. Nor had he any prepossession in favour of one kind of scientific work more than another. His scientific temperament was thoroughly catholic and sympathetic to anything which was not a mere regrinding of old scientific dry bones. He would show his visitors an *Epipactis* which for years came up in the middle of a gravel walk with almost as much interest as some new point which he had made out on a piece of work actually in hand. And though he had long abandoned any active interest in systematic work, only a few months before his death he had arranged to provide funds for the preparation of the new edition of Steudel's Nomenclator, which, at his earnest wish, has been projected at Kew.

(*To be continued.*)

MASCART AND JOUBERT'S "ELECTRICITY AND MAGNETISM"

Leçons sur L'Électricité et la Magnetisme. Par E. Mascart et J. Joubert. Tome I. (Paris, 1882.)

MANY of our readers must already be familiar with the "Électricité Statique" of M. Mascart. They will therefore turn with high expectations to the perusal of the "Leçons sur l'Électricité et le Magnétisme," of which he is one of the authors. On the whole they will not be disappointed. They will find in it all the limpid clearness, all the vivacity, all the elegance of presentation, both spiritual and material, that characterise the best French text books; and they will find withal none of the shallowness with which their grudging admirers have been wont to credit them. It is a wonderful national gift that our Gallic neighbours have—their power of scientific exposition. We Britons, with a stray exception, are far behind them; still farther are our German cousins. Notwithstanding our undoubted kinship in language and descent with the Germans, and all our well-founded appreciation of their excellence, we weary of their very virtues. One turns from their copious Gründlichkeit, as from the indispensable *labour* of life, and one finds in the reading of a good French text-book a never-failing *pleasure.*

Only the first volume of the Leçons is as yet before us, and some of our criticisms may have, on that account, to be taken with allowance; for the head, however important, is not the whole body. We see at once that there is little in common between them and the "Électricité Statique;" the plan of the work, so far as it has gone, is quite different. It originated, so the preface tells us, in the lectures of one of the authors at the Collège de France. The first volume is general and theoretical; the second is to be special and practical. As to the propriety of such an arrangement, much depends on the class of students to which it is addressed. If it is meant for such as have already a considerable knowledge of electrical phenomena, and some practice in accurately conceiving and describing them, then the plan is good. If, on the other hand, the reader is supposed to be a beginner in electrical science, knowing nothing of the phenomena, but furnished merely with the requisite mathematical knowledge, then we do not think well of it. We prefer in that case, the arrangement of the "Electricité Statique," that is, a fuller account of the phenomena upon which the fundamental principles rest, with a mathematical treatment sufficient to prevent vagueness of impression, and thereafter a detailed deductive account of the consequences of the fundamental principles, and a full description of the phenomena irrespective of their agreement or disagreement with theory. Assuming that we have to deal with a student, who has the first element of a physicist, viz. a tolerable mathematical education, perhaps the greatest danger to be avoided is formalism, or blind swearing, *in verba magistri.* Nothing is more likely to encourage this, than hurried and hasty discussion of fundamental facts. Nothing in reality is gained by driving the learner express to the law of the inverse square, and then leisurely expounding its consequences. Far better, that we should first secure for him a thorough qualitative understanding of the natural phenomena; and then teach him how they can be built together upon an abstract frame-work, whose lines they will follow, not necessarily with absolute coincidence. The learner must be taught at the very outset that analysis is the servant and not the master of the physicist; and that a physical idea is not always simplified by clothing it in an analytical suit of buckram. This much as a warning to possible students of this volume.

With one feature of the plan of these Leçons we must express unqualified satisfaction; that is the adoption of the methods of Thomson and Maxwell. At times these are so closely followed that the paragraphs are little more than translation; at other times considerable changes, chiefly in the way of simplification, are introduced. At the same time, the authors have not scrupled to borrow from other sources, where good material was to be had. They have gone on the principle of Molière, "je prends mon bien où je le trouve"; and rightly, for scientific light (unlike political or theological), is not supposed to be the property of one sect or one country. The English reader will not find much that is new, or perhaps we should say not accessible to him in his own language, however much he may learn as to arrangement and demonstration. Originality apparently is not aimed at; the authors put before their readers such of the modern development of electrical theory as they deem most important in themselves, or most likely to be useful to the physicist. We are of opinion that their selection on the whole has been judicious; and therein lies the chief merit of the book. It will, therefore, fill a great gap in French scientific literature. Possibly the second volume may help to fill the corresponding gap in the experimental part of the subject, which exists, unfortunately, in English as much as in French literature.[1] How urgently such treatises are wanted, and how ignorant one nation may be of what is common-place to another, is well exemplified by the fact that a distinguished *savant* like Prof. Clausius lately published, both in *Wiedemann's Annalen* and in the *Philosophical Magazine*, as something new and noteworthy, the theorem of mutual potential energy and certain consequences therefrom, that have been familiar to us ever since we knew anything of electrical theory, *i.e.* some ten years or more.[2]

We are thus led to notice the one serious defect of this treatise—the entire want of all references to original sources of information. These Leçons can have been meant only for those that contemplate a special study of electricity or original work of some kind bearing upon it; for such learners knowledge at first hand in some degree is essential; and who is to lead the scientific sheep to the water-springs if their responsible shepherds do not? We are well aware, from bitter experience, of the drudgery involved in this part of book-making, and of the difficulty, with all care, of being absolutely accurate and just; but utter neglect of the duty is inexcusable. Here is a provoking instance. The reader is aware that there are two different ways of representing the action of a mass of polarised molecules:—First, by a volume and a surface-distribution of attracting centres; second, by a surface distribution alone. The first of these is undoubtedly due to Poisson. The second is continually used in German books, and attributed to Gauss (the first method, and Poisson with it, they mostly ignore). Now MM. Mascart and Joubert add to the diversity by quoting the second method as Poisson's. It is certainly news to be told that Poisson knew of any such general theorem, and a cursory re-examination of his memoirs failed to find it. Until the exact reference is given, we must hold our previous conviction that the theorem in question was virtually first given by Green in his essay on "Electricity and Magnetism" (Nottingham, 1828). It was discovered independently by Gauss, whose statement of it (the first explicit one) is given in Art. 2, "Intensitas Vis Magneticæ, &c.," read December, 1832, to the Royal Society of Göttingen. His demonstration is given in Art. 36 of the "Allgemeine Lehrsätze, &c." Again, the corollaries from Gauss' Theorem of Mutual Potential Energy in Art.

---

[1] The Germans have the admirable treatise of Wiedemann, which, in its forthcoming shape, with electrostatics added, will be the greatest experimental treatise on electricity in existence.

[2] The theorem is simply a particular discrete form of Green's theorem; and in this shape was originally given by Gauss in his "Allgemeine Lehrsätze, &c." In one point of view it is simply a property of homogeneous functions of the second degree, and plays a part in many branches of mathematics, *e.g.* curves and surfaces of the second degree, theoretical dynamics, strains and stresses, &c.

63 *may* have been originally drawn by M. Bertrand; but, as no reference is given, we cannot meantime be sure whether his claim is any better than that of Clausius.

Detailed analysis being clearly out of place here, we conclude with a few running comments on the different parts of the work. The first part deals with Electrostatical Phenomena. Except that we think the introductory chapter somewhat hurried and meagre, we commend the general simplicity of the arrangement. A quasi-physical proof of most of the general propositions concerning electrified systems is given, and, we think, in the interest of the physical reader, that this is right. The seventh chapter of this part is especially recommended to the notice of our readers; there, so far as we know for the first time, Sir W. Thomson's theory of dielectrics finds its place in a text-book on Electrostatics; both here and in the corresponding chapters on Magnetism the authors show a complete appreciation and mastery of this important step in mathematical physics. Until Maxwell's treatise was written, this piece of Thomson's work had been apparently forgotten. It has lately been taken up in Germany, more especially by Helmholtz *more suo.* This neglect is no doubt to be explained by the equal neglect of the ideas of Faraday, of which Thomson's theory is the mathematical embodiment. The errors one occasionally finds on this subject in continental text-books of authority are very surprising, *e.g.* it will be found stated that a small sphere of magnetic or diamagnetic substance tends to move *along the lines of force;* the better diffusion of the true theory will surely tend to prevent such fundamental mistakes as this. The application of Thomson's theory to dielectrics is most interesting and important theoretically; but great difficulty has been found in verifying it experimentally, owing to the scarcity of bodies that will insulate sufficiently well. Its application to magnetics has been most successful, as our readers doubtless know.

The second part treats of electric currents, stationary and variable, and will probably be found well suited for the higher class of practical electricians; the account of the theory of telegraphic signalling deserves special mention. In Chapter II. of this part the authors are more cautious as to Volta's law of contact than they are at the end of the former part, knowing doubtless, as sound practicians, that they are on delicate ground.

The theory of magnetism, which constitutes the third part, suffers, as did the electrostatics, in the beginning, from the suppression of experimental detail. We cannot reconcile ourselves to the definition given of the magnetic axis as the line joining the poles of the magnet. This seems a very artificial and difficult way of introducing this fundamental conception; and we do not see the advantage over the ordinary method, which defines it as that direction which is always found parallel to a certain fixed vertical plane when the magnet is suspended freely under the earth's action alone at a given time and place. We also fail to see why, in mentioning the hypotheses advanced to explain terrestrial magnetism, Gilbert and Biot should be mentioned, and Halley and Hansteen forgotten. In other respects, this part of the work gives as good an account of its subject as most treatises we have seen. Our readers may note the discussion of the direct magnetic action of the heavenly bodies as something fresh in a text-book.

The last part of the work deals with Electro-magnetism. The connection between a current and the equivalent magnetic shell is deduced in a very ingenious (although we scarcely think simple) way from the law of Biot and Savart. The other method, which we prefer, is also given, in which the elementary proposition is that a plane circuit, whose linear dimensions are infinitely small compared with the distance of the point at which its action is considered may be replaced by a small magnet. A separate chapter is very properly given to the Methods of Ampère, and the authors have shown their judgment in refraining from loading their pages with the various solutions of the indeterminate problem to find the elementary law of electrodynamic action of which we have lately had a superfluity. An excellent account is given of the general theory of Maxwell. The only thing we would take objection to is yet another meaning given to that overburdened word Electromotive Force; the authors use *Force Electromotrice Totale* in place of Maxwell's *Vector Potential.* The deduction of the rotation of the plane of polarisation from Hall's phenomenon is given; but Prof. Rowland's name is not mentioned in connection with it; although we are under the impression that it was first given by him in the *American Journal of Mathematics.*

In a supplementary chapter some examples are given of the application to electrical phenomena of the principles of Carnot. Certain of these, due to M. Lippmann, are ranged under the somewhat high-sounding title of the Conservation of Electricity. We are a little inclined to question the propriety of this phrase; but we are certainly obliged to MM. Mascart and Joubert for a succinct account of what we are to understand by it.

We shall look with much interest for the second volume of this work, in which, among other things of interest to practical electricians, we are promised a discussion of the efficiency of electric generators and electromotors, a subject on which the recent experience of the authors at the Paris Exhibition must have well qualified them to give an opinion.

OUR BOOK SHELF

Die Gasteropoden der Meeres-ablagerungen der ersten und zweiten miocänen mediterran-stufe in der Oesterreichisch—Ungarischen Monarchie. Von R. Hörnes und M. Auinger. Lieferung 1, 2, 3. (Vienna: Hölder, 1879-1882.)

A MERITORIOUS and useful contribution to our knowledge of the tertiaries of middle Europe. The first-named author is the worthy son of a worthy sire, the late Prof. Hörnes, whose work on the fossil shells of the Vienna Basin is so familiar to palæontologists. The total number of species hitherto described or noticed in the present publication is 220, including 94 new species or forms. Out of all this number 11 only are given as recent or living; and two more may be added (viz. *Nassa semistriata* and *Columbella corrugata* of Brocchi), which inhabit the Mediterranean as well as the North Atlantic. These recent species have survived from the Miocene epoch—a period of incalculably remote antiquity—without the slightest change. The rest may be regarded as the οἱ πλέονες in the same sense as we use euphemistically for our dead. Perhaps some more fossil species may be hereafter identified with living species when palæontologists work in unison with naturalists, or when conchologists become acquainted with both kinds of species. This is a great desideratum; and for want of it several eminent palæontologists (Nyst, Hörnes, and others) made regrettable mistakes in such identification, having been misled by names and not things. We may observe that Gastropoden, instead of Gasteropoden, is the more correct and usual spelling of the word. The plates, sixteen altogether, are admirably executed; and the publication does great credit to the Imperial Institute of Geology at Vienna.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The Winter of 1881-82

YOU have given some figures about the winter of 1881-82 in Great Britain. It was relatively much warmer here. The mean temperatures and its variation from average for November, 1881, to April, 1882, was:

	Nov.	Dec.	Jan.	Feb.	March.	April.
Mean	32·0	23·2	29·5	25·0	31·5	38·2
Diff. from average	+2·7	+3·1	+14·5	+8·4	+8·0	+3·1

The general character of these months is thus a very decided high temperature. That of January was the warmest on record in the 130 years' observation. If we take the mean of the three months, January, February, and March, it is also the highest on record, viz., 28·7; the other years in which these three months had the highest temperature were: 1822, 28.1; 1863, 27·4; 1843, 26·9; 1794, 26·6. The temperature of the five months, November to March, viz, 28·2 in 1881-82, was surpassed only once, in 1821-22, 29·3; the other years when these months were warmest are: 1842-43, 27·6; 1761-69, 27·1; and 1826-27, 26·9.

The Neva was frozen less than four months, while on the average the ice lasts nearly five months (147 days), and in the winter of 1880-81 the river was frozen 184 days, the longest time on record since the observations began, that is, for about 175 years. The date of opening of the river this year, March 30, is the earliest, except that of 1822 (March 18).

The last winter is, besides, noticeable for its deficiency of snow, there being scarcely ten days of fair sleighing. The precipitation of the months from November to March was 1″·9 less than the average, that of December alone by 0″·8, that is, by nearly two-thirds. Besides, a large part of it fell as rain. On account of the want of snow, the rivers had not their ordinary spring floods, and great quantities of timber, prepared to be floated for the use of St. Petersburg, could not be moved.

On the middle and lower Wolga, the snowfall of last winter was excessive, and even Taschkent and the valley of Ferghana, in Central Asia (lat. 40°-42°), had an exceedingly cold winter, with permanent and deep snow. The winter was also very cold in Transcaucasia, the minimum temperature in November, 1881, being lower than ever observed before in Tiflis.

St. Petersburg, May 27 A. WOEIKOF

The Mean Temperature of the Atmosphere at the Surface of the Earth as Determined by Observations and by Theory

WHEN several people, not knowing each other, arrive at the same results, the one by compilation and computation of observations, the others by theory, these results present a good probability of correctness, and the theory involved ought to be of interest to science.

In NATURE, vol. xxv. p. 395, I read—"The temperature of the southern hemisphere has lately been investigated by Dr. Hann with the aid of recent observations of temperature in high southern latitudes, especially those made during the Venus transit in 1874. For mean temperature of the whole atmosphere he obtains 15°·4 C., and as that of the northern hemisphere was estimated by Ferrel to be 15°·3 C., it is very probable that both hemispheres have the same mean temperature. Dr. Hann, however, also shows that between 40° and 45° south latitude, the southern hemisphere becomes warmer than the northern in the same latitude, and that a difference between the two persists at least to the confines of the hypothetical antarctic continent. . . ."

In "On some Properties of the Earth," 1880 (Wertheimer and Lea, publ.) occur the following passages, founded on and connected by theory alone (p. 95):—"We thus find the average temperature of the atmosphere at the surface of the earth to be 20° C., the isotherms of 20° C. having in their mean the parallels of 30° for basis; this figure, obtained by reasoning, is confirmed by isothermal maps. We will see *why the* 20° *are lowered to* 15°·22 *C., the true mean temperature of the atmosphere at the surface of the earth*."

And on pp. 123 to 126: "The line of greatest heat is in the mean moved $\frac{1}{29·78}+\frac{1}{175}$ of the sphere, or 3° 58′+4′ latitude, north of the equator. Temperature is therefore in a compressed or higher state in the lower latitudes of the north." . . .

"Inside the isotherms with the parallels 38° 58′ as basis, the temperature of the north is in excess over that of the south. This isotherm of the mean atmospheric temperature reaches over sea so far north as to embrace those seas which may be called the Mediterranean . . . it reaches on land to 47° 50′-3° 56′, where the temperature of Genoa in 43° 51′ N. lat. is 15°·7 C., and that of Alais 44° 10′ N. lat. is 15°·4 C. Beyond this isotherm, or beyond the bases of 38° 58′ lat., the difference between north and south decreases [which implies that the temperature at the south gets gradually warmer than at the north, chiefly in longitudes examined by Dr. Hann]. . . . At the isotherms of 1°·666 C., of which that at the south is quite maritime, and almost without curving, the equilibrium of temperature between south and north is re-established, the isotherms coincide, each in its mean, in both hemispheres, with their parallels or bases, they divide the hemispheres in proportion 1 : 4·78 . . ."

O. REICHENBACH

Sea-shore Alluvion—the "Chesil"

GREATER attention and speculation have been bestowed on this than any other of our marine littoral moles, the Transactions of various societies abounding in papers describing it, and as the westernmost of our south coast beaches, within the limits of the narrow seas, may well terminate a review thereof.

Leland, Camden, Lambarde, and Holinshed, all describe it, and how it fluctuates in quantity dependent on the wind. Leland used the word "Chesil" (which became a proper name as applied to this particular bank) as a general term, descriptive of shingle banks, throughout his work. Lilly, who wrote in 1715, describes it most accurately. Hutchins calls it "Steepstone," and derives its name from "Ceorl," the Saxon for gravel. Gough adopts the same derivation, calling it "a prodigious heap of pebbles thrown up by the sea, beginning at Chesilton, in Portland, and reaching beyond Swyre, 16⅔ miles."

The most remarkable feature is the top "full" about fifteen feet above the lower ones at the Portland end forming a huge seaward wall or mole, exceeding anything of the kind to be seen along our coasts, the land-slope of which is flat. At the east end it is thirty to forty feet above high water of springs, gradually lowering westward, and the stones decreasing in size. The land-locked tidal lake, the "Fleet," between it and the main, is another feature so common to these formations; it terminates opposite the valley to Abbotsbury, down which runs a small mill-stream. Between Lord Ilchester's castle and the Abbotsbury Coastguard Station the great beach ceases, the bight terminating in low tertiary cliffs, which intercept the top "full," the lower "fulls" continuing of an average height, as at Deal and elsewhere; two to three miles west of Abbotsbury the beach is thrown up into very sharp slopes, which, from the fineness of the material, become very solid, and continues to decrease in size and altitude, intercepted by the cliffs at Burton, and again formed into a moderate "full" on each side of Bridport harbour. The great elevation attained by the eastern end of this bank, where it abuts against the Island of Portland, exhibits an exceptional accumulation of water-driven material in the hollow of, and to the north-east of the Great West Bay, which bears, with seamen, the ugly name of "Dead Man's Bay," from an embayed vessel caught in a south-west gale seldom escaping shipwreck. More than half a century back, Fleet was inundated from a breach in the beach, and the church washed down, and many houses in Chesilton destroyed.

It is said locally, that the material is so finely graduated, that a native boatman or fisherman can tell in the darkest night the exact locality his boat may come ashore or be beached on, by picking up a handful of the gravel. In a south-west gale it is next to impossible to stand on the eastern crest, from the rain of pebbles projected over its summit by the breaking waves.

The Chesil is shown with great accuracy in early manuscript maps, especially in a remarkable series of drawings collected by the great Cecil, well known at the British Museum as "Lord Burleigh's Book;" also in drawings by Collins and Lilly. From these it would appear, that two or three centuries back the "Fleet" was wider, leading to the inference that the beach had retreated landward; but a close inspection of the bank does not support this conclusion, but appears to show that the surplus material is driven in heavy weather right over the crest sloping towards the "Fleet," the area of which has been narrowed and reduced by this continued process.

The gradation of material here again shows the ultimate leeward movement from west to east, due to preponderance of winds from the first quarter; the altitude from three to four times that of the normal elevation of ordinary English beaches above high water; also the upper plateau above the usual neap and spring "fulls" are striking features, showing its abnormal character.

The largest shingle travelling to leeward and to the summit, is illustrative of the accumulative energy of the heavier projectiles, and their being less acted on by the recoil than the smaller materials.

It may be well to notice here the soundings taken in H.M.S. *Beagle*, between Santa Cruz and the Falkland Islands, referred to by the late Mr. Darwin in his work "Geological Observations," published in 1876, and which he truly describes as presenting the usual phenomena in such cases. The material quickly and regularly decreasing in size with increased depth and distance from shore, under two miles out large and small pebbles were found intermixed.

Miles.	Depth, fathoms.	
At 2 to 4	11 to 12	Pebbles size of walnuts and smaller.
4 to 7	17 to 19	Do. size of hazel nuts.
10 to 11	23 to 25	$\frac{3}{10}''$ to $\frac{4}{10}''$ ms. diameter.
12	30 to 40	$\frac{2}{10}''$ diameter.
22 to 150	45 to 65	$\frac{1}{10}''$ do. to fine sand.

This is confirmatory of, or supported by, observations around our own coasts.

Meteor

ON Wednesday, June 7, 9 45 p.m. G.M.T., at a station 396 yards north-west by west of the transit-circle of the observatory, Mr. W. H. Robinson's attention was attracted by the sudden appearance of a fine meteor about 3° below Mars, which passed through a point 5° below Regulus, and, continuing its course about 12° further, finally disappeared. Almost instantly after being first seen, it shone very brightly, then assumed a train of detached luminous beads, and towards the end of its path burst, presenting an appearance similar to the bursting of a rocket. Its greatest brilliancy was equal to Venus. The length of the whole track was about 25°, and the time of visibility of the train was about five seconds.

Earthquakes in Naples

THE seismographs of the Vesuvian Observatory and of the Naples University have shown increased activity the last two days. This culminated this morning at 6.47 a.m. in a distinct shock seven seconds duration, direction north to south, chiefly undulatory, but elevatory towards the end. From these facts Prof. Palmieri considered it to come from a distance, and not of local origin. This was proved by telegrams from Isurnia and Vinchiaturo in the Apennines. All to-day the amount of vapour from Vesuvius is much more abundant, and this evening it is brilliant; the quantity of lava flowing is increased. This is a good example on a small scale of seismic activity having its focus in a mountain chain affecting the neighbouring volcanoes.

Naples, June 6

H. J. JOHNSTON-LAVIS

THE "POLYPHEMUS"

HER MAJESTY'S ship *Polyphemus*, which has been five years under construction, is now being prepared for her final trials. She contains so many peculiarities of design and novelties of various kinds in her machinery and fittings that much scientific interest attaches to her performances. Her form is different from that of any other ship ever built. The part above water has been described as resembling a cylinder floating on its side and deeply immersed, which is tapered at the ends to form a bow and stern. An idea of her appearance above water may be obtained by imagining such a cylinder to be flattened over a large portion of its area to form a deck, and to float at a height of 4 feet 6 inches out of water. The whole of the exposed part of this surface, which has great curvature near the water line, and enters the water at an angle of about 45 degrees, is plated over with steel armour, which is carried some distance below water. The curvature of the sides is continued to a depth of several feet below the water line, and from this point they turn sharply in and converge towards each other at the keel almost in straight lines. A cross section of the vessel is similar to a pegtop, which is floating in water at a depth below its greatest breadth, and the emersed part of which presents a convex surface only. Upon this form of hull an iron superstructure is mounted, which carries a hurricane deck from which the ship is worked, and to which the openings into the main body of the ship are carried up. Two protected coverings are fitted on this deck, one at each end, which are connected with the structure of the hull, and give means of communication with the interior. There are three revolving turrets on each side, which are each armed with one of the heaviest Nordenfelt guns. This superstructure may all be shot away without injuring the vessel or impairing her powers, except as regards the use of the Nordenfelt guns.

The lines of the ship are very fine, and have been determined chiefly with a view to great speed. The armour plating is very light; no heavy guns are carried; many devices have been adopted to reduce the weight of the machinery; and some of the main fighting qualities of most other men-of-war have been sacrificed, in order that a high speed may be realised. The speed she was designed for is 17 knots; although with the great amount of horse-power; for her size, she is intended to indicate, a higher speed might be expected if it is efficiently utilised. The offensive weapons of the *Polyphemus* consist of the ram and torpedo. She will carry no guns except six Nordenfelt machine-guns, which will each be carried in a projecting turret at the height of the flying deck. These will serve to repel boat attack; but for offensive operations against powerful vessels, she will only be able to employ the ram and torpedoes. The successful use of these weapons will depend primarily upon speed. High speed is essential, to prevent failure in ramming; and in using torpedoes under heavy gun-fire, it is very important to be able to approach an enemy quickly, and to get away again with all possible celerity, as the contingencies of this mode of fighting may require. The efficiency of the *Polyphemus* thus being a question of speed, it will be understood why so many sacrifices have been made in order to enhance this quality. The vessel has been constructed as light as possible throughout, and saving of weight has been carried to a great extent.

The hull is built of mild steel; the frames being of Bessemer, and the bottom plating of Landore-Siemens steel. There is a double bottom, and the hold of the ship is largely divided into separate watertight compart ments by means of bulkheads. A longitudinal bulkhead is fitted at the middle line; the boilers are contained in four separate water-tight compartments; the engines in two; and the coal bunkers are also water-tight.

The engines and boilers are manufactured by Messrs. Humphreys and Co. There are two pairs of engines working twin screws. They are of the horizontal compound type, the cylinders of each pair being 38 inches and 64 inches in diameter, and the stroke 39 inches. They are intended to indicate an aggregate horse power of 5500. These engines are remarkable for their lightness and the comparatively small space they occupy. Most of their novel features have been adopted for the purpose of economising weight and space. They are almost entirely of wrought iron, Whitworth steel, and gun-metal; very little cast iron being used in their construction. The screws are three-bladed, and are 14 feet in diameter, with 15 feet to 17 feet pitch. The shafts are left bare where they come outside the hull of the ship, and are not surrounded by tubes, as is usual in ships of the Navy. These tubes have been dispensed with for the purpose of diminishing the resistance. The boilers are of the locomotive type; and these also were adopted in preference to the ordinary marine boiler, for the purpose of saving weight and space. They are 5 feet 3 inches in diameter, and 14 feet 4 inches in length, and work with a steam pressure of 120 tons per square inch. The shells are of steel, the fire-boxes of iron, and tubes of brass; and they are similar to ordinary locomotive boilers, except that the tubes are shorter and the fire wells less deep. The stoke-holds are closed in, and forced draught is worked with, as in the fast torpedo boats. This is supplied by four fans, two of which are 4 feet and the other two 3 feet 6 inches in diameter. The fan engines have 9-inch cylinders, and 4½ inches stroke, and run at the rate of 900 to 1000 revolutions per minute when working at full speed.

The trials of the machinery have, so far, not been successful, chiefly on account of difficulties with the boilers. During the first series of trials, on March 2, 4, and 6 last, nothing could be done on account of priming. The greatest speed realised was 10 to 12 knots, when the boilers primed so badly that a stop had to be come to. On March 31 there was another trial, the last down to the present time, when the difficulties of priming were mainly got over. The indicated horse-power on that occasion was about 5000, and the speed a little over 17 knots. The air-pressure in the stoke-holds, which gave the forced draught, was equivalent to 5 inches of water. On this occasion the boiler-tubes leaked very badly, so that the full power could not be realised. The priming was due to oil from the engines getting into the boilers, and this now appears to be remedied. In the torpedo boats that are fitted with locomotive boilers, the same difficulty arises, and oil is not used at all in the cylinders, or only very sparingly. The leaking of the tubes is a more serious difficulty to get over, although in the *Polyphemus* the arrangements appear to admit of improvement. For instance, solid iron stays were fitted in the midst of the brass tubes; and it must be obvious that the unequal rate of expansion of the stays and tubes when heated to a high temperature must have considerably strained the tube plates. These stays are now being removed, and new tubes are being fitted throughout, the ends of which are to be screwed into the tube plates.

This difficulty of leaky tubes is not peculiar to the *Polyphemus*. Messrs. Thornycroft are in the same position with a large number of torpedo boats they have completed for the British Government, and which are undergoing a similar ordeal of testing by the Admiralty engineers. These boilers cannot be got to stand satisfactorily, and a number of experiments have just been carried out at Portsmouth upon tubes fitted in various ways in a torpedo boat boiler, which, it is hoped, will show how the present defects can be remedied. Locomotive boilers are not adapted for working continuously at a high rate, and for steaming at full speed over long distances. The strain put upon the boiler, and the work attempted to be got out of it, is too great under these circumstances. What is being done in the *Polyphemus* and in the torpedo boats, is to get the advantage of the lightness of this type of boilers; and only to press them up to their full power for comparatively short times when required in an emergency.

The armour plating is of steel; and here again we find an attempt to combine great defensive power with extreme lightness. It extends over the whole of the above water-portion of the hull, and for a short distance below the water-line. There are first two half-inch thicknesses of Landore-Siemens steel, upon which are placed plates of Whitworth fluid-compressed steel, one inch thick. Outside of this is another layer of hard Whitworth steel, one inch thick, which is tested to a strain of sixty-eight tons per square inch. This outer layer is fitted in small plates or scales ten inches square, secured with coned steel screw bolts, one at the centre of each of the plates, and one at each of the corners. Along the middle of the turtle-back deck these scales are omitted, and the armour is there only 2 inches thick. The bases of the trunks from the hatchways to the flying deck are protected by a glacis of 6-inch steel armour to a height of 3 feet 6 inches above the deck; and the front of the foremost trunk is plated to a height of about 5 feet above the flying deck, with 8 inches of steel-faced armour, which gives protection to the pilot tower.

The armament, as has been stated, merely consists of six Nordenfelt machine-guns, which are each mounted in a revolving turret that projects from the side of the flying deck. The fighting weapons she possesses are the ram and torpedoes. The former is very long and strongly constructed. It is, however, interfered with by a tube for ejecting torpedoes right ahead, which is fixed in the centre of the ram. This seems a doubtful expedient to adopt, and to endanger to some extent both the ram and the torpedo-tube. The bow has been made so as to protect this tube as much as possible. The torpedo armament consists of the tube referred to for ejecting torpedoes right ahead, and of two tubes on each side, also placed under water, in a compartment at the fore side of the boiler-rooms. In this torpedo compartment one tube on each side is fixed right abeam, and the other in the direction of about 20 degrees at the fore side of the beam. There is only means of firing one torpedo end on, the other four tubes being on the broadside. It is questionable as to the merits of this arrangement, considering that the end-on position will be the one for attacking from in the *Polyphemus*, for the purpose of using the ram, and also to enable the greatest possible resistance to be got out of her thin armour. Independent air-compressing machinery for the torpedoes is carried in each of the torpedo-chambers, in which also a number of torpedoes will be carried ready for use.

The height of the hull proper above the water line is, as we have said, 4 feet 6 inches. It is kept low to reduce the chances of penetration; but to furnish more buoyancy than this small freeboard gives, a strange device has been adopted. At the keel of the ship a deep rectangular recess is made in which about 300 tons of iron ballast is carried. This ballast is so fixed that it can be let go at pleasure, and the ship lightened accordingly. The draught and trim may thus be regulated to some extent should the ship be injured in action. If the whole of the ballast is let go it will lighten her about 14 inches.

As manœuvring power is of great importance to such a vessel as the *Polyphemus*, an attempt is made to increase it by means of bow rudders. Two of the rudders, of the balanced form, are placed forward, one on each side of the bow torpedo tube. They can be drawn up into apertures inside the hull when not required for use; and when working they may be coupled up with the engine working the stern rudder, and all three rudders worked together. The dead wood has been cut away aft to a large extent in order to reduce the resistance to turning.

DOUBLE STARS

SOME stars when looked at in a telescope are seen really to consist of two stars so near together that the naked eye is not able to distinguish them, but sees them as a single star.[1] The knowledge of some of these objects may be presumed to be almost as old as the telescope. In fact Hevel remarked some of them in the middle of the seventeenth century, but no attention was paid to them, as it was thought that they were really far asunder in space, and merely appeared close together in the heavens, because they were nearly in the same visual ray. It thus escaped notice that one star frequently moves round the other, and Lambert, as late as 1761, founded his opinion that those fixed stars that appear near others, were in no physical connection with them, upon this absence of relative motion, because, as he says in his "Cosmologische Briefe," if they do not move round each other, and still gravitate towards each other, they must long ago have collapsed. But a few years after the Rev. John Michell applied the rules of the calculation of probabilities to the stars in the Pleiades, and showed that it was exceedingly improbable that these stars could appear so near together, if their proximity was the result of a random scattering of the stars over the heavens, and he showed that among 40,000 stars, one could expect to find only one pair within twelve seconds of arc of each other, and none nearer. These speculations were, however wholly conjectural, as long as no proper observations were available, and it was therefore to the purpose when the highly merited Jesuit, Christian Mayer, of the observatory at Mannheim, founded by the Elector of Pfalz, commenced to search for, and systematically to observe, double stars. But he met with no support from his contemporaries, and had to defend his opinions in several polemical pamphlets. His instrument, a mural quadrant by Bird, was scarcely sufficient for the purpose, and his opinion, that, "satellites" of the brighter fixed stars were found at a distance of as much as three degrees, was certainly wrong in the instances he adduced, though Mädler has shown that stars as far asunder may possibly be physically connected.[2] We must, therefore, consider William Herschel to be the first who proved the existence of double stars. This he did by aid of micrometric measures,[3] which he originally had made with the view of finding the parallax of fixed stars, similar observations having previously been attempted by the Rev. Roger Long, of Pembroke College, Cambridge, who, however, had not been very successful.

Herschel commenced micrometric measures in 1776, when he observed θ Orionis. In 1779 he began systematically to search for and measure double stars, and as early as 1782 he laid his first "Catalogue of Double Stars" before the Royal Society. It contained 269 objects, but few of which had been observed by Chr. Mayer. Subsequently he published other catalogues, which, however, contain many stars more than 32″ asunder, which are not now considered as double stars proper; but of the latter Herschel discovered between four and five hundred. He measured double stars micrometrically up to 1785, and again for some years after 1790. The measures showed some discrepancies, but it was impossible to decide whether the relative motion of the components—for changed their position some of them evidently had—was rectilinear or otherwise, and whether it in some cases perhaps arose from the proper motion of one star. However, already in 1794 Herschel explained how they must move in curved paths on account of their mutual gravitation, and in 1803 appeared that famous "account of the changes that have happened during the last twenty-five years in the relative situation of double stars," in which he, from actual measures, proved this to be a fact. But Continental astronomers were nevertheless slow to give in to so novel and startling a revelation. In France even Lalande openly expressed his want of faith in these disclosures, notwithstanding his high regard for Herschel's merits in other respects.—At the end of his active career Herschel had the pleasure to see his son John Herschel take up this subject with fervour. South, the friend of this illustrious astronomer, joined him in this work, and obtained thus a place in the scientific world, to which his own merits, only for this connection would scarcely have entitled him. J. Herschel went in 1834 to the Cape of Good Hope, where he discovered and made some measures of above two thousand double stars on the southern sky with his 20-feet reflecting telescope. He continued to take an active interest in these stars till his death in 1871, when he left behind unfinished manuscripts that showed that he had been engaged on a general catalogue of double stars and the observations made of them. It contained about 10,000 entries.

FIG I.

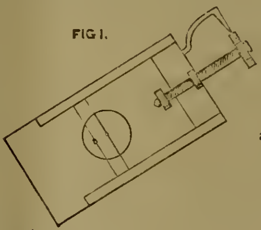

FIG 2.

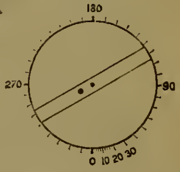

Meantime Struve in Russia had commenced a series of double-star measures, which is even now unsurpassed, as well with regard to extent as to consistency. In 1824 he received a 10-inch refractor, mounted equatorially, from Fraunhofer of Munich, and with this magnificent instru-

---

[1] Mizar and Alcor, the "test-star," in the great bear, present to the naked eye very much the same appearance as a double star does, when seen in a telescope. Their distance is about a lunar radius. It is sometimes said that distances less than five minutes are not visible to the eye, but when wearing glasses I see ϵ Lyræ, the distance of whose components is less than four minutes, double.

[2] It was evidently Chr. Mayer's opinion that the smaller star shone in reflected light. The term "double star" had been applied by previous observers, who little dreamt that these stars would become so interesting.

[3] It may be as well to explain in a few words the instrument with which such minute quantities are measured. It is called a micrometer, and forms the eyepiece of a large telescope. It is well known that in the focus of the object-glass of a telescope, the image of the object contemplated appears inverted. Now in this focus are stretched two parallel spider lines, at least one of which is moveable by an extremely fine screw. The magnitude of the object or the distance between the two components of the double star are thus measured in revolutions or fractions of a revolution of this screw; for which purpose the head of the screw is divided into hundredths, the tenths of which are estimated by the eye (see Fig. 1). The value in seconds of arc of each revolution of the screw is either ascertained by measuring some known distance or by measuring the length of a revolution in parts of an inch (a very small quantity) and dividing this by the focal length of the object-glass expressed in inches. The value of a revolution is generally found to vary a little with the temperature, as the steel of which the screw is made expands or contracts with the heat, but this is counteracted by changes in the focal length of the object-glass. It is of more importance to examine the irregularities of the screw, the different turns of which might not exactly be of the same size. Even parts of each turn might be slightly different. However modern engineers have carried the making of screws on the lathe to so high a perfection, that there are screws made in which no errors can with certainty be ascertained. It also deserves to be remarked that it is more easy to make a screw accurate the finer it is.—But the screw gives us only the distance of one star from the other. We require to know also in what direction it is situated. For this purpose the plate on which the micrometric screw and the wires are fixed can be revolved, and the wires placed parallel to the line joining the centres of the two stars. The angle is read off on a circle in firm connection with the tube. This, the so called angle of position is counted from the line connecting the principal star with the pole. From north 0° round through east 90°, south 180°, and west 270° (see Fig. 2). This circle is adjusted by allowing the stars in their daily motion to run from east to west along the wires. The index should then point to 90° or 270°. But it must be kept in view that the images are inverted, so that *e.g.* when looking southwards, north appears down.

ment he worked indefatigably for thirteen years, making above 10,000 measures; and it may be said that by this telescope the genius of its maker carried the palm on behalf of refractors in measuring minute quantities in the sky, while the reflectors stepped into the background, and were subsequently preferred only in cases where the definition is of less consequence than light-grasping power.[1] Struve not only made measures—thanks to Fraunhofer's excellent micrometer and his skill in handling it—more accurate than had been possible up to that time, but he also catalogued about 3000 double stars between the pole and fifteen degrees southern declination. He had their places exactly determined with Ertel's meridian-circle, and these observations, compared with those of later date, have in many cases established the fact that the proper motion was common for two stars, that revolved so slowly that no change in their relative position had been discovered by aid of the micrometer. Thus their physical connection is then established, but indeed "optical double stars" are so uncommon within the limits here considered, that the discovery of an optical couple is almost a greater curiosity. In such a case the micrometric measures serve to accurately fix the amount of the proper motion of one star, the other being generally so distant that it appears stationary, as well as to ascertain the parallax of the nearer star if perceptible. Struve also every night carefully noted the magnitude and colour of the stars he observed, and divided them into *Lucidæ* and *reliquæ*, according to whether the smallest star is above or below the eighth magnitude. According to their mutual distance, he divided them into eight classes, as follows:—

Class I.	Distances from	0″ to 1″	Class V.	Distances from	8″ to 12″
,, II.	,,	1 to 2	,, VI.	,,	12 to 16
,, III.	,,	2 to 4	,, VII.	,,	16 to 24
,, IV	,,	4 to 8	,, VIII.	,,	24 to 32

Struve's principal works are: "Stellarum duplicium et multiplicium mensuræ micrometricæ per magnum Fraunhoferi tubum annis a 1824 ad 1837 in Specula Dorpatensi institutæ," and "Stellarum fixarum imprimis compositarum positiones mediæ deductæ ex observationibus meridianis a 1822 ad 1843 in Specula Dorpatensi institutis."

Though Struve achieved his main results after the arrival of Fraunhofer's refractor, he had made double-star observations as early as 1814, but his apparatus were then so deficient, that he had to try to make use of differences of right ascension observed with a small transit instrument, an attempt that, in spite of his experience as an observer, could not but prove a failure. His observations were subsequently continued, under his direction, by his son, who, with the 14½-inch refractor at Pulkowa, discovered about 500 additional objects. He has made about 7000 measures during the last forty years, and thus we are in possession of observations continued during about seventy years by the Struves, after the same methods.

Meantime, similar investigations had made considerable progress elsewhere. In England, the subject was taken up by the Rev. W. R. Dawes, who, taking into consideration the smallness of his means, achieved more than any contemporary observer. He is justly considered one of the most distinguished of those amateur astronomers, to whom British science is so much indebted. He made about 2000 measures in all. Subsequently, Baron Dembowski, in Italy, commenced micrometric observations of double stars, and though the means originally at his disposal would have been wholly inadequate in other hands, the accuracy of his measures was about as great as that attained at more richly-furnished observatories. Pushed on by his success, he acquired larger and better instruments from Fraunhofer's successor at Munich, and entered upon a series of observations, in which he greatly surpassed the accuracy of other observers. It is therefore to be regretted that the mass of observations he accumulated during a quarter of a century, has not yet been more than partly laid before the public. Investigators were, however, expecting a volume that would completely embody Dembowski's work, when the mournful news of his death in January, 1881, spread over Europe. Compared to his observations, those made by Sir W. Herschel appear to be as rude as observations made before the invention of the telescope, compared to those of the nineteenth century.

It was in the course of the researches carried on by the latter observers, that circumstances came to light which have proved to be of the utmost importance. I allude to the existence of systematic errors. Already Struve found that he measured angles of position differently, when he inclined his head to either side, and he found that in any case, his distances were different from those given by other observers. He did not, however, follow up this remark, but merely kept his head straight while observing, and with regard to the distances he did not see how his own results could deviate from the truth; but his son, though he is in possession of such a great refractor, has been found to measure double stars altogether erroneously. This he has remedied by observing artificial double stars (white ivory disks on a black ground), and after applying the corrections thus ascertained to his measures on the sky, the accuracy of his results has been sensibly increased, though of course the circumstances attendant on such operations are very different from those under which astronomical observations are made during the night, *e.g.* the artificial double stars are always seen near the horizon and are stationary, while the stars are ever moving, and have to be followed by aid of a more or less deficient clockwork driving the telescope. Dawes also, found systematic errors in his measures. He tried to do away with them by slightly inclining his head when the stars were nearly in a vertical, and by the use of a prism, fixed before the eyepiece, to make them appear vertical, when the line joining their centres formed a great angle with the vertical. He says, in the introduction to his observations, that no one about to draw a straight line with a ruler would lay this crooked on the table; one prefers to lay it parallel to the line joining the two eyes. It is in fact most agreeable to measure a double star when the components are either nearly vertical or nearly horizontal. Dembowski's observations seem free from systematic errors, but with praiseworthy diligence he has thought fit to subject this circumstance to a minute scrutiny. To this end he was observing circumpolar double stars of different classes in every hour angle round the pole, as these errors have been found to depend upon not only the angle the line joining the stars makes with the line joining the eyes of the observer, but also on their mutual distance, and as the error diminishes quickly as this increases, it is recommended to use always the highest magnifying power which the state of the atmosphere and the quality of the object-glass will allow.

Space would not allow me to refer to all the astronomers, who at one time or another have paid attention to the subject, or to discuss the relative value of their work. Father Secchi made some good measures in Italy, Duner, in Sweden, has published about 3000 valuable observations, and Gledhill, in Halifax, has also successfully taken up this work. In spite of the skies of Connaught, that clear so seldom and so irregularly, I have tried to do my best, but I have not succeeded in getting

---

[1] The definition of an image seen in a large reflector is inferior to that in a smaller refractor, both on account of the greater influence of any defect in grinding the surface of a mirror, and because, when the aperture is larger, the rays of light from the object have to pass through so much larger a portion of the atmosphere, the irregularities and motions in which render the image unsteady and badly defined.

more than 1000 observations up to this. Latterly, this branch of science has made distinct advances in America, where Burnham has made excellent use of the gigantic refractors, which are made by Alvan Clark of Boston. He has discovered a number of important double stars, the components of which cannot be separated at all in older telescopes.[1]

In 1878 the French astronomer Flammarion, who is so favourably known from his excellent popular treatises, published his "Catalogue des Étoiles doubles et multiples en Mouvement relatif certain, comprenant toutes les Observations faites sur chaque couple depuis sa découverte, et les résultats conclus de l'Étude des mouvements," a work that is highly valued by double-star investigators, but private observers will do well in consulting also Messrs. Crossley, Gledhill, and Wilson's "Handbook of double-Stars," with its "Supplement."

As remarked above Herschel found that changes had taken place in several systems of double-stars, and in 1836 Struve was able to give a list of a hundred systems, where the components appeared to revolve; but on account of the difficulty of the measures, it was not easy to decide whether this was owing to actual motion of the star or in some cases to divergences of the observations. But he proved beyond dispute in about half the cases that the companion had revolved, and Mädler, who was one of the most indefatigable double-star observers, as well as the most prominent calculator, raised this number to several hundreds. His work, "Tabula generalis stellarum duplicium indicationem motus gyratorii exhibentium," was published in 1849, and contains 650 entries, but many of these were mere surmises, and have not been corroborated by subsequent research.

If the observations were absolutely free from errors, it would be an easy task to investigate the path of the companion, but in addition to the imperfection of every observed position, we have as explained above to guard against systematic differences between the different observers. In long series of observations of quickly revolving stars, this gives occasion to endless discussion. We draw, for instance, a powerful aid in discerning systematic errors, from Kepler's law, that the areas described by the radius vector are proportional to the intervals of time; but he would be a bold man, who in the present state of our knowledge, would affirm that all binary stars have been proved to revolve according to this law in elliptic orbits, in the focus of which the main star is situated,[2] or would condemn all observations that could not be made to fit into such an hypothesis. But though this assumption is a mere hypothesis, and may remain so for a long time to come, we have nothing else to guide us. In fact we cannot calculate an orbit at all except by aid of these laws.[3]

W. DOBERCK

(*To be continued.*)

---

[1] The difficulty of separating close double stars renders them fit tests for the performance of a telescope. Some idea of the quality of a telescope may be gained, when it is stated that it is able to separate objects of a certain class, be it *lucidæ* or *reliquæ*, but withal, it is preferable to try its performance on terrestrial test objects. A third sub class "delicate" double stars, or those in which the companion is so minute compared to the main star, as to require a high degree of optical power to perceive it, has been added by Sir John Herschel, but it deserves to be remarked that the appearance of such objects depends quite as much upon the state of the atmosphere. The companion of Sirius, for instance, has been repeatedly seen in 4-inch refractors under exceptionally favourable circumstances, though in a great latitude. A large aperture is therefore not always an advantage. The situation of the observatory is of much greater importance. Piazzi Smyth has the merit of having for years insisted upon this point. The Lick Observatory, about to be founded on Mount Hamilton, California, will offer unusual advantages. Mr. Burnham has there already discovered some difficult double stars with a minor telescope.

[2] Both stars revolve, of course, round their common centre of gravity, but it is easy to see that the *relative* position of the two stars is all the same then as if only one revolved. If the changes in the absolute place of one of the stars were known, we would have the means of computing the relative masses; but this has only been possible in a few cases at most.

[3] In case of certain triple stars, whose movements do not fit into Keplerian ellipses, we have to represent the motions by aid of epicycles, just in the same way as Ptolemæus represented the motion of the planets in the system named after him.

THE MARIANNE NORTH GALLERY OF PAINTINGS OF "PLANTS AND THEIR HOMES," ROYAL GARDENS, KEW

MANY readers of NATURE are doubtless aware that the large collection of beautiful and instructive pictures of flowers painted in various countries by Miss Marianne North, is now, through the noble generosity of this lady, the property of the nation. The collection is in a handsome building specially erected in Kew Gardens for the purpose, at Miss North's expense, and from designs given by Mr. James Ferguson, F.R.S. Last week the gallery was opened without any ceremony whatever, and henceforward it will be open and free to the public at the same times and hours as the museums and other buildings in the Gardens.

Now that this is an accomplished fact, a few words respecting the history and the principal features of the collection may be useful. Impelled by a love of nature, Miss North has spent many years travelling from country to country, and painting the most striking scenes and objects that came under her observation; and from time to time some of these paintings have been exhibited in London. The more Miss North travelled and painted, the more the desire to travel and paint seems to have grown; the result being a large collection of pictures. Then arose the question, what should be done with them? and happily in this Miss North was influenced by the kindly feeling that she would like other less fortunate persons to see and enjoy what she herself had seen and enjoyed so much. This idea once conceived, the warm-hearted artist and traveller set to work more assiduously than before, in order to carry it into effect, even visiting Australia and New Zealand, for the purpose of painting the vegetation of that region. In a country where the love of flowers is general from the poorest to the richest, such a gift as that now offered to the public will assuredly be fully appreciated.

The collection is designated in the title of the catalogue as paintings of "plants and their homes," and this title is justified by the fact, that in nearly all the pictures, plants have supplied the motive, the other objects represented being accessories. Altogether there are upwards of six hundred pictures, representing vegetation in nearly all temperate and tropical parts of the world except Europe and Africa, unless we regard Teneriffe as belonging to the latter country. A descriptive catalogue, compiled by the writer of this notice, and published at Miss North's expense, contains not only the titles of the pictures, but also short notes concerning the life-history, products, &c., of the plants painted, inserted with the intention of making it as instructive as possible to those who know least of such things. There are representations probably of not less than a thousand species, and these include members of nearly every natural order in the vegetable kingdom. The fruit and other useful plants of the different countries are numerous; and associated with them are many of the most ornamental and most striking wild and cultivated plants. In dealing with trees and shrubs, the artist has usually painted a flower-bearing or fruit-bearing branch, or both, in front, and given the habit of the tree or shrub in a landscape behind. Without being botanical, the paintings of the plants are so thoroughly naturalistic, that a botanist has little difficulty in determining such as are not known to him by sight. In so far as regards its prominent features and peculiar types, the Australian flora is more completely portrayed than any other, about seventy-five pictures being devoted to this region. Miss North visited Queensland, New South Wales, Victoria, Tasmania, South Australia, and West Australia; and from each of these colonies she brought home paintings of a large number of the most striking and characteristic plants. Thus of Eucalyptus there are portraits of *E* *amygdalina*, *calophylla*, *colossea*, *cordata*, *ficifolia*, *globulus*, *tetraptera*, and several others; of other characteristic Myrtaceæ, the genera Callistemon, Syncarpia, Agonis, Melaleuca, Beaufortia, and Leptospermum; of Leguminosæ, Acacia, Gompholobium, Kennedya, Clianthus, Platylobium, &c.; of Epacrideæ, Leucopogon, Richea, Epacris, Lissanthe, and Styphelia; of Proteaceæ, Banksia, Grevillea, Xylomelum, Telopea, Hakea, Lambertia, Macadamia, Petrophila, &c.; of genera belonging to other natural orders, taking them in the order they occur in the pictures: Phyllocladus, Doryphora, Casuarina, Pimelea, Prostanthera, Billardiera, Exocarpus, Anigozanthus, Xanthorrhæa, Kingia, Cephalotus, Cheiranthera, Xanthosia, Leschenaultia, Stylidium, Johnsonia, Trichinium, Isotoma, Byblis, Actinotus, Nuytsia, Doryanthes, Fusanus, Comespermum, &c., &c. In conclusion I may state that there is a complete index to the catalogue, so that it is possible to ascertain what plants are figured by reference thereto.

W. BOTTING HEMSLEY

AN ELECTRIC RAILWAY

THE following account of the electric railway of Breuil-en-Auge is taken from an article by M. Gaston Tissandier in our contemporary, *La Nature*. The subject of electric railways, which has recently claimed public attention; and the recent construction on a commercial scale of a practical electric railway in the department of Calvados in France derives additional interest from the fact that the motive power is, in this instance, furnished by electric accumulators. We propose to give a general description of the railway, but will first briefly state the object for which the line has been constructed.

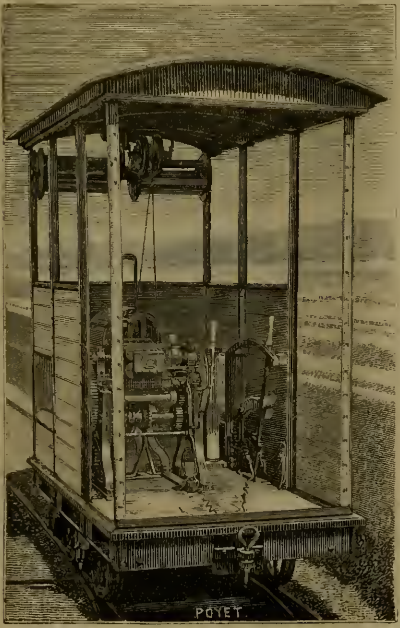

FIG. 1.—The locomotive, with dynamo-electric motor and driving-gear.

The linen-bleaching establishment of M. Paul Duchesne-Fournet is situated at Le Breuil-en-Auge, and is a large concern to which most of the linen fabrics manufactured at Lisieux are sent to be bleached. The complete process of bleaching consists in successively exposing the linen pieces first to the action of chlorine, then to alkaline baths, lastly to the sun's rays. The last operation is of course conducted out of doors by laying out the linen in the open meadows. Each length of linen measures about 100 metres, and the establishment boasts a bleaching ground of 15 hectares (37 acres). The operation of taking up the pieces is laborious, necessitating several workmen.

M. Clovis Dupuy, engineer-in-chief of the works, proposed a mechanical device for picking up the linen pieces by the aid of a railway which carried the requisite mechanism. But a railway worked by a steam-engine could not be tolerated in the bleaching field, as the smoke produced by the burning fuel and the ashes projected from the funnel would play havoc with the linen laid out beside the line. M. Dupuy therefore determined to build an electric railway, the construction of which is now finished, and which works very satisfactorily.

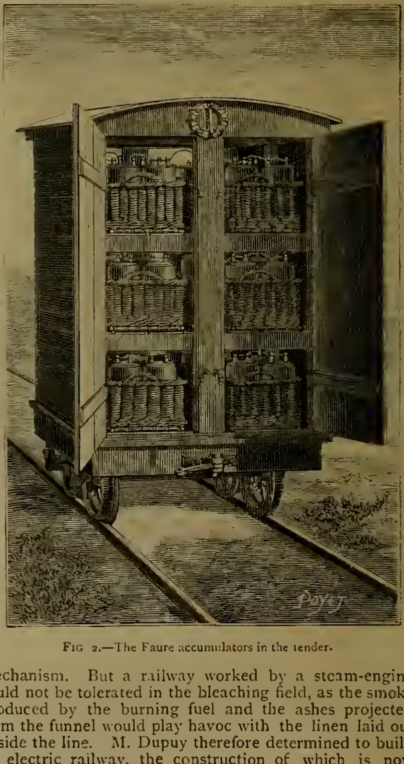

FIG 2.—The Faure accumulators in the tender.

The electric railway of Le Breuil-en-Auge passes the end of each of the many plots upon which the linen is laid out, there being a piece of straight line 500 metres in length, and twenty-one branch lines. The total length is 2040 metres. The rails are of the narrow gauge of 0·8 metre (2 feet 7½ inches).

The train is driven by a locomotive shown in Fig. 1, the driving machinery being a Siemens' dynamo-electric machine working as a motor. The currents to drive the motor are supplied from a battery of Faure accumulators contained in a separate tender, depicted in Fig. 2. The train starts from the factory with the wagons empty. Arrived at the bleach-field, it stops. By the movement of a handle, the motor is thrown into gear with a set of windlass rollers employed to wind up the linen. Passing between these rollers the linen ascends to another roller in the top of the car, which covers the machinery, where it passes to a workmen, who packs it in folds in a little truck (Fig. 3). Preferably all the linen pieces laid out upon the plot of neighbouring ground, are united to one another by their ends, so that a single workman can pick up 5000 metres of linen in thirty minutes, an operation usually requiring eleven hours to perform. Fig. 4 shows the train of little trucks returning loaded with 10,000 metres of linen. Having thus described the general system, it will be convenient to examine the details.

Fig 3.—Hauling in the bleached linen.

Fig. 4.—The return of the electric train from the bleaching ground.

The motor, or locomotive (Fig. 1) consists, as we have said, of a Siemens' dynamo capable of being reversed at will. The armature rotates very rapidly, the motion being reduced by a chain-gearing in the proportion of 1 to 9. A lever handle (see Figs. 1 and 5) controls the machine. As shown in Fig. 5, in a vertical position the brake is on, and no electrical action is taking place. By lowering the lever, contact is made, enabling the electric current to flow. A "rheostat-chain," the invention of M. Reynier, who in 1881 applied a similar device to a sewing machine driven by electricity at the Paris Exposition, is thereby stretched. As its tension increases, there is better contact electrically between its links, and with this better contact the electric resistance diminishes; the flow of current and consequently the speed of the engine, is therefore increased. By moving the lever in one direction or the other, the speed of the train may therefore be varied at will. When the lever is put back to its position of rest, it not only breaks contact, but also puts on the brake. To reverse the motion of the train, there is a second lever, which shifts the brushes of the dynamo. A third lever sets the wheels of the dynamo in gearing either with the axle of the locomotive, or with the hauling machinery previously mentioned.

The tender (Fig. 2) attached to the locomotive holds the accumulators, which are of the type constructed by M. Reynier, consisting of two lead plates covered with red lead, and wrapped in felt or serge, rolled together in a spiral, placed in dilute acid in a stoneware jar. These cells are arranged (Fig. 2) in three tiers in baskets, each basket holding six cells. On each shelf are four baskets, except on the uppermost, which holds two only. The sixty accumulators weigh 500 kilogrammes (half a ton).

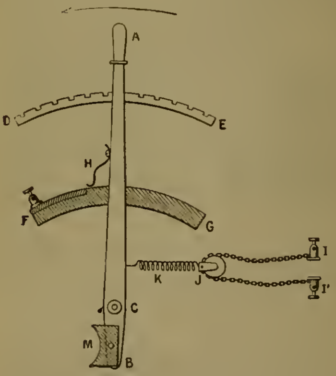

FIG. 5.—The starting-gear, with chain rheostat.

The total weight of the locomotive is less than a ton, that of the tender 700 kilos. (1543 lbs.), and that of each loaded truck 800 kilos. (1763 lbs.). With the workmen and six passengers, the total weight of the train is 6400 kilogrammes (about 6½ tons). The accumulator cells are charged at the factory by the current of a Gramme machine, which has been used since 1879 to light the establishment by eleven Reynier lamps. The power available in the works is 60-horse. Only 3 horse-power is, however, required during the charging of the cells, which takes from five to eight hours.

In the top of the tender is a switch, by means of which the accumulators can be used in rotation, beginning with a minimum of twenty-four, and increasing successively by sixes up to sixty cells.

This railway has worked since March last with results advantageous in every way. The speed of the train attains 12 kilometres (about 7½ miles) per hour; but in this special case, great speed is not desired. According to the information furnished by M. Dupuy, the train can work for three hours; being limited only by the charge that can be imparted to the accumulators.

This application of electricity to a purpose for which a steam-engine would be out of the question, is not only novel, but suggestive. We feel disposed to query how long it will be before that great section of the public of London who travel by the Metropolitan Railway, insist that their lungs and eyes have as much claim as the linen of M. Duchesne-Fournet to be protected from the disastrous presence of the smuts and scoriæ of the steam-engine.

THE WEATHER OF THE PAST WEEK

THE very disagreeable weather we have had these last few days deserves a passing notice. Strong persistent northerly winds for nearly a week have swept over the whole of the British islands. On Sunday and Monday a continuous north-easterly gale blew over Shetland and Orkney, completely interrupting all communication among these islands, accompanied with heavy rains, floods, and hailstorms; and at the same time much snow fell in the upland districts of the interior of North Britain, draping the mountains of Aberdeenshire and Perthshire in their winter covering of snow down nearly to their bases. On the other hand, in England and Scotland, much thunder and hail occurred towards the end of last week, and not a few lives were lost by the severity of the thunderstorms. These disagreeable and remarkable phenomena were attendants on an atmospheric depression signalled by the Meteorological Office on Thursday morning, last week, as about to advance over the more southern parts of these islands. The depression appeared in course, its centre following the line of the Cheviots; and its northern side being characterised by unwonted high pressures, it proceeded with singular leisureliness over the North Sea, and only reached Christiania by the morning of Monday. The slow onward rate of motion of this cyclone, the steep gradients formed on its north and north-west sides, and its southerly route across the North Sea readily explain the extent, strength, persistence, and disagreeably low temperature of the gale, and the unseasonable snowfalls which accompanied it. It is to such low depression-centres brooding over or slowly crossing the North Sea, that we owe our coldest summer weather; and it is a continued repetition of these in the critical months of June, July, and August that brings disaster to the farming interests. In the middle of June, 1869, a similar storm occurred when equally strong winds prevailed, when even more snow fell, particularly in the north-west of Great Britain, and temperature sank some degrees below freezing over extensive districts; but the storm was of shorter duration than the one we have just had. In this case, also, the cyclone formed steep gradients for northerly winds, and its centre crossed England and the North Sea, but it advanced over North-Western Europe at a more rapid rate than the present storm, which has formed so marked a feature of the weather of June, 1882.

NOTES

WE take the following from the *Times*:—At the meeting of the Royal Society last week, the fifteen undernamed candidates were elected Fellows:—Prof. Valentine Ball, M.A., George Stewardson Brady, M.D., F.L.S., George Buchanan, M.D., Charles Baron Clarke, M.A., F.L.S., Francis Darwin, M.A., F.L.S., Prof. William Dittmar, F.C.S., Walter Holbrook Gaskell, M.D., Richard Tetley Glazebrook, M.A., Frederic Ducane Godman, F.L.S., Prof. Jonathan Hutchinson, F.R.C.S., Prof. Archibald Liversidge, F.G.S., Prof. John C. Malet, M.A., William Davidson Niven, M.A., Robert Henry Inglis Palgrave, F.S.S., Walter Weldon, F.C.S.

IT is interesting to notice, that in connection with the vote of sympathy of the Common Council on the death of Garibaldi, the Lord Mayor stated that "on the death of the great philosopher and man of science, Mr. Darwin, he received over twenty telegrams from cities in Italy, expressive of Italian sympathy with the loss this country had sustained."

WE have received from Bucharest a little *brochure* of the greatest interest, in the shape of a translation into Roumanian of Sir John Lubbock's British Association address, "Fifty Years of Science," by Prof. J. P. Licherdopol. The translation, we learn from the title page, is made from the report in NATURE. Prefixed is a brief address to Sir John Lubbock, which is written in vigorous and almost perfect English. "Your 'Fifty Years of Science,'" the translator writes, "has impregnated itself in the heart of the people who populate the plains and mountains of the Lower Danube. The scientific truths and literary beauties of such a work of genius cannot remain unknown to the Roumanians; I therefore took upon myself the pleasing duty of making it more known among them. I beg of you, therefore, to glance at it, and to receive it as your own; you will recognise it, perhaps, by its forms, which are impossible to be changed." As the translator styles himself Professor of Natural History and Physical Science, ex-Assistant Naturalist to the Museum of Natural History, and preparator in the Chemical Laboratory; and as a list of other scientific works, original and translated, is prefixed, it is evident that science has a hopeful place in Roumanian education and literature.

A COMMITTEE of members of the Academy of Sciences, the Academy of Medicine, the Society of Agriculture, and the faculty of science in the Superior Normal School of Paris, has been formed for the purpose of presenting to M. Pasteur a medal in commemoration of his fruitful researches.

WE regret to announce the death of Mr. Scott Russell, the eminent engineer, which took place on Thursday morning last, in the seventy-fifth year of his age. John Scott Russell, according to *Engineering*, was the eldest son of the Rev. David Russell, a Scotch clergyman. His great predilection for mechanics and other natural sciences induced his father to allow him to enter a workshop, to learn the handicraft of the profession of an engineer. He subsequently studied at the Universities of Edinburgh, St. Andrews, and Glasgow, and graduated at the last at the early age of sixteen. He had attained to such proficiency in the knowledge of the natural sciences, that on the death of Sir John Leslie, Professor of Natural Philosophy in Edinburgh, in 1832, the young Scott Russell, though then only twenty-four years of age, was elected to fill the vacancy temporarily, pending the election of a permanent professor. About this time he commenced his famous researches into the nature of waves, with the view to improving the forms of vessels. His first paper on this subject was read before the British Association in 1835. The interest created by this paper was so great that a committee was appointed by the Association to carry on the experiments at their expense. Mr. Scott Russell discovered during these researches the existence of the wave of translation, and developed the wave-line system of construction of ships in connection with which his name is so widely known. In 1837 he read a paper before the Royal Society of Edinburgh, "On the Laws by which water opposes resistance to the motion of floating bodies." For this paper he received the large gold medal of the Society. In 1844 Mr. Scott Russell removed to London. In 1847 he was elected a Fellow of the Royal Society. He for a short time occupied the post of the secretary of the Society of Arts, which place he resigned to become joint secretary with Sir Stafford Northcote of the Great Exhibition of 1851. He was, in fact, one of the three original promoters of the Exhibition, and under the direction of the late Prince Consort, took a leading part in organising it. Mr. Scott Russell was for many years known as a shipbuilder on the Thames. The most important work he ever constructed was the *Great Eastern* steamship. Mr. Scott Russell was one of the earliest and most active advocates of ironclad men-of-war, and he has the merit of having been the joint designer of our first sea-going armoured frigate the *Warrior*. In early life he took a great interest in steam locomotion on ordinary roads, and while at Greenock he constructed a steam coach which ran for some time successfully between Greenock and Paisley. His greatest engineering work was without doubt the vast dome of the Vienna Exhibition of 1873. The last engineering work which Mr. Scott Russell ever designed was a high level bridge to cross the Thames below London-bridge. It was intended to cross the river with a span of 1000 feet, and to allow of a passage beneath it for the largest ships.

THE death is announced of Mr. James Spence, Professor of Surgery in Edinburgh University, in the 70th year of his age.

WE regret to announce the death of Dr. P. A. Bergsma, late director of the Batavia Observatory. He died on May 1, during his passage through the Red Sea, on the way home from India. We quite recently announced the retirement of Dr. Bergsma from his post in Batavia Observatory, where he has done so much good work.

IN anticipation of the jubilee meeting this year the *British Medical Journal* devotes most of its last number to a Historical Sketch of the British Medical Association.

AS a result of the action taken by the Essex Field Club with reference to the preservation of Epping Forest in its natural condition, a conference was held on Friday evening, June 9, at the residence of Mr. E. N. Buxton at Woodford. Of the verderers there were present besides Mr. Buxton, Sir T. Fowell Buxton, and Mr. Andrew Johnston. The scientific claims of those to whom the preservation of the forest as such is a matter of importance, were ably advocated by many well-known naturalists who had been invited to take part in the discussion. Among the speakers were Dr. Henry Woodward, Dr. M. C. Cooke, Mr. J. E. Harting, Mr. Charters White, the President of the Quekett Club, Mr. G. S. Boulger, and Messrs. R. Meldola and Wm. Cole, the President and Secretary of the Essex Field Club. The results of the conference were, as we learn, satisfactory with respect to the future of the forest.

THOSE entomologists who study fossil insects, and palæontologists generally, should feel grateful to Mr. S. H. Scudder for having compiled "A Bibliography of Fossil Insects," forming No. 13 of the "Bibliographical Contributions" appearing in the *Bulletin* of Harvard University. It extends (including an appendix) to 47 pages in double columns, and must include nearly 1000 references, to each of which, as a rule, are appended a few lines of explanatory notes. The subject is made to include spiders and myriopods, in addition to true insects. No trouble appears to have been spared in order to render it as complete as possible; on this point Mr. Scudder laments that the enormous increase of popular literature that has taken place latterly, containing hosts of minor papers wholly popular in character, has vastly increased the labour of compilation without corresponding advantage. He doubts if as much activity is now shown in the department of fossil entomology as when the labours of Heer gave a sudden impetus to its study. Possibly the often eminently unsatisfactory and speculative nature of the subject has something to do with this.

WITH reference to Prof. Riley's extracts from Dr. Macgowan's papers on the utilisation of Ants in Horticulture, in China, a correspondent calls our attention to a long article in the *Ceylon Observer* for April 26, in which is reprinted the following extract from Tennent's Natural History of that island:—"To check the ravages of the coffee bug (*Lecanium coffeæ*, Walker), which for some years past has devastated some of the plantations in Ceylon, the experiment was made of introducing the red ants, who feed greedily on the coccus. But the remedy threatened to be attended with some inconvenience, for the Malabar coolies, with bare and oiled skins, were so frequently and fiercely assaulted by the ants as to endanger their stay on the estates."

The *Rèvue Scientifique*, one of the most influential scientific periodicals in France, has been purchased by a company for the purpose of extending its publication and improving its programme.

On Tuesday evening Mr. Keane exhibited at the Anthropological Institute, on behalf of the finder, Mr. M. S. Valentine, of Richmond, Virginia, some very remarkable stone objects recently discovered by that archæologist in the neighbourhood of Mount Pisgah, North Carolina. In the course of his remarks Mr. Keane explained that these were merely a few typical specimens selected from an extensive collection of over 2000 articles, partly in stone and partly in micaceous clay found in this upland region, between the Alleghany and Blue Mountains, during the years 1879-82. The material of the stone objects is almost exclusively steatite, or soap-stone, which abounds in the district, and which might almost seem to have been sculptured with metal instruments, so perfect is the workmanship. The objects themselves are absolutely of a unique type, consisting partly of human and animal figures, either in the round or in various degrees of relief, partly of household utensils, such as cups, mugs, basins, dishes, and the like, partly of purely fancy, and other miscellaneous articles, illustrating the tastes, usages, and culture of the unknown people by whom they have been executed. Collectively they present, Mr. Keane maintains, a unique school of art developed at some remote period in a region where the presence of civilised men had not hitherto been even suspected. The human type, which presents great uniformity, while still by no means conventional, is distinctly non-Indian, according to Mr. Keane, but whether Mongolic or Caucasic it would at present be premature to decide. All are represented as fully clothed, not in the hairy blanket of the Red Man, but in a close-fitting well-made dress somewhat after the modern "united garment" fashion. Some are seated in armchairs exactly resembling those known as "Ingestre Chairs," while others are mounted on the animals, which they had domesticated. These animals themselves are stated to be marvellously executed. Some of them represent the bear, the prairie dog, and other quadrupeds, as well as birds of North America. But others seem to represent types of the Old World, such as the two-humped Baktrian camel, the rhinoceros, hippopotamus, and European dog. There are also some specimens obviously executed since the appearance of the white man, as shown by the horse with his rider, firearms, shoes, &c. The material of all these has a much fresher look than the others, and is of much ruder workmanship, as if they were the work of the present race of Indians. These races are undoubtedly of the pure Indian type, Mr. Keane stated, and recognised themselves as intruders in this region, where they had certainly been preceded by more civilised peoples, such as the Mound-builders and others, of whom they had traditions, and whom they had extirpated long before the arrival of the Europeans. Amongst these extinct peoples were the Allegs or Alleghewis, whose name survives in the "Alleghany Mountains." These Alleghewis are said to have been a different race from the Indian, and it is possible, Mr. Keane thought, that in their new homes in the Alleghany uplands they may have continued or developed the culture of which we have met remarkable evidence in these stone objects. It is evident, however, that before any conclusions can be built on this interesting find, the conditions under which it was found must be carefully sifted by archæological specialists.

The Municipal Council of Paris has voted the funds for executing six aëronautical ascents on the occasion of the festivities of July 14 next. Two of these balloons will be connected by a telephone wire in order to keep up constant verbal communications. These two connected balloons will ascend from the Place du Trone. It is hoped that by sending up balloons so connected many interesting observations can be made for the velocity of sounds at different altitudes, the differences of temperature of velocity of wind and of direction, &c., as well as differences of electrical tension.

During the progress of some excavations on Lord Normanton's estate, near Crowland, Peterborough, the workmen have exposed about three acres of a subterranean forest 10 feet below the surface. Some of the trees are in an admirable state of preservation, and one gigantic oak measures 18 yards in length. The trees are in such a condition that oak can be distinguished from elm, while a kind of fir tree seems to be most abundant, the wood of which is so hard that the trees can be drawn out of the clay in their entirety. The surrounding clay contains large quantities of the remains of lower animal life.

The working of subterranean telegraphic lines is stated to be unsatisfactory in France and in Germany as well, and it is doubted whether the process shall be continued in France, although credits have been voted by the French Parliament for a sum of several millions of francs. These circumstances ought to be carefully investigated, as it is contemplated, we understand, to introduce the continental subterraneous method into this country.

M. Cochery, the French Minister of Postal Telegraphy, has decided that the electrical laboratory established with the proceeds of the late Electrical Exhibition will be placed in the Bois de Boulogne. The reason alleged is the necessity of avoiding the shaking of the ground by the passing of carriages so frequent in Paris. The establishment will be open to the public under certain limitations and regulations, which will be printed in the *Journal Officiel*. The development of the institution will be only gradual, the profits realised amounting to only 300,000 francs, and the total sum required to 1,000,000 francs.

The works of the French Company for the Channel Tunnel are progressing favourably. A number of workmen are engaged in mounting the engine designed by Col. Beaumont, which is placed in the lower gallery, and will be in working order in a few weeks. The boring will be executed under the supervision of an English foreman, who conducted the excavation of the first 500 metres on the English side.

From the Report of the Mitchell Library, Glasgow, it seems evident that it is in a fair way of becoming one of the first libraries in the kingdom; the avowed aim of its trustees is to make it for Glasgow what the British Museum Library is for London. It contains already 40,000 volumes, a large proportion of which are scientific. The number of works taken out during the year in "Art, Science, and Natural History" (a curious classification), bore a large proportion to those on other subjects.

Mr. Joseph Simmons, the balloonist, made a journey on Saturday in his balloon the *Colonel* from Maldon in Essex, across the Channel to beyond Arras in France, a distance of 170 miles, in one hour and three-quarters.

A peculiar and interesting auroral phenomenon, witnessed from the steamship *Atlantic* off the Newfoundland coast, on

September 12 last year, has been described by Mr. Eogler to the St. Louis Academy. While an aurora of normal type was clearly seen in the northern sky, there appeared in the south-east, about 30 to 35 deg. above the horizon two horizontal streaks of light, about 5 deg. apart, and 15 or 20 deg. in length. Their pale hazy light resembled moonlight. From the upper streak were suspended, by small cords of light, a number of balls, brighter than either of the streaks, which were continually jumping up and down in vertical lines, much like pith-balls when charged with electricity. Above the upper streak was a bright gauze space with convergent sides, seemingly composed of streamers of light, the brightness diminishing from the streak outwards. From the lower streak extended a similar mass, differing only in a greater inclination of the streamers. The balls and cords gradually disappeared first, then the streamers, then the streaks; and the whole phenomenon lasted about half an hour. No explanation is offered. It is noteworthy that on the same evening and at the same hour, a most remarkable band of white light was seen at Albany, N.Y., Utica, N.Y., Hanover, N.H., Boston, Mass., and elsewhere in the North Atlantic States, spanning the heavens from east to west near the zenith.

THE sixth part of the *Transactions* of the Cumberland Association for the Advancement of Literature and Science, is a volume of 180 pp., and comprises the annual reports of the different local societies, amalgamated under the title, with a selection of papers read before the Association and the local societies. We have already given full details of the formation and working of the Association. The report of the secretary, Mr. J. D. Kendall, F.G.S., is encouraging, showing, that though there is a slight falling off in the number of members, due to the cause already noticed, there are now 1811 on the books. The present volume of *Transactions* is one of the most valuable the Association has yet published. It is divided into two parts, the first containing the President's address and the papers read at the annual meeting, and the second consisting of papers communicated to the different societies, and recommended by the Council for publication. Among the papers are—Public water-supplies of West Cumberland, by Mr. A. Kitchin, F.C.S.; Grasses of Mid-Cumberland, by Mr. W. Hodgson; Observations on the flowering-plants of West Cumberland, by Mr. J. Adair; the lichens of Cumberland, by Rev. W. Johnston; Notes on the occurrence of the Iceland falcon in Edenside, by Mr. J. G. Goodchild, accompanied by an excellent drawing of the bird; and Physical geography of North-West Cumberland, by Mr. T. V. Holmes. The second part includes an historical sketch, "The Chaloners Lords of the Manor of St. Bees," by Mr. W. Jackson, F.S.A., and an exceedingly interesting paper on bird-life, by Dr. Chas. A. Parker. Mr. Holmes contributes notes on a submerged forest off Cardurnock, on the Solway, and on the destruction of Skinburness by the sea about the year 1305. A valuable list of West Cumberland flowering-plants and ferns, by members of the Botanical Section of the Whitehaven Society, records the observed plants of the district. This appears to be the most complete list that has yet been published, though a few errors have crept in. The concluding paper is on the distribution of the Diatomaceæ, by Mr. B. Taylor, and consists of a list of the species obtained by him in the locality.

IN reference to Mr. S. M. Baird Gemmill's letter on the Aurora (*antea*, p. 105), the writer asks us to state that the aurora was observed on May 15th (not the 18th).

THE additions to the Zoological Society's Gardens during the past week include a Sykes's Monkey (*Cercopithecus albogularis* ♂) from West Africa, presented by Mr. Ballantine Dykes; a Common Marmoset (*Hapale jacchus*) from Brazil, presented by Mrs. Wingfield; a Yellow-bellied Liothrix (*Liothrix luteus*) from India, presented by Miss Mabel Crosbie; two Common Nightingales (*Daulias luscinia*), a Blackcap Warbler (*Sylvia atricapilla*), British, presented by Mr. H. Grant; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Mr. David Rowell; a Common Nightingale (*Daulias luscinia*), British, two Yellow-bellied Liothrix (*Liothrix luteus*) from India, deposited; two Wood Larks (*Alauda arborea*), European, received in exchange; two Japanese Deer (*Cervus sika* ♂ ♂), two Mouflons (*Ovis musimon* ♂ ♂), a Cape Buffalo (*Bubalus caffer* ♂), born in the Gardens. The following insects have emerged during the past week:—Silk Moths: *Samia cecropia, Attacus mylitta, Attacus cynthia, Actias selene*; Butterflies: *Lycæna iolas, Limenitis sibylla, Argynnis paphia, Vanessa urticæ, Papilio podalirius*; Moths: *Sphinx pinastri, Chærocampa elpenor, Sesia formicæformis, Sesia conopiformis, Sesia muscæformis, Trochilium apiforme, Trochilium melanocephalum, Sciapteron tabaniforme, Callimorpha dominula, Odonestis potatoria.*

OUR ASTRONOMICAL COLUMN

MASKELYNE'S VALUE OF THE SOLAR PARALLAX.—Several inquiries have been lately made with regard to the authenticity of a value of the sun's parallax, attributed in many works to Maskelyne, the former Astronomer-Royal.

This value (8″·723) was deduced by Maskelyne in an application of what he calls a new method of determining the effect of parallax on transits of the inferior planets, and is given in an article which he appears to have communicated to Vince, Plumian Professor of Astronomy at Cambridge, who published it both in his large work, "A Complete System of Astronomy," and in his elementary treatise intended for the use of students in the University. We have not been able to consult the earlier editions of these works, to ascertain whether, as is probably the case, the article was published in Maskelyne's life-time, but it is found in Vol. I. of the "System of Astronomy," which appeared in 1814, and is dedicated to Maskelyne, and also in the fourth edition of the "Elements of Astronomy," Cambridge, 1816. The article is entitled "A new method of computing the effect of parallax, in accelerating or retarding the time of the beginning or end of a transit of Venus or Mercury over the sun's disc, by Nevil Maskelyne, D.D., F.R.S., and Astronomer-Royal." After explaining his method and how an approximate value may be corrected, as a numerical example he compares the duration of the transit of Venus in 1769 as observed at Wardhus and Otaheite, assuming as an approximate value of the mean horizontal parallax 8″·83 (nearly that found by Du Sejour), and concludes: "Hence the mean horizontal parallax of the sun = 8″·83 × (1 − 0·0121) = 8″·72316." In the "Elements of Astronomy" there is the additional sentence: "we assume, therefore, the mean horizontal parallax of the sun = 8¾″"; but this does not appear in Vince's larger work, nor is it quite clear whether it is an addition of Maskelyne's or his own."

Lalande says the first edition of Vince's "Elements of Astronomy" was published in 1790, and Vol. I. of the large work in 1797. Probably some of our readers may be able to refer to the earlier editions.

COMET 1882*a* (WELLS, MARCH 17).—The following ephemeris of this comet is deduced from the elements last given in this column:—

At Greenwich Midnight

	R.A.	Decl.	Log. distance from	
	h. m. s.	° ′	Earth.	Sun.
July 1	9 35 58	+11 57·0	0·0501	9·8925
3	9 50 49	11 23·2	0·0673	9·9205
5	10 4 21	10 50·2	0·0850	9·9461
7	10 16 43	10 18·2	0·1027	9·9697
9	10 28 2	9 47·4	0·1202	9·9916
11	10 38 26	9 17·9	0·1375	0·0120
13	10 48 1	8 49·6	0·1545	0·0310
15	10 56 54	+ 8 22·4	0·1711	0·0489

On July 1, the comet sets 1h. 44m. after the sun at Greenwich, and the theoretical intensity of light is equal to that on May 16; on July 15, it sets 1h. 50m. after the sun, with a brightness equal to that on April 19.

On June 7, Mr. Barber of Spondon, Derby, observed the comet with his 8-inch refractor, at 8h. 30m., or less than ten minutes after sunset: there was a large white disc, but no tail was visible at this time.

A SUSPECTED VARIABLE STAR.—Mr. S. M. B. Gemmill writes from Glasgow, expressing the opinion that ϕ Draconis will prove to be a variable star. For some time past he has observed it to be almost equal to χ in the same constellation, whereas Groombridge and others had given a difference of one magnitude. The "Durchmusterung" has 4·7 and 3·8 for these stars respectively, and the first Radcliffe catalogue, for which the magnitudes were very carefully estimated, has 4·4 and 3·7. Heis assigns a difference of half a magnitude. Mr. Gemmill states he has found a very slight fluctuation in ψ^1 Draconis, which seems to be periodic. Baily, in his notes to the *British Catalogue*, says: "This star is marked as of the 7th magnitude in the *British Catalogue;* but in the original entries it is designated once as 4½, once as 3½, and once as the 5th."

THE UNIVERSITY OBSERVATORY, OXFORD.—The Savilian Professor of Astronomy, director of the University Observatory, has issued his annual report, which was presented to the Board of Visitors on the 1st inst. It is mentioned that a somewhat elaborate memoir is now printed in the *Transactions* of the Royal Astronomical Society on the application of photography to delicate celestial measurement. The inquiry into the relative motions of some forty stars in the Pleiades has been brought to a successful conclusion, the results agreeing generally with those recently deduced by M. Wolf, of the Observatory at Paris, who employed a very different instrument and method. A complete survey of the relative brightness or magnitudes of all the stars in the northern hemisphere reputed to be visible to the naked eye has been commenced, and it is hoped that before the date of the next report, all the stars brighter than the fifth magnitude, some five hundred in number, will have been measured. The report touches also upon the discordances between the observed degree of brightness of Comet 1882 *a*, with the results deduced from theory. The expenditure for the purposes of the Observatory, has, it is stated been under the amount provided by Convocation; a sum of 600*l.* per annum is available for three years from December last, and this the Savilian Professor considers will probably suffice for the future efficient maintenance of the Observatory, the only difficulty that might arise relating to necessary repairs, &c., of the present instruments, or the addition of new ones that may be needed.

GEOGRAPHICAL NOTES

M. LESSAR's paper on his excursion from Askabad to Saraks (*Izvestia*, vol. xviii. fasc. 2) will be read with pleasure by those who are interested in the topography, inhabitants, and social conditions of this country. With regard to natural science, we notice the result of the levelling which was made along the line of the Transcaspian railway; it proved, that contrary to what was presumed, the country does not have a general slope from east to west. At the Aïdin wells there are several places situated below the present level of the Caspian, and all the tract between this place and the present shore of the Caspian—M. Lessar states—cannot be regarded as the former bed of a river; it was probably the bottom of a very large gulf of the Caspian, which extended towards the east. It is most probable—he adds—that a levelling between the Tekke oasis and Khiva or Bokhara, will also show in the sand-steppes many tracts situated below the level of the Caspian, as has been found in the Sara-kamysh depression; and it will prove that the Murghal and Tejent could not flow into the Oxus, but flowed into the Caspian, much extended at that time towards the east. We notice in the same paper a remark with regard to termites; their hemispherical moulds, one to two feet in diameter, are very numerous in certain localities; numberless galleries are discovered under these moulds, which galleries are peopled with ants and with termites, about half an inch long, of an amber-colour; they cover the brushes and pieces of wood with numberless pipes in clay, and totally destroy them. The buildings of the Transcaspian railway have much to suffer from the attacks of the termites.

WE have received from Mr. Fisher Unwin several of his useful "Half-Holiday Handbooks." They are all for the districts around, and easily accessible from London. They are really handy, in paper covers, easily carried in the pocket, and well printed. Considering their low price, they contain a great deal of varied information and many useful and well-executed illustrations. Besides the objects which attract the ordinary tourist, they give a fair amount of information concerning the natural history of the districts to which they refer, and illustrations of the principal flowering plants, and occasional geological curiosities. We have no doubt these "Handbooks" will meet with a wide sale; and we trust they will be the means of encouraging hard-worked Londoners to explore the beauties and natural productions of the interesting district around the metropolis. The districts so far included in the series are Richmond, Bromley and Keston, Kingston-on-Thames, Tunbridge Wells, Greenwich and Blackheath, Reigate, Croydon to the North Downs, Dorking. With the exception of Kingston, they have all maps and bicycle routes. As a general accompaniment to these, there is one volume devoted to geological rambles and tours, with twenty-five illustrations and sketch-maps.

"DIE Afrika-Literatur in der Zeit von 1500 bis 1750 N.Ch." is the title of a small volume by Prof. Philipp Paulitschke, published by Brockhausen and Bräuer of Vienna. It consists of the titles, with other bibliographical information, of 1212 works and papers and maps on Africa, published during the period embraced. These are arranged under five headings—General, North, West, South, and East Africa. Prefixed is a short, scholarly, and useful introduction on the growth of our knowledge of Africa from 1500 to the time of the great map reformer, D'Anville. The great utility of such a work must be obvious to all, and geographers owe a debt of gratitude to Dr. Paulitschke for the great trouble he has been at in compiling the list, involving, as it must have done, extensive research and correspondence. No doubt omissions will be found that can be supplied in subsequent editions, but the work could scarcely have been better done. We should be glad to know on what authority Dr. Paulitschke states that Lobo's "History de Ethiopia" was *published* at Coimbra in 1859. In the great Portuguese Bibliography there is no mention of its publication, except as embodied in Tellez's "Historia Geral" of 1660. The translation into French by Legrand was made from MS. Under North Africa is given Sir Peter Wyche's "Short Relation of the River Nile," which should have been under East Africa, as it is really only a translation of part of Lobo's narrative published by the Royal Society in 1669. But these are comparatively small matters.

DR. FRIEDRICH EMBACHER's "Lexikon der Reisen und Entdeckungen" is a little work that will be welcome to all interested in the history of geographical discovery; it is published at Leipsic at the "Verlag des Bibliographischen Instituts." It seems to be one of a long series of reference-books ("Meyer's Fach. Lexika") relating to different subjects. Dr. Embacher's volume is neat and well printed; contains brief notices of the leading geographical explorers, from the earliest times down to the present day, including even those now living; for example, there is a long notice of Stanley, and another of Prjevalsky. The first part is followed by a sketch of the progress of exploration in each of the great divisions of the world. The work seems to us to be done with great care, and the bibliographical references will prove very useful. The only omission of importance is the name of Mr. Darwin, which, since the work includes the names of Sir J. D. Hooker, the late Mr. Belt, and even the late Dr. Leared, surely ought to have found a place.

FROM Ferdinand Hirt of Breslau, we have received a volume of "Geographische Bildertafeln," edited by Dr. Oppel of Bremen, and Dr. Ludwig of Leipsic, with the co-operation of several specialists. This is only the first part, and is devoted to general geography. It consists of a series of carefully selected and arranged pictures, illustrating everything that ought to come under the general subject, which, in the German acceptation, seems to be a very wide one. There are in all, twenty-four sheets, containing a varied selection of illustrations of such subjects as the general surface of the earth and instruments of measurement, the geological periods, geological faults, mountain types, glaciers, volcanoes and hot springs, hills and plains, islands and coasts, oceans and seas, harbours natural and artificial, rivers, navigation, charts and meteorology, woods and forests, ethnography, scenes and means of travel, the chase, and so on. The utility of such a collection of pictures is evident. The selection seems to us to be carefully made, many of the illustrations being from well-known books of travel. As a supplement to any text-book of geography, it would be of great service, and would be sure to be welcome to the pupil.

A NEW THERMOGRAPH[1]

THE instrument under consideration is a thermograph for recording the atmospheric temperature, the fluctuations of which are much less regular and more frequent than one who has not made a study of it would suppose. It records the temperature directly from the column of mercury in the tube of a thermometer by dots or perforations upon a sheet of paper previously ruled with degrees and hours.

Its principal parts are, as shown in Fig. 1 of plate:

1. A thermometer in the form of an ordinary mercury thermometer, but open at the top of the tube, and having a wire entering the bulb and connected to one pole of a battery, the other pole of which is connected to the mechanism of the instrument.
2. An upright cylinder revolving by clockwork, covered with a paper which is divided vertically into twenty-four parts by lines representing the hours, and horizontally by lines representing the degrees.
3. A bar raised and lowered by mechanism driven by clockwork, furnished below with a needle entering the tube of the thermometer, and carrying a pencil—or preferably a point—driven forward by a small electro-magnet when the circuit is closed by the needle entering the mercury, and then making a mark at the proper place upon the paper and indicating the temperature.

The bar carrying the needle rises about half an inch from the point at which the needle leaves the mercury, and then descends until the needle again touches the mercury, whether that in the meantime shall have risen or fallen, when the point makes its mark upon the paper and the bar again commences to rise.

This movement is accomplished by the mechanism shown in the drawing, of which only the wheel E, gearing into the rack upon the needle-bar, is shown in Fig. 1, but which is shown in full and upon an enlarged scale in Fig. 2, which is a top view. The two wheels A and B are moved by clockwork (not shown), and are constantly revolving in opposite directions, as indicated by the arrows. These wheels are not attached to the shaft u on which the wheel E is fixed, but are attached to sleeves which move without affecting that wheel except when they are joined to it by the clutches C or D. They are so geared that when the wheel E is joined to them, its rim moves at the rate of half an inch per minute. Upon the shaft with the wheel F is also a loose sleeve F, which is free when the clutch C is not in action, but which moves with that wheel when that clutch is on.

The levers actuating the two clutches unite and move upon a common pivot, from which point they extend as an arm, which is capable of a lateral movement between two stops, bringing one or the other of the clutches into action.

Opposite to the wheel E, the needle-bar passes through a guide, which is furnished on the back with a small wheel taking the thrust of the gear and reducing friction. For a lower guide, the needle-bar is furnished on each side with a rod parallel to the needle, and of nearly the same length. These rods are at such distance apart that they pass clear of the thermometer tube. They are not shown in the drawing, as they would lie directly in front of and behind the needle and tube.

The teeth of the clutches are partly V-shaped and partly square, or nearly so, as shown in Fig. 3; that is, they have slightly tapered sides but V-shaped points and bases, so that they enter freely, as entirely V-shaped teeth would do, and when in action they have no outward thrust. The V-shaped base strengthens the tooth and admits the point of the opposite tooth.

A very small spring on each side of the sleeve F holds it out of gear while the clutch C is off.

Beneath the clutch arm is a pressure spring, one end of which presses against the end of the arm, and the other against a plate moving upon the same pivot with the arm, which plate also is capable of a lateral movement between its stops.

If this spring-plate is moved in either direction to its stop, carrying with it the base of the spring, the clutch-arm will be moved in the other direction, and the clutch on that side will be brought into action; and if the position of the spring-plate with the base of the spring be reversed, the position of the clutch-arm will be reversed—that clutch will be disengaged, and the other one will be engaged—the wheel E being moved, and the needle-bar raised or lowered accordingly.

To the sleeve F is attached an arm which is connected by a draft-rod to the spring-plate.

When the clutch C is in action—as shown in the drawing—connecting the wheel A with the wheel E and the sleeve F, raising the needle-bar, the arm of the sleeve F draws upon the spring-plate—moving to that side the base of the reversing-spring, which, when its base has passed the line between the pivot and the end of the clutch-arm, presses that arm to the other side, disengaging that clutch, loosing the sleeve F, engaging the other clutch, and reversing the motion of the needle-bar, which now descends.

The length of the arm on the sleeve F is such that when the needle-bar has risen half an inch the spring-plate is moved over, and the clutch-action is reversed.

When, by descending, the needle is brought in contact with the mercury and a circuit is made, the large electro-magnet, thus vitalised, attracts its armature, which is attached to a lever connected with and drawing upon the spring-plate, and moves the base of the reversing spring to that side, changing the position of the clutch-arm, and reversing the action of the clutches and the movement of the needle-bar, while at the same time the recording-point upon the needle bar is, by its electro-magnet, driven into the paper, and the temperature is recorded upon the scale.

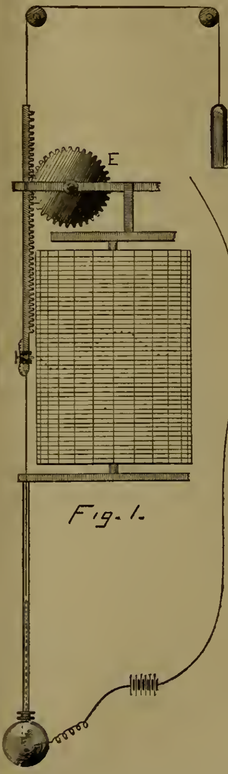

Fig. 1.

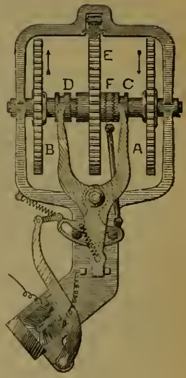

Fig. 2.

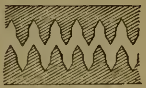

Fig. 3.

The sleeve F, being loose, yields to the movement of the spring-plate, and is afterwards held by its clutch, and acts as before.

The action of the large electro-magnet is supplemented by that of a spring drawing upon the same side of the spring-plate, whose strength is such that it is not quite sufficient of itself to overcome the thrust of the reversing spring, but whose force is greatest when that of the electro-magnet, by reason of

---

[1] A paper by G. Morgan Eldridge, read at the stated meeting of the Franklin Institute April 26, 1882. Contributed by the Author.

its distance from its armature, is least, the greatest possible portion of the work being thus put upon the clockwork, and the least upon the battery.

This spring aids the electro-magnet, but does not in anywise reduce the effect of the reversing spring in holding the clutch to its work ; so long as the base of that spring is unmoved, its action is unimpaired. The resistance of these springs occurs only during the ascent of the needle-bar, which is, therefore, counterpoised to excess, and the resistance and the motion are thus rendered uniform. By reason of the form of the clutch-teeth before described, there is no outward thrust upon the clutches while in action, and hence the reversing spring requires only to be strong enough to throw the arm over and to shift the clutches. The stop of the clutch-arm next the electro-magnet is an insulated plate, to which the battery-wire leading from the magnet is connected, so that as soon as the arm has left the stop the circuit is again broken, although the needle may for a short time remain in contact with the mercury; the recording-point is at once withdrawn, and thus makes upon the paper a single perforation which must be a true record of the position of the mercury in the tube, unaffected by friction or other disturbing cause, since this action must always take place at the moment of contact of the needle with the mercury, and these dots or perforations are repeated at the end of each interval of time required for the needle-bar to ascend and descend the required distance, which will be about two minutes with the wheel-motion designated.

The gradation of the scale upon the paper must correspond with the movement of the mercury in the tube of the thermometer as accurately as the graduation of the scale of an ordinary thermometer corresponds with the movement of the mercury in its tube.

If but one instrument of this sort is to be made this is very easy, the rate of motion is a certained, a scale is made to fit it, and the paper is ruled to that scale.

In all thermometers heretofore made the scale has been made to fit the tube, but if more than one of these instruments is to be made, it becomes necessary, or at least very convenient, to have one set of ruled papers that will fit all the instruments, and it then becomes necessary to reverse the practice and to make the tubes to fit the scale.

The rise and fall of mercury in a thermometer depends upon the proportion between the diameter of the tube and the volume of mercury in the tube and bulb, and while it is possible to construct these parts in such proportion as to obtain proximately a given motion, it is not possible thus to obtain it exactly.

The tube and bulb are made in separate parts, as shown in Fig. 1, of such size that when the tube is thrust half way into the bulb, the volume of mercury filling the tube half way at 32° Fahrenheit is as nearly as may be properly proportioned to the diameter of the tube. If now there be found too much motion, the capacity of the bulb is diminished by thrusting the tube further in, and *vice versa*, and the proper height of mercury at 32° for that purpose is marked upon the tube.

Mercury exposed to the air will slowly form a coating of oxide upon its surface. To prevent this, a small quantity of glycerin or of oil free from oxygen is placed in the thermometer tube above the mercury. If, notwithstanding, the oxide shall accumulate to an inconvenient extent, the observer in charge of the instrument will remove the thermometer from its place, and will put the bulb in warm water until the oxide is floated off. He will then supply the loss with pure mercury, determining the proper quantity by immersing the bulb in broken ice, when the mercury column should stand at the mark for 32°.

The whole apparatus, except the thermometer itself, can be inclosed, and so protected from the weather and dust, while the thermometer is exposed to the air below.

The system is equally applicable to a barometric record, in which case, on account of the small range of motion, the needle-bar is connected to a lever, thus increasing the range of the record.

SCIENCE IN BOHEMIA[1]

THE Bohemian Society of Science continues its useful career, which has already lasted for eighty-four years, and its latest publications (the *Memoirs*, the *Proceedings*, and the annual *Reports*) contain many valuable papers, devoted partly to science in general, but mostly to the exploration of Bohemia itself in its various aspects. The last volume of its *Memoirs* ("Abhandlungen" for 1879–1880, series vi. vol. x.) contains a series of very interesting papers, each of them being the result of careful and extensive research. Prof. Franz Farsky gives the results of varied experiments which were undertaken at the experimental agricultural station at Tabor, on the growth of food-plants in water containing solutions of those salts which constitute the ash of the plant. The influence of alkaline and acid solutions, and especially that of chlorine, which proved to be a most important element of vegetation, were submitted to varied experiments, all the results of which are published in full. The general reader will notice with interest the beautiful results obtained by the culture of oats and barley in glasses of water, which contained the necessary salts, the plant being simply planted in a bit of cotton. Dr. F. J. Studnicka publishes in the same volume the complete tables of observations on the amount of rain in Bohemia during the years 1879 and 1880, at no less than 312 stations in 1879 and at 289 stations in 1880. If we remember that besides these stations there are very many others established by the Bohemian Foresters' Society, and that the whole number of stations where the amount of rain is accurately measured day by day, amounts to 800, we can see that Bohemia has probably the widest network of ombrological observations in Europe. We notice that the most rainy places in Bohemia are Maader, Rehberg, and Neuwelt (1744, 1572, and 1505 millimetres per year respectively), all these situated at great heights (985, 848, and 683 metres), whilst the less rainy places are Kapic, Slaten, and Kladno (431, 438, and 456 millimetres), situated respectively at altitudes of 322, 246, and 380 metres.

Dr. F. Ullik contributes a paper on the matter suspended and dissolved in the water of the Elbe, at Tetschen. Samples of water were taken three times every day, and the samples of each day were analysed separately with regard to the matter suspended, as well as to the quantity of chlorine, ammonia, nitric acid, and organic substances. Besides, 22 complete analyses of different types of water, and 12 of ooze, were made. The water passing through the Elbe at Tetschen proved to be 9,903,510,660 cubic metres during the year October 15, 1876, to October 15, 1877), which contained 776,309,959 kilograms of suspended or dissolved matter. During the year 1877, the amount of water run was 9,456,939,810 cubic metres, which contained 36,557 metrical tons of K^2O, 69,631 tons of Na^2O, 266,081 tons of CaO, 48,915 tons of MgO, 120,553 tons of SO^3, 83,336 tons of chlorine, 778 tons of ammonia, and 11,196 of nitric acid. As to the sources of these immense quantities of mineral substances, Dr. Ullik points out that the amount which is supplied by waste water of manufactures and sewage is usually over-rated. Thus, if the well-known sulphuric acid manufacture at Aussig would pour all the acid it produces into the Elbe, it would give only 5000 tons of SO^3 per year, that is, only the 24th part of sulphuric acid anhydride contained in the waters of the river. The amount of mineral substance poured into the river by all the breweries of Bohemia would give only 401 tons per year, that is, the 1562nd part of all the minerals contained in the Elbe water. And, if all mineral substance contained in the sewage from the 5,000,000 inhabitants of Bohemia would reach the Elbe, it would yield only 33,250 tons, that is, 1-20th of what is really contained in the water of the river. Therefore, it is obvious that the chief source of these substances in the river-water must be sought for in the supply brought in by springs.—Dr. Siegmund Günther contributes to the same volume an interesting notice on the "Algorithmus Linealis," by Heinrich Strömer, which appeared in 1512, being one of the products of the revival of taste for mathematics which characterises, in Germany, the beginning of the sixteenth century. The same volume contains an elaborate paper on the Christian Calendar and on the methods of improving it, by Dr. W. Matzka; and a notice on the electrical clock of Rebicek, by Dr. A. Waltenhofen. It is worthy of notice that all papers that appear in the *Abhandlungen* are written in German, and are sold by the Society as separate pamphlets.

The *Sitzungsberichte*, or Proceedings, contain such a mass of valuable papers that we can notice only the more important of them. They are especially rich in mathematics, and we find (in the volume for the year 1879) papers by Dr. S. Günther, on the application of orthogonal co-ordinates to one problem of the potential theory; on the normals to parabolæ, by Dr. K.

---

[1] "Abhandlungen der Mathematish-Wissenschaftlichen Classe der K. Böhmischen Gesellschaft der Wissenschaften, vom Jahre 1879-1880, vi Folge, Band x. (Prag. 1881). "Sitzungsberichte" of the same Society, for 1879 and for 1880. "Jahresberichte" of the same, for 1879 and 1880.

Zahradnik; a very interesting paper by Prof. Carl Pelz, on the construction of radii of curvature of conic sections, all considered as mere corollaries of one theorem of Steiner; and several papers, by Dr. Franz Studnicka, concerning the theory of determinants and polynomes; and by Prof. J. Solin, on graphical integration.; Prof. A. Safarik contributes a paper giving the results of his observations on the Transit of Mercury on May 6, 1878. After having compared the photographs of the sun during the years 1875 to 1878, with observations on storms at Greenwich, Prague, and Vienna, Prof. Zenger arrived, as is known, at the conclusion that the 12·6 days' periodicity of "storms" on the surface of the sun had the effect of producing the same periodicity in the appearance of tornadoes in the West Indian and of typhoons in the Indo-Chinese Seas. Now, he discusses the storms noticed at Windsor (Australia) during the years 1863-75, and discovers in their appearance the same periodicity; the average deviations from it for the 29 duodecades of each year, being mostly but fractions of one day. But it must be observed that, for calculating the average error of these deviations, Prof. Zenger not only does not make use of the methods of least squares, but takes into account the *signs*, positive or negative, of the deviations, which method considerably diminishes the errors. Discussing Quetelet's tables of falls of meteorites, he arrives at the conclusion that these last also show the same periodicity. An elaborate paper, by Prof. Augustin, gives the results of thirty-eight year's observations of temperature at Prag, the averages being: winter, –0°·56 Cels.; spring, 8°·77; summer, 19°·01; autumn, 9°·60; year, 9°·18.

Several communications are devoted to mineralogy, and we notice among them the papers of Prof. Krejci on the crystallisation of quartz, and on the homœmorphism of Sphalerite, Wurtzite, and Greenokit; on transformation-symbols, by Dr. N. Daubrawa; and on minerals from the Kuchelbad diabase, by MM. Preis and Urba. The papers on palæontology, geology, zoology, and botany, mostly deal with the fauna and flora, fossil or existing, of Bohemia itself. Dr. Ant. Fric gives a list of all fossil animals found in the coal and limestone of the Permian formation in Bohemia; whilst only two species were known from this formation in 1868, M. Fric's list includes no less than 87 species, mostly labyrinthodonts and fishes. Dr. O. Novak publishes his researches on hypostoms of trilobites; and Dr. O. Freismantel contributes three papers: on Nöggerathias of the Bohemian coal-fields; notices on the *Nöggerathia*, Stbg., *Nöggerathiopsis*, Fstm., and *Rhiptozanistes*, Schmalh., and the description of a new Calamaria, *Discinites bohemicus*. M. K. Taranek gives a description of Diatomaceæ from Bohemian marshes; Dr. J. Schöbl publishes the results of his researches on the reproduction of Isopod crustaceans; and Dr. Ullik, the results of several analyses of Bohemian waters. In the Ethnographical Department we notice a paper by Dr. Jirecek, on Walachians and Mauro-Walachians, according to documents found at Ragusa.

The next volume of the *Sitzungsberichte*, for the year 1880, is as rich as the preceding one. Dr. F. Studnicka continues his researches on the theory of determinants, and describes a new property of them, already observed by M. Catalan; and M. F. Mertens gives a new geometrical application of the rule of multiplication of determinants. Dr. A. Seydler studies the movement of a point on given curves and superficies. In the domain of physics we notice but one paper, by Dr. K. Domalip, on the alternating discharges of electricity in rarefied space, in which paper the author deals especially with luminous back-currents. The researcees of Prof. W. Zenger on the 12·6 days' periodicity, are continued in this volume. He remarks that this period is equal to one-half of the duration of each rotation of the sun, and tries to prove that the earthquakes in Southern Italy, from 1349 to 1873, as given by Prof. Suess, also fell on such days as closely coincide with the 12·6 days' period. He discovers the influence of the same periodicity in the dates of the passage of comets, from A.D. 371 to 1864, through their perihelium, as well as in the dates of meteoric showers. In further papers he tries to establish that the same periodicity might be discovered as to the maxima and minima of atmospheric pressure, of temperature, &c., and of magnetic disturbances. Finally, he shows that the sidereal durations of the revolutions of all planets are but multiples of the half rotation of the sun, and he finds that the same number appears also in the lengths of the months of the moon and of the satellites of Jupiter, Saturn, and Uranus. He concludes that "the cause of the movements in our solar system must be sought for in the rotation of the sun," and that all phenomena of gravitation, magnetism, and electricity are but modifications of the same cause which occasions the rotation of the sun. Dr. F. Augustin contributes a paper on the climate of Prag, being a *résumé* of the meteorological observations made since 1840, and another paper on the influence of clouds on the diurnal march of temperature at Prag. Among geological papers we notice: the communication by Dr. Fric on the discovery of fossil remains of a bird, *Cretornis Hlavaci*, in the chalk of Bohemia ("Iserschichten"); the description of a new Tertiary Batrachian, *Palæobatrachus bohemicus* (H. v. Meyer), from the brown coal at Böhmisch-Kamnitz, very similar to the *Palæobatrachus Goldfussi*, but different from it in the structure of several parts of the skeleton. M. Carl Heistmantel contributes two papers on the fossil flora of the Hangend-ridge of the Kladno-Rakonitz coal-basin, characterised by the abundance of *Filices*, *Alethopteris Serli*, and *Cyatheites arborescens*, being most common, and appearing in masses, whilst the *Sphenopteris* is scarcely represented, the *Neuropteris*, so characteristic of the lower deposits, completely disappears, and the Lepidodendrons become very rare. The group of *Leiodermaria* becomes, on the contrary, most usual, and acquires a new representative in the Permian *Sigillaria denudata*, Göpp., whilst Conifers become more numerous. The flora acquires thus a decidedly Permian character. Mr. J. Woldrich contributes a paper on the diluvial fauna at Sudslavic, close by Vimperk; it bears a decidedly northern character, as it contained remains of *Myodes torquatus*, *Nyctea nivea*, *Leucocyon lagopus*, *Fœtorius Erminea*, *Lepus variabilis*, *Arvicola nivalis*, *A. gregalis*, *Lagopus alpinus*, &c. Prof. A. Belohoubek gives an interesting sketch of the influence of geological structure on the chemical composition of water in very many springs and wells from different geological formations: old gneisses, Huron, Silurian, Carboniferous, Permian, Chalk, Tertiary, and Diluvium in Bohemia. The best water, as far as can be concluded from M. Belohoubek's researches, which he considers himself as only preliminary—is given by the Gneiss, Permian, and partly also by the Chalk; the worst, by the Carboniferous and Silurian. Dr. Vejdovsky gives a list of Rhizopods inhabiting the wells at Prag, several species of *Amœba*, *Centropyrix*, *Euglypha*, *Trinema*, &c., being characteristic for special wells. M. Taranek gives a description of Diatomaceæ at Warnsdorf. Prof. J. Dedecek gives a sketch of Bohemian Polytrichaceæ, and deals in another paper with the distribution of Hepatic mosses in Bohemia.

In the *Annual Reports* we notice, besides the public lectures read at the annual meetings, a most useful, complete bibliographical indexes of works and papers published by different members of the Society since the beginning of their scientific careers.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—From the annual report on the local lectures in populous centres, we learn that 12 out of 23 courses of lectures in the Michaelmas Term of 1881, and 10 out of 20 courses in the Lent term of 1882, were on scientific subjects, and were delivered to audiences amounting in all to 1042 persons in the former term and 645 in the latter. This refers only to the work exclusively conducted from Cambridge, without including the courses of lectures in London and in the counties of Durham and Northumberland, which are also largely under the influence of the Cambridge system.

University College, Nottingham, has applied to be affiliated to Cambridge.

A further report of no progress has been made by the Sedgwick Museum Syndicate. It is estimated that 14,716*l*. is the present value of the investments and balances of the Memorial Fund. All that can be said as to the prospects of building is that further acquisitions of sites near the new museums make satisfactory proposals more possible. Prof. Hughes has addressed a letter to the Vice-Chancellor showing that a considerable proportion of the funds for building the present Woodwardian Museum and Library was sought and given expressly for a geological museum, so that the University may fairly be expected to find 15,000*l*. as the value of the present museum if it takes possession of it for the use of the Library.

The first part of the Natural Sciences Tripos has placed 24 men in the first class, 20 in the second, and 10 in the third, while

7 receive an ordinary degree, and 5 are excused the general examination. Six lady students are formally classed, the three in the first class being Girton students. Thus we have the unprecedented total of 72 names in one tripos list in natural science at Cambridge. Of those in the first class, Trinity and Christ's Colleges furnish 6 each, St. John's 5, Caius and King's 2 each, and Emmanuel and Clare and the non-collegiate students one each.

UNIVERSITY COLLEGE, LONDON.—Mr. L. F. Vernon-Harcourt, M.Inst.C.E., has been appointed Professor of Civil Engineering and Surveying. Mr. Kennedy retains the Professorship of Engineering and Mechanical Technology.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 5.—On the relations between galvanic polarisation and the surface-tension of mercury, by A. Koenig.—On the work of external forces furnished in a closed circuit, by R. Colley.—On galvanic polarisation, and on the Smee element, by W. Hallock.—Theory of circulatory and elliptically-polarising media, by E. Ketteler.—On the change of the colour-tone of spectral colours and pigments with decreasing intensity of light, by E. Albert.—On the influence of deformation on electric conductivity, by A. Witkowski.—Researches on the height of the atmosphere and the constitution of gaseous heavenly bodies, by A. Ritter.

Journal de Physique, May.—Electro-chemical figuration of equipotential lines on any portions of a plane, by A. Guébhard—Note on the tangent-compass, by M. Mascart.—Variation of the coefficient of viscosity with the velocity, by B. Elie.—Apparatus for showing and measuring in projection, and simultaneously, the plane of polarisation of the analyser and of the crystalline plate, by L. Laurent.—Register of the duration of rain, by M. Schmeltz.

Bulletin de l'Académie des Sciences de St. Pétersbourg (vol. xxviii. fasc. 1).—Analysis of samples of water from lakes and sources in Tibet, by Dr. C. Schmidt.—Measurements of crystals of Datolith, Amphibol, and Vanguelinit, by B. Koksharow.—On the necessary degree of sensibility of magnetic variation instruments, by H. Wild.—Galvanic phenomena in the cerebrospinal axis of the frog, by J. Setschenow.—Remarks on the Amphisbænids, by Dr. A. Strauch.—New researches on the hypothesis of a resisting medium, by O. Backlund.—Effects of the tension on the electrical resistance of copper-wires, by O. Chwolson.

WE notice in the last number of the "Journal of the Russian Chemical Society" (vol. xiv. fasc. 4), an interesting paper by M. Radoulowitch, on the formation of peroxide of hydrogen during the oxidation of the terpenes, in which he tries to establish, contrary to the opinions of MM. Berthelot and Papasogli, that the oxidation processes manifested by the turpentine oil are not due to the presence of oxygenated compounds of nitrogen, but to the presence of peroxide of hydrogen. In the same number of the "Journal" Prof. Menshutkin gives a summary of his extensive work on the formation of ethers. M. Schwedoff contributes a paper in which he refutes the opinions as to the tails of comets being the result of the repulsive force of the sun on the matter of the comets, and especially the conclusions arrived at by Prof. Bredikhin on the subject; and M. Jouk publishes numerical results as to the temperatures of boiling of methyl alcohol and amylene.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, June 8.—S. Roberts, F.R.S., president, in the chair.—Messrs. J. W. Berry, A. R. Forsyth, and J. Wood were elected Members, and Mr. R. A. Roberts was admitted into the Society.—The following communications were made:—On the extension of certain theories relating to plane cubics to curves of any deficiency, A. Buchheim [the object of the paper was the extension, by the use of Abelian functions, of certain theories which, in the case of plane cubics, are immediate consequences of the representation of the co-ordinates of a point of the curve as elliptic functions of a parameter. The theories considered were: (1) the theory of Steiner's polygons, and (2) Prof. Sylvester's theory of derived points (cf. Clifford's "Classification of Loci")].—On the differentiation with respect to the modulus of the amplitude of elliptic functions, Rev. M. M. U. Wilkinson.—Two notes: (1) a definite integral; (2) equation of the director circle of a conic, Prof. Wolstenholme [(2) got, in the case of oblique cartesian co-ordinates, in the form $\frac{d^2u^{\frac{1}{2}}}{dx^2} + \frac{d^2u^{\frac{1}{2}}}{dy^2} = 2\frac{d^2u^{\frac{1}{2}}}{du\,dy}\cos\omega$].—Theory of orthoptic loci, Rev. Dr. Taylor [the *orthoptic locus* of any curve is the locus of intersection of tangents at right angles].

Linnean Society, June 1.—Frank Crisp, LL.B., treasurer, in the chair.—Mr. H. C. Burdett was elected a Fellow of the Society.—Mr. H. N. Ridley drew attention to an *Equisetum maximum* from Swanage, having a spike of fructification surmounted by a branch-bearing portion, and remarkable on account of the transition of the sporophores along with the brown acuminate leaves..—The Rev. G. Henslow exhibited malformed specimens of wallflower, of rhododendron, and of the Garden Ranunculus.—Mr. Marshall Ward read a paper on his researches on the life history of *Hemileia vastatrix*, the fungus of the coffee-leaf disease. The phenomena attendant thereon shows great analogy to those of the Uredine fungi. The spores, under favourable conditions, viz., moisture, a due supply of oxygen, and a temperature of 75° F., usually germinate in from twelve to twenty-four hours.—Complete infection or establishment of the mycelium in the intercellular passages of the leaf occurs about the third day after the formation of the germinal tubes. The so-called yellow spot or ordinary outward visible appearance of the disease manifests itself about the fourteenth or fifteenth day, but may be delayed; its development and course being dependent on secondary causes, such as atmospheric conditions, monsoons, age of the coffee-leaf, &c. By watching the progress of the spots it has been ascertained that the spores therefrom may be continuously produced for from seven to eleven weeks or even more. Some 150,000 spores have been estimated as present in one yellow cluster spot, and as 127 disease spots have been counted in one pair of leaves, the quantity of spores thus regularly produced must be enormous. According to the amount of diseased spots, the sooner the leaf falls; and though young leaves arise, the fruit-bearing qualities of the plant necessarily are seriously interfered with. The various sorts of coffee plant are all liable to infection; the only possible remedy is the difficult one of destruction of the spores, and these are supposed originally to have been introduced from the native jungle, and rapidly spread under the favourable conditions of artificial cultivation.—Dr. Hoggan read a paper on some cutaneous nerve-terminations in mammals. He related observations on the habits of the mole (*Talpa*), with reference to its nasal organ, as a special sense of touch, and of the tail as a tactile organ. The so-called "Organ of Eimer" in the mole's nose, its fibres and cells, are similar in character to the ordinary sub-epidermic nerve-cells and their intrapidermic fibrillar prolongations. There is a probability that the inner circle of fibrils possesses the power of touch, and that the centre ones and those of the outer circle provide the sense of temperature, pain, and other sympathetic functions. The Paccinian bodies at the root of the organ probably register pressure.—Mr. C. B. Clarke read a paper on two Himalayan ferns erroneously described in the ferns of British India.—A communication was made on the Ascidians collected in the cruise of the yacht *Glimpse* in 1881, by Mr. H. C. Sorby and Prof. W. A. Herdman. Twelve species were noted, one *Molgula cæpiformis*, from near Poole, being new.—Mr. P. H. Carpenter followed by descriptions of new or little-known Comatulæ, being material derived from the *Challenger* expedition and Hamburg Museum. The author institutes the new genus *Eudiocrinus* for Semper's *Ophiocrinus*.—Two other papers read were:—Notes on recent additions to the New Zealand flora, by Mr. Thos. Kirk, and descriptions of four new species of *Donax*, by Mr. Sylvanus Hanley.

Physical Society, June 10.—Prof. Clifton, president, in the chair.—New member, Major-General Martin, R.E.—Mr. W. F. Stanley read a paper on sonorous vibrations, especially those of the tuning-fork. The larger and more visible movements of a sounding-body do not appear to be best fitted to propagate musical-sounds as was shown by placing disks on the prongs of a powerful fork, which, when vibrating, could then only be heard a short distance, whereas, by its smaller longitudinal motions, when placed on its resonator, it produced a penetrating sound. The vibration down the stem of the fork was shown not to depend upon a vibrating ventroid, as suggested by Chladni, for a fork cut in the end of a solid steel bar communicated sonorous vibrations equally well to the resonator. To set a fork in vibration it was necessary to bow one prong only, therefore, in this case, the vibration must proceed along the prongs. A light fork 1 metre long was fixed in a heavy vice, and it was shown by it that vibrations passed down one prong and up the other alternately. By means of dust, ripples were shown to run down an ordinary fork in vibration. Light pieces of metal were fitted to the ends of a powerful fork, and these immersed in mercury, the reflected surface of which was shown on a screen, where it was seen that the whole mercury surface was broken into fine ripples. It was suggested that such small waves are also perceived by the ear. By these, certain conditions of harmonics could be better accounted for, as, for example, by division in smaller waves, the rarefaction of a note in space would not suffer interference by the condensation of its octave falling in the same space and time.—Lord Rayleigh explained several of Mr. Stanley's experiments on the known theory of sound.—Mr. Walter Bailey then exhibited a model of a new "integrating anemometer." This apparatus contains a horizontal plane, in which are two slits forming a cross with arms towards the cardinal points. Each slit is fitted with a sliding-piece, and the two slides are connected by a bar; the arrangement being that of the well-known instrument for drawing ellipses. The slides carry beneath them wheels with their planes perpendicular to the slits, and passing through the pivots of the bar. The wheels rest on a horizontal disk, whose centre is beneath the centre of the cross. The centre of the bar is to be connected to a weathercock which will keep it in the direction of the wind when looked at from the centre of the instrument. The disk is to be revolved by Robinson's cups. The number of revolutions of the wheels then give the integral of the resolved parts of the wind in the direction of the cardinal points. In the working model of the instrument exhibited there was an electrical arrangement connected with four indicators, one for each of the cardinal points. At each turn of a wheel a circuit was completed, and the corresponding indicator moved. Recording instruments are to be substituted for indicators, and the amount recorded on each in a given time will be proportional to the total motion of the wind towards the corresponding cardinal point.—Mr. Lecky pointed out that a good anemometer was a great desideratum at present.—The Society meets at Oxford on the 17th, and South Kensington on the 24th of this month.

Anthropological Institute, May 23.—General Pitt-Rivers, F.R.S., president, in the chair.—A paper was read by the Right Hon. Sir H. Bartle Frere, Bart., on systems of land tenure among aboriginal tribes of South Africa." The author indicated the points regarding which further inquiry is needed, and urged the importance of recording observations whilst it is still possible to obtain information from sources which in the course of another generation may be closed for ever by the extinction of races. The Zulu title to the lands in South Africa rests simply on force, the land being his property only so long as the occupant can hold it by himself, or with the assistance of the chief who protects him. The tenure cannot be transmitted by inheritance without being constantly sapped by the influence of two institutions universal among the Zulus, viz., polygamy and slavery. Christianity has a special bearing on the subject of land tenure, because it is mainly through its agency, indirect as well as direct, that we may look for such changes in the customs of the races of South Africa as may civilise and settle them, and put an end to the ceaseless wanderings which have tended so powerfully to keep them in a state of ever-recurring barbarism. The author's impression was that the advancement and civilisation of the native tribes of South Africa depend greatly upon the extent to which individual tenure of property can be extended, whilst some patriarchal authority such as seems inherent in the head of a family or kraal is recognised, and invested with some sort of magisterial and judicial functions, sufficient to meet the everyday exigencies of village life. The President opened the discussion with some remarks on the peculiarities of land tenure in various parts of the world, and was followed by Dr. Rae, Mr. Hyde Clarke, and Miss Buckland.—On the motion of Prof. Flower, a cordial vote of thanks was given to the president and Mrs. Pitt-Rivers for their kindness in allowing the meeting to be held at their house.

Edinburgh

Royal Society, June 5.—The Right Hon. Lord Moncrieff, president, in the chair.—Obituary notices of Dr. Lauder Lindsay, Mr. David Smith, and Prof. Peirce of Harvard, were read.—The Council announced the award of the Keith Prize for the Biennial Period 1879–81, to Prof. Chrystal, for his paper on the differential telephone, which is published in the Society's *Transactions* (1879-80), and gives a new, simple, and accurate method of measuring capacities and co-efficients of mutual and self-induction (see Nature, vol. xxii. p. 331); and of the Neill prize, for the triennial period 1877-80, to Mr. John Murray, for his paper on the structure and origin of coral reefs and islands, communicated to the Society on April 5, 1880, and printed (in abstract) in the *Proceedings* of that date (see Nature, vol. xxii. p. 351).—Prof. Tait communicated Part II. of his paper on mirage. Having formerly shown that the observed phenomena could be explained in a general way by assuming a certain relation to exist between the refractive index of the air at any point, and its situation between two planes of approximately stationary density; the author, in his second paper, proceeded to investigate the conditions more carefully, so as to find, if possible, a distribution of atmospheric density which should be at once probable, and produce mirage phenomena the same in all important particulars as those observed by Scoresby, Vince, and others, and at the same time be capable of easy mathematical treatment. Two horizontal strata of uniform but different densities, separated by a stratum whose density varies continuously from the one to the other, were found to give results in close agreement with observation. That a stratum of air should remain of practically uniform density through even a comparatively small height requires a lowering of temperature to compensate for the diminution of pressure as the height increases; but this rate of change of temperature Prof. Tait showed was not greater than had been observed in balloon ascents. With given thicknesses of strata, there was a critical minimum distance at which mirage could be obtained. For greater distances there were three images, two direct and one inverted. The inverted one was always larger than the lower direct one, but only appreciably so when the distance of the object approached this critical minimum value, for which the phenomenon known as "looming" became evident. The second direct image is usually much the smallest, being, except at distances near this same critical distance, so small as to be practically invisible. This seems fully to account for the comparatively few instances in which the three images have been observed. Multiple inverted images, as observed by Scoresby, were explained as due to thin successive layers of varying density at different heights. It was shown that Wollaston's illustrative experiment, in which three images are produced, is *not* quite analogous to the state of affairs which produce them naturally. In order to make it so, the tank must be greatly increased in length, and the difference of density of the interdiffusing fluids greatly diminished; so that the rays may enter and leave the transition stratum by its lower side, and *not by its ends*. The rest of the paper showed how Wollaston's arrangement could be simply and accurately applied to measurement of rates of diffusion.—Mr. Milne Home communicated the Eighth Report of the Boulder Committee. This dealt mainly with the boulders around Ben Nevis, which had been examined by Prof. Heddle, Prof. Duns, and Mr. Livingston of Fort William.

Berlin

Physical Society, May 26.—Prof. du Bois-Reymond in the chair.—Prof. Landolt showed a new polarisation-apparatus, whose polarising part is formed according to the method of M. Cornu, modified by Herr Lippich, and which has this advantage over others, especially, that it is not mounted on a foot, but on a solid base, whereby bending and torsion of the tube which holds the liquid are avoided. This tube is inclosed in a cylindrical envelope, in which water of any desired temperature can circulate. By a simple lever movement, the tube filled with the experimental liquid can at any time be directly replaced by an empty tube, and conversely; so that the zero point can be controlled as often as desired. In its present form, the apparatus is pretty perfect for scientific researches; further improvement must be directed principally to the production of a good light-source. Some proposed alterations of the apparatus, now in hand, will afford the opportunity of examining vapours in reference to their rotatory power.—Dr. Hagen reported on experiments for measuring the vapour-tension of mercury at different temperatures. He first indicated briefly the apparatus Regnault used, and the results obtained with it, by that physicist. The values given by Regnault are met with in all text-books of physics; yet they differ very considerably from the amounts found by Regnault in his experiments, and these do not agree together. The author, therefore, undertook a new determination of these values. The apparatus consisted of a U-shaped tube, having at the lower part a long straight tube, united to it by fusion, while above, either branch terminated in a tube twice bent at a right angle, and closed at the lower end. By means of a Hagen air-pump this tube-system was gradually evacuated to a pressure of 1-12,000,000 mm. mercury, and the long straight tube opened under mercury at the lower end. The mercury rose in both branches of the U-tube to barometric height. One of the lateral ends of the apparatus was now kept constant at 0°; while the other was first cooled to – 42°, and then heated to various temperatures; each time the position of the mercury in the two branches was observed with a cathetometer, and the difference of their heights gave the vapour-tension. The values so obtained for the vapour-tension of mercury were less for all temperatures than those given by Regnault. Thus, *e.g.* Herr Hagen found the tension at 0° = 0·015 mm., Regnault 0·02; at 20°, Hagen 0·021, Regnault 0·037; at 100°, Hagen 0·61, Regnault 0·75; at 200°, Hagen 16, Regnault 19·9 mm. Though the values now found have no claim to absolute accuracy (owing to the difficulty of taking readings with the cathetometer, through round glass), these experiments at least make certain that the Regnault values for the vapour-tension of mercury, which have passed into all text-books, are considerably too large.

PARIS

Academy of Sciences, June 5.—M. Jamin in the chair.—The following papers were read:—On double salts prepared by fusion, by MM. Berthelot and Ilosvay.—Report on the expedition to Cape Horn, by H. Milne-Edwards. This meteorological mission, to start soon, for a year's sojourn at Cape Horn, will have two medical men, Drs. Hyades and Han, who have undertaken to collect and make observations as the Academy may indicate. A Committee of the Academy has urged the Government to add a preparer of collections, and nominated M. Sauvinet for this post; total additional cost 3625 fr. The wish is expressed that specialists in zoology, botany, and geology could have been appointed; but the resources did not allow of this.—Zoological instructions drawn up for the members of the Cape Horn Mission by M. Alph. Milne-Edwards. Special attention should be given to the large mammalia—seals, sea-elephants, otaries, cachalots, &c., some of which are rapidly disappearing. Various penguins and other sea-birds call for study; the fishes are imperfectly known, and a good harvest from dredging operations may be looked for.—The true puceron of the vine (*Aphis vitis*, Scopoli), by M. Lichtenstein.—History of standards of the metre, by M. Wolf.—On the waves produced by the emersion of a solid at the surface of a quiet wave, when there is occasion to take account of two horizontal co-ordinates, by M. Boussinesq.—On the boiling-temperature of selenium, by M. Troost. Employing a method described March 29, 1880, he arrives at the figure 665° C. for pressure near 760 mm. It is shown that glasses of small fusibility, such as Bohemian and certain French glasses, may be kept at that temperature without deformation, and so used for long chemical reactions.—On a calorimeter dependent on cooling, by M. Violle. This is for use where the initial temperature is between 100° and 400° or 500°. It consists of a small, narrow-necked bottle of thin glass, with double envelope, and a vacuum produced in the interval before closure. Through the neck is introduced a thermometer and a stirrer.—Determination of the specific heats of small quantities of substances, by MM. Thoulet and Lagarde. The method is designed for pure mineral species (0·1 gr. to 0·5 gr.). Its principle is this: If two thermo-electric junctions be put in tubes holding a liquid of known specific heat (*e.g.* water, or oil of turpentine), one may measure, by the deflection in a galvanometer, the rise of temperature resulting from immersion in one of the tubes of a body raised to a known temperature, and compare it with that in a second experiment made with a typical body (*e.g.* copper). The method (which is illustrated by a figure) is shown to be exact.—On a new condensation-hygrometer, by M. Crova. A small tube of nickel-plated brass, carefully polished within, is closed at one end with ground glass, and at the other with a lens of long focus, through which one looks along the tube towards a light-source. Through two terminal tubulures, the air to be examined is drawn through the tube, which is cooled by means of sulphide of carbon traversed by an air current in a metallic envelope round the tube. The changes of aspect in the tube at the temperature of saturation, enable one to estimate the dew-point to one-tenth of a degree.—Law of freezing of aqueous solutions of organic matters, by M. Raoult. The molecules of different organic matters, dissolved in the same quantity of water, cause sensibly the same retardation in its freezing-point.—Method for determination of the ohm, by M. Joubert.—Influence of the positive electrode of the battery on its chemical work, by M. Tommasi.—On oxychlorides of zinc, by M. André.—Action of sulphide of carbon on silicium, by M. Colson.—Preliminary note on didymium, by M. Clève. This points to the existence of a new element accompanying didymium. The author proposes to designate it provisionally by the symbol Di β; it is characterised by the strong line *l* = 4335·5.—On a new monochlorinated camphor, by M. Cazeneuve.—On spontaneous fermentations of animal matters, by M. Béchamp. He reviews past researches, and indicates a number of deductions from them.—MM. Cazeneuve and Daremburg called attention to the fact of proof having been given by them in 1874, that in general all the substances called *colloid* by Virchow and his school, strongly decompose oxygenated water.—On the nerve-tissue of the spinal cord, by M. Ranvier.—Experimental attempt at anatomical localisation of symptoms of toxical delirium in the dog, by M. Danillo.—Essence of absinthe was injected into dogs. The integrity of the optic thalami is not necessary for production of toxical delirium. The cortical region throughout is exclusively concerned.—M. Larroque furnished some data regarding the thunderstorm of May 30. In some regions there was torrential rain, in others hail.—On a new combination of the lenses of the microscope, by M. Zenger. With a great focal distance he obtains a magnification equal to 2000.

VIENNA

Imperial Academy of Sciences, May 11.—L. I. Fitzinger in the chair.—H. Hammerl, contributions to the knowledge of the formation of hydrates of salts.—P. Wesselsky and R. Benedikt, on some nitro-products from the pyrocatechin series.—F. Exner, determination of the ratio-electrostatic and electro-magnetic absolute unit.—A. Tschinkel, communication on experiments relating to the action of electricity on the growth of plants.—F. Heger, continuation of the fifth report of the Prehistoric Commission on two excavations near Chotzen (Boh.) and near Hallein (Salzburg).—G. Bruder, contributions to a knowledge of the Jurassic deposits in Northern Bohemia.—E. Stefan, on the lines of force of a field symmetrical round an axis.

May 25.—Anniversary Meeting.—E. v. Bruecke was elected vice-president in room of V. Burg.—In the Mathematical class, Theodor v. Oppolzer (Vienna), Julius Wiesner, and Emil Weyr Vienna, were elected Members.—Fr. E. Schultze (Gratz), V. v. Ebner (Gratz), M. Neumayr Vienna), L. v. Pebal (Gratz), H. Durège (Prague) Correspondents, Friedrich Woehler (Göttingen) Honorary Member, L. Pasteur (Paris) G. G. Stokes (Cambridge) and T. Lovén (Stockholm) foreign correspondents.—The meeting was opened by the curator of the Academy, Archduke Rainer. The reports for the past year were read by the general secretary, Prof. Siegel and the secretary of the Mathematical Class, Prof. Stefan.—Then Prof. E. Much (Prague) gave an address on the economic nature of physical research.

CONTENTS

THURSDAY, JUNE 22, 1882

CHARLES DARWIN[1]

V.

THE effects upon Psychology of Mr. Darwin's writings have been so immense, that we shall not overstate them by saying that they are fully comparable with those which we have previously considered as having been exerted by the same writings on geology, botany, and zoology. This fact at first sight can scarcely fail to strike us as remarkable, in view of the consideration that Mr. Darwin was not only not himself a psychologist, but had little aptitude for, and perhaps less sympathy with, the technique of psychological method. The whole constitution of his mind was opposed to the subtlety of the distinctions and the mysticism of the conceptions which this technique so frequently involves; and therefore he was accustomed to regard the problems of mind in the same broad and general light that he regarded all the other problems of nature. But if at first sight we are inclined to feel surprised that, although possessing none of the special mental equipments of a psychologist, he should have produced so enormous an influence upon psychology, our surprise must vanish when we consider the matter a little more attentively. For the truth of this matter is that psychology, in being the science furthest removed from the reach of experimental means and inductive method, is the science which has longest remained in the trammels of *a priori* analysis and metaphysical thought; therefore Darwin, by casting the eye of a philosophical naturalist upon the facts, without reference to the cobwebs which the specialists had woven around them, was able to gather directly much new information as to their meaning. And the rare sagacity with which he observed and reflected upon the phenomena of mind merely as phenomena or facts of nature, led to the remarkable results which we shall presently have to consider—results which have done more than any other to unmuffle the young science of psychology from the swaddling clothes of its mediæval nursery.

The portions of Mr. Darwin's writings which refer to mental science are very limited in extent—comprising, in fact, only one chapter in the "Origin of Species," three in the "Descent of Man," and a short paper on the development of infantile intelligence. The importance of the effect produced by them is therefore rendered all the more remarkable; but in this connection it seems desirable to state that the chapters to which we have alluded represent, in an exceedingly condensed form, the result of extensive thought and reading. A year or two ago Mr. Darwin lent the present writer the original drafts of these essays, together with all the notes and memoranda which he had collected on psychological subjects during the previous forty years, and so we can testify that any one who reads these MSS. is more likely to be surprised at the amount of labour which they indicate than at the effect which has been produced by the compressed publication of its results. What strikes one most in reading the MSS. is that which also strikes one most in reading the published *résumé* that has grown out of them—namely, the honest adherence throughout to the strictly scientific, or, as the followers of Comte would say positive method of seeking and interpreting facts; speculation, hypothesis, and straw-splitting are everywhere, not so much intentionally avoided, as alien to the whole conception of the manner in which the sundry problems are to be attacked. We all know that this conception has not met with universal approval—that more than one writer, adhering to the traditional methods of psychological inquiry, has expressly joined issue upon it. But although it is an easy matter for a technical psychologist to point to an absence of technical thought, and so of a recognition of technical principles, in these parts of Mr. Darwin's writings, we are persuaded that the *exposé* only serves to reveal a beam in the eye of the technical psychologist which prevents him from seeing clearly how to remove the mote from Mr. Darwin's. In other words, although it is true that Mr. Darwin does not recognise the niceties of distinction which seem so important to what we may term the professional mind, it is no less true that in the cases to which we have alluded, the professional mind has failed in its duty of filling up for itself the technical *lacunæ* in Mr. Darwin's expositions. Such *lacunæ* no doubt occur, but they never really vitiate the integrity of the conclusions; and a trained psychologist would best fulfil his function as an under-builder, by supplying here and there the stones which the hand of the master has neglected to put in. To ourselves it always seems one of the most wonderful of the many wonderful aspects of Mr. Darwin's varied work, that by the sheer force of some exalted kind of common sense, unassisted by any special acquaintance with psychological methods, he should have been able to strike, as it were, straight down upon some of the most important truths which have ever been brought to light in the region of mental science. These we shall now proceed to consider.

The chapter in the "Origin of Species" to which we have referred, is occupied chiefly with an application of the theory of natural selection to the phenomena of instinct, and in our opinion it has done more than all other psychological writings put together to explain what instinct is, why it is, and how it came to be. Before this chapter was published, the only scientific theory concerning the origin of instincts that had been formed was the theory which regarded them as hereditary habits. Because we know that in the individual intelligent adjustments become, by frequent repetition, automatic, it was inferred that the same might be true of the species, and therefore that all instincts were to be regarded as what Lewes has aptly termed "lapsed intelligence." In this view there is, without any question, much truth, and the first thing we have to notice about Mr. Darwin's writings with reference to instinct is that they not only recognised this truth, but, by elucidating the whole subject of heredity, placed it in a much clearer light than it ever stood before. Mr. Darwin, however, carried the philosophy of the subject very much further when he argued that, in conjunction with the cause formulated as "lapsing intelligence," there was another at least as potent in the formation of instincts—namely, natural selection. His own statement of the case is so terse that we cannot do better than quote it.

"If Mozart, instead of playing the pianoforte at three

---

[1] Concluded from p. 147.

years with wonderfully little practice, had played a tune with no practice at all, he might truly be said to have done so instinctively. But it would be a serious error to suppose that the greater number of instincts have been acquired by habit in one generation, and then transmitted by inheritance to succeeding generations. It can be clearly shown that the most wonderful instincts with which we are acquainted, namely, those of the hive-bee and of many ants, could not possibly have been acquired by habit.[1]

"It will be universally admitted that instincts are as important as corporeal structures for the welfare of each species, under its present conditions of life. Under changed conditions of life, it is at least possible that slight modifications of instinct might be profitable to a species; and if it can be shown that instincts do vary ever so little, then I can see no difficulty in natural selection preserving and continually accumulating variations of instinct to any extent that was profitable. It is thus, I believe, that all the most complex and wonderful instincts have originated."

Briefly, then, in Mr. Darwin's view instincts may arise by lapsing intelligence, by natural selection of accidental and possibly non-intelligent variations of habit, or by both principles combined—seeing that "a little dose of judgment" is often commingled with even the most fixed (or most strongly inherited) instincts. One good test of the truth of the view as a whole is that which Mr. Darwin has himself supplied—namely, searching through the whole range of instincts to see whether any occur which are either injurious to the animals exhibiting them, or beneficial only to other animals. Now there is really no authentic case of the former, and the latter are so few in number that they may reasonably be regarded, either as rudiments of instincts once useful (so analogous to the human tail), or as still useful in some unobservable manner (so analogous to the tail of the rattlesnake). The case of aphides secreting honey-dew for the benefit of ants occurred to Mr. Darwin as one which might be adduced against his theory in this connection, and he therefore made some experiments upon the subject, which led him to conclude that "as the excretion is extremely viscid, it is no doubt a convenience to the aphides to have it removed; therefore probably they do not excrete solely for the good of the ants."

A discussion of the variability of instinct, and of the probability that variations should be inherited, leads him to consider the important case of the apparent formation of artificial instincts in our domestic dogs by continued training with selection, and also the not less important case of the effects produced upon natural instincts by the long-continued change of environment to which other of our domestic animals have been exposed. All the facts adduced as resulting from these long-continued though unintentional experiments by man, go to substantiate, in a very unmistakable manner, the theory concerning the origin and development of instincts which we are considering. The chapter concludes with a close consideration of some of the more remarkable instincts which occur in the animal kingdom, such as the parasitic instinct of the cuckoo, the slave-making instinct of ants, and the cell-making instinct of bees. A flood of light is thrown upon the latter, and the old-standing problem as to how the bees have come to make their cells in the form which requires the smallest amount of material for their construction, while affording the largest capacity for purposes of storage, is solved.

From this brief account of the chapter on "Instinct," it is evident that the new idea which it starts, and in several directions elaborates, is an idea of immense importance to psychology, and that the broad marks or general principles laid down by it afford large scope for a further filling in of numberless details by the attentive observation of facts. The phenomena of instinct, indeed, cease to be rebellious to explanation, and range themselves in orderly array under the flag of science.

But not less important than the chapter on "Instinct" are the chapters in the "Descent of Man" on the mental powers of man as compared with those of the lower animals, on the moral sense, and on the development of both during primæval and civilised times. Our estimate of the value of these chapters is so high that we gladly endorse the opinion of the late Prof. Clifford—who was no mean judge upon such matters—when he writes of them as presenting to his mind "the simplest, and clearest, and most profound philosophy that was ever written upon this subject." As the three chapters together cover only 80 pages, it seems needless to render an abstract of them, so we shall only observe that although it is easy to show in them, as Mr. Mivart and others have shown, a want of appreciation of technical terms, and even of Aristotelian ideas, nowhere in the whole range of Mr. Darwin's writings is his immense power of judicious generalisation more conspicuously shown. So much is this the case that in studying these chapters we have ourselves always felt glad that Mr. Darwin was not the specialist in psychology which some of his critics seem to suppose that he ought to have been if he presumed to shake their science to its base; had he been such a specialist the great sweep of his thought might have been hindered by comparatively immaterial details.

Of the three chapters which we are considering, the most important is the one on the moral sense. As he himself says:—

"This great question (the origin of the moral sense) has been discussed by many writers of consummate ability; and my only excuse for touching upon it, is the impossibility of here passing it over; and because, so far as I know, no one has approached it exclusively from the side of natural history. The investigation possesses, also, some independent interest, as an attempt to see how far the study of the lower animals throws light on one of the highest psychical faculties of man."

The result of this investigation and study has been to give, if not a new point of departure to the science of ethics, at least a completely new conception as to the origin of the faculties with which that science has to deal; and without attempting to discuss the objections which have been raised against the doctrine, or to enumerate the points of contact between this doctrine and older ethical theories—to neither of which undertakings would our present space be adapted—we may say in general that, as in the case of instinct, so in that of conscience, we feel persuaded that Mr. Darwin's genius has been the first to bring within the grasp of human understanding

---

[1] Because the individuals which exhibit them, being neuters, can never have progeny. It is indeed surprising, as Mr. Darwin further on observes, that no one previously "advanced this demonstrative case of neuter insects against the well-known doctrine of inherited habit as advanced by Lamarck."

large classes of phenomena which had been previously wholly unintelligible.

"The Expression of the Emotions in Man and Animals" is an essay which may be more suitably mentioned in the present article than in any of the preceding. The work is a highly interesting one, not only on account of its philosophical theories, but also as an extensive accumulation of facts. "The three chief principles" enunciated by the former are: (1) "the principle of serviceable associated habits"; (2) "the principle of antithesis"; and (3) "the principle of actions due to the constitution of the Nervous System, independently from the first of the Will, and independently to a certain extent of Habit." It is shown that the first of these principles leads to the performance of actions expressive of emotions because "certain complex actions are of direct or indirect service under certain states of mind, in order to relieve or gratify certain sensations, desires, &c.; and whenever the same state of mind is induced, however feebly, there is a tendency through the force of habit and association for the same movements to be performed, though they may not then be of the least use." The second principle arises because, "when a directly opposite state of mind is induced, there is a strong and involuntary tendency to the performance of movements of a directly opposite nature, though these are of no use; and such movements are in some cases highly expressive." And the third principle occurs because "when the sensorium is strongly excited, nerve-force is generated in excess, and is transmitted in certain definite directions, depending on the connection of the nerve-cells, and partly on habit." All these principles are more or less well substantiated by large bodies of facts, and although the essay, from the nature of its subject-matter, is necessarily not of so transforming a character in psychology as those which we have already considered, and although we may doubt whether it gives a full explanation of every display of expressive movement, we think there can be no reasonable question that the three principles above quoted are shown to be true principles, and therefore that the essay is completely successful within the scope of its purposes.

Lastly, we have to allude to the brief paper published in *Mind* on the psychogenesis of a child. These notes were not published till long after they were taken, so that Mr. Darwin was the first observer, by many years, in a department of psychology which—owing chiefly to the attention which his other writings have directed to the phenomena of evolution—is now being very fully explored. The observations relate entirely to matters of fact, and display the same qualities of thoughtfulness and accuracy which are so conspicuous in all his other work.

On the whole, then, we must say that Mr. Darwin has left as broad and deep a mark upon Psychology as he has upon Geology, Botany, and Zoology. Groups of facts which previously seemed to be separate, are now seen to be bound together in the most intimate manner; and some of what must be regarded as the first principles of the science, hitherto unsuspected, have been brought to light. No longer is it enough to say that such and such actions are the result of instinct, and so beyond the reach of explanation; for now the very thing to be explained is the character and origin of the instinct—the causes which led to its development, its continuance, its precision, and its use. No longer is it enough to consider the instincts manifested by an animal, or group of animals, as an isolated body of phenomena, devoid of any scientific meaning because standing out of relation to any known causes; for now the whole scientific import of instincts as manifested by one animal depends on the degree in which they are connected by general principles of causation with the instincts that are manifested by other animals. And not only in respect of instincts, but also in respect of intelligence, the science of comparative psychology may be said for the first time really to have begun with the discovery of the general causes in question; while from the simplest reflex actions, up to the most recondite processes of reason and the most imperious dictates of conscience, we are able to trace a continuity of development. A revelation of truth so extensive as this in the department of science which, in most nearly touching the personality of man, is of most importance for man to explore, cannot fail to justify the anticipations of the revealer, who in referring to psychology, could "in the future see open fields for far more important researches" than those relating to geology and biology. If the proper study of mankind is man, Mr. Darwin has done more than any other human being to further the most desirable kind of learning, for it is through him that humanity in our generation has first been able to begin its response to the precept of antiquity —*know thyself.*

The series of brief articles whereby we have endeavoured to take a sort of bird's eye view of Mr. Darwin's great and many labours have now drawn to a close. But we cannot finish this very rudimentary sketch of his work without alluding once more to what was said in the opening paragraphs of the series, and which cannot be more terseley repeated than in Mr. Darwin's own words there quoted with reference to Prof. Henslow:—"Reflecting over his character with gratitude and reverence, his moral attributes rise, as they should do in the highest character, in pre-eminence over his intellect."

In the gratitude and reverence which we feel in a measure never to be expressed, we sometimes regret that the ill-health which led to his seclusion prevented the extraordinary beauty of his character from being more generally known by personal intercourse. True it is that the world has shown in a wonderful degree a just appreciation of this character, so that many thousands in many nations who had never even seen the man heard that Charles Darwin was dead with a shock like that which follows such an announcement in the case of a well-loved friend; still it seems almost sad that when such an exalted character has lived, it should only have been to so comparatively few of us that the last farewell over the open grave at Westminster implied a severance of feelings which had never been formed before, and which, while ever living among the most hallowed lights of memory, we know too well can never be formed again. But to those of us who have now to mourn so unspeakable a loss, it is some consolation to think, while much that was sweetest and much that was noblest in our lives has ended in that death, his great life and finished work still stand before our view; and in regarding them we may almost bring our hearts to cry—Not for him, but for ourselves, we weep.

IMITATION CHEESE

IN NATURE, vol. xxv. p. 269, we gave an account of the mode of manufacture of "butterine," a compound containing about 90 per cent. of a mixture of animal fats known as "oleomargarine."

"Butterine," as the name would imply, is an imitation butter which is largely imported into this country from America and from Holland. "Oleomargarine" is principally made in the United States by the patented process of Mége-Mouries, which consists in heating disintegrated suet to a temperature of 120° F., when a clear yellow oil is (to borrow a term of the metallurgists) "liquated out." This is allowed to solidify, and "refined" by subjecting it to pressure at a temperature of about 90° F. "Oleomargarine" is converted into "butterine" by adding about 10 per cent. of milk to it and churning the mixture, colouring the product with annetto, and rolling it in ice to "set" it. Some idea of the development of this industry may be gleaned from the fact that Mr. Nimmo, the chief of the United States Statistical Department, reported that the export of oleomargarine for the year ending June 30, 1880, was close upon 19,000,000 pounds. And this is probably under-estimated, as it is certain that considerable quantities of "butterine" passed through the Customs under the designation of butter. It is not very easy to get data which are altogether trustworthy; but looking to the rate of increase furnished by the statistics of previous years, it is probable that the present export of oleomargarine from America is not less than from 25,000,000 to 30,000,000 lbs. per annum. Oleomargarine was the subject of some discussion in the House of Commons during the last session, and the matter was again brought up a few nights ago in the form of some interrogatories addressed to the President of the Board of Trade.

It appears that oleomargarine has recently taken a new departure, and that its use is no longer confined to the manufacture of "butter substitute," or "butterine." Our ingenious friends on the other side of the Atlantic have discovered that a mixture of oleomargarine and blue skim milk make what Mr. H. M. Jenkins, the Secretary of the Royal Agricultural Society of England describes as an excellent imitation of "American Cheddar." Indeed, so excellent is the imitation, that competent judges in the City and elsewhere informed Mr. Jenkins that unless they had been told, they could not have distinguished the oleomargarine cheese from ordinary American cheese, and that they valued it from 52*s.* to 56*s.* per cwt. wholesale, and from 8*d.* to 9*d.* per lb. retail. American cheese of presumably legitimate origin is of course a well-established article of importation into this country; the estimated value of the cheese we import is upwards of 5,000,000*l.*, of which at least one-half is credited to the United States; and "American Cheddar," "American Cheshire," "American Stilton," &c., are well-recognised terms among retail provision dealers. We are now to have "Imitation American Cheddar," "Imitation American Stilton"—Stilton and Cheddar, in fact, several times removed; and Mr. Jenkins tells us that a very extensive trade will be shortly established in these articles, provided that their quality proves to be sufficiently good for the English market. Samples of these imitation cheeses have been examined by Dr. Voelcker, the chemist to the Royal Agricultural Society, who pronounces them to be perfectly wholesome articles of food. If the "oleomargarine" which enters into their composition be obtained from healthy fat or suet, there is, of course, no reason to doubt their wholesomeness or their alimentary value. Provided that the proportion of skim milk and oleomargarine be properly adjusted, the composition of the imitation cheese will differ but slightly from that of the best English made cheese, and will, so far as its nutritive value goes, be probably preferable to the ordinary skim milk cheeses of this country, or even to the more esteemed varieties of Gruyère and Parmesan. "Imitation factory cheese," as Americans call the new produce, will, of course, be almost entirely wanting in the characteristic fats of milk, such as butyrin, caprin, and caproin, to the decomposition of which the ripening and flavour of good cheese is mainly due. As is well known, hard solid cheese, in which the proportion of fat is comparatively low, ripens but slowly, and unless artificially flavoured, as in the case of Parmesan, acquires little or no piquancy. On the other hand, a rich cheese rapidly loses the acid reaction which it has when new; the casein and the fat suffer change, and the fatty acids thus formed combine with the products of the decomposition of the nitrogenous constituents giving rise to compounds, which, when accompanied by a due proportion of the green mould of *Aspergillus glaucus*, or the red mould of *Sporendonema casei*, afford the piquant flavour and aroma of the more valuable varieties of cheese. Such cheeses, however, soon run into putrefactive decay; they become strongly alkaline, and may even give rise to poisonous products. The fats of "oleomargarine" consist mainly of olein, stearine and their congeners, and are much more stable compounds; hence the cheese in which these bodies function will ripen comparatively slowly, and would of themselves never acquire the flavour of such rich cheeses as Stilton or Double Gloucester. Still art can do much, and he would be rash who would attempt to set a limit to American ingenuity; but we may at least hope that *Aspergillus* and *Sporendonema* may prove to be beyond the reach of the imitative power of the Transatlantic cheese-merchant.

T. E. THORPE

THE IRRAWADDI RIVER

Report on the Irrawaddi River. Part I. Hydrography of the Irrawaddi River. Part II. Hydrology of the Irrawaddi River. Part III. Hydraulics of the Irrawaddi. Part IV. Hydraulic Works connected with the Nawoon River. Parts I. and II. (in one vol.), 195 pp.; Part III., 227 pp.; Part IV., 151 pp. fol. By R. Gordon, Esq., M.I.C.E., &c. (Rangoon, 1879-80.)

THIS is a valuable Monograph on the Irrawaddi River by the Executive Engineer of the great Embankment Works of the Irrawaddi Delta, the well-known experimenter and writer on river hydraulics. The mode of publication does not do justice to the great labour and research shown in so large a work (573 pp. folio). It is apparently a Government Report, written in the period 1877-80, and printed at the Government Secretariat Press, Rangoon, in 1879-80. Great allowances must always be made for the difficulties in proper correction of the proofs of a work published at a small native press at a great distance from the author. Still the misprints in this work are quite unusually numerous, sometimes *three* in a single line of French or German, sometimes *four* in a single page of ordinary matter; this throws some doubt on the accuracy of the printed Tables (which cover about 130 pp. folio). The complete Report must have included about 29 plates (constant reference being made to them), but only three are published; the absence of these plates makes it often difficult, sometimes impossible to follow the author's argument. Again, the want of uniform transliteration of proper names causes difficulty in identifying unfamiliar places, the same place being often spelt in two or more ways (*e.g.* Shoaygheen, Shwaygheen, Shwégyeen, &c.). There is a too frequent use of local words (*e.g. choung* = river, *eng* = lake, &c.), and also of odd un-English words (*e.g.* divagation, prescinding, &c.). These are, however, trifling drawbacks compared with the fact that the work is one of great value, combining the results of unusual knowledge of the literature about the Irrawaddi with probably unique practical knowledge of the Irrawaddi Delta.

The work contains three very distinct subjects: 1, the question of the sources of the Irrawaddi (Parts I. and II.); 2, the hydraulic works on the Irrawaddi (Part III.) and Nawoon Rivers (Part IV.); 3, the theory of the flow of water in rivers (Parts III. and IV.).

Sources of the Irrawaddi.—Parts I. and II. form a monograph on the vexed question of the lower course of the great Thibetan River (Tsanpou or Sanpo); its upper course from west to east within the heart of the Himálya mountains has long been roughly known (by travellers' reports), but its lower course beyond the Himálya is still strangely obscure. The Indian Survey maps have long shown the Sanpo as continuous with the Brahmaputra. But the author adopts the view of the great French geographer, D'Anville (*circa* 1730), that the Sanpo is the upper course of the Irrawaddi. He discusses at great length the general features of the Thibetan plateau and of the Brahmaputra and Irrawaddi valleys, especially as to the distribution of mountain and valley, and as to rainfall and river discharges. The chief argument is that just above the *débouchure* of the highest known large affluent (the Mogoung), a little above Bhámo, at a distance of 800 miles from the sea, the Irrawaddi is still an immense river 1000 yards wide and with a flood discharge of over 1,000,000 cubic feet per second, and therefore requiring a large drainage area above Bhámo. Now within 100 miles above Bhámo, the five great rivers—Brahmaputra, Irrawaddi, Salween, Mekhong, and Yang-tse-kiang—are known to be contained within a narrow strip of 200 miles width; from this it would seem that the sources of the Irrawaddi must be very distant (from the want of numerous large affluents). By collating the various travellers' accounts of the Sanpo, it is shown that they are consistent with its being continuous with the Irrawaddi.

Most of this appears to have been written in 1877. But in 1877-78 the Indian Survey Department conducted some special investigations on the question; their explorers traced the Sanpo downwards to within about 100 miles of the nearest regular survey party then at work on the affluents of the Brahmaputra near the limits of British territory; this gap of 100 miles was left a *terra incognita*, so that the question was still open to conjecture. After some discussion of this later work, it is shown rather to favour the author's earlier writings.

Besides the main (geographical) argument there is much interesting matter in these two parts on the geology, meteorology, and some minor features of the Sanpo and Irrawaddi basins. The want of a good detailed map is much felt here in attempting to follow the geographical argument.

Hydraulic Works.—Parts III. and IV. deal chiefly with the (engineering question of) Embankment Works in the Delta of the Irrawaddi, intended for reclaiming the rich alluvial land and for shutting out flood water. In a practical sense this is much the most important part of the Report; but in the absence of the plates it is impossible to follow the great detail given. Still there is much of general interest admitting of some notice here.

Firstly, it is explained that most of the easily cultivable land in British Burma having been already taken up, the country—though apparently thinly populated—is actually well populated over the only good land; and that, to prevent over population, what is now really wanted is more land. In this view the reclamation of good land acquires great importance. This work in some way resembles that in the Mississippi Delta, with the important difference that the latter is a rich country with ample funds for the prosecution of large works, whilst Burma is a poor country without adequate means for the same. Indeed, the history of the works as herein set forth is throughout one of insufficient provision of funds for their rapid prosecution, and sometimes even for their proper repair; this was very disadvantageous, as of all works the timely repair of an embankment is perhaps the most urgent, as its breach may be simply disastrous.

In early days high floods on the Irrawaddi seem to have been rare; at any rate the floods of late years (1868, 1871, 1875, 1877, 1879) have all risen considerably above the highest supposed possible from local inquiry in 1862. It seems possible that this is due partly to the gradual destruction of the forests above, which causes the rainfall to be more violent while it lasts and also favours its rapid descent to the main stream, and partly to the erection of the embankments themselves which confine the floods to the main river.

A very curious instance is noticed that the 1875 and 1879 floods were *foretold* by the Burmese astrologers.

Flow of Water.—The uncertainty of hydraulic knowledge nowadays is well illustrated by the various opinions of successive engineers on the rise that would ensue in the river consequent on embanking it on both sides throughout the Delta. It is said that Col. Stoddard reported in 1869 that the rise would not exceed the average of one foot, whilst the professional adviser of Government considered that it might amount to 3 or 4 feet at Henzahda, and the author himself considered from 7 to 12 feet a probable rise. It is obvious that these results cannot be said to be any better than conjectural; their discrepancy showing that the formulæ in use for such sort of calculation were (as too often happens) inapplicable to the case in hand. The Government naturally declined to sanction the project.

The author then undertook an extensive series of direct discharge-measurements of the river nearly on the lines of the Mississippi work, viz. by direct velocity-measurements at numerous points of certain selected sites. Besides the practical value of these as necessary data for the embankment projects, the details may be of great use in the study of the flow of water. And indeed this forms the most interesting portion of the work in a scientific sense, being a mass of original experiment on the flow in a mighty river. Much credit is due to the author for the zeal with which he had these experiments carried on for several years, in the face of great difficulties and discouragements. The experiments are discussed only so far as necessary to explain the application of the results (chiefly discharge-measurements) to the embankment projects. A further special report upon the experiments themselves is promised, which should be of great value.

The velocity-measurements appear to have been entirely made with the "double-float," whereof the surface-float was a wood disc $6'' \times 6'' \times 1''$ joined by a cord $^1/_{16}''$ thick, of various lengths, to a cylindric wood sub-float $6'' \times 6'' \times 12''$ loaded with clay, and sunk to various depths from 1 to 24 mètres. At moderate depths this instrument would be pretty efficient; unfortunately the efficiency of all double-floats decreases with the depth of immersion, and at the greatest depth of 24 mètres this one must have been very inefficient; for—supposing even that the sub-float retained its most favourable (the upright) position—the relative areas of connector and sub-float exposed to direct current-action would be as 73 to 100, and to lateral current-action as 52 to 100; so that the observed velocity of the instrument was certainly not that of the current at 24 mètres depth (as it is taken to be). Notwithstanding the inherent objections to the double-float, there seems to be as yet no better instrument available for mighty rivers.

Two sorts of velocity-measurements were undertaken, viz. (1) at one mètre depth at many points (from 30 to 60) across the channel; and (2) at every mètre of depth upon selected verticals in the channel. The latter were considered the more important. This sort of work must necessarily have been very tedious in flood-seasons on a mighty river; at such times only ten complete series could be done daily; altogether about 10,000 such series were done. This is a collection of experimental data quite unique in river hydraulics, of which the author may justly be proud. From these data, together with the cross-section figure, the discharges were computed; the mode of computation seems to have been as good as the data admit of.

The mode of presenting the results is open to some objection—*e.g.* many of the velocities are carried to *four* decimals of feet per second, a degree of accuracy quite unattainable; again the discharges are given in *several* different forms, viz. in cubic feet per second, in cubic mètres, and also in tons and in "mètre-tons" per day, per month, and per year, and in some tables the unit is not stated. The author points out that one cubic mètre of water weighs about $55 \div 56$ths of a ton, so that the two measures (cubic mètres and tons) may be used indifferently with an error of less than 2 per cent., and he emphasises this coincidence by the use of a new term, "mètre-ton"; but by all modern usage this term means either the "moment of one ton of pressure at one foot leverage," or the "work done in raising one ton weight through one foot height," so that this new usage is inconvenient.

As to the theory of running water some novel views are brought forward. It is stated that, speaking broadly, two theories of flow in open channels have existed; viz. that previous to Du Buat's time the motion had been supposed due solely to pressure, and since his time has been supposed due solely to surface-slope, so that the earlier formulæ involve pressure, and the later surface slope. The author himself is the advocate of a "new theory," viz. that the motion is due to both pressure and surface-slope; his arguments appear to be chiefly two, viz. (1) that formulæ involving only one of these elements all fail under varying conditions; (2) that in many cases the ratio of the deep-seated velocities to those near the surface (which is usually < 1) rises with increase of depth of the stream, and may sometimes even exceed unity in very deep streams. These views can hardly be admitted. Firstly, as to causality, surface-slope is really only a *property* of running water, not a *cause* of motion. All change of motion is due to and is evidence of the action of some *unbalanced* force (or pressure). In the case of running water the unbalanced active force (effective in forward motion) is the part of the earth's attraction *not directly* balanced by the normal resistances (ultimately of the margin), *i.e.* the resolved part thereof parallel to the motion, the *measure* of which is $g\rho \sin i$, and actually enters into all modern hydraulic formulæ in various equivalent forms, *e.g.* as $(p - p')$, $(dp \div dx) . \delta x$, $g\rho(h - h')$, $g\rho \sin i$, $g\rho S$, &c.; it cannot therefore be said that pressure is excluded from modern formulæ (although, after substituting numerical values for $g\rho$, the evidence of it is apparently lost). In the argument it seems also to be implied that the increase of pressure due to increase of depth should cause increase of velocity, but the fact is that increase of pressure does not of itself affect motion at all, unless the increase be (at least in part) unbalanced.

An interesting series of discharge-measurements was made at three sites in concert, viz. at Saiktha, near the head of the Delta, and at Zaloon and Thapangyo, which are situate on the two largest Delta streams. There appear to be only some minor local *affluents* into and *effluents* out of the space between the upper and lower sites. It would seem therefore that the discharge-measurements at the upper and at the two lower sites together should be nearly equal; this affords a valuable test of the consistence of the results. The field work seems to have been done at *each* of the three sites on seventy-three days in 1872-73, thus giving seventy-three pretty complete results; other eighty-three days' results are also given, but these are partly interpolated, and therefore of less value. The discrepancies are sometimes very large, ranging from a *gain* of 27 per cent. to a *loss* of 15 per cent. in the daily results; most of them (97 out of 154) are on the side of gain. After making allowance for the utmost possible supply from the minor affluents between the sites (by adding in the whole rainfall all over their drainage-basins) the residual discrepancy is attributed to the "storage power" of the river area (about 305 square miles) between the sites. While there is no doubt some (temporary) "storage power," it seems more likely that most of the discrepancy is due to real error in the results themselves, the fact being that only *very rough* approximation can be expected in the discharge-measurement of mighty rivers in flood. This collection of river discharge-measurements being made in such a way as to test each other is almost unique, most published results being isolated results incapable of test.

ALLAN CUNNINGHAM

OUR BOOK SHELF

The Botanical Atlas; a Guide to the Practical Study of Plants. By D. McAlpine, F.C.S. (Edinburgh: W. and A. K. Johnston, 1882.)

THE above is the title of a publication appearing in monthly parts, each containing, in the words of the prospectus, "four beautifully coloured plates and descriptive letterpress." Part I. deals with common representatives of the natural orders *Caryophyllaceæ*, *Cruciferæ*, *Fumariaceæ*, *Geraniaceæ*, and *Labiatæ*.

We are perplexed as to the intentions of the author of this work, which is advertised as designed "for the use of medical schools and Universities." If the "Botanical Atlas" is intended to supply candidates for certain elementary examinations with the facts absolutely necessary for a "pass" certificate, it seems fair to expect accuracy in the drawings of common objects.

The author, however, appears to think otherwise; not only are there gross inaccuracies in the execution of the conspicuous figures, but the types are ill-chosen and imperfectly referred to.

In illustration of this may be noted Fig. 2, on Pl. xiv., professing to represent a vertical section of the common wallflower; the reference "long stamen," points to the anther of a short one, and the words "short stamen," are referred to a green band, which might be imagined as intended for filament, petal, or sepal, and seems to do duty for all three.

In the figures standing for other vertical sections of flowers—*e.g.* Fig. 3, Pl. xvi., and Figs. 2 and 3, Pl. xxiii.—no one can avoid noticing the mysterious vagueness in the lower portions of the drawings; the same remark applies to the sections on Pl. xv. Is the author undetermined as to the relations of the parts composing the andrœcium and gynœcium, or does he expect students, for whom elaborately-coloured drawings of sepals and petals have been prepared, to discover the forms and relations of the smaller essential organs without aid—or, rather, in spite of the misleading caricatures here placed like pitfalls in his path?

Similar faults are apparent in the diagrammatic plans of the flowers, and one wonders at the ingenuity displayed in going so far out of the way to prepare imperfect and inaccurate drawings of common objects.

Among other equally ingenious misrepresentations may be named Figs. 9 and 10, Pl. xv.—the marvellous streaks in a somewhat oval frame (Fig. 11, Pl. xvi.) supposed to represent a longitudinal section of the seed of *Geranium*, the incomprehensible *stigma* in Fig. 8, Pl. xxiii., with reference to which we cannot agree with the author when he says: "The figures will show the arrangement of the parts better than any description."

Passing over such errors as Nostoe, Hydrodietyon—possibly printer's mistakes—and the questionable mixtures of Latin and English names, we may notice one or two specimens of description appended to these gaily-tinted plates. We are told, without further remark: "The form and arrangement of the different parts (Fumitory) are evidently suggestive of some purpose." Also, the description of the wallflower commences: "Wallflower is a universal favourite, no less from its beautiful colour than from its sweet smell," and then passes on to a highly condensed and imperfect synopsis. We are told that the "Campion" "also smells in the evening in order to guide and attract insects," and that in Herb Robert "the stem forks a deal, and is very brittle at the joints."

Such drawings and writing speak for themselves. We can only express the hope that if the other parts are published, more attention will be paid to accurate delineation and exhaustive description, and less to merely gaudy colouring. So far, the "Botanical Atlas" must be considered as but a very inefficient and faulty "guide to the practical study of plants." W.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Magnetic Storms of 1882, April

THE Astronomer Royal having received from Mr. Charles Carpmael, superintendent of the Meteorological Office at Toronto, Canada, copies of the Toronto records of the double magnetic storm of April last, has had them compared generally with the Greenwich records. Some results of this comparison I am desired by him to communicate to you for insertion, if you think proper, in the columns of NATURE.

The records comprise traces of the changes of magnetic declination, horizontal force, and vertical force. The commencement of disturbance on April 16 was sudden, in all elements, as was also the renewal of disturbance on April 19. Measuring out the times, both for Greenwich and Toronto, the following results are found:—

Element.	Toronto time of commencement of disturbance. h. m.	Corresponding Greenwich time. h. m.	Greenwich time of commencement of disturbance. h. m.
Declination ...	April 16, 6 17 ...	16, 11 35 ...	April 16, 11 31
Hor. Force ...	,, 6 15 ...	,, 11 33 ...	,, 11 31
Ver. Force ...	,, 6 16 ...	,, 11 34 ...	,, 11 35
Means		April 16, 11 34 ...	April 16, 11 32
Declination ...	April 19, 10 15 ...	19, 15 33 ...	April 19, 15 34
Hor. Force ...	,, 10 16 ...	,, 15 34 ...	,, 15 34
Ver. Force ...	,, 10 16 ...	,, 15 34 ...	,, 15 37
Means		April 19, 15 34 ...	April 19, 15 35

The times are mean solar. In the first case the mean of the Greenwich times is but 2m. earlier than that of the reduced Toronto times; in the second case 1m. later, indicating no real difference. This confirms, what has been before observed, that in times of storm the commencement of disturbance at different places appears to be simultaneous.

As regards the variations registered during the progress of the storm there does not seem to be any very close correspondence between the records of the two places excepting in one particular, the occurrence of a very remarkable decrease of horizontal force, soon after the first outbreak on April 16, which continued for some hours, and is a striking feature in both records.

Earthquakes in China

PLUSIEURS secousses de tremblement de terre ressenties en Chine pendant l'année 1881 ont été rapportées dans les journaux de Shanghai, de Hongkong et de l'étranger. Voici sur deux d'entr'eux quelques circonstances toutes particulières qui sont venues à ma connaissance et dont on n'a pas parlé.

Le 20 Juillet, un peu après 9h du soir, une secousse assez forte ébranla la ville de Tchong-kin, capitale de la Province de Sze-tchuen, longitude 104° E. de Paris; immédiatement après, écrit un Missionnaire, la ville fur couverte d'une brume tellement dense qu'on ne voyait pas à 10 pieds devant soi; de plus une odeur de soufre très sensible se repandit partout. On prit tout d'abord cette brume et cette odeur pour un indice d'incendie;

mais on le chercha en vain. La terreur était d'autant plus grande dans la ville que le peuple, à cette époque même, multipliait les superstitions, et les sacrifices en l'bonneur des divinités protectrices contre les incendies. Aussi le grand mandarin de Tchong-kin avait prohibé la vente et l'usage des allumettes chimiques importées par les étrangers (yang ha) et celui du pétrole (yang ieon) qui avaient naguère occasionée une terrible conflagration.

Voici une note de Mr. Harding, l'ingénieur chargé d'elever un phare à la pointe sud de l'île Formose.—Le 11 Décembre 1881, vers 4h du matin, trois chocs distincts de tremblement de terre furent ressentis." The first, of which the motion was oscillating, and which was the most severe, lasted abnut 3 to 4 seconds; then an interval of about 10 seconds followed by the second shock—an interval of 1 or 2 seconds, followed by the third shock—direction from S.S.W to N.N.E. These shocks, which were of great severity, were also felt in Tai-wan-foo and Takow (environ 75 et 52 milles an nord nord-ouest du cap sud). The water at South Cape rose 16 feet, causing great destruction to the cargo boats moored near the beach, and was accompanied by a heavy southerly swell. The water which at spring tides only rises 3 feet 8 inches, had resumed its ordinary level at 7 a.m.

On March 19, 1882, at about 5 p m., a slight shock of earthquake (toujours au cap sud), with a gentle oscillating motion from south to north. Duration of shock about 3 seconds."

J'ai pensé que ces curieux faits intéresseraient les lecteurs de NATURE.

Le Directeur de l'Observatoire,
MARC DECHEVRENS, S.J.

Observatoire de Zi-ka-wei, près Shanghai, Chine, Avril 25

P.S.—Une grave perturbation magnétique a été enregistrée à Zi-ka-wei le 17 Avril dernier. Elle débuta brusquement à 7h. 36m. du matin (temps moyen de Zi-ka-wei, longitude 8h. 5m. 50s. de Gr.) par une augmentation de la composante horizontale de l'intensité et une diminution de la déclinaison. Vers 8h. un mouvement inverse commença pour se continuer avec de larges ondulations mêlées de saccades brusques et nombreuses jusqu'á 2h. 22m. de l'après midi, moment où la déclinaison atteignit son maximum. Entre le minimum, qui fut enregistré quelques minutes après le début de la perturbation, et ce maximum de 2h. 22m. la déclinaison a varié de 21'·1, valeur considérable à Zi-ka-wei. La composante horizontale eut son minimum d'intensité (apparent à cause de la variation de température) d'abord á 4h. 20m. du soir, puis encore à 7h. 20m. du soir. Ou peut se rendre compte de l'énorme baisse enregistrée en cette occasion, en sachant que le 19, par exemple. où la variation de la composante fut normale, la courbe photographiée à une amplitude totale de 15 millim, tandis que le 17 pendant la perturbation la variation totale s'éleva à 76 millim. entre 7h. 36m. du matin et 4h. 20m. du soir. Les grandes ondulations se dessinèrent pendant le minimum d'intensité entre 2h. du soir et 10h. du soir. Vers 11h. 30m. du soir la composante se releva très-brusquement, oscilla encore 3 ou 4 fois ce vers 3h. du matin 18 la perturbation était finie. A cette augmentation brusque d'intensité correspondit une diminution non moins rapide de la déclinaison, suivie aussitôt après d'une forte augmentation qui mit aussi fin à la perturbation de cette boussole.

Pendant tout ce temps l'aimant de la composante verticale oscilla constamment mais dans de très-petites limites; il n'y eut que deux ondulations qui se dessinèrent assez nettement, l'une entre 8¼ et 8½ du soir l'autre à 11.30.

Le 20 Avril, nouvelle perturbation aussi intéressante commençant avec une soudaineté et une violence extraordinaire à 11h. 40m. du matin par une énorme diminution de la composante horizontale, suivie de sauts ou d'ondulations amples et assez rapides. Inutile de dire que la déclinaison a varié proportionellement et en sens inverse. Le maximum de déclinaison fut enregistré à 3h. 43m. de l'après-midi; entre le minimum normal de 9h. et ce maximum de l'après-midi la variation à été de 13'·2 seulement. La perturbation prit fin à 2h. 20m. du matin le 21, quoique la déclinaison continuât à être irrégulière dans la journee.

A cette double perturbation magnétique ont correspondu des troubles profonds dans toutes les lignes telégraphiques, marines ou terrestes, de l'extrême Orient, de Singapore et Manille jusqu'à Tientsin. Les moments ou les courants perturbateurs furent observés furent surtout, le 17, entre 10h. et midi (Nagasaki-Shanghai Shanghai-Hongkong), à midi 50m. (Hongkong-Amoy-Shanghai), à ce moment la correspondance entre Hongkong, Manille, et Singapore entiérement interrompue; entre 2h. 5m. et 2h. 20m. Shanghai Amoy). Le 20, à midi (Shanghai-Nagasaki).

Tout cela indique pour l'Europe de belles aurore boréales. Ici rien.

Non-Electric Incandescent Lamps

IT is I believe well known that a method of obtaining light by means of incandescent platinum was patented by A. Cruckshanks in 1839. The following extracts from his specification (No. 8141) will, I think, show that there is no essential difference between the lamp devised by Prof. Regnard (NATURE, vol. xxvi. p. 108) and the invention of the patentee, which is described as follows:—

"In order to increase the light obtained from substances that are rich in carbon and to obtain light from gases and vapours that do not contain the proportions of carbon necessary to produce a bright flame, I construct a cage of fine platina wire gauze or network of the form of the flame and just so much smaller than the flame, that it may be entirely immersed in the outer portion of it, where it will soon become intensely ignited."

Further on it is stated that the platinum (covered with lime) may be heated by jets of the "vapour of inflammable liquids mixed with atmospheric air," and the patentee says that "the most advantageous method in practice" of obtaining the mixture "is to pass a current of air through such liquid."

The use of incandescent platinum as a source of light was again patented in 1849 by Gillard, and put in practice at Narbonne and some other small towns in France, but after a fair trial the experiment was abandoned (see King's "Coal Gas," vol. i. p. 53).

Conservation of Solar Energy

THE views of Dr. C. William Siemens suggest a consideration of the influence of solar rotation upon the æthereal atmosphere, at various distances from sun's centre.

Laplace's limit of equal rotary and planetary velocity is at $36{\cdot}35\, r_{\circ}$, $r_{\circ}$, being sun's semidiameter. The centrifugal force of rotation at that limit would be 1321·3 times as great as at sun's surface, while the centripetal force of gravitation is only $\frac{1}{1321{\cdot}3}$ as great. The lately-published photographs of the solar eclipse indicate an atmospheric oblateness which may be due to the equilibrating tendencies of the two opposing forces.

If the æthereal disturbances from this source are not sufficient to account for luminous and thermal vibrations, we may look next to the velocity which the subsiding particles would acquire in falling from the equatorial limit to the solar poles. If there were no resistance, this velocity would be

$$\left(\frac{35{\cdot}35}{36{\cdot}35} \times 2gr\right)^{\frac{1}{2}} = 376{\cdot}8 \text{ miles per second.}$$

Any diminution of this velocity by resistance would be converted into heat.

If we apply Coulomb's formula of torsional elasticity, $f = \frac{\pi a^2 lW}{2gt}$, to solar rotation, W may represent sun's mass, a the coefficient of the radius of torsion, f the coefficient of torsion, g gravitating acceleration at sun's equatorial surface, t time of oscillation when the force of torsion is removed, or time of a solar half-rotation. Then

$$f = \frac{m}{2} = \frac{W}{2} \cdot \frac{\pi^2 a^2 r_{\circ}}{gt^2}; \therefore \pi a^2 r_{\circ} = gt^2 = \pi^2 l.$$

But g', or the projectile velocity that is represented by sun's rotary oscillation, is *the velocity of light*; gt^2 is the modulus of light at sun's equatorial surface; $a^2 r_0$ is the theoretical length of a pendulum, at sun's surface, which would oscillate once in each half rotation; $ar_{\circ}$ is the length of an equatorial radius rotating with sun, and having the superficial orbital velocity, $\sqrt{gr}$, at its emote extremity.

PLINY EARLE CHASE

May 27

The Function of the Ears in the Perception of Direction

UNFORTUNATELY, through the bungling of my late agents, I am unable to refer to NATURE, vol. xxiv. p. 499, as quoted by

Mr. S. E. Peal, I may, therefore, be communicating stale information; but as it is the result of personal experience, what I have to relate may be of some use as confirmatory of statements of others. Mr. Peal would not be able accurately to estimate direction, unless the sense of hearing—the capacity to receive sound—was precisely equal and similar in each ear. A greater sensibility in one than in the other, would incline him to the right, or the left, as the case might be.

Few people know that they may be partially deaf on one side, and yet not perceive it, just as some are right- or left-eyed, without knowing it. A good test is a watch slid along a two-foot rule, the end of which touches the cheek. The watch is moved away, inch by inch, till the ticking is no longer audible—if the distance is the same on both sides, the sensibility of each ear is of course equal.

I shall not forget my horror when my medical man, applying this test, showed that while with my right ear I could distinguish the ticks far beyond the 2 feet, my left ear was impervious to the sound until within an inch or two of the watch. Hearing on that side has now totally ceased, and the result is *I have not the slightest idea of the direction of sound.* I can hear certain sounds (for I am becoming deaf on the right side also), but to whichever side I incline my right ear, from thence do I fancy the sound to come.

To me, with my passion for ornithology, it is a terrible deprivation. In my youth my senses were intensely acute. I could instantly detect and proceed to the faintest note uttered by a bird in the forest. Now the loudest call only puzzles me the more. But I was a long time before I found this out. I fancied more than once that the bird I was pursuing had powers of ventriloquism; then that there were two or more, calling from different directions. As soon, however, as I found, as before stated, that I was deaf on one side, I began experimenting on myself, and quickly arrived at the conclusion that in order to estimate direction, both ears needed to be equally sensitive.

A curious instance of correct judgment as to direction and distance of sound is given by one of the South African explorers, Green, I think. He had been much annoyed by a lion which roared round his camp. Taking his rifle and some of his native followers, he went outside in the direction of the sound. Halting, they listened intently, and at the next roar caught the exact direction, and judged the animal to be at (I think) about 300 yards. Carefully levelling his rifle, he fired, and had the satisfaction of hearing the well-known "thud" of the bullet, and a change of note from the midnight serenader. Next morning showed traces of blood, and following up the track they found, and despatched the wounded beast.

Colour-blindness is represented in the other sense, by an inability to distinguish certain sounds. That this is caused by partial deafness, I am now pretty well certain. My father-in-law, who never knew he was deaf, never heard the chirrup of the cricket, and I now find I cannot do so. Only last night my wife observed "what a noise the crickets are making," to me there was unbroken silence as regarded outward sounds. I only heard the continuous "buzzing" that sounds in my head, augmented by the regular "thud thud" of my pulse.

I have a clock, the hours of which strike on a sweet-toned, metallic bell. If my right ear is turned towards it, at a moderate distance, I hear the ringing note; if turned away, I am only conscious of the "burr" of the works, and a dull "thud, thud," denoting the stroke. Why do I hear the "burr," which is not so loud, or clear, as the metallic "ting"? That wave of sound seems to pass by and not affect me; it is like the sharp note of the cricket.

The cause why certain sounds are inaudible to certain ears is a subject well worthy of investigation, as bearing on the placing of sentries or outposts at night, in time of war; also for sportsmen hunting large dangerous game. E. L. LAYARD

Jamaica Petrel

MR. D. MORRIS asks (NATURE, vol. xxv. p. 151) for some clue to the locality and general character of the nesting-places of petrels. As I fail to find any reply in your pages up to January 19, I venture to send my mite by way of response to Mr. Morris.

Most of the petrels (*Æstrelata*), the Storm Petrels (*Thalassidroma*) and the Shearwaters (*Puffinus*) breed in holes in the ground, excavated by themselves; sometimes on small islands, at other times on high mountains, at considerable distances from the sea. Their movements to and fro are almost always performed at night, and as they are capable of a very rapid flight, a distance of fifteen or twenty miles is quickly traversed.

Here, in New Caledonia, the well-known *Æstrelata mollis* breeds on the summit of Mont Mou (about 4000 feet) in January-March, in great numbers, laying one white egg, as usual. I am informed that in some places the ground is honeycombed with their burrows. I am also told that during the non-breeding season numbers come to roost in their old holes.

The larger, *Æ. rostrata*, Peall, nests in similar places, but at a much less elevation, on the Island of Uen, the most southern portion of New Caledonia, and hardly divided from it by the celebrated Wodin passage.

Other species are said to frequent other mountains in the interior, but I have no personal knowledge of them.

In Fiji I obtained *Puffinus ungax*, which bred far away in the mountainous interior, and there are other true petrels which do the same.

Vast numbers of various petrels and shearwaters are found in these seas, and I fancy all burrow, more or less, in the earth, to lay their eggs. Of the "Great Grey Petrel" (*Adamastor cinerea*) Capt. Hutton says, that it "burrows horizontally into the wet, peaty earth" (of Kerguelen's land) "from two to eighteen feet."

That the "Jamaica Petrel" resorts to the Blue Mountain range of Jamaica, for the purposes of breeding, I have not the smallest doubt, and if the holes are examined at the right time of year, I feel sure eggs will be found. The birds probably do use the holes as resting places, during certain periods of the year. They do not, however, *lay their eggs at sea!* and sooner or later Mr. Morris may be sure of finding eggs, though he may not find much of a nest.

The breeding of the Mutton Bird (*Puffinus brevicaudus*) on many of the Australian islands has been often described. Its burrows render walking positively dangerous. If Mr. Morris can refer to Gould's "Birds of Australia," he will find much information on this head. E. L. LAYARD

THE REGNARD INCANDESCENT LAMP.—In reply to several correspondents who find a difficulty in the use of petroleum for this lamp, we think they may be more successful with benzoline.

DOUBLE STARS[1]

II.

WE are in possession of numerous methods of computing double star orbits. Sir John Herschel gave one of the first solutions of this problem, and his method has been used more than any other up to this, and so far from becoming obsolete, it is yearly gaining ground at the cost of the methods that have been proposed elsewhere. It starts with the construction of the orbit, which the companion appears to describe round the main star. It is clear that as the planes of the orbits may be inclined in every direction in space, we see only the projection of the real orbits on the heavens, but this, as well as every other projection of an ellipse on a plane surface, is another ellipse, though the main star does no longer appear situated in the focus. Five points determine an ellipse, if we therefore possess five complete observations, we can determine the apparent ellipse. Now the observations are not perfectly accurate, but the calculus of probabilities furnishes us with means to ascertain the most probable ellipse from a great number of observations, to which different weight may be attributed, according to their reliability, as far as known. But at Herschel's time, though the angles had been fairly observed, the measurement of these minute distances was still in its infancy. He, in consequence, threw them away, and computed distances by aid of the Keplerian law referred to above, from the angular velocities, concluded from a comparison of observations separated by moderate intervals. He improved the angles in the following way:—On a paper neatly divided into squares, he lays down a

---

[1] Continued from p. 155.

point for every observed angle of position, the epoch in years and decimals being measured as an abscissa along the horizontal lines, and the angle in degrees as an ordinate along the vertical ones. A series of points are thus obtained, which, if the observations were exact, would necessarily admit of a regular curve being drawn through them, whose nature is of course determined by the laws of elliptic motion, and one of whose essential characters is to have within those limits of the abscissa, which correspond to a whole period of revolution (that is, to a difference of 360 units in the ordinates), in some cases two, in some four, points of contrary flexure, but never more than the latter, nor fewer than the former, and to have, moreover, in all its points, a peculiarly graceful and flowing outline. The errors of observation, however, prevent the drawing of such a curve through all the points. It must be drawn with a free but careful hand, not through, but among the points, and so that it shall deviate less from every point, according as it is more or less reliable. Now after Herschel's time the accuracy of the observed distances has wonderfully improved, and we are therefore able to draw another curve representing the distances as ordinates, which then ought to agree with those deduced from the angles, and the angles ought to agree with those deducible by aid of integral calculus from the distances. The curves must be varied till they thus mutually support each other, and then we may construct any number of points of the apparent orbit by reading off the angles and distances for the corresponding epochs on the curves, and if we find the arc described sufficiently extensive, the apparent ellipse is simply drawn as nearly as possible through them. From the apparent orbit the elements of the real orbit, described in space, are then determined. These are seven in number :—

a. The major semi-axis, expressed in seconds of arc, *i.e.* the angle under which their mean mutual distance would appear if placed perpendicular to the line of vision, *i.e.* the straight line joining us with the star.

ϵ. The eccentricity of the real ellipse.

γ. The inclination of the plane of the real orbit to the plane perpendicular upon the line of vision.

Ω. The node, *i.e.* the angle of position of the line in which the plane of the orbit intersects the plane perpendicular upon the line of vision.

π. The longitude of the projected peri-astron, *i.e.* the angle of position of the companion at the epoch of its actual nearest approach to the main star.

T. The epoch, when the nearest approach in space occurs.

P. The period of revolution, *i.e.* the time it takes the companion to complete an entire revolution round the main star.

It is impossible to say what part of the orbit is inclined towards us, and what is removed from us,[1] we cannot therefore, distinguish between an ascending and a descending node.

Both before and after Herschel's investigations, several methods of calculating double-star orbits have been proposed. Savary, at Arago's request, was the first who gave an analytical determination of an orbit from five points. He also proposed a method, subsequently improved by Encke, for calculating the seven elements of the real orbit from four complete observations. These furnish eight co-ordinates corresponding to known epochs, and as only seven quantities, the elements are sought, the problem is over-determined. It has to be solved with different values of one of the data, in order that all the other data may be represented. The case is, at the time it generally was possible to obtain but three complete positions from the discussion of modern observations, while the fourth, depending upon Herschel's measures, gives seldom even an approximate value of the distance. After that, a longer series of angles had become available. Klinkerfues proposed to determine at once the seven elements from six observed angles, and at least one distance. The dimensions of the orbit could evidently not be obtained without the aid of observed dimensions, though all the other elements can be derived from the angles. It sometimes occurs that the companion moves in an orbit, the edge of which is turned towards us. The inclination is then about ninety degrees, and all the angles are nearly equal to, or half a circumference different from the longitude of the node. We are then obliged to make more extensive use of the distances. Several analytical methods have been adopted to this contingency, which has actually occurred in a few cases. It seldom happens that an orbit founded upon a few positions, even if these are distributed over a great part of the arc described, is the most accurate that could possibly be deduced from all the observations at our disposal. It is therefore advisable to finally correct the elements according to the rules of the calculus of probabilities, so that the errors ultimately left behind in the representation of the observed places, may, taking into account their relative accuracy and their different peculiarities, be as small as possible. In this country, Hind, one of the greatest authorities on anything relating to double stars, has made most extensive calculations of this nature.

The number of those double stars whose orbits can be computed is limited to between thirty and forty. The time during which micrometric measures have been made is so short, that one but seldom can make anything like a correct guess of what the whole orbit may turn out to be like, when the period is above three hundred years ; and even so, the peri-astron passage must happen to fall within a hundred years from now ; that is, if the eccentricity is not unusually small. The eccentricity of these orbits is generally large, and it appears to be larger the greater the period and the greater the axis is. Now in the cases—by far the most frequent—where the measures do not embrace a larger part of the orbit, we represent the motion of the companion by formulæ, deduced in accordance with the proportionality of the areas with the times. These formulæ suffice to foretell the co-ordinates for some few years to come, and they are interesting in other respects, too. Thus, if the distance of a double star from the solar system were known to us, we would also know the dimensions of the orbit in miles, and then we could calculate its mass by aid of Kepler's laws. Now their distances from us are not known, but if we assume the mass to be on an average *e.g.* about three times the mass of the sun, then we obtain—if we make the further assumption that the distance actually measured in seconds of arc between the components is in an average of a very great number of stars equal to their mean distance from each other—from the period of revolution (concluded from the variation of the angle) through the inverse calculation their distance from us. Now these hypotheses can only be used in discussing the results of an average of a great number of systems that have certain characters in common, *e.g.* brightness, colour, or distance. I am at present engaged with such researches, from which I hope to arrive at interesting results.

Most of the double stars, that so far have been found to revolve, are close and more or less difficult objects. Few of them are more than six and a half seconds of arc asunder. The components are in most cases of about the same brightness, but the companion is, on the whole, smaller, the greater the distance.

There are two kinds of revolving double stars. The first of them consists of bodies whose colours are strictly identical, whereas the second consists of bodies whose colour is generally complementary. The principal star in both cases is white or yellow—white stars preponderating in the first case, yellows in the second. In systems of

---

[1] This could be ascertained if we could at any time observe the speed in miles per second with which the companion approaches to or recedes from us in the line of vision. Spectroscopists are making some progress in similar researches, but their apparatus are not as yet sufficient for our purpose.

the latter kind, the companion is generally bluish, and the number of blue companions increases rapidly with the distance, so that the close pairs are generally of the same, more or less white colour, and not very different in magnitude, whereas the wide pairs are of complementary colours, and the companion much fainter than the primary. We see then that the brightness is, on the whole, more different, the more different the colour is—a circumstance first pointed out by Struve. Now it is well known that the colour of a solid or liquid cooling body passes from white through yellow to red, and these are the colours in which the single stars, without exception, appear to us, whereas the blue and purple stars are found only as small companions to brighter stars. Holden, in Washington, has suggested that these colours are due to absorptive atmospheres—an opinion, the decision of which we leave to spectroscopists. Pickering, in Cambridge, U.S., has shown, from the absence of polarisation, that they do not shine with reflected light.

The last remarks remind us of the planets, that, no doubt, revolve round those distant suns, and derive from them their light and heat. When we reflect upon the complicated nature of the orbits, which the planets and comets describe round our sun, we get some idea of how remarkable must be the nature of those curves that planets describe round double suns, compared to which the motion of our moon is simple, and easily understood. Perhaps the same comets that disappear to our gaze, leaving the sphere of attraction of the sun, are attracted, and for a time become members of those wonderful systems. Our mathematics do not suffice for solving the problems that are thus suggested, but it is not unlikely that, unless situated very close to one or other of the suns—so close that the other appears not much larger than a star, though comparable in brightness to the nearest sun—the planets are whirled out in the cold space by the gravitational influence of the other sun, as very likely many a minor planet was ejected from the solar system under the influence of Jupiter. What must be the nature of those worlds illuminated by two different suns, one yellow and another purple? Now rises the one, and all is clothed in yellow, now the other, and illuminated from complementary sources, every object appears in its natural colour. Then sets the yellow sun, and what must be the diversity of the effects as it approaches the horizon! And behold nature puts on a purple mantle. Then also that sun sets, and in the darkness of night, though there is seldom night where there are two suns, the starry heavens are seen much the same there as here, except perhaps for moons reflecting light from the differently-coloured suns. But stars that seem large to us are hardly visible there, while our sun is perceived in the telescopes of the mysterious beings that inhabit those strange globes as only a faint star, and metaphysicians there prove from *a priori* considerations to their attentive pupils, that no life could bask in the feeble glare of a single sun—how all would famish but for the opposite effects of the two suns. And no doubt! life there is heightened, and the wonders of nature are unravelled by aid of and under the influence of the energy of several suns, more highly developed science, seeing how glorious is the creation on this poor orb, that is kept alive by but one. Not only the play of colour must there be more varied than here, but phenomena of which we have not the faintest idea, must be produced also through the action of heat, electricity, and magnetism.[1] Indeed, upon subjects like these, science gives no information, and we may therefore give our fancy free reins. Oh! that we did possess the power of appreciating these things like the divine Milton, when in truly prophetic strain he wrote:—

> "Other suns, perhaps,
> With their attendant moons, thou wilt descry,
> Communicating male and female light,
> Which two great sexes animate the world,
> Stored in each orb, perhaps, with some that live;
> For such vast room in nature unpossess'd,
> By living soul, desert and desolate,
> Only to shine, yet scarce to contribute
> Each orb a glimpse of light, conveyed so far
> Down to this habitable, which returns
> Light back to them, is obvious to dispute."

W. DOBERCK

---

[1] The tides upon the planets caused by the two suns must be very interesting. Of course they also produce tides upon each other, and their spots present no doubt most peculiar features. It is not unlikely that in some cases the phenomena presented by new as well as by some variable stars are to be explained as the effect of tides caused by darker companions.

ON THE PHOTOGRAPHIC SPECTRUM OF COMET (WELLS) I., 1882[1]

ON May 31 I obtained a photograph of the spectrum of this comet, with an exposure of one hour and a quarter. On the same plate I took a spectrum of α Ursæ majoris for comparison. The comet's spectrum on the plate consists of a strong continuous spectrum extending from about F to a little beyond H. I am not able to distinguish any of the Fraunhofer lines in this continuous spectrum. The slit was rather more open than was the case in photographing the spectrum of the comet of last year; this would make these lines less distinct, but the lines G and H are well seen in the star's spectrum taken under the same conditions. We may therefore conclude that the part of the comet's original light which gives a continuous spectrum is much stronger relatively to the reflected solar light in this comet, than was the case in the comet of last year, and for this reason the Fraunhofer lines are not distinguishable.

Observations of the visible spectrum had already shown that the comet differs remarkably from the hydrocarbon type common to all the comets, some twenty, which have appeared since spectrum analysis has been applied to these bodies.

The photographic spectrum shows, as was to be expected, that this essential difference of spectrum exists also in the more refrangible region. The very strong ultra-violet group assigned to cyanogen is not to be seen on the plate, and the bright groups between G and *h*, and between *h* and H do not appear to be present.

The head of the comet was in sharp focus upon the slit, and the continuous spectrum with defined edges corresponds to the nucleus which in this comet was very distinct. In this continuous spectrum at least five separate places of greater brightness are seen, which very probably represent groups of bright lines, though they are not sufficiently distinct in the photograph to admit of resolution. That this interpretation is correct, seems probable, from the circumstance that these groups, as shown in the diagram, project beyond the strong continuous spectrum on one side. This side corresponds to where the light of the coma, on the side of the nucleus next the sun, falls upon the slit. We learn, therefore, that the light of this part of the coma consists for the most part in this part of the spectrum of these groups, as here on the plate only an exceedingly faint continuous spectrum can be seen.

It is not possible to measure with any useful accuracy the beginnings and endings of the groups, as they are too faint at these points. Measures as accurate as the circumstances would permit have been taken of the brightest parts of the groups. The wave-lengths of these brightest parts are :

$$\left.\begin{array}{l}\lambda\ 4253\\ \lambda\ 4412\\ \lambda\ 4507\\ \lambda\ 4634\\ \lambda\ 4769\end{array}\right\}$$

In the visible spectrum the bright lines of sodium

---

[1] Substance of note read before the Royal Society, June 15, 1882.

appear to have been strong, and it may be that some of the light of some of the groups may be due to this substance.

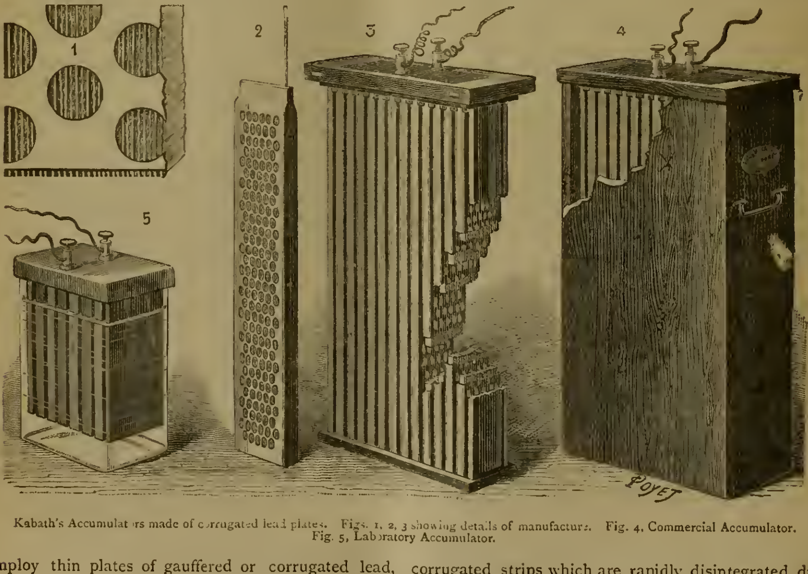
Prof. A. Herschel and Dr. von Konkoly showed long ago that the spectra of the periodic meteors are different for different swarms, and it does not seem surprising that we have now a comet, the matter of the nucleus of which under the sun's heat shows an essential chemical difference from the long series of hydrocarbon comets which have appeared since 1864.

Mr. Hind has kindly furnished me with the distance of this comet from the sun at the time the photograph was taken. The comet was then 42,380,000 miles distant from the sun, while the comet of last year was 69,420,000 miles when I obtained the photograph of its spectrum.

WILLIAM HUGGINS

KABATH'S ELECTRIC ACCUMULATORS

AT intervals since the introduction of accumulators or secondary batteries by M. Gaston Planté, various modifications have been made with a view to constructing cells on a commercial scale. The most renowned of these modifications was that of Faure, who applied red lead to the surface of the lead plates, so as to furnish a greater thickness of the spongy mass that is the effective agent in the storage process. In this development he had been anticipated by d'Arsonval, who sought to increase the efficacy of the oxidised lead electrode by covering it with a layer of lead dross. De Meritens, Tommasi, and others have worked in another direction by employing many sheets of lead foil presenting a large amount of surface, whilst Swan, Sillon, and Volckmar have taken another departure in applying perforated plates of lead with disintegrated material packed into the interstices. From our contemporary *La Nature* we have borrowed the accompanying illustration of another form of accumulator due to M. Nicolas de Kabath, whose suggestion is to employ thin plates of gauffered or corrugated lead, so as to secure a large amount of effective surface. The thin corrugated sheets are cut into narrow strips and packed between two stouter sheets of lead pierced with holes, through which the dilute acid liquor can circulate freely. The details of construction will be amply explained by the figures. The object of the perforated exterior is to prevent the cells from becoming short circuited by the possible falling down of the thin corrugated strips which are rapidly disintegrated during the preliminary charging or "formation" of the cell. The perforated leaden cases are themselves placed side by side in an appropriate cell, and are connected so that they serve alternately as positive and negative plates. Smaller cells are used for laboratory work. No details have yet been published, so far as we are aware, of their performances or capability of retaining the charge that has been imparted.



Kabath's Accumulators made of corrugated lead plates. Figs. 1, 2, 3 showing details of manufacture. Fig. 4, Commercial Accumulator. Fig. 5, Laboratory Accumulator.

SCIENTIFIC RESULTS OF THE ECLIPSE

THE following communication appeared in the *Daily News* of Tuesday from its special correspondent with the English Eclipse Expedition :—

In my last letter,[1] written as it seems, an age ago, for the incidents since the eclipse have been more or less emotional, I promised in a final one to give the opinions of the astronomers as to the bearing of the work they have been fortunate enough to do in Egypt this year upon the general question of solar inquiry. Hence we have to consider both results and methods, and the latter should include the questions which it seems now most desirable to put to the sun the next time he is eclipsed. First, then, as to results. There seems good ground for supposing that the outermost part of the sun's atmosphere suffers changes as does that lower portion in which sun-spots are observed, and that the changes synchronise. Now, in the case of spots, as is generally known, we have a maximum number every eleven years or thereabouts, and in the interval we have a minimum, during which no spots are seen for weeks together. Hence the so-called maximum sun-spot period and minimum sun-spot period. This supposition was first hazarded in 1878, a minimum sun-spot year, as a result of the comparisons of the observations of that year with those obtained in 1871, a maximum sun-spot year. In 1871 the corona was most extended away from the equator ; there was no special structure at the poles, and the hydrogen in it was strongly developed and it was very luminous. In 1878 it was most extended along the equator ; there was very special structure at both poles, the hydrogen had almost disappeared, and it was faint. Now in 1882, that is eleven years from 1871 and in another maximum sun-spot year, the corona has again put on its condition of eleven years ago. Hence observation has shown that the supposition is so far quite justified by the facts, and accepting this connection as a working hypothesis astronomers and physicists have now to try to connect the absence of spots in the lower atmosphere with a condition of things which gives us a great equatorial extension of the atmosphere, and very definite structure at the poles, associated in all probability with a lower temperature, or at all events a greater admixture of cooling material.

Before the Eclipse Expedition had left England Dr. Siemens had proposed a theory of the solar atmosphere which postulated exactly such conditions as appeared to be revealed in years of least solar activity. The coincidence between hypothesis and fact was, to say the least, extremely curious, and there is no doubt that the fact that when the sun is most active the correspondence seems to vanish, will have to be carefully considered. But we have learned more touching the outer atmosphere than its changes. There has been a chemical touch added. When in 1869 its chemical nature was first investigated by means of the spectroscope, it seemed to be built up almost entirely of a substance of which we knew nothing here—a substance revealed by a line in the green part of the spectrum, at 1474 of the scale employed by Kirchhoff for his maps, which were then generally in use. In 1870 hydrogen was added to this unknown substance, if we are to interpret spectroscopic phenomena in the usual manner ; and now again, with the same proviso, calcium has been added ; that is to say, some lines seen in the spectrum of calcium have now been detected in the spectrum of the sun's outer atmosphere. It is now some years since the strange behaviour of calcium when observed in the spectroscope was noticed, and it was the first substance used to point the moral that the spectra of terrestrial substances are sometimes strangely transformed when their lines are examined among those visible in the ordinary spectrum of the sun. Thus the widest lines of all in that spectrum—the lines lettered H and K for purposes of reference—are seen in the spectrum of calcium when high temperatures are employed, though they are absent at low temperatures, when, however, a line in the blue which is but feebly represented among the solar lines is thick and brilliant. The observations of the eclipse in Siam in 1875 strongly suggested that the so-called calcium was really an important constituent of the lower layers, while it is now known that it plays an important part in every spot and prominence ; indeed, in the spectra of sun-spots photographed by Mr. Lockyer at South Kensington, the H and K lines behave differently from all the other lines photographed. But the point of this year's work is that this calcium has been carried very high into the solar atmosphere, where it exists in such tremendous quantity that the eclipse colouring in all its weirdness can be traced to it, and the proof that this violet light is lighting up our atmosphere more powerfully than any other is found in the fact that in one of the photographs taken on Abney's plates the air between us and the dark moon is shown to be of this colour. This is photographic proof certain and sure, and will remind those learned in these matters of an observation made by Captain Maclear during the eclipse of 1870. It will be seen then that this year's work has left its marks both on the physics and chemistry of the outer atmosphere. We must now descend a little into the lower regions of the solar incandescent air.

Here we approach a very interesting part of the subject, but one on which it is difficult to say anything without going somewhat into detail. Up till a few years ago the idea that our terrestrial elements, such as iron, hydrogen, and the like, were anything but elements never entered the heads of astronomers as they were daily recording solar phenomena. It was obvious that the sun was very hot—so hot that it may be said the vapour of iron plays the same part there as the vapour of water plays here ; but the possible result of the high temperature remained practically unconsidered, and our notions of the structure of the solar atmosphere were influenced by terrestial chemistry. Hence, when it was found that the upper atmosphere consisted mainly of hydrogen, all the lines of the solar spectrum except those due to hydrogen were supposed to owe their origin to absorption of the solar light at very low levels, and close to the sun there was supposed to be a thin stratum, the work of which was so efficient in this direction that it was called the "reversing layer." But after a time, as facts were accumulated, the question whether our elements really could and did stand the temperature of the sun without breaking up into something more elementary still was fairly asked ; and as in other cases the question had to be discussed in a scientific manner—that is, cases had to be taken in which the question could be put to the facts in such a way that if the observations were of one kind one view would be strengthened ; if of another kind then the other explanation would be more likely the correct one. It was pointed out some time ago that there are two very definite kinds of observations which can be made during eclipses, by which much information might be gained bearing directly upon this question of dissociation—that is to say, the question whether our "elements," as we know them, are or are not capable of existing at solar temperatures. These observations had to do, one with the "reversing layer," the other with the outer atmosphere. The challenge was of the most direct kind touching the reversing layer It went so far as to say that the former observations had been erroneously interpreted. This, however, must not be held to cast doubt upon former observers. The contention was that the former work, dating from 1870, had been of too general a nature, and that when a small part of the field of observation was studied with minute accuracy it would be found that the general statement would be untenable, that general statement favouring the view that the elements are still truly

---

[1] Reprinted in NATURE, vol. xxvi. p. 129.

elementary at solar temperatures. It will be seen that the issue raised then could not be complained of as lacking crispness and definiteness. What then are the facts? The facts have been exactly as they were predicted on the rival hypothesis—the hypothesis, namely, that the elements are not elementary; and in future we are not likely to hear much more of the "reversing layer." The solar spectrum, indeed, appears now to be the result of the absorptive work of an innumerable number of strata one over the other, from top to bottom of the solar atmosphere. If we could see the work of any one of these layers by itself, it would be impossible for us, with our mere terrestrial laboratory experience, to recognise it, whereas we do recognise the sum total, because we get, and can only get as a rule, a sum total in our laboratory experiments. Should this result be generally accepted as one of the results of this year's work a great step will have been gained. Whether accepted or not, it is quite clear that such observations as those to which attention has been directed will demand much attention when next the sun is eclipsed. Nor is this all. It is not too much to hope now that M. Thollon has so admirably succeeded in furnishing astronomers with a spectroscope which combines the maximum of dispersion and light that observations suggested by the new view may be made on the uneclipsed sun and bring their tribute of precious facts every day the sun shines. Such work, indeed, was actually started at Sohag, and the test then afforded gave out no uncertain sound; but on this point it is not necessary to enlarge upon the present occasion, as both MM. Thollon and Trépied are pledged to utilise the beautiful climates of Nice and Algiers in carrying on this new survey at the earliest possible moment, and the world of science will doubtless soon hear something of the result of this new attack.

There is little doubt that on the occasion of future eclipses attention will be much more concentrated on the spectrum of the corona, and more specially-constructed instruments will be brought to bear on it than has been the case hitherto. We may already take for granted that the blue lines photographically recorded (in addition to H and K in the violet,) will have their position determined with the greatest accuracy, and their coincidence or not with marked Fraunhofer lines will have an important bearing upon the questions to which attention has been directed in the present letter. The work, too, has shown that the new plates are so sensitive that it will be quite easy at the next eclipse by means of a circular rotating plate, or some such contrivance, to record all the spectroscopic phenomena, however evanescent they may be, visible at the moment of disappearance or reappearance of the sun. Such a method will not only give us a complete history of what goes on, but will furnish us with a scale of exact reference. So science advances. Each effort, and especially the one most wisely planned, instead of exhausting the supply of new phenomena brings still newer efforts and richer harvests in its train.

I have been very unfaithful to the task imposed upon me if I have not convinced your readers that the expeditions whose work it was my duty to chronicle have been richly rewarded for their long preparations and tedious journeyings. They will all leave Egypt with the liveliest sense of gratitude for the manner in which all their efforts for the advancement of knowledge among men have been seconded by the Khedive and the Egyptian Government.

PROF. W. B. ROGERS

THE death is announced of Prof. William Barton Rogers, whose name is so well known in connection with the Massachusetts Institute of Technology at Boston, U.S. Prof. Rogers died suddenly, of apoplexy, while giving an address, on May 30 last, in connection with the Annual Graduating Exercises of the Institute. From the *Boston Daily Advertiser* we obtain some facts concerning Prof. Rogers' life and work:—

William Barton Rogers, the second son of four in a family noted for its scientific acquirements, was born in Philadelphia, in December, 1805. His father, Patrick Kerr Rogers, was a learned and enthusiastic lover of natural science, and is credited with being among the first in the United States to establish systematic courses of instruction in chemistry and experimental physics for the general public. Young Rogers was educated at William and Mary College, in which institution his father had been appointed Professor of Natural Philosophy and Chemistry. At the age of twenty-one he delivered, at the Maryland Institute, Baltimore, his first lectures on science, and one year later he succeeded to his father's position as professor at William and Mary College. In 1835 he accepted the appointment to the chair of natural philosophy in the University of Virginia, and there began instructing in mineralogy and geology. He remained there until 1835, and was next appointed to the chair of natural philosophy in the University of Virginia. There he added the subjects of mineralogy and geology to his course of instruction, and organised the geological survey of the State. He remained at the head of the Geological Survey until its discontinuance in 1842, and published annual reports, together with much valuable material which had been carefully collected. While at the University he published, for the use of the students, a short treatise on "The Strength of Materials," and a volume on "The Elements of Mechanical Philosophy." This period of his life was a very busy and attractive one, much of his time being given to original work in geology, and largely also in chemistry and physics. In the Association of American Geologists and Naturalists, organised in 1840, Prof. Rogers took a leading part. He contributed to its volume of *Transactions* many valuable memoirs, among them observations on the subterranean temperature in the coal mines of Eastern Virginia. In the exploration of the physical structure of the Appalachian chain, which formed the subject of one of the memoirs above alluded to, Prof. W. B. and H. D. Rogers were associated. Their generalisations were so novel and important in the estimation of European, as well as American geologists, as to give "the Gebrüder Rogers" a prominent place among their number. While a member of the Association of American Geologists he was elected several times its chairman. He presided at the meeting which expanded this last-mentioned Society into the American Association for the Advancement of Science, in 1847, and presided over the latter association at its meeting in Buffalo in 1876.

In 1853 Prof. Rogers removed to Boston, and at once identified himself with prominent educational interests here. With a committee of gentlemen no less interested than himself in the establishment in Boston of a school which should place the teachings of science upon a more practical plane than had hitherto been attempted, he drew up a scheme entitled "Object and Plan of an Institute of Technology," and embraced therein also a school of industrial science, a museum of arts, and a society of arts. To the accomplishment of this purpose he bent every energy, and at length a charter from the State was granted, providing the land upon which the institute buildings now stand. Subsequently the plans prepared by Prof. Rogers were almost completely carried out; and he, more perhaps than any other one man, brought about that admirable system of teaching which so characterises the institute, and which finds its place in the laboratories. His connection with the institute has been a most prominent one. He occupied the chair as president for many years, and at the start was at the head of the department of physics and geology. Since his removal to Boston, as well as before, Prof. Rogers has contributed largely to scientific journals in the United States and

Great Britain, and his articles embrace a very wide range of topics relating to the several departments of scientific research to which he had devoted himself, and many of his researches have attracted unusual attention from their value as adding to scientific knowledge.

At the age of seventy-six his failing health compelled him to give up active duties as president, and he resigned to give place to Mr. Francis A. Walker. He still continued to hold the position of professor *emeritus*, and retained it at the time of his death. His health has permitted him to continue at his duties, but he has not been strong, and the cause of his death, as above stated, is supposed to have been apoplexy. He was appointed by President Hayes as President of the National Academy of Sciences, and had returned from Washington only a few days before his death, where he had been presiding over a meeting of the academy.

The *New York Nation*, in reference to the death of Prof. Rogers, says:—

The death of Prof. Wm. B. Rogers, in Boston, on May 30, removes not only one of the foremost of our scientific men, but perhaps the one who had in the highest degree the faculty of presenting the claims of science on popular interest and respect with force and lucidity. He had a remarkable gift of expression, and an unusually winning and persuasive manner, both of which were supported by a character of the utmost purity and simplicity.

NOTES

THE Council of the Society of Arts have awarded the Albert Medal of the Society of the present year to Louis Pasteur, Member of the Institute of France, For. Memb. R.S., for "his researches in connection with fermentation, the preservation of wines, and the propagation of zymotic diseases in silk worms and domestic animals, whereby the arts of wine making, silk production, and agriculture, have been greatly benefited. The Council have awarded the Society's Silver Medals to the following readers of papers during the Session 1881-2:—To Prof. Silvanus Thompson, D.Sc., for his paper on "Storage of Electricity"; to J. Emerson Dowson, for his paper on "The Production and Use of Gas for Purposes of Heating and Motive Power"; to Col. G. F. Pearson, for his paper on "The Teaching of Forestry"; to Prof. Barff, M.A., for his paper on "A New Antiseptic Compound, and its Application to the Preservation of Food"; to Spencer Walpole, for his paper on "The Fish Supply of London"; to George F. Deacon, for his paper on "The Constant Supply and Waste of Water"; to Capt. Richard F. Burton, for his paper on "Gold on the Gold Coast"; to R. Warington, for his paper on "Some Practical Aspects of Recent Investigation in Nitrification"; to S. G. Thomas and Percy C. Gilchrist, for their paper on the "Manufacture of Steel from Phosphoric Pig-iron"; to Alexander M. Chance, for his paper on "The Recovery of Sulphur from Alkali Waste by Schaffner's Process, a record of recent results"; to James Mylne, for his paper on "Experiences of an European Zemindar (landholder) in Behar." Thanks were voted to the following Members of Council for the papers they had read:—To Capt. Douglas Galton, C.B., F.R.S., for his paper on "The American System of Heating Towns by Steam"; to W. H. Preece, F.R.S., for his paper on "Electric Lighting at the Paris Electrical Exhibition"; to Lieut.-Colonel C. E. Webber, R.E., for his paper on "Telephonic Communication"; to Sir Rutherford Alcock, K.C.B., for his paper on "The Opium Trade."

THE following has been forwarded to us from the Royal Society for publication:—

Florence, May 23, 1882

MY LORD,—An interesting commemoration in honour of Charles Darwin was held on Sunday last, the 21st instant, in the great hall of the Florence "Istituto di Studi Superiori." The commemoration was promoted by the Students in Medicine and Natural Science. The proceedings were simple, consisting of a few opening words by the Chairman of the Committee, Signor Fairman, a medical student, and a well turned and appreciative discourse by Prof. Mantegazza, whose scientific reputation is not confined to Italy. A bust of Darwin, in terra cotta, stood on the platform and marked the occasion. There were present the Prefect of Florence, the Council and Professors of the Institute, &c., while the large hall was crowded to overflowing with a mixed and attentive audience of ladies and gentlemen, showing the interest that the occasion had evoked.

I have, &c.,
(Signed) D. E. COLNAGHI,
H.M. Consul-General.

The Right Hon. Earl Granville, K.G., &c.

AN appreciative paper on Darwin, by the eminent naturalist, M. Alph. de Candolle, appears in the May number of *Archives des Sciences*. Darwin was prompt to acknowledge the work of his predecessors—Lamarck, Erasmus Darwin, and others—but seems with others to have overlooked the observations and ideas of Duchesne (1766), an evolutionist before Lamarck, to which M. de Candolle was able to call his attention while visiting him in 1880. Duchesne says: "The genealogical order is the only one that nature indicates, the only one that fully satisfies the mind; every other is arbitrary and vain (*vide d'idées*)." In the manner of exposition of facts and in reasoning, Charles Darwin (in M. de Candolle's opinion) rather resembles Duchesne than Lamarck or Erasmus Darwin. Lamarck is more systematic. Erasmus perceives much that he does not profoundly investigate; he is diffuse and lacks scientific method. Among other things. M. de Candolle remarks that nearly all *littérateurs* and men of science of the first rank have lived, during part of the year at least, in a town. One can hardly cite more than two exceptions (and they are very different), viz. Voltaire and Charles Darwin. The author gives an interesting picture of his visit to Darwin, who, as a septuagenarian, he says, "etait plus animé et paraissait plus heureux que je ne l'avais vu quarante-et-un ans auparavant, Il avait l'œil vif et une expression enjouée, tandis que ses photographies montrent plutôt sa conformation de tête d'un philosophe de l'antiquité. Sa conversation variée, franche, gracieuse, tout à fait d'un *gentleman*, me rappelait celle des savantes d'Oxford et de Cambridge." The author was struck with the sight of the domestic animals at Down, showing a "tranquillité qui suppose de bons maitres. . . . Vraiment, me disais-je, l'histoire des variations chez les animaux a été faite ici, et les observations doivent continuer, car Darwin n'est jamais inactif."

THE death is announced (though on doubtful authority) of Dr. Jules Crevaux, who has recently done so much for the exploration of French Guiana and the Amazon Valley. Dr. Crevaux, it is reported, has been assassinated, with his whole party, by Tobas Indians, while ascending the Pilcomayo River, on Argentine or Bolivian territory. He had started from Buenos Ayres, and had discovered near Salto the ruins of an ancient native city. The unfortunate explorer was only thirty-five years of age. He was a surgeon in the French Navy, and in July, 1877, undertook his first expedition into the interior of Guiana. Starting from Cayenne, he traversed an almost entirely unknown region, crossed the Tumuc-Humac Mountains, the water-shed between the Maroni and the Yari, a tributary of the Amazon. On a second journey in 1878-79, Crevaux went from Cayenne to the Oyapock, followed it up, and discovered the Kow, an unknown affluent of the Yari, followed the latter to its sources, and visited and explored to their sources the little-known affluents of the Amazon, the Paru, Iça, and Yapura. In 1880 he again set out, this time to the Magdalena and the

Orinoco, whose tributary, the Guyabero, he surveyed. A few months ago the indefatigable explorer started for Rio Janeiro for the purpose of exploring the country between that and the Middle and Upper Amazon, and in attempting to carry out this enterprise he, it is rumoured, has met with his untimely fate. We hope it will turn out to be without foundation.

THE death is announced of Mr. Alexander Leslie, whose name is associated with that of the distinguished Arctic explorer, Nordenskjöld. Mr. Leslie, who was a native of Aberdeenshire, was in his fifty-fourth year. He devoted much time to the study of practical farming, and acquired a considerable knowledge of agricultural [chemistry. Proceeding to Sweden, Mr. Leslie resided there for several years, and upon his return to this country he published, in 1879, through Messrs. Macmillan and Co., a narrative of the "Arctic Voyages of Adolf Eric Nordenskjöld, from 1858 to 1879." Our readers will remember that Mr. Leslie was the translator of the famous explorer's own account of "The Voyage of the *Vega* round Asia and Europe." Mr. Leslie was an occasional contributor to the columns of NATURE.

THE Danish steamer *Arcturus*, from Iceland, arrived at Leith on Saturday, and reported heavy casualties and serious loss of life during the recent storms. On May 13, Capt. Schonstrup met with immense ice-floes about fifty miles from the east coast of the island. He afterwards steamed to the south-west, west, and north coasts, but was unable, after leaving Reykjavik, to get near any of the ports for the ice. These coasts were again attempted on June 6, but with the same result, the fields of ice from Spitzbergen and the Polar seas being as extensive and impenetrable as before. Large districts are said to be suffering severely from famine, as the vessels are unable to land the provisions, on the customary arrival of which they depended. The severity of the weather is preventing the growth of the crops, and large numbers of sheep and ponies are dying. Measles, which have not been known in Iceland for the last thirty-five years, are very prevalent, and in Reykjavik alone no fewer than 200 persons were suffering from the epidemic when the steamer left.

DR. HJALTELIN, the distinguished physician of Iceland, so well known for the ready and hearty assistance he gave to all scientific explorers of the island, died suddenly at Reykjavik on June 5.

TORNADOES of unexceptional severity and destructiveness are reported from the Western States of America, particularly Iowa, Illinois, Missouri, and Kansas. One half of the town of Grinnel, Iowa, is stated to have been destroyed, and more than 100 persons killed, this tornado having swept over a tract twenty-five miles long and half a mile wide, with devastating energy.

THE seventh annual report of the Japanese Minister of Education states that there are 28,025 common schools in Japan of which 16,710 are public, and the remainder private; there being an increase of 1316 and 125 respectively, as compared with the previous year. The number of high schools is 107 public and 677 private, there being an increase of 42 and 63 respectively. Besides the above, many *Kindergarten* and primary schools were established. These private schools, even now, play a most important part in Japanese national life and education. Many of them have hundreds of students attracted by the fame of a single teacher. Youths flock from all parts of the country to sit at the feet of a renowned scholar, as men did in Europe to hear Abelard. The most celebrated of these leaders of youth—for this they are, rather than simple schoolmasters in our sense of the word—is Mr. Fukusawa of Tokio, whose translations from European books and original works on the political and social questions of the day, are read far and wide in Japan. The students of this gentleman fill many of the most important offices in the state; some of them recently formed themselves into a patriotic society, and established a newspaper, in which the acts of the government are subject to much caustic criticism. Long after the ordinary educational work of their teacher is done, and the young men have gone out into the world to do for themselves, they continue to reside near him, to study under his direction, and to form classes in which important public questions can be freely discussed under his guidance. One of his classes translated the whole of Adam Smith's "Wealth of Nations" into Japanese, with annotations, and many other important European works, especially those on philosophy and politics, owe their appearance in European dress to Mr. Fukusawa and his pupils. The school has been a real, and, we believe, a highly beneficial power in the state. These "private schools," which have been political associations, and debating clubs, as well as scholastic establishments, have occasionally played important parts at crises of Japanese history. The members of the private schools established in Kagoshima, the capital of Sakuma, originated and led the great rebellion of 1877. Fortunately Mr. Fukusawa's pupils are more peaceful in their objects and methods.

THE French Government has established a prize of 2000*l.*, to be given to the person who in the course of five years—from July 1, 1882, to July 1, 1887—will have invented the most useful application of the Volta pile. Foreigners are allowed to take part in this competition, which was instituted for the first time by Napoleon I., almost as soon as Volta invented his admirable instrument, and has been reopened at several periods.

THE proprietors of houses having a view of the Parc Monceaux have subscribed among themselves a sum for illuminating this garden with a number of Jablochkoff lights. Similar steps will be taken for other public gardens in Paris. The tradesmen located in the Palais Royal are establishing a private company for the same purpose. An experimental trial will be made within a few days with incandescent lights.

ON June 15 M. Marcel Deprez delivered, in the large hall of the Conservatoire des Arts et Métiers, Paris, a lecture on the transmission of electricity to great distances. The lecturer proved that magneto-electric machines could be moved by a current which had circulated through four kilometres of german-silver wire, whose resistance was twelve times longer than a similar wire of copper, and having a few millimetres diameter. M. Marcel Deprez declares that he will go almost to any length in diminishing indefinitely the diameter of the wire of his dynamo-magnetic machine, and that it is by resorting to large dynamos that he will be able to produce a current sufficiently powerful.

COL. LAUSSEDAT, director of the Conservatoire des Arts et Métiers, has placed at the disposition of aëronauts, a dynamometer of special construction for testing scientifically the resistance of their canvass before and after varnishing.

TWO German expeditions will go to American stations in order to observe the transit of Venus in December next. Observations will be taken at Stratford, Connecticut; at Aiken, South Carolina; at Bahia Blanca; and at Punta Arenas.

MR. GILDER, one of the correspondents of the *New York Herald* in Siberia, telegraphs from the Lena Delta, April 24, that he has found the bodies of Capt. De Long and his companions, who, it may be remembered, were in the missing boat belonging to the *Jeannette*. The poor men had evidently perished of cold and hunger.

DR. HASSELBERG of Pulkova has been able to trace the bright line of sodium seen by many observers in the spectrum of Comet Wells, to some distance in the tail of the comet.

THE Merchant Venturers' Company of Bristol have resolved to erect, at an expense of 30,000*l.*, a new Technical School on the site of the old Bristol Grammar School, for the use of the

Bristol Trade and Mining School, founded by the exertions of the late Canon Moseley, in 1855.

A RECENT report by Dr. Bürkner to the Göttingen Royal Society of Sciences, on his "Polyklinik" for ear disorders, gives some instructive facts. In 1881 the number of patients was 516 persons (338 male and 178 female), with 583 different forms of ear disorder. The doctor reckons that a cure was effected in 61·85 per cent. of the patients, and improvement in 15·12 per cent. 211 (or 40·9 per cent) of the patients were of juvenile age, 15 and under. There were 139 cases of injury of the external ear, 15 of the tympanum; 322 of the middle ear, 27 of the inner ear, and 13 sundry. For otorrhœa, pulverised boric acid was largely used. The greatly praised iodoform was fully tried in ear-treatment, but Dr. Bürkner considers it has "no future" in this sense. Leiter's heat-regulator, consisting of very flexible lead tubes, through which water of any desired temperature is conveyed to injured parts of the body, did good service, especially in inflammation.

FOR the Sanitary Institute Congress at Newcastle-upon-Tyne, September 26, the following gentlemen have accepted the presidentship of the various sections:—Dennis Embleton, M.D., F.R.C.P., Section I. Sanitary Science and Preventive Medicine; Henry Law, M.I.C.E., Section II. Engineering and Sanitary Construction; Arthur Mitchell, M.A., M.D., LL.D., F.R.S., Section III. Meteorology and Geology.

MR. W. G. INNES, of Great St. Helens, has sent us a few specimens of photographs of New Zealand scenery, taken by Burton Brothers, of Dunedin. They are beautiful specimens of the photographic art, and many of them are of interest from a geological and ethnological point of view. One photograph gives an excellent idea of the White Terrace at the Rotomahana Hot Springs, others show some of the grand mountains and beautiful bays, native life, &c.

MR. BRYCE WRIGHT has, we understand, received a very fine specimen of the interesting gem known as Alexandrite, from India.

THE enormous glacier, Fon or Svartisen (69° 25′ N., 35° 15′ E.) on the Senjen Island in Norway, and which is the northernmost of its kind in Europe, will shortly be made the object of a remarkable enterprise. It appears that a number of speculative merchants in Bergen have obtained the right of cutting block-ice for export from its surface. Some blocks have already arrived at the latter place, and as the quality of the ice has been found to be good, large shipments may be expected. The glacier is about 120 square miles, and as the distance from its border to the sea is only a couple of miles, the ice may be obtained very cheaply. A similar attempt to utilise the glacier Folgefonden was made some years ago, but failed, owing to the blocks in their downward course repeatedly breaking through the wooden bore or conductor in which they were slid down to the sea.

THE Zoological Museum of the Lund University has just received as a gift from Prof. Nordenskjöld a splendid specimen of the sea-cow, *Rhytina Stelleri*, now extinct, brought by the *Vega* from Behring Island.

PASTEUR's discoveries having been doubted in Germany, they have been submitted to the appreciation of a special commission in Berlin, and M. Pasteur sent thereto one of his assistants to perform vaccination on sheep. The report has been sent to Paris, and is said to approve the process and to show that it has been quite as efficient in Germany as in France.

THE *Daily News* correspondent at Maritzburg reports that a brilliant comet has been observed there for the last two or three days, in close proximity to the sun.

WE have on our table the following books:—China, by Prof. R. K. Douglas (S.P.C.K.); White's Manual of Naval Architecture, 2nd edition (John Murray); Electric Lighting, by Th. du Moncel, translated by R. Routledge (George Routledge and Sons); La Bourboule, by Dr. G. H. Brandt (H. K. Lewis); the Funeral Tent of an Egyptian Queen, by Villiers Stuart (John Murray); Hot Water Heating, by F. A. Fawkes (Batsford); Notes on Cage Birds, edited by W. T. Green (Upcott Gill); Botanical Atlas, Part II., by Dr. M'Alpine (W. and A. K. Johnstone); Im Fernen Osten, 2 vols, by Gustave Kreitner (A. Hölder); Results of Rain and River Observations made in New South Wales during 1881, H. C. Russell, Sydney; Handbook of Invertebrate Zoology, by W. K. Brooks (Cassino, Boston, U.S.); How to Overcome the Potato Disease, by J. S. Jensen (Menzies); A Synopsis of Elementary Results in Pure and Applied Mathematics, vol. i., section 9, by G. S. Carr (Hodgson and Son).

THE additions to the Zoological Society's Gardens during the past week include an Arabian Baboon (*Cynocephalus hamadryas* ♂) from Abyssinia, presented by the Messrs. James; a Bonnet Monkey (*Macacus radiatus* ♂) from India, presented by Master G. H. Clark; a Chima-chima Milvago (*Milvago chimachima*) from Demerara, presented by Mr. G. H. Hawtayne; two Upland Geese (*Bernicla magellanica* ♂ ♀), five Ruddy-headed Geese (*Bernicla rubidiceps*), a Loggerheaded Duck (*Tachyeres cinereus*) from the Falkland Islands, presented by Mr. F. E. Cobb, C.M.Z.S.; a Rufous-necked Weaver Bird (*Hyphantornis textor*) from West Africa, a Common Lapwing (*Vaneltus cristatus*), European, presented by Mr. J. S. Baldwin, F.Z.S.; a Loggerhead Turtle (*Thelassochelys casuana*) from the Straits of Bonifacio, presented by Lord Lilford, F.Z.S.; a White-backed Piping Crow (*Gymnorhina leuconota*) from Australia, deposited; a Black-fronted Antelope (*Cephalophus nigrifrons*) from Africa, a Water Chevroain (*Hyomoschus aquaticus*) from West Africa, three Darwin's Rheas (*Rhea darwinii*) from Patagonia, two Spanish Blue Magpies (*Cyanopolius cookii*) from Spain, purchased; an Egyptian Goose (*Chenalopex ægyptiaca*), a Chiloe Wigeon (*Mareca chiloensis*), five Mandarin Ducks (*Aix galericulata*), bred in the Gardens. The following insects have emerged during the past week:—Silk Moths: *Actias selene*, *Samia cecropia*; Moths: *Sphinx pinastri*, *Deiliphila euphorbiæ*, *Trochilium apiformis*, *Sciapteron tabaniformis*, *Sesia conopiformis*, *Sesia museæiformis*, *Hypochera io*, *Callimorpha dominula*; Butterflies: *Vanessa xanthomelas*, *Vanessa urticæ*, *Aporia crabægi*.

OUR ASTRONOMICAL COLUMN

THE APPROACHING TRANSIT OF VENUS.—In deducing the following expressions for determining the times of contacts in the transit of Venus on December 6, for any point upon the earth's surface, the positions of the planet have been taken from Hill's Tables, which had an advantage over Leverrier's at the last transit, and Auwer's semi-diameter is adopted. For the sun the semidiameter deduced by Leverrier from the transits of Mercury has been employed.

For *first external* contact, there results—

Dec. 6, 1h. 56m. 12s. $+[2{\cdot}5442]\, r \sin l$
$-[2{\cdot}4793]\, r \cos l \cos (L - 87^\circ\ 35'{\cdot}0)$.

For *first internal* contact—

Dec. 6, 2h. 16m. 52s. $+[2{\cdot}5822]\, r \sin l$
$-[2{\cdot}4768]\, r \cos l \cos (L - 85^\circ\ 31'{\cdot}9)$.

For *last internal* contact—

Dec 6, 7h. 54m. 0s. $-[2{\cdot}2894]\, r \sin l$
$+[2{\cdot}6261]\, r \cos l \cos (L - 138^\circ\ 18'{\cdot}8)$.

For *last external* contact—

Dec. 6, 8h. 14m. 41s. $-[2{\cdot}2152]\, r \sin l$
$+[2{\cdot}6142]\, r \cos l \cos (L - 134^\circ\ 38'{\cdot}1)$

The angles from N. point for *direct* image are respectively 145°·1, 148°·4, 116°·9, and 113°·5.

In the above formula r is the radius of the earth at the place, l the geocentric latitude, and L the longitude from Greenwich, reckoned *positive* towards the *east*. The resulting times are

Greenwich mean times. The quantities within square brackets are logarithms of seconds of time.

THE CORDOBA OBSERVATION OF COMET 1881 II., ON JUNE 11.—In NATURE, vol. xxv. p. 519, we gave an account of Dr. Gould's observations of the great comet of last year, on the evening of June 11, when he compared it with an object which he could not identify as a fixed star, and it was mentioned that Mr. Tebbutt had suggested that the objects really observed were not the comet and a star, but the two stars λ Eridani and Bradley 718, which have almost precisely the differences of right ascension and declination that were recorded on the night in question. This explanation we considered a probable one, and the same view was taken by the editor of the *Astronomische Nachrichten*, which has occasioned a further communication on the subject from Dr. Gould, who rejects Mr. Tebbutt's suggested solution of the difficulty.

Dr. Gould says the appearance of the comet on June 11 precluded the slightest doubt as to its identity. "The tail itself could not be seen with the telescope, it is true, but the large, diffuse, and very elongated head, much brighter and more definite on the advancing side, was sufficient to enable the veriest tyro to recognise it as a comet." He was placed necessarily on the top of a high observing chair, which he did not leave during the observations, the records being made by his assistant. He had made several sweeps to find a suitable comparison-star, and was about to commence a new one, when he saw the object referred to above, "at the upper part of the field on the left, while the comet was on the right, below." The four published comparisons were then made, and whilst he was in the act of pointing the micrometer-thread upon the comet for a fifth, it disappeared below the horizon. He adds, that no jar of the instrument had taken place; "the field of the telescope was fully under control from the beginning, the declination-clamp remaining tight throughout," and he insists that no one who saw the comet could have entertained the idea that any amount of blurring could have given such an aspect to a fixed star, though it were far brighter than λ Eridani. And he doubts whether a star of the sixth magnitude would have been visible under the circumstances. He made experiments on subsequent evenings, by looking at known stars of different magnitudes when close to the horizon and through different degrees of haze, but in no case did he find one offer the appearance noted on June 11. Hence, he proceeds: "I can only suppose another comet to have been in the field. That it was not a companion-comet is manifest, not only from the relative motion, and from an examination made the next day, but still more from the abundant scrutiny in the northern hemisphere, which could not have failed to detect any companion. That it was not a fixed star, was evident from the beginning."

Thus the matter is left by Dr. Gould, who, it must be admitted, is by far the most competent judge of the probable explanation of the difficulty.

MASKELYNE'S SOLAR PARALLAX.—By communications from Mr. J. Morris, Hatfield Hall, Durham, and Mr. B. J. Hopkins, Marlborough Road, Dalston, we learn that the value of the solar parallax given by Maskelyne, to which allusion was made in this column last week, appears in the third edition of Vince's "Elements of Astronomy," Cambridge, 1810: it was therefore published during his life-time.

THE ROYAL SOCIETY OF CANADA

THIS Society, which has been founded under the auspices of the Marquis of Lorne, and is intended to be to Canada what the Royal Society and the Institute are to England and France respectively, held its first meeting on May 25, 26, and 27. Inaugural addresses were delivered on the 25th by the Marquis, Principal Dawson, and the Hon. P. J. O. Chauveau. For the purpose of reading and discussing papers, the Society is divided into four sections:—(1) French literature, history, and allied subjects; (2) English literature, history, and allied subjects; (3) mathematical, physical, and chemical sciences; (4) geological and biological sciences. The following papers were read in Section 3:—Note on zinc sulphide, by T. McFarlane. On the "transition" resistance to the electric current at the bounding surface between amalgamated zinc and solutions of zinc sulphate, by Prof. J. G. MacGregor, D.Sc. The "transition" resistance in this case was shown to be at any rate not greater than a small fraction of an ohm, the current being weak and the electrodes large. The method of measurement employed was a modification of that formerly used by Beetz.—On the measurement of the resistance of electrolytes by means of Wheatstone's bridge, by the same. In this paper, a new mode of using the bridge was described. Alternate currents were sent through the bridge, and brought into the same direction by a commutator in the galvanometer branch, in which one of Thomson's galvanoscopes was inserted. Two of the arms contained equal metallic resistances; the other two contained, besides metallic resistances, electrolytic cells the same in all respects, except as to length. Thus the errors due to polarisation and possible "transition" resistance were eliminated.—On molecular contraction in natural sulphides, by Prof. E. J. Chapman.—On the law of facility of error in the sum of n independent quantities, each accurate to the nearest unit, by Chas. Carpmael, M.A. The chance of the error in the sum lying between y_1 and y_2, where $y_2 - y_1$ is small, was shown to be

$$\frac{1}{\lfloor\underline{n-1}}\left\{\left(\frac{n}{2}+y_1\right)^{n-1} - n\left(\frac{n}{2}+y_1-1\right)^{n-1} + \frac{n\,.\,\overline{n-1}}{1\,.\,2}\left(\frac{n}{2}+y_1-2\right)^{n-1} - \&c.\right\}(y_2-y_1),$$

the series to be continued as long as the part raised to power $n-1$ is positive. This series is approximately equal to

$$\sqrt{\frac{6}{\pi n}}\,.\,e^{-\frac{6y^2}{n}}\,(y_2-y_1).$$

—A symmetrical investigation of the curvature of surfaces; including a discussion of the plane sections of quadrics, the axes of conic sections and of quadrics, by Prof. A. Johnson, LL.D. In this paper it was shown that the leading theorems concerning principal radii of curvature, directions of principal sections, umbilics, lines of curvature, &c., can be obtained directly by a purely analytical investigation, elementary and symmetrical in its character, of the plane sections of a quadric.—Note on the deduction of the equation of continuity, by Prof. Loudon.—Note on the motion of a chain on a fixed curve, by Prof. Cherriman.—Note on the application of a remarkable determinant, by the same.—Note on a question of probabilities, by the same.—On the general regulation of civil time, by Sandford Fleming, C.E.—On the utility of geometry as applied to the arts and sciences, by Chas. Baillarge.

The following papers were read in Section 4:—The distribution of some saline and other plants in the West, by Prof. Maconn. This was an oral exposition, aided by a large map of certain peculiarities in the distribution of maritime Eastern and Western plants in the interior of the continent, and of some peculiar extensions of Southern plants to localities far north of their usual range.—Note on a general section from the Laurentian axis to the Rocky Mountains, north of the 49th parallel, by Dr. G. M. Dawson. This paper gave a summary of the latest facts respecting the succession and distribution of Cretaceous and early Tertiary beds in the North-West Territories, and of the facts obtained respecting their subdivision into groups, and the useful deposits of coal and lignite contained in them.—On the cretaceous and tertiary floras of British Columbia and the North-west territory, by Dr. J. W. Dawson, F.R.S., &c. The researches of the Geological Survey have resulted in the collection of series of fossil plants from a number of localities in the cretaceous of the Pacific coast, and of the eastern base of the Rocky Mountains, in the laramie or lignitic group of the plains, and in the Tertiary Lake Basins of British Columbia. From these it appears that while up to the Middle Cretaceous a flora of strictly Mesozoic character, consisting of pines, cycads, and ferns prevails, the Middle and Upper Cretaceous show the introduction of a larger number of broad-leaved evergreens of modern types. Though there seems to be a continuous prevalence of warm and temperate conditions, from the Upper Cretaceous, up to the Pliocene, the groups of plants observed may be classed as—(1) Lower and Middle Cretaceous; (2) Middle and Upper Cretaceous, with modern evergreens, as *Salix*, *Populus*, *Magnolia*, *Betula*, *Quercus*, &c., and fan palms and cycads; (3) Laramie or Fort Tunis group, probably a transition from the Cretaceous to the Eocene, with many new forms; (4) Tertiary Flora of the probably Miocene Tertiary of British Columbia. Descriptions and figures of these plants are being prepared, and it is hoped may soon be published.—On the anatomy and development of cestoid worms, by Prof. Ramsay

Wright.—On lacustrine concretions from Grand Lake, N.S., by Prof. Honeyman, D.C L.—Illustrations of the fauna of the St. John, N.B. group, by G. F. Matthew.—On birds from Hudson's Bay, by Prof. Bell.—On a new classification of Crinoids, by Prof. E. J. Chapman. This classification is based essentially on the presence or absence of a canaliculated structure in the calyx and arm plates. Three leading divisions are thus recognised. In one, the plates are without internal canals; in the second, the arm plates are perforated internally; and in the third, a system of canals radiates from the base of the calyx to the extremities of the arms. The subdivisions have been worked out to bring readily under grasp the more salient or broadly distinctive features of all the better-known families and types; and as the common names of families embody very little indication of these features, an additional grouping into sections is adopted.—On the Lower Cretaceous rocks of British Columbia, by J. F. Whiteaves.—On the introduction and dissemination of some noxious insects, by Wm. Saunders.—On the geological history of the St. John (N.B.) river valley, by Prof. L. W. Bailly.—On recent discoveries in the life-history of *Botrydium granulatum*, a terrestrial Canadian alga, as illustrating phases of development in the lower forms of vegetation, by Prof. G. Lawson, Ph.D., LL.D.—On the Quebec group of rocks, by Dr. A. R. C. Selwyn.

The following officers were elected: President, J. W. Dawson, C.M.G., LL.D., F.R.S., Principal of McGill College, Montreal; Vice-President, Hon. P. J. O. Chauveau, LL.D.; Hon. Secretary, J. G. Bourinat, F.S.S., Ottawa; Hon. Treasurer, J. A. Grant, M.D., Ottawa.

ON SMELL

THE sense of smell is caused by the contact of certain substances with the terminal organs of the olfactory nerves, which are spread as a network over a mucous membrane lining the upper part of the nasal cavity. Each nerve consists of a number of small bundles, themselves capable of being split into extremely fine nerve fibres. There are spindle-shaped cells connected with these nerves, from which proceed two processes—one to the surface, provided with bundles of long hairlets; the other passes to the interior. It is these hairlets which are proprobably the proximate cause of smell.

Let us consider, first, by what are smells excited? The operation of smelling is performed by sniffing, that is, by a series of short inhalations of air, bearing with it the odorous body. The first question which suggests itself is: Is the substance which excites sensation a liquid, solid, or gas? It has been tried by Weber, to fill the nose with eau-de-Cologne and water, lying on the back for that purpose, and pouring the liquid into the nostrils by a funnel. No sensation is produced. I have myself tried the experiment, and can confirm his observation. There is an irritating feeling, but no smell. Of course, on washing out the nose, or blowing it, the characteristic smell is at once noticeable.

It is easy to prove that solid particles are not the cause of smell. If the air conveying the odour be filtered through a tube filled with cotton wool, and inserted into the nose, a smell is still discernible, although all solid particles must thereby be kept back. But it is a very remarkable circumstance that it is so, for one would not suspect such extremely non-volatile substances as copper, iron, silver, &c., to give off gas, if indeed the smell which they most certainly evolve when rubbed is due to the gas of the substance.

We must, therefore, conclude that the sense of smell is excited by gases only. It is of course necessary to include under the name gases the vapours of liquids or solids which have low vapour-tension, and which, in consequence, give off vapour at the ordinary temperature. It has been proved that this is the case even with mercury, the boiling point of which is over 300° Centigrade. We may consequently conclude that many other substances of which it is impossible to measure the vapour-tension at ordinary temperatures, owing to its extreme minuteness, also evolve gas, if only in very small quantities. But it is well known that all gases have not the power of exciting a sense of smell. Let us compare some gases which have smell, with some which have none, and endeavour to discover if those which have smell have any other property in common.

The following is a list of gases which have no smell:—Hydrogen, oxygen, nitrogen, water-gas, marsh-gas, olefiant-gas, carbon monoxide, hydrochloric acid, formic acid vapour, nitrous oxide, and ammonia. Those which possess smell are chlorine, bromine, iodine; the compounds of the first two with oxygen and water, the second three oxides of nitrogen (or perhaps it is right to say nitric peroxide, for the other lower oxides are changed into it when they come into contact with air); the vapours of phosphorus and sulphur; arsenic and antimony; sulphurous acid, carbonic acid, and almost all the volatile compounds of carbon, save those already mentioned; some compounds of selenium and tellurium; the compounds of chlorine, bromine, and iodine, with the above-named elements; and some metals.

In considering this list, I submit first, that the property of smell is peculiar to some elements and their compounds. Thus, chlorine, bromine, iodine, sulphur, selenium, and tellurium, which are volatile or give off vapour at ordinary temperatures, have a characteristic smell. We should expect their compounds to have a smell, and we find this to be the case. Second, those substances which have no smell, or produce simple irritation of the nostrils have all low molecular weight. Such is the case with hydrogen, the element of lowest specific gravity. Such also is the case with oxygen and nitrogen; but this as well as the absence of smell in water-vapour, may be ascribed to the constant presence of these gases in our atmosphere, and their necessary constant presence in our nostrils, so that we may be insensible to their smells because we are always inhaling them; but I think it probable that this is not so. Hydrochloric, hydrobromic, and hydriodic acids, and ammonia, have purely an irritating effect, and cannot be described as smells. When ammonia is pure and free from compounds containing carbon, it has no trace of smell. Nitrous oxide is also the lowest of the oxides of nitrogen, and as such has the lowest specific gravity. But it is when we turn to compounds of carbon that we are best able to draw general conclusions; for that element, *par excellence*, has the faculty of forming almost innumerable compounds, and series which resemble each other in properties, but differ in specific gravity. And here we are most struck with the fact that increase of molecular weight, *i.e.* increase of specific gravity in the form of gas, produces, to a certain point, smell. Let us examine the simplest series, viz. the marsh-gas or methane series, commonly called the paraffins. The first two of these have no smell. Ethane, indeed, which is fifteen times as heavy as hydrogen, begins to have a faint trace, but it is not till we arrive at butane, which is thirty times heavier than hydrogen, that a distinct sensation of smell is noticed. In the same manner, the olefine series, of which the first member is ethene, or olefiant gas, gains in smell with rise of molecular weight. Of course, the highest members of this series have no smell, for they are non-volatile, but this is the case with most carbon compounds of which the molecular weight is high.

A similar relation is noticeable among the alcohols. Methyl alcohol, in a state of purity, is smell-less; ethyl, or ordinary alcohol, when freed from ethers and as much as possible from water, has a faint smell, and the odour rapidly becomes marked as we rise in series, till the limit of volatility is reached, and we arrive at solids with such a low vapour tension that they give off no appreciable amount of vapour at the ordinary temperature. Again, with the acids, formic acid is smell-less, and produces a pure sensation of irritation. Acetic acid has a slight but characteristic smell; and the higher acids of the series, propionic butyric, valerianic acid, &c., gain in odour with increase in density in the form of gas. If we consider the nitrogenous compounds of carbon, we are led to the same conclusion. Prussic acid is not smelt by more than four persons out of every five; but the nitriles, which bear the same relation to prussic acid as the higher members of a series bear to the lower, have all very characteristic odours. Acetylene would appear to form an exception to this rule; but carefully purified acetylene has little odour, and it is surpassed by its higher homologues. We may therefore, I think, accept this as a principle—that the intensity of the smell rises with rise in molecular weight.

It is also noticeable that the *character* of a smell is a property of the element or group which enters into the body, producing the smell, and tends to make it generic. Thus we can characterise the compounds of chlorine and its oxides as chlorous; indeed we may group the three elements—chlorine, bromine, and iodine, together, and name the characteristic odour of them and their oxides haloid smells. Similarly, sulphur, selenium, and tellurium, in their compounds with hydrogen, have a generic smell; and likewise arsenic and antimony. The only oxide of nitrogen which is smelt is nitric peroxide, so that it is impossible to pronounce on a generic smell for this substance. It is, again, easier to classify carbon compounds. The smell of the paraffins is generic; so is that of the alcohols, the acids, the nitriles, the amines with their irritation like that of ammonia, the bases of the pyridine series, the hydrocarbons of the benzene group, the higher hydrocarbons, such as naphthalene, anthracene, and phenanthrene. Give any one of these to a chemist familiar with the smell of any one of each series, and accustomed to use his sense of smell, and he will at once refer the body to its class.

The tendency of a rise in the series is to make the smell "heavier," less ethereal, and more characteristic. It also becomes more able to affect the olfactory nerves.

The rate at which smell travels is doubtless the rate at which the vapour which gives rise to it diffuses. Still it is impossible to test this experimentally. For the ease with which a smell is perceived varies with the molecular weight of the substance. Thus, if a piece of cotton wool be impreguated with ethyl alcohol, and placed in one end of a long tube, which is immediately corked, and a similar arrangement be adopted with amyl-alcohol, the fifth of the series of which the former is the second; although their specific gravities have the ratio of 23 to 44, and the ethyl-alcohol should diffuse $1\frac{2}{5}$ times as rapidly as amyl-alcohol, yet the smell of the latter will be perceived first, because a much smaller quantity produces the sensation.

It is possible, with practice, to make a fairly accurate analysis by means of the sense of smell. The method is, knowing the constituents of a mixture, to prepare one which has the same smell, measuring the proportions of the ingredients. The only precaution to be observed is that the smell of no member of the mixture be so overpowering as to mask those of the others. Thus I have analysed, or rather synthesised, a mixture of chloroform with ether, alcohol with ether, and these liquids with carbon disulphide, provided the latter be pure, to within 2 per cent.; but I failed with members of the pyridine series. Yet it was possible to detect the proportions of members of that series to each other; and it is not difficult, however extraordinary it may appear, to guess approximately the boiling-point of a mixture of members of a series, after some practice, purely by its smell.

So far as I know, no theory has been brought forward to account for the sense of smell; and I therefore venture to supply this want, premising that what follows is merely a tentative explanation, and as such will, I hope, not be too severely criticised.

There is a probability that our sense of smell is excited by vibrations of a lower period than those which give rise to the sense of light or heat. These vibrations are conveyed by gaseous molecules to the surface network of nerves in the nasal cavity. The difference of smells is caused by the rate and by the nature of such vibrations, just as difference in tone of musical sounds depends on the rate and on the nature of the vibration, the nature being influenced by the number and pitch of the harmonies.

Let us see what evidence can be adduced for the theory. Among the lightest substances which have smell are sulphuretted hydrogen and phosphoretted hydrogen, both of which are seventeen times as heavy as hydrogen itself. Prussic acid is fifteen times as heavy as hydrogen, and has a smell. But all persons are not able to perceive it. I have remarked an average of one in every five persons who are totally unable to detect its odour. Here we reach the lowest limit of molecular weight. *To produce the sensation of smell, then, a substance must have a molecular weight at least fifteen times that of hydrogen.* If we compare the hydrocarbons of the paraffin series, with each other, and similarly the olefine series, we notice that the lower members have no smell. The specific gravity of marsh-gas, CH_4, is 8; that of ethane, C_2H_6, 15; propane, C_3H_8, is twenty-two times as heavy as hydrogen, and here we first notice smell. Olefiant gas, C_2H_4, has the specific gravity 14, and has no smell; propene, C_3H_6, has a faint smell with a specific gravity of 21; and the higher members of the series increase in intensity of smell with increase in specific gravity. Hydrocyanic acid is smelt by most persons, but not by all. Its specific gravity is 15. The higher members of the series, called the nitriles, have all very characteristic smell. Formic acid vapour has the specific gravity 23, and has a purely pungent odour. Acetic acid, 30 times as heavy as hydrogen, has a faint smell when pure; opionic, butyric, and valerianic acids have strong smells. Methyl alcohol has no smell; its specific gravity is 16; ethyl alcohol, 23 times heavier than hydrogen, has a faint smell; and, as usual, the intensity, and if I may so term it, the flavour of the smell, increases as we rise in series.

These are the most typical instances of the carbon compounds, and they suffice, I think, to show the justice of the assertion that the intensity of smell increases with rise of molecular weight. The hypothesis of vibration satisfactorily explains this. The period of vibration of the lighter molecules is too rapid to affect our sense; there is a limit to this power; and just as some people have the power of hearing more acute sounds than others, so some senses are limited by a specific gravity of 15, and cannot smell prussic acid. Such people also have difficulty in perceiving the odours of bodies of slightly higher molecular weight than prussic acid.

Let us now inquire what is the probable rate of such vibrations. Mr. Johnston Stoney and Prof. Emerson Reynolds have made investigations of the ratio of the bright lines of some spectra, and have calculated their relations to each other. An analogy will make the nature of this relation more evident. When a note, say C, below the treble clef is sounded on a piano, not only the tone C is heard, but its octave C on the third space; also G above the line, C on the third leger line, E on the fourth, G on the sixth, B flat above the G, and other notes. These are called harmonics, or over-tones. Now if we knew these over-tones, it would be possible to refer them to their fundamental. So with light. The light evolved by incandescent gases consists of certain colours, which have each their own rate of vibration. Knowing these rates it is possible to calculate the rate of vibration of the fundamental. This has been done by Mr. Stoney (Royal Irish Academy, January 9, 1871) with hydrogen, with the following results.—

Wave-lengths, *h*, 4102·37 tenth-seconds
,, F. 4862·11 ,,
,, C, 6563·93 ,,

These are the 32nd, 27th, and 20th harmonics of a fundamental whose wave-length is 0·1313 millimeters. The time of vibration is 4·4 fourteenth-seconds. It may be objected that these coincidences are not a proof. But Mr. Stoney and Prof Reynolds have measured the lines of the spectrum of chromyl chloride, and its 31 lines coincide with those calculated. The probability of the correctness of such a calculation approaches to almost absolute certainty. Now we have no means of recognising such fundamental vibrations, unless, indeed, the sense of smell is one means of receiving them. And it is this which appears to me probable; so probable, indeed, as to form a working theory.

But it is to radiant heat, I think, that we must look for indications of harmonics of the fundamental vibrations which are, according to this theory, the cause of smell. And a fresh proof may be drawn from the indications already seen. Prof. Tyndall has shown the power which odours have of absorbing heat-rays. There is no doubt that by refracting such heat-rays by means of a rock-salt prism, after they have passed through an atmosphere of odour, certain portions of the heat-spectrum show colder spaces, each corresponding to the particular rate of vibration which is absorbed by the vapour, through which the heat-rays have passed. By measuring the position of such gaps in the heat-spectrum, calculating the particular rate of vibration of the rays at such gaps, and referring them to their fundamental, we should arrive at the rate of vibration of the molecule which causes smell.

We may now inquire what it is which produces quality of smell. This, I think, can also be explained by the vibration theory, and depends on the harmonics of the vibration. Thus, the quality of tone of a violin differs from that of a flute by the different harmonics or overtones, peculiar to each instrument. I would ascribe to harmonics the quality of smell possessed by different substances. And it is to this that compounds of chlorine, phosphorus, &c., owe their peculiarity of odour. The odour of compounds resembles that of these elements to some extent; this may be accounted for by the similarity of overtones of compounds and their elements. Then we notice a similarity in quality of the odour of a compound of a series like the alcohols, and yet the quality grows flatter and heavier with increase in molecular weight.

Smell, then, may resemble sound in having its quality influenced by harmonics. And just as a piccolo has the same quality as a flute, although some of its harmonics are so high as to be beyond the range of the ear, so smells owe their quality to harmonics, which, if occurring alone, would be beyond the sense. It must be remembered that the harmonics are not heard separately from the fundamental, unless special means be adopted to render them audible, but they add their vibrations to those of the fundamental.

When two sounds are heard simultaneously, they give a concord, or a discord, but each may be separately distinguished by the ear. Two colours, on the other hand, produce a single impression on the eye, and it is doubtful whether we can analyse them. But smell resembles sound and not light in this particular. For in a mixture of smells, it is possible, by practice, to distinguish each ingredient, and as I have shown, to match the sensation by a mixture.

With regard to the mechanism by which smell is conveyed to the nerve, all that can be said is pure speculation. But as it is supposed that the vibrations of sound are conveyed to the auditory nerve through the small cirrhi, or hairs which spring out of round cylindrical nerve-cells in the superficial layer of connective tissue of the epithelium of the internal ear, and that each is attuned to some particular note of vibrations, so it may be imagined that the hair-like processes connected with the spindle-shaped cells, themselves communicating with the nerve-fibres of the olfactory nerve, are the recipients of the vibrations causing smell. Although the rate of such vibrations is extremely rapid, no less indeed in the case of hydrogen than 4,400,000,000,000,000, or the four quadrillions, four trillionth part of a second, yet the wave-length is by no means so small, for it averages the 2-100th of an inch, a magnitude quite visible with the naked eye. And hydrogen has no smell; those bodies which have smell, and higher molecular weight, must necessarily have a slower period of vibration, and possibly greater wave-length.

It is doubtful whether there exists a lower limit to our sense of smell. The vapours of osmic acid, carbon tetrabromide, selenium, tellurium, and arsenicous and antimonious oxides are among the heaviest known, and they have a most distinct smell. There appears to be a limit in practice, however, owing to the non-volatility of substances of high molecular weight at such temperatures at which smell may be perceived. The intense perfume of flowers is to be ascribed to the terpenes, of which common turpentine is one, or to their products of oxidation, and these bodies all possess a molecular weight of 136, and the specific gravity 68, a specific gravity which appears to excite the olfactory nerve most powerfully.

I bring forward the theory adduced with great diffidence. The problem is to be solved, in my opinion, by a careful measurement of the "lines" in the spectrum of heat-rays, and the calculation of the fundamentals, which this theory supposes to be the cause of smell. Such measurements and calculations, even if they proved the theory untenable, would have great value for their own sake, and labour expended in this direction would not be lost. Whether successful or not, it would at least be a first assault on what old John Bunyan called "Nose-gate of the City of Mansoul." WILLIAM RAMSAY

University College, Bristol

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—A syndicate, on which Dr. Ferrers, Prof. Stokes, Prof. Balfour, Mr. Todhunter and Mr. Trotter may be taken to represent the interests of science, has been appointed to frame regulations for the new degrees of Doctor of Science and of Letters. Candidates for these degrees are required by the new statutes to have made some original contribution to the advancement of science or of learning.

In the last Mathematical Tripos under the old regulations (January, 1882) the full marks were 27,150, and the average marks of the first ten wranglers were 6712, of the last ten 2890; first ten senior optimes average 2093; first ten junior optimes, 818. Out of 1407 marks given to the problems in the first three days, the first ten wranglers gained an average of 255; out of 8161 given to the problems in the last five days, the same ten averaged 849.

An important report by Mr. G. H. Darwin, who was the additional examiner in the same tripos, criticises severely the style in which the work of many men was done. Not a few sent up answers in atrocious handwriting, and omitted to define many symbols employed. The subjects which exhibited the average weakness of grasp most flagrantly was thermodynamics. A great many men had read something of it, but very few really understood what they attempted to explain. "Extraordinary muddle and confusion" was sent up in answer to a question on the absolute scale of temperature. On another question, while the very elements of the subject were unknown to those who answered, the same men reproduced faultlessly the algebraical calculation of the thermodynamic function for a perfect gas. Mr. Darwin strongly recommends such changes in the style of questions as that half intelligence may be more stringently treated, and men induced to read less and master more, and to gain a comprehension of physical principles.

The affiliation of University College, Nottingham, to Cambridge University has been formally recommended, so soon as the constitution of its governing body has been altered so as to admit a representative of the University. Scientific subjects have full recognition in the college course of study, by which exemption from one year's residence at Cambridge may be obtained, provided the student takes a degree in honours.

When Statute B comes into operation, the present Board of Natural Science Studies is to be replaced by two Boards—that of Physical and Chemical Studies and that of Biological and Geological Studies. These Boards will include, besides the Professors and Readers belonging to these studies, the Tripos Examiners of two years in the respective subjects belonging to the Boards, and three members of the Senate elected to serve for three years.

The second part of the Natural Sciences Tripos this year has no name in the first class, a result probably attributable to the transition state of the Tripos. Next June a better result may be anticipated, unless students with one consent let alone the more advanced parts of all the subjects. If this is the consequence of the recent changes, it will be much to be regretted.

OXFORD.—The term that has just ended has been chiefly remarkable for the fact that the new Statutes have come into operation in default of obstruction in Parliament. Already at several of the colleges, tutors and lecturers who have vacated their fellowships by marriage, have been re-elected "official Fellows;" and others who hold fellowships under the old ordinances have transferred themselves to the new official class.

But little legislation has been effected in Convocation: the only proposal of the Hebdomadal Council which provoked opposition was that to raise the University dues from five shillings to seven and sixpence a term, and to double the fee for Responsions (smalls), making it 2*l.* instead of 1*l.* Both proposals were carried on a division. The new Statute on Private Halls—containing provisions for bringing the master and students of such halls under the direct supervision of the University—was passed after being amended in Congregation. A Statute postponing the date of the University Examinations was also passed; so that in future the final honour schools will not commence before the last week of term.

During Michaelmas term, there will be offered two scholarships for proficiency in Natural Science. At Balliol there will be an election to a scholarship on the foundation of Miss Hannah Brakenbury, "for the encouragement of the study of Natural Science," worth 80*l.* a year (55*l.* and tuition free), tenable during residence for four years: open to all such candidates as shall not have exceeded eight terms from matriculation. This examination will begin on Thursday, November 16, at ten o'clock. Papers will be set in the following subjects:—(1) Mechanical Philosophy and Physics; (2) Chemistry; (3) Biology. But candidates will not be expected to offer themselves in more than two of these. There will be a Practical Examination in one or more of the above subjects, if the Examiners think it expedient. There will also be an optional paper in Mathematics; and the literary qualifications of the candidates will be tested by an English essay, or by a paper of general questions.

At Trinity College one Millard and Combe Scholarship, of the annual value of 80*l.*, without limit of age, will be awarded in October next for proficiency in Natural Science if any Candidate of sufficient merit offers himself. The Scholarship is tenable in the first instance for two years, and will be prolonged for two years more, if the President and Fellows are satisfied with the industry and good conduct of the scholar. For special reasons it may be prolonged for a fifth year. The subjects of examination will be Chemistry and Physics. Candidates may also offer Mathematics, if they wish to do so and give notice a week before the examination. Special weight will be attached to excellence in one or two subjects, rather than to a less thorough knowledge of all. Candidates will also have an opportunity of doing one Classical paper. The scholar elected will not necessarily be required to commence residence immediately. The President will receive the names of candidates and their testimonials of character on Tuesday, October 10, between 8 and 9 p.m. The examination will commence on Wednesday, October 11, at 9 a.m.

SCIENTIFIC SERIALS

Proceedings of the American Philosophical Society, vol. xix. No. 109, June to December, 1881.—Continuation of notes on an Egyptian element in the names of the Hebrew kings, &c., by S. P. Lesley.—Notes on the geology of West Virginia, by J. C. White.—Bhotodynamic notes, III. and IV., by P. E. Chase.—On Alaskaite, a new member from the series of bismuth sulphosalts, by G. A. König.—The auriferous gravels of North Carolina, by H. M. Chance.—On some mammalia of the lowest eocene beds of New Mexico, by E. D. Cope.—Notes on the Quinnemont coal group in Mercer Co. of West Virginia and Tazewell co. of Virginia, by J. J. Stevenson.—Notes on the coal-field near Cañon City, Colorado, by the same.—The brain of the cat (*Felis domestica*); I., Preliminary account of the gross anatomy, by B. G. Wilder.—Exploration of the River Bene with the hitherto unexplored regions of Bolivia, by E. R. Heath.—The names of the Gods in the Kiche myths, Central America, by D. G. Brenton.

The Transactions of the Academy of Sciences of St. Louis, vol. iv. No. 2, 1882.—The hieroglyphic tablet of Pompeium grammatically translated and commented on, by E. Seyffurth.—Notes on North American *Microgasters*, with descriptions of new species, by C. V. Riley.—Descriptions of some new *Tortricidæ* (leaf-rollers), by the same.—On certain problems in refraction, by F. E. Nipher.—Magnetic determinations in Missouri during the summer of 1880, by the same.—"Reversion of type" in the digastric muscle of the human being, by C. A. Todd.—Ephemeris of the satellites of Mars for the opposition of 1881, by H. S. Pritchett.—The genus *Isoetes* in North America, by E. Engelman.—Auroral phenomenon, September 12, 1881, by E. A. Engler.

Revue d'Anthropologie, Paris. Deuxieme, Fascicule (1882), contains:—A paper by Dr. Paul Broca—left incomplete at his death—on so-called Ectromelian monstrosities, or those in whom there is an abnormality, but not an absence, of certain parts of the body.—Contributions to the study of muscular variations in human races, by Théophile Chudzinski. This paper is one of a series, the earlier parts of which appeared in the *Revue* for 1873-1874, and which will be continued in subsequent numbers.—On the cephalometric square, and its mode of application, by Dr. Topinard, who also describes the respective merits and demerits of the methods usually employed by artists to determine the facial angle and its relation to other parts of the body.—On the populations of the peninsula of the Balkans, by the late French geographer and traveller, Guillaume Lejean, sometime vice-consul at Khartoum, and at Massaouah. This portion of the author's exhaustive history of the origin and settlements of all the various peoples who have occupied the Hemus peninsula since it was held by the ancient Thracians, ends with the complete subjection, in the thirteenth century of the Slaves by Latin princes holding lands under the Greek Empire.—In a paper entitled "Les Griots," Dr. Berenger-Feraud describes those itinerant musicians who are to be met with in every part of Central Africa, from the shores of the Atlantic to the Indian Ocean, and who, notwithstanding the low castes to which they belong, constitute a distinct confederation under the authority of a chief, who exercises great authority over its scattered members, and levies a heavy tax for his own use from their general receipts. These people, whose name of Griots is a French corruption of the Onolove word "Gwewonal," are regarded with fear and repugnance by the negro natives of the lands which they traverse, and where they are looked upon as members of an impure caste, whose dead are capable of bringing sterility and perpetual drought to the ground in which they are buried. They are skilled in improvising and reciting; and while some play the violin and guitar, the least gifted among them beat the tam-tam or play on various discordant wind-instruments. The confederation is undoubtedly of long-standing, and while the Griots, who perpetuate many ancient myths and songs, contribute towards the maintenance of some degree of intercommunication among the African races, they are credited with fomenting frequent dissensions, by trafficking with the information which they acquire through the extraordinary license granted them of going where they will among rich and poor, both in times of war and peace.—A critical review of all that is known of the Chukches, or Yu-its, by M. J. Deniker, gives the substance of what has been learnt of the ethnological and social standing of these Arctic peoples from the narratives of Nordqvist, Nordenskjöld, the Russian Argoustinovitch, Krause, Dall, and others.

Mathematische und Naturwissenschaftliche Mittheilungen, &c. (Berlin Academy), Heft 1, 1882.—Report of work in connection with the Humboldt foundation for natural research and travel, by E. Du Bois Reymond.—The thermo-dynamics of chemical processes, by H. Helmholtz.—On abnormal forms of pine-cones, by A. W. Eichler.—On the molecular refraction of liquid organic compounds, by H. Landolt.—The embryonal excretory apparatus of the gill-less *Hylodes martinicensis*, by E. Selenka.—On the differences of phase of electric vibrations, by A. Oberbeck.—On twisted rock-crystals, by E. Reusch.—On geognostic observations by G. Schweinfurth in the desert between Cairo and Suez, by E. Beyrich.—Investigation of volcanic rocks from the region of Abu-Zabel, on the Ismailia Canal, by E. Arzruni.—On the terminal growth of phanerogam roots, by S. Schwendener.—On an abundant exhalation of sulphuretted hydrogen in the Bay of Mesolungi, by G. Von Rath.—On transformations of amide by action of bromine in presence of alkalies, by A. W. Hofmann.—On the phosphates of thallium and lithium, by C. Rammelsberg.—The present state of science, by E. du Bois-Reymond.—On the production of amides of mono-basic acids of the aliphatic series, by A. W. Hofmann.—On the production of mustard-oils, by the same.—Crystallographic researches on sublimated titanite and amphibole, by A. Arzruni.—Congratulatory addresses to Von Bischoff and to Henle on attaining their doctor-jubilee.

THE last number of the *Journal* of the Russian Chemical and Physical Society (vol. xiv. fasc. 5) contains several valuable papers. Prof. Mendeleeff contributes an interesting paper "on the heat of combustion of hydrocarbons," and a note on his experiments on the resistancce opposed by water to the motion of solid bodies.—Prof. Butleroff contributes a notice on the important question as to the variability of atomic weights, and another on the oxidation of isodibutylene by permanganate of potassium; and M. Woeikof discusses the influence of local topographical conditions of meteorological stations on the average temperatures of winter.—Besides, we notice papers on the formation of hypochlorites and chlorates during the decomposition of chlorides by means of a current, by MM. Lyadoff and Tikhomiroff.—On the separation of barium from strontium and calcium by means of chromates, by M. Meschersky.—On the structure of nitrated products of the fat series, by M. Kisel.—On the critical state of bodies, by M. Stoletoff.—On the electrical conductibility of vacuum, by M. Kraewitscb.—On vibratory telephonic signals, by M. Jacoby.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 15.—"On a Deep Sea Electrical Thermometer." By C. William Siemens, D.C.L., F.R.S.

In the Bakerian Lecture for 1871, delivered before the Royal Society (*Proc. Roy. Soc.*, vol. 19, p. 443), I showed that the principle of the variation of the electrical resistance of a conductor with the temperature might be applied to the construction of a thermometer, which would be of use in cases where a mercurial thermometer is not available.

The instrument I described has since been largely used as a pyrometer for determining the temperatures of hot blasts and smelting furnaces, and Prof. A. Weinhold (*Annalen der Physik und Chemie*, 1873, p. 225), using the instrument with a differential voltameter described in my paper referred to, found its indications to agree very closely with those of an air thermometer within the limits of his experiments from 100° to 1000° C. I am not aware, however, that any results have been published of its application to measuring temperatures where a much greater degree of accuracy is required, as in the case of deep sea observations. My friend, Prof. Agassiz, of Cambridge, U.S., ordered last year, for the American Government, an instrument designed by me for this purpose, and during the autumn it was subjected to a series of tests on board the United States Coast and Geodetic Survey steamer *Blake*, by Commander Bartlett.

The apparatus consists essentially of a coil of silk-covered iron wire ·15 millim. diameter, and about 432 ohms resistance, attached to an insulated cable by which it can be lowered to the required depth, and connected so as to form one arm of a Wheatstone's bridge. The corresponding arm of the bridge is formed by a second coil made precisely similar to the former one and of equal resistance. This coil is immersed in a copper vessel filled with water, and the temperature of the water is adjusted by adding iced or hot water until the bridge is balanced. The temperature of the water in the vessel is then read by a mercurial thermometer, and this will also be the temperature of the resistance coil.

To avoid the error, which would be otherwise introduced by the leads of the resistance coil, the cable was constructed of a double core of insulated copper wire, protected by twisted galvanised steel wire. One of the copper cores was connected to each arm of the bridge, and the steel wire served as the return earth connection for both.

Sir W. Thomson's marine galvanometer with a mirror and scale was employed to determine the balance of the bridge.

Mr. J. E. Hilgard, assistant in charge of the United States Coast and Geodetic Survey, has sent me the results of Commander Bartlett's experiments. The apparatus was set up on board the *Blake* in April, 1881, and experiments were made off the east coast during August. In each series of experiments the temperatures at different depths were first taken by Miller-Casella thermometers attached to a sounding wire. A sinker was then fastened to the resistance coil, and it was lowered by the cable to the same depths, and the temperature read by means of the mercurial thermometer attached to the comparison coil. The depths at which readings were taken ranged from the surface down to 800 fathoms, and experiments were made both in rough and still water. The temperatures recorded varied from 38·5° to 81·5° F. In every case the readings of the electrical instrument were precisely the same as those of the Miller-Casella thermometers for the surface and the maximum depth; but for intermediate positions it was observed that the electrical thermometer in almost every case gave a slightly higher reading. This discrepancy may be accounted for, I think, by the circumstance that the electrical thermometer gives the temperature of the water actually surrounding the coil at the moment of observation, whereas the Miller-Casella instrument brings to the surface, or at least its readings are effected by, the maximum or minimum temperatures encountered in its ascent or descent, which may not coincide with that at the point of stoppage. This furnishes a very strong argument in favour of the superior accuracy of the electrical instrument.

It was found that about five minutes must be allowed at each observation for the resistance coil to assume the temperature of the water surrounding it, and a second period of five minutes for adjusting the temperature of the comparison coil on deck. Allowing five minutes more for lowering the cable, fifteen minutes sufficed to complete a deep sea observation.

Chemical Society, June 1.—Dr. Gilbert, president, in the chair.—The following papers were read:—Determination of nitric acid in soils, by R. Warington. The sample should be taken in dry weather from the subsoil, as well as from the surface. It is dried at 55° C., and powdered. About 200 to 500 grms. are extracted in a vacuum filter with about 100 c.c. of water; the extraction requires ten to forty-five minutes. The nitric acid is determined by a modification of Schlœssing's method, the nitric oxide gas obtained being measured.—On a spectroscopic study of chlorophyll, by Dr. Russell and Mr. Lapraick. The anthors have not endeavoured to isolate a pure substance, but have endeavoured to follow spectroscopically the changes of a body (or bodies) which gives a particular absorption spectrum. This chlorophyll was extracted by a mixture of alcohol and ether, and gives the well-known absorption spectrum of four bands easily seen, and three other bands in the violet end, which are not noticed with gaslight. This chlorophyll, by treatment either with a small quantity of almost any acid, or with some salts, as ferric chloride, mercuric chloride, &c., or by heat, is changed, and gives another characteristic spectrum, to which the authors gave the laboratory name of "half-acid" chlorophyll; by the action of strong hydrochloric acid, a further change is produced, and an absorption spectrum is obtained, which is named "acid" chlorophyll. Alkalies act on chlorophyll, and give eventually an absorption spectrum of one broad band in the red. Very concentrated caustic potash solution splits this band into two bands, one of which ultimately disappears. The eye observations and measurements were checked with photographs taken by Capt. Abney. All leaves gave similar results, except some acid leaves, from the vine, &c., which gave half-acid chlorophyll instead of the normal product, when extracted with alcohol and ether.

Zoological Society, June 6.—Prof. W. H. Flower, F.R.S., president, in the chair.—The Secretary called the attention of the meeting to the curious way in which the young Cormorants lately hatched in the Gardens were fed by the parent birds, and exhibited a drawing by Mrs. Hugh Blackburn illustrating this subject.—A communication was read from Prof. St. George Mivart, F.R.S., containing a series of observations on certain points in the anatomy of the Cat-tribe (*Æluroidea*).—Mr. Howard Saunders read a paper on some *Laridæ* collected by Capt. H. H. Markham, R.N., on the coasts of Peru and Chili; comprising, amongst other rarities, the third known example of the large Fork-tailed Gull (*Xema furcatum*), a species which had been vainly sought for on the Pacific coast of America for upwards of thirty years. The author drew attention to the peculiarities distinguishing the various species of gulls found in the Pacific from those of the rest of the globe, and pointed out that, owing to oceanic currents, the connection between the species now only found on opposite sides of the equator had evidently been much more recent in the Pacific than in the Atlantic.—Prof. F. Jeffrey Bell read a paper containing an attempt to apply a method of formulation to the species of the *Comatulidæ*, and added the description of a new species, which he proposed to call *Actinometra annulata*.—Mr. Francis Day, F.Z.S., read some notes on the supposed identity of a specimen of a fish determined by Dr. Günther as *Anguilla kieneri* with a Gadoid *Lycodes*.—Mr. E. J. Miers read the second portion of his paper on the crustaceans received by the British Museum from the Mauritius, and called special attention to what appeared to be a variety of *Palinurus longimanus* of the West Indies which occurred in it.—Mr. W. A. Forbes read the fifth of his series of papers on the anatomy of Passerine birds. The present communication was devoted to the consideration of the structure of the genus *Orthonyx*, which was shown to be a true Oscinine form.—Mr. H. J. Elwes exhibited and made remarks on a Stonechat (*Saxicola*) which he had obtained during a recent expedition to the Aures Mountains of Algeria.—The Secretary exhibited a series of the diurnal and nocturnal lepidopterous insects bred in the Insect House in the Gardens during the present season.

Royal Horticultural Society, May 23.—Sir J. D. Hooker in the chair.—*Foliage injured by salt in the late gale*:—Dr. Church described experiments he had made at Cirencester during the last fifteen years to ascertain the amount of salt in the rain brought by autumnal gales, especially from the south-west. He found from 5 to 7 grs. per gallon, while the ordinary amount was only ·5 grs. The average winter amount was but slightly in excess of the average summer quantity. He noticed that in Oakley Park, one side of the trees was severely injured, and that, if no rain followed for a few days after the gale, the salt sparkled on the trees, even at a distance of thirty-five miles from the sea. The salt abstracted the moisture from the leaf-cells, and formed a condensed solution, so that the leaf became completely dried up, and perished. Mr. McLachlan added that salt had been observed on windows at Lewisham, as at Croydon, and elsewhere. Sir J. D. Hooker remarked that Dalton was the first to record a similar observation at the beginning of this century. With regard to beeches withstanding the gale better than oaks, as mentioned at the last meeting, it was elicited that they were unhurt at Kew, and Valewood, Haslemere, but at Cirencester, in Dorsetshire, and Cornwall, they suffered severely. Mr. Blackmoor exhibited foliage of pears, &c., from Teddington, some of which was quite unhurt; of other trees growing adjacent to them, the leaves were much injured. Vines and peaches showed similar differences. He suggested that it could not be salt in this case. The opinion generally entertained was that such discrimination were due to the trees being of relatively hardy and less hardy kinds.—*Rhododendron triflorum*: Mr. Mangles exhibited sprays of this species from the Himalayas. It belongs to the scaly-leafed section, and he observed that members of this group will not hybridise with any species of rhododendron without scales on the foliage.—*Malformed tulip*: Mr. Smee exhibited a tulip having petals distributed down the peduncle, a not uncommon occurrence. Mr. Henslow remarked on the fact that when such a petal was half-green and half-coloured, the tendency of the latter half is to check the growth and elongation of the peduncle. This causes the latter to bend over towards the side on which the petal is attached, and often so much so that it cracks on the opposite side, and may even decapitate itself.—*Change of sex in Rhododendrons:* The Rev. G. Henslow showed a flower in which the corolla was doubled, the stamens partially petaloid, while the pistil was open below with stamens, a tuft of imperfect petals and stamens arising from the base. He showed a drawing of a somewhat similar condition made in 1875, in which the style had become strap-shaped, was partially coloured red, and bore anther-cells on the margins; the pollen, however, was evidently abortive.

Entomological Society, June 7.—Mr. H. T. Stainton, F.R.S., president, in the chair.—Mr. P. B. Mason exhibited dark varieties of *Zygæna filipendulæ*, and *Callimorpha dominula*, as well as of the insect formerly supposed to be *Agrotis helvetina*, Boisd., but which was now believed to be a remarkable variety of *Noctua augur*.—The President remarked that there had been a great mortality this spring among the young larvæ of the currant saw-fly (*Nematus ribesii*).—Mr. McLachlan read a revised list of British *Trichoptera*.—Mr. W. L. Distant read descriptions of new species and a new genus of *Cicadidæ* from Madagascar.—Mr. A. G. Butler communicated descriptions of heterocerous *Lepidoptera* collected in Chili by Mr. Edmonds: *Geometrites*.

Victoria (Philosophical) Institute, June 15.—Annual meeting; the Right Hon. the Earl of Shaftesbury, K.G., in the chair.—Prior to the delivery of an address on the scientific aspects of the last Palestine survey, by Mr. Trelawney Saunders—who gave a careful analysis of the valuable results of the survey of Palestine, especially noticing the accord of the results with the Bible narrative—the honorary secretary, Captain F. Petrie, read the report, from which it appeared that the total number of members was now upwards of 950, Prof. Pasteur and many other well-known men of science having joined the Society in the past year.

Paris

Academy of Sciences, June 12.—M. Jamin in the chair.—The death of M. Conalia, Correspondent in Rural Economy, was commented upon.—On a point of the mathematical theory of effects in the game of billiards, by M. Resal.—Characters and *rôle* of double salts formed by fusion, by MM. Berthelot and Ilosvay.—Remarks on the use of zinc-carbon couples in electrolysis, by M. Berthelot.—Note on some explosive alloys of zinc and platinum-metals, by MM. Deville and Debray. Osmium is the only one of the platinum metals which does not retain zinc when one treats its alloy having a large excess of zinc, with an acid capable of dissolving this metal. The action of zinc on osmium-iridium is explained, according to laws of thermo-chemistry. (The heat liberated in union of zinc with iridium is enormous, and greatly exceeds that in union of osmium and iridium).—M. de Lesseps reported on the Suez Canal, and gave an account of the s.s. *Austral*.—M. Schlœsing was elected Member in Rural Economy in room of the late M. Decaisne.—Programme of astronomical work to be done by the scientific expedition sent to the south pole, by M. Lœwy. Classing the observations as (1) accidental, and (2) regular, those of the transit alone belong to the first; the second class include determination of the hour, the latitude and the longitude; of the radiant points of the southern heavens; and search for comets.—Observation of the Venus transit at Cape Horn, by M. Mouchez. The Transit Committee reluctantly gave up the island of Cape Horn for the mouth of the River Santa Cruz in Patagonia (for the most southerly station), the chances of good weather being so small; but they urge the importance of providing the Cape Horn scientific mission with instruments for transit observations.—Instructions for the naturalists of the Cape Horn Mission, for investigation of the animals on Terra del Fuego and adjacent islands, by M. Blanchard. *Inter alia*, the small mammals, as unable to cross wide arms of the sea, should throw light on questions in physical geography. Do the land birds migrate to the continent in winter? Are there batrachians in those parts? &c. Special means must be taken in those cold and wet climates for discovery of insects, few species of which attract notice by number or bright hues.—Instructions for the mission to Cape Horn, by M. Duchartre. In botany, special regard should be given to marine algæ.—Geological instructions, by MM. Daubrée and Des Cloizeaux. Search for fossil *débris* and for earthy meteorites and masses of native iron is urged; also investigation of raised beaches.—Programme of meteorological and magnetic observations, by M. Angot. Direct observations to be made at 4 and 8 a.m. and p.m. at midday and at midnight, (the expedition has a complete series of registering apparatus, and for certain instruments, a double series). *Inter alia*, full instructions are given for observation of austral auroras.—Observations of planets 221, 222, 223, 224, and of Comet *a* 1882 (Wells) at Paris Observatory, by M. Bigourdan.—Observations of the same comet with the 7-inch meridian circle at Bordeaux Observatory, by M. Rayet.—Ditto with the 6-inch Brunner equatorial at Lyons, by M. Gonessiat.—On a mode of transformation of figures in space, by M. Venecek.—On the law according to which the electromotive force of a magneto-electric machine varies in function of the resistance of the exterior circuit, by M. Deprez. The diminution of electromotive force in the ring, when the current becomes very intense, is due to insufficiency of the inductors. The wires of the ring cut the magnetic lines of force at an angle increasingly different from a right angle (at which maximum force is had).—Oscillations of the plane of polarisation by the discharge of a battery; simultaneity of electrical and optical phenomena, by MM. Bichat and Blondlot. A Leyden jar was discharged through a coil round a transparent body (*e.g.* flint) between polariser and analyser, and each time there was reappearance of the extinguished light. In one arrangement the image of a slit in the polariser was viewed in a rotating mirror, with a telescope, at each discharge; and one saw a series of bright bands (as in the case of a spark). The plane of polarisation was proved to oscillate about its normal position.—Decomposition of salts by matters in fusion, by M. Ditte.—Action of heat on an acid solution of sulphate of nickel in presence of sulphuretted hydrogen, by M. Baubigny.—On the mechanism of putrid fermentation, and on the alkaloids resulting from it, by MM. Gautier and Etard.—On the decomposing action of certain organic matters on oxygenated water; *à propos* of a memoir by MM. Bert and Regnard, by M. Béchamp.—On the aptitude communicated to cold-blooded animals to contract charbon by raising their temperature, by M. Gibier. Charbon was communicated to frogs (five out of twenty) compelled to live, after inoculation, in water at 35° to 37°. The bacteria developed were longer than usual (due to slow circulation).—Does the mechanism of absorption of virus vary with the nature of the wounds? Does the nature of the wounds affect the efficiency of surgical intervention? by M. Rodet. The nature of the wound affects only the rapidity of the propagation, not at all the mechanism of absorption; the penetration is, in by far the most cases, by the lymphatic vessels, very rarely by the blood-vessels exclusively, and seldom, comparatively, by blood-vessels and lymphatics.—On the sub-basaltic alluvions of the Corions (Ardèche), by M. Torcapel.—Probable lowering of the current water in the valley of the Seine during the summer and autumn of 1882, by MM. Lemoine and de Préandeau.—M. Carré described a new fire-alarm; an iron wire, constantly stretched by a spring, and closing a circuit (with bell) when elongated by heat; communication is made by rupture, as well as by expansion of the wire.

THE FUNERAL TENT OF AN EGYPTIAN QUEEN

The Funeral Tent of an Egyptian Queen. By Villiers Stuart, of Dromana, M.P. (London: John Murray, 1882.)

THE startling discoveries of the royal mummies in the pit of the Deir-el-Bahari has already been the subject of great interest, and cast an unexpected light on the history of embalming and the vicissitudes of the dead as well as the living, revealing the unexpected transport of the monarchs from their costly chambers and sarcophagi of the Biban-el-Molouk to the Deir-el-Bahari in the fifth year of a monarch named Herhor, of the 21st dynasty, one of that line of ambitious pontiffs who, at a time of national decay, mounted the Egyptian throne. That the tomb of the Deir-el-Bahari was the resting-place of Herhor himself and his family appears from the discovery of their mummies at the same site along with 6000 sepulchral objects, some of which are already filtering to Europe, and others discovered at least ten years ago, already enrich the collections of the Louvre. The numerous duplicates of the smaller and portable objects can neither be all retained in the country, nor is it desirable they should be in the interests of science, for the interest would be languid which allowed them all to remain on the banks of the Nile. The reason why these archæological treasures were deposited in the Deir-el-Bahari is quite uncertain, and as the hieratic inscriptions on the shrouds only speak of their removal and condition, the cause is likely for the present to remain undiscovered. The Deir-el-Bahari was built by Thothmes I., II., Hatasu, the ambitious queen, and her warlike brother Thothmes III., as it was a spot especially favoured by the 18th dynasty. Probably the 21st dynasty was descended by the female line from the 18th, for families do not readily become extinct in that direction, and there are living descendants of the Plantagenets at the present day. The resumption of the titular names of the 18th dynasty by the 21st also points to a connection between the two families, although it is difficult to conceive the precise point from which it started. As however the first monarch of the 21st had been a prince of Kush or Æthiopia, and these princes or viceroys were continued in a lineal descent during the 18th and 19th dynasties, it may perhaps be the case that Pinotem I. and II. were descended by that family from the monarchs of the 18th dynasty.

It is not necessary to dwell on the mummies, but some of the facts mentioned by Mr. Villiers Stuart in his work are remarkable, such for example as the wailing of the Arab women along the Nile on their removal by the steamers to the Museum of Boulaq, for although professional mourners the lamentations of these women were spontaneous and gratuitous. On the arrival of the mummies at Cairo, that of Thothmes III. was unrolled, and that illustrious soldier, a little man, a martial pigmy of the most fragile mould, far more fragile than the flowers with which he was surrounded, vanished like a dream after, as it is said, a rapid photograph had been taken of his features, so that only a carte de visite of his remains has been left for posterity. Rameses II. was a hero of the grenadier type, for his height is at least six feet, but he has not been unrolled, the loss of Thothmes III. having discouraged the Boulaq authorities, so that for the present the vexed question of his features, whether the heroic aquiline nose or the ordinary flat Egyptian, remains in abeyance. The other mummies which have been partly denuded are the priest Nebseni, of the 18th dynasty, whose features are good Egyptian, and Pinotem II., whose capacious mouth and thick lips announce a Nigritic origin or intermixture of blood; others, as Isiemkheb and Makara, have been left in their bandages for a future period to unravel. The queen Notemut, the grandmother of Makara, and a remote progenitor of Isiemkheb, had however hair streaked with silvery gray, and was an old woman still retaining the coquetry of a careful plaiting of her locks. Some of the family were of mixed origin, and when was the Egyptian race otherwise, except when foreign conquests introduced other blood into the country. The greater portion, however, of Mr. Stuart's work is occupied with the description of the leather canopy of the queen Isiemkheb. This ancient pall was composed of numerous pieces of leather tanned by the bark of the *sont* or acacia, and sewn together by red cord, and is supposed to have covered the mortuary cabin of the sacred boat or horse, to which it formed a kind of baldacchino. It is exceedingly brittle, and the colours are still well preserved, the centre 9 feet long by 6 feet wide, and divided into two equal sections, one of which is covered by pink and yellow rosettes on a blue ground, the other displaying six flying vultures flying with extended wings and holding feather sceptres in their claws; they are separated from one another by horizontal lines of hieroglyphs, the name and titles of Masaharuta, high priest of Amen Ra, the deity of Thebes, and a row of pink rosettes on a yellow ground. On either side is a flap divided from the central section by four bands of colours—blue, red, yellow, and green—and further divided by a border of spearhead pattern. Below this comes a row of panels containing a row of emblematical devices, predominant amongst which is the scarabæus, flying with extended wings, thrusting forward the solar disk—emblems of the sun-god—but having with this emblem the representation of a gazelle, supposed to be the favourite of the queen, twice repeated, a singular representation of two united ducks, and ornaments like the Greek antefixal and the cartouche or royal name of Pinotem II. seven times repeated. Below this is a border of pink and blue chequers at the bottom, with a broad kilt of pink or perhaps originally scarlet. This magnificent work of leather measures 22 feet 6 inches in length, and 19 feet 6 inches wide, containing a space of 201 square feet of leather. It is the most remarkable object next to the historical mummies of the whole collection, and exhibits the greatest technical skill in preparation, and artistic excellence in execution and design. Its age is somewhere about the time of Solomon, but the length of the reigns of the monarchs of the 21st dynasty lies entombed in the vaults of the Serapeum, which contained the 24th, 25th, and 26th Apis mummies, and which Mariette found practically inaccessible from the collapse of the vault. The period, however, was that of foreign alliances, as shown by the flight of Adad, the Idumæan prince, to Egypt, and his marriage with the sister of the queen. Besides the devices the canopy was ornamented with a hieroglyphical inscription, the purport of which appears to be that the queen in the future state was in the arms of Khonsu, one of the deities of Thebes, son of Mut and Amen, "redolent with perfumes sweet as those of Punt," the present Somali or Guardafui, and "crowned with flowers." Those found in the coffins of this period, and which still preserved their original colours, have been determined to be blue larkspur, yellow mimosas, or acacias, and the white lotus, besides which, according to Mr. Stuart, a moss was discovered in the coffins resembling a kind found only in Greece. The coloured plate of the canopy which accompanies this part of the work gives an idea of the brilliancy of this remarkable piece of leather embroidery as it appeared nearly three thousand years ago. Specimens of this leather canopy, which have been brought to England, show that the colours with which it was painted or dyed still retained their original lustre. From some unknown circumstance they have, like the flowers, never paled by the effects of time.

In his commentary on the text, which it is unnecessary to follow here in detail, Mr. Stuart has given an account of the scarabæus, known as the *Copris Isidis* of Savigny, and detailed a fact not generally known or described in the account of that insect. Instead of propelling the clay ball or pellet or the dung cased in with clay as the other kinds of this family are said to do with their hind legs, the male *Copris Isidis* carries the ball on its head and neck, for which the peculiar formations of the horns and projections of the thorax are specially adapted. One has been found wending its way over the ground with its spherical load, another has been knocked down bearing it as the beetle hummed his drony flight through the air.

Besides the description of the leather pall, Mr. Stuart gives some account of the recently discovered pyramid of Pepi at Sakkarah and that of Haremsaf. The interior of these pyramids, unlike any of the others, was covered with incised inscriptions coloured green, a peculiarity seen also on some sepulchral tablets. The inscriptions of these pyramids are mythological phrases, consisting of formulas like those of the Ritual comparing the passage of the soul of the deceased kings after death through the heavens to the movement of the constellation Orion and the course of Sothis or the Dog Star. Amongst the other new facts mentioned in these inscriptions is that of the tree of life, which is placed in the island of the blest amongst the pools of the fields of the Aahlu or Egyptian Elysium. A new light is shed on the earlier mythology by these texts, which chiefly turn on the Nut or goddess of the Ether, from whom Osiris and the monarch in the character of that god is descended. These remarkable texts have been translated by Brugsch-Bey, and Lauth. It is much to be regretted that these inscriptions are so entirely religious, and that these earliest of hieroglyphic monuments offer no contribution to the history of that remote period, Meidoum, is surrounded by tombs, in one of which the author found the name of Senofru of the 3rd dynasty. The attempts to solve the antiquity of this sepulchre from other sources has failed like all the earliest works of Egypt; for the passage is uninstructive, some scribes of a later age have scrawled or scratched a memorandum of a visit, but the walls are otherwise silent, and the chamber has not been found in which the royal tenant was deposited. The mastabas of the age do not abound in relics, and the antiquity of some of the terra cotta vases has been impugned, the criteria of the different kinds of pottery being obscure. At Dashour the author found a very early tomb of a person named Afoua, but although the style of art announced a high antiquity, the inscriptions curt, and in the oldest form, offered no novel points of interest, they were like those of the slab of the 3rd dynasty at Oxford, supposed to have been brought by Greaves from Egypt.

Mr. Stuart has published the tomb of Rameses, the governor of Thebes, in the reign of Amenophis IV., and the so-called Khuenaten, and enters into a discussion of the difference between Amenophis IV. and the heretic monarch. The general idea is that Amenophis IV. adopted the worship of the sun's disk soon after his accession, and altered his name from Amenophis, or "the peace of Amen," to that of Khuenaten, or the "splendour of the disk," in honour of the orb of heaven, whose worship he had substituted for that of the Theban god. The fact that the features of Amenophis and Khuenaten essentially differ, the one depicted as a rotund youth, the other that of a haggard septuagenarian, had long attracted attention, and been explained on the hypothesis that the portraits of Egyptian royalty were conventional, and therefore not to be depended on, and that the introduction of the new worship had unshackled the technical details of the Egyptian artists. But who was the mysterious Khuenaten? was he an emasculated virility of the harem, or a withered senility of the Nigritic race who had ascended the throne of Egypt? Was he possibly the old queen Tii, who, ambitious of power, had assumed manly costume and, attended by a mock or daughter queen and attendant princesses, endeavoured to set up a new capital and a foreign cultus at a small but rival capital. All is mystery, the facts pointed out by Mr. Stuart of the different features which could not change with the same facility as the name, the different functionaries of the two courts, the strange and servile homage paid by the courtiers of the old heretic and perhaps impostor, the copious bribery of the novel monarchy only add to the unsolved problem, and are not the least interesting part of the work. The identity of the two monarchs as two single gentlemen rolled into one will be long contested, as even the tomb at Thebes gives the same name and titles to the erased and mutilated heretical forms of Khuenaten. Amongst his miscellaneous plates are one of the mummy of Thothmes III. in its bandages, a box of the queen Makara, and some mummies of the find at Deir-el-Bahari.

These are also known from the photographs of M. Emile Brugsch, attached to the report of Maspero. Some discussions and examples of the Indo-Germanic nature of the Egyptian language are given; but this branch of philology is a knotty point, for the Egyptian language is not of a decidedly Indo-Germanic construction, although many of the words undoubtedly have Indo-Germanic analogies.

The main interest of the work, however, centres in the monuments of the Deir-el-Bahari, especially the leather canopy of Isiemkheb. There are, however, in Egypt such an enormous mass of unpublished monuments and inscriptions that even the Deir-el-Bahari find is not to compare with the inscriptions on the temples of Denderah and Edfu, and those of the caves of Siut.

HYDROGRAPHICAL SURVEYING

Hydrographical Surveying; a Description of the Means and Methods employed in constructing Marine Charts. By Capt. W. J. L. Wharton, R.N. (London: Murray, 1882.)

CAPT. WHARTON, who has had considerable experience in nautical surveying, having been in command of surveying vessels for nearly ten years, has devoted his time, during the short interval he has been unemployed, to writing a work on this part of the naval profession which he modestly describes, in his preface, as an endeavour to collect together information, which has existed for years in a traditionary form amongst surveyors, for the benefit of young officers who may wish to devote themselves to surveying work in the future.

A book of this sort was certainly much needed as since the time of Sir Edward Belcher, only one treatise has been written by a naval surveyor—Capt. R. Mayne, R.N., C.B.—and we think Capt. Wharton deserves the thanks of the profession for his exertions, and we hope to see his work adopted as the text-book for instruction at the Royal Naval College.

Before however reviewing Capt. Wharton's treatise we propose to state briefly what we consider to be the requirements of a nautical survey.

The perfection of marine surveying appears to us to be the representation in a graphic form, readily understood, of the coasts and harbours of the world with their various off-lying dangers; marking distinctly the various features of high and low water lines, showing the dangers to be avoided and the channels available for navigation, placing prominently on the chart those objects on the land which serve best to ascertain the position of a ship, and subordinating all other features to these objects, so that the channels to be used, and the marks by which those channels can be recognised, are easily distinguished; as well as representing the set of the tides and currents and the errors of the compass. To execute such a survey it is evident considerable care must be bestowed in ascertaining accurately the positions of the land marks, as on these depend the whole of the work, but this accuracy need not be carried to such a degree of minuteness that it cannot be shown on the chart; for, after all, the principal object of a *chart* is to show the soundings; and enough care has been bestowed on the land-marks if their positions are ascertained with sufficient precision for soundings. Of course circumstances occasionally arise when, from other causes, it may be advisable to modify this arrangement, but not for the purpose of navigation.

Capt. Wharton appears to have kept these objects steadily in view in writing his work. The work commences with a description of the instruments used in nautical surveying, which, although previously given by Heather and by Simms, cannot be considered out of place, and then gives a description of marine surveying in general, afterwards entering into particulars. We regret that in the description of the sextant the important errors of centering and graduation have been overlooked.

We much commend the following remark at p. 54, too often ignored by surveyors:—"The accuracy necessary in many details of a chart depends very much upon its scale. Over-accuracy is loss of time. Any time spent in obtaining what cannot be plotted on the chart is, as a rule, loss of time."

Of course the scale on which a survey should be executed should be settled after due consideration. It is evident that an inaccessible coast, off which there is deep water, does not require the same accuracy of delineation as a coast studded with bays and harbours, or off which numerous dangers exist; or those portions of the globe little frequented by shipping the same care as the coasts of the United Kingdom. These points must to a great extent be left to the officers in charge of a survey, but the scale once settled no time should be wasted over details which cannot be shown on that scale.

Capt. Wharton's remarks on soundings are excellent. There is no doubt that this, the most important work of the marine surveyor, is very monotonous. To sit in a boat day after day, from early morn to dewy eve, marking in a book soundings and angles, with the salt from the spray drying up one's skin, and the sun blistering one's nose requires more than ordinary zeal, patience, and perseverance; and only long practice enables the surveyor to really take an interest in this work. Young surveyors should, however, remember, that every other detail is subordinate to this, and that until they can really sound, thoroughly, over a given patch of ground without loss of time they cannot be considered masters of the profession.

Capt. Wharton's remarks on obtaining latitudes and running meridian distances are excellent. We think indeed that, in the latitude, the same results might be obtained with less figures, but it is by no means easy to draw a hard and fast line.

In the remarks on tides, no mention is made of the importance of referring the result obtained to a fixed mark on the shore, nor any observation as to the diurnal inequality, and consequently the necessity of, on all occasions, when practicable, registering both day and night tides. In the Eastern Archipelago the diurnal inequality is in some places 4 to 5 feet, and in Australia the mean tide level also differs at different times. These facts appear to have escaped Capt. Wharton's notice, but probably will be inserted in another edition.

In the remarks on searching for Vigias, and ascertaining the position of a ship at sea, Capt. Wharton seems to think accurate observations cannot be obtained, as he asserts the position of a ship to be doubtful to three miles.

On this point we must differ from him, as long experience has proved, to our own satisfaction, that provided the weather is fairly clear the position of the ship can be obtained to half a mile. Nor in asserting this do we rest on single evidence, as Capt. Moriarty, R.N., C.B., in the *Great Eastern*, had no difficulty in picking up the end of the Atlantic cable when it had been slipped from the ship.

The fact is the great error in sea observations is due to the refraction of the horizon, but it must be borne in mind that, excepting in shallow water, this is but slight, and that it can always be corrected by observing on opposite sides of the horizon.

By taking advantage also of the bright planets passing the meridian in the day time good observations can be obtained for latitude and longitude *at the same time* (a great point), whilst the sun is above the horizon, as well as at sunrise and sunset, when by Sumner's method three or more stars can be combined to give the position. We admit that constant practice is required to take these observations accurately, but they *can* be obtained, and as it is very useful to be able to make certain of a ship's position, as often as possible, all officers should practise themselves in observing both Venus and Jupiter with the sun above the horizon.

Whilst however not agreeing with Capt. Wharton on some few points, we think his work will be found most useful, not only for young officers taking up surveying but also as a book of reference for older surveyors, and personally feel much obliged to him for combining in one volume so many useful remarks and tables which have hitherto been only in MSS. or pamphlets.

THE HORSE IN MOTION

The Horse in Motion as shown by Instantaneous Photography; with a Study on Animal Mechanics, founded on Anatomy and the Revelations of the Camera, in which is demonstrated the Theory of Quadrupedal Locomotion. By J. D. B. Stillman, M.A., M.D. Executed and Published under the Auspices of Leland Stanford. (London: Trübner and Co., 1882.)

THE above is the somewhat long title of a large and important work issuing from the well-known Cambridge (U.S.) University Press. Long as is the title, the name of the principal contributor to the volume is left unrecorded there, though indeed even a cursory glance over its contents shows how much indebted is the whole question of the mode of motion in the horse to the elaborate series of investigations of Mr. J. Muybridge.

Leaving aside the anatomical and teleogistic arguments of Dr. Stillman, as contained in some hundred pages of letterpress, we cull from a postscript to the same the following interesting information, which we give as we find it in the book. Some time in 1872, Mr. L. Stanford, of Palo Alto Farm, in California, had his attention called to the very controverted question as to the action of a trotting horse, and conceiving the idea that the photographic camera might be made available to illustrate the action, he, according to the authority before us, consulted with Mr. Muybridge and induced him to undertake some experiments in instantaneous photography. Some ten years ago, a photograph taken in the space of the one-twelfth of a second was considered quite a success, and it would seem that the experiments made then by Mr. Muybridge were inconclusive. In 1877 Mr. Muybridge, however, renewed his experiments. A few pictures were taken of "Occident," a noted trotter belonging to Mr. Stanford, while he was in motion, and one of these, representing the horse with all his feet clear of the ground was enlarged, retouched, and distributed. This result was so extraordinary and so successful, that it was determined to try others on a more extended scale. It was assumed that if one picture could be taken instantaneously, an indefinite number might also be taken, and so the various positions assumed by the horse in a single complete stride could be illustrated.

Mr. Muybridge was authorised to procure the needed apparatus, and a building suitable to the purpose was erected on Mr. Stanford's farm. By 1878 preparations were complete, and every resource of the photographic art had been provided. Twelve cameras were placed in the building at intervals of twenty-one inches, with double shutters to each, and these shutters were so arranged that the whole series of exposures were made in the time occupied by a single complete stride of a horse. The very ingenious mechanism invented by Mr. Muybridge it would be impossible to describe without the assistance of illustrations, but it may be stated that he was thereby enabled to double the number of his cameras, and the whole of the large series of twenty-four figures each, which are used to illustrate this volume, were taken by him. They were very accurately taken, and the heliotypes are perfect transcripts of the original photographs.

Thanks to the zeal and energy of Mr. Muybridge, and the liberality of Mr. Stanford, we are now enabled to see for ourselves the various attitudes assumed by a horse in running, trotting, leaping, and the result is most strange. It would seem as if most civilised nations had failed to recognise the true action of this noble quadruped, as if all had settled down into being content with a conventional idea of how a horse in motion ought to be represented. Now our artists will have no excuse; they can directly interrogate nature, as represented to them in these silhouettes, no doubt at first they may follow her with fear, for some of the positions look strange, not to say grotesque, but soon both artist and the public will have learnt to recognise the truth: and once this is so, the old style will be in its turn regarded as grotesque, and as representing but an early stage in the development of art.

Mr. Muybridge's photographs will be of immense importance to all art students, and they should be attentively studied by all admirers of the horse. A few other photographs are given in this volume of the various stages of motion in the cow, dog, deer, and boar.

OUR BOOK SHELF

Unexplored Báluchistán: a Survey of a Route through Mekrán, Bashkurd, Persia, Turkistan, and Turkey. By Ernest A. Floyer. (London: Griffith and Farran, 1882.)

AN entertaining book of travel, but by no means an exploration of "Unexplored Báluchistán," as is indeed sufficiently evident from the sub-title. Nevertheless, Mr. Floyer has investigated and partly solved some interesting geographical questions in the little-known province of Bashkurd (Bashakard), on the Perso-Mekrán frontier, which he visited on two separate occasions during the years 1876-7. This region, which had been merely skirted by Goldsmid, Lovett, Ewen Smith, St. John, and others connected with the Perso-Balúch Boundary Commission of 1872, and with the development of telegraphy in Persia and Mekrán in 1873-4, was ascertained to comprise six separate territories or districts — Gavr and Pa.ment in the east, Jagda in the west, Marz and Pizgh north and south respectively, and Daroserd with the capital, Angurhán, in the centre. The town, which appears to be a place of great natural strength, was found to lie in 26° 40′ N. lat., 57° 55′ E. long., or about thirty miles from the position assigned to it on Major St. John's map. The Aphen-i-Band range, between Daroserd and Pizgh, was crossed near its western extremity, and ascertained to run east and west under 26° 30′ N., at a mean elevation of 3600 feet, the culminating point of the whole province being apparently the Gu-Koh peak (6,400 feet) in the Parment district.

A survey of the Ab-washur water-parting, between Bashkurd and Hormuz Strait, considerably reduced the supposed eastward extension of the Mináb basin, and showed conclusively that it was in no way connected with the Bampur River, which many geographers have hitherto made to discharge through the Mináb into the Persian Gulf. Mr. Floyer now argues with much force that the true outlet of the Bampúr is the Sadích (Sadaich), which reaches the coast in 58° 40′ E., in the Gulf of Omán, and which seems to flow from the Shahri country, through the Shimsani Pass, in the Band-i-Marz range. He found that where he crossed the Haliri in 28° N., 57° 40′ E., it was already a considerable stream, 90 feet broad, and $4\frac{1}{2}$ feet deep. The furthest head-waters of this important river, of which next to nothing was previously known, are in the Jemal Bariz range, whence it flows in a south-easterly direction to the Rudbar and Shahri districts. Here it would be almost necessarily joined by the Bampúr River, coming from the north-east, and the united stream, whose further course has hitherto remained an unsolved problem, would appear to flow thence through the Shimsani Pass southwards to the Sadích. Hence the Sadích would seem to be the lower course of the Haliri-Bampúr, thus draining nearly the whole of the region in south-east Persia, between 57°–61° E., and 25° 30′–29° N. But this interesting point cannot, of course, be finally determined without a more thorough exploration of the Rudbar and Shahri districts between Bampúr and the Ab-washur water-parting.

The work, whose chief fault is its misguiding title, is written in a pleasant, vivacious style, and contains much useful information touching the ethnical, social, and linguistic relations of the Balúchi tribes on the Perso-Mekrán frontier.

A. H. KEANE

A Synopsis of Elementary Results in Pure and Applied Mathematics: containing Propositions, Formulæ, and Methods of Analysis, with Abridged Demonstrations. By G. S. Carr, B.A. Vol. i., Section ix. (London: C. F. Hodgson and Son, 1882.)

IN our notices of the previous sections we have sufficiently indicated the scope of this work. The present section is devoted to the integral calculus, and takes up its numbered articles at 1900, and closes at 2997: the pagination being pp. 313–440 of part ii. of vol. i. The same honest work, for which we have already commended the author, is conspicuous here, and the utility of having such a handy manual on the calculus is evident. It would be impossible to furnish here the results of a thorough examination of the text; the preparation for such a task would take up a very long time; but we would recommend a testing of the several parts to which a reader may have occasion frequently to refer, so that the book might be consulted with full confidence. We are glad to find that the likelihood of the occurrence of such errors as we mentioned in our notice of the first part, is reduced to a minimum by the very careful method of revision now adopted by Mr. Carr. We have much pleasure in commending this new section to the notice of our mathematical readers.

A Collection of Examples and Problems on Conics and some of the Higher Plane Curves. By Ralph A. Roberts, M.A. (Dublin: Hodges, Figgis, and Co., 1882.)

THESE Examples will serve as an excellent compendium of results to a student who is working through Dr. Salmon's Treatises on Conic Sections and on the Higher Plane Curves. In fact it was whilst the author was reading the above-named works that he conceived these useful illustrative exercises. Mr. Roberts shows himself to be an apt mathematician, and to have a very extensive acquaintance with the classes of curves considered. These are mostly curves of the second, third, and fourth orders. The Problems have been, in general, suggested by Dr. Salmon's treatises and by Dr. Casey's Memoir on Bicircular Quartics: Mr. Roberts also acknowledges his indebtedness to Darboux's Sur une classe remarquable de courbes et de surfaces algébriques. Occasional explanatory matter is thrown in here and there, and concise proofs are given in several cases. As the text-books contain a limited number of examples, this work will be a useful supplement to them. We like almost everything about the book except the paper, and that appears to us to be of a very inferior character.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Recent Unseasonable Weather

IN view of the recent unusually cold weather in England and Scotland, which has been so well described and proximately explained in last week's NATURE, the following paragraph, extracted from the *Standard* of June 15, appears to me highly suggestive, especially as regards one of the probable causes for the "unwonted high pressures" on the northern side of the depression which is accused of being the immediate source of these unseasonable conditions:—

"News from Iceland states that the Spitzbergen floe-ice surrounds the north and east coast, entirely preventing navigation. A Norwegian steamer endeavouring to reach Bernfiord, on the south-east coast, last week, was caught in the ice and had to put back. Owing to the presence of these immense ice-fields vegetation has made no progress, causing a great loss of horses and sheep through starvation. Epidemics of measles and small-pox have been introduced into the island from Europe, and are making extensive ravages among the population; the former is especially prevalent in Rejkjavik."

Now it has been ascertained with some considerable degree of certainty by Messrs. Blanford and Eliot, the Government meteorologists in India, that a heavy winter snowfall over the North-west Himalaya exercises a marked and prolonged influence in lowering the temperature and elevating the atmospheric pressure and thereby directly affecting the winds and weather, over the whole of Northern India, and parts of Central India; and indirectly to a much greater distance. Turning to Europe, we find the distance from Rejkjavik, on the west coast of Iceland to London is about 1140 miles, or about the same as from Lahore to Calcutta (1080 miles), while from Cape Horn on the east coast of Iceland to Edinburgh the distance is only 750 miles, or about the same as from Calcutta to Agra. To any one familiar with Indian weather charts or the meteorology of that country, it would appear absurd not to attempt to correlate the meteorological conditions at places so comparatively near as the above-mentioned towns; and in fact experience has shown that the meteorology of the Punjáb is not only intimately connected with that of Lower Bengal, but also with that of Southern India. If therefore it has been found that an abnormally heavy snowfall in the North-West Himalaya, such as that which characterised the winters of 1876-77 and 1877-78, exercised a marked effect on the meteorology of Northern India, which was felt at places situated 1000 miles or more from the seat of action, may it not be reasonably inferred that the presence of a large mass of ice or snow in the Icelandic area would be likely to give rise to similar atmospheric conditions over these islands? It seems therefore not at all improbable, that the abnormal weather during the past few weeks may be directly due in some considerable measure to the coincident appearance of large masses of ice off the eastern coasts of Iceland, like those which, from the account in the *Standard*, appear to be at present prevailing to an unusual extent.

In the case of India an abnormally heavy fall of snow in the

Himalayan zone is found to be associated, not only with the subsequent conditions already named, but also with an *initially*, and therefore according to experience *subsequently* weak southwest monsoon, which in its turn invariably causes local, if not general drought and famine. These heavy snowfalls are found to have a tendency to recur at the minimum sun-spot epochs, and are proximately due to some condition of the upper anti-monsoon current, at present not exactly known, by which a larger amount of vapour is deposited in the winter, on the Himalaya as snow, and on the North Indian plains as the "winter rains."

It does not appear that we can so readily account for the occurrence of the present ice-floes off Ireland or for the large masses which have been encountered this spring in the Western Atlantic. They must however to some extent be due to the unusually warm winter which seems to have prevailed pretty uniformly over the North Atlantic and North-West Europe, and which has detached a larger proportion than usual of the Arctic ice-fields. And though it is improbable that we shall find any such regular periodicity in the amount of these ice-floes in the Atlantic as in that of the Indian winter snows and rains, it is worthy of notice to observe that they have a decided tendency to occur to an unwonted extent about the times of maximum sun-spot—like the present. Thus Prof. Fritz, of Zurich,[1] gives the following as the list of years in which floating ice was found most abundantly in the lower latitudes of the North Atlantic:—

Years of greatest frequency of floating ice.	Epochs of maximum sun-spot.
1789	1788·1
	1804·2
1816–18	1816·4
1828–29 1831	1829 9
	1837·2
	1848·1
1862–64	1860·1
1868 1869	1870·6

It is also interesting to notice that in 1862 Heis's "Wochenschrift" mentions that the floating ice-masses in the Atlantic caused "a noticeable cooling of the weather in *June* over Europe." And it is further significant to find in a detailed list of the ice met with every month in the Atlantic by ships belonging to the North German lines from 1860 to 1869, that 1868 and 1869 (the year in which similar weather to the present is mentioned as having been observed by the writer of the paragraph in NATURE) were the years in which the greatest quantity of ice was encountered. Though I agree with Dr. Hann in attributing more importance to the *tropical* than to the *polar* area, in influencing the *general* weather of these latitudes, I think it very probable on theoretical grounds that we are relatively more influenced by the *latter* area in *summer* and by the *former* in *winter*, and that just as it has been inferred that the regular recurrence of periods of diminished temperature in Europe, is due to the regular movements of the ice in the polar area so we may reasonably conclude that abnormal movements of the ice, especially in the Spitzbergen area, are likely to produce periods of abnormal coolness such as that which at present prevails. In any case the moral to be drawn, if we really do intend to solve the weather problem, is by all means to have a meteorological station in Iceland, and endeavour to study the weather as we are fortunately able to do in India, on a *large scale*, instead of merely confining our attention to the minute range of conditions we are able to observe within the limited area of these islands.

E. DOUGLAS ARCHIBALD

The Analysis of the Tuning Fork

IN NATURE last week there is a short description of Mr. W. F. Stanley's well-devised experiments, by which the tuning-fork "is shown not to depend upon a vibrating ventroid."

Few persons would readily obtain the experimental steel rod, or would care to attempt the feat of sawing through the bend of the fork down into the stem, and some musical readers may like to know that (missing, of course, the pretty effects) there is a less arduous way of arriving at the conclusion to which Mr. Stanley has directed attention. By very simple experiments I have been accustomed to show that Chladni's analysis, as generally accepted, is not in all particulars borne out by the evidence of facts. If a vibrating tuning fork is held in its upright position by means of a knife-blade passed through the prongs, pressing upon the inner bend so that the stem is in contact with the table, without its being held by the fingers, there will be a communication of vibrations fully as strong as when held in the usual manner, with variation of intensities according to differences in the degrees of pressure. In this experiment the fork at its bend is subjected to pressure both above and below. The argument, therefore, is that the existence of a segment in transversal vibration, occupying the bend of the fork as figured in Chladni's analysis, is incompatible with the evidence. As in all musical instruments, the communicating of transversal vibrations from one solid to another is invariably through the nodes, and as segments are always destroyed by firm pressure, it seems clear that the analysis should be amended. If a vibrating fork is drawn across a stretched string with pressure, the prong passing from the bend towards the point or end, the integrity of the vibrations of the fork is not impaired, and there is but a slight transference of vibration to the string; but it is otherwise with respect to a stretched wire, as when the prong comes into contact with the wire, its vibrations cease; the wire will not be subordinated to the coercive activity of the prong as the string is; yet if the fork is placed with the prongs astride the wire, so that the bend, at the seat of the alleged segment, rides upon the wire, the wire readily conveys the vibrations, and acts as a sound-post. It may be shown that the stem of the fork acts likewise as a sound-post, since we may substitute a free stem; if a vibrating fork is held by the stem, and if through the prongs another fork has the shoulder of its stem pressed upon the bend, then, when the point of this second stem is brought into contact with a solid, the vibrations of the fork are transmitted through it from the bend, with nearly the strength of tone as would be produced by the original fixed stem. The stem itself may be dispensed with as a part of the system, for if the fork is held so that the external part of the bend, where it joins the stem, is pressed against the edge of a table or other solid, its vibrations are not interfered with; neither is the strength of tone diminished, except as in each of these instances, varying in the usual way according to the degree of pressure.

HERMANN SMITH

June 19

"Combing" of Waves

ALL who have watched waves breaking on the sea-shore must have noticed the furrowed or "combed" appearance of the back of a wave as it curls over. If the water is not much disturbed by wind, it is seen, on attentive watching, that this "combing" appears suddenly, and begins at the advancing edge of the crest, and spreads backwards. With small waves a foot or so in height and of long extended front, such as are seen in shallow water, it may be observed that the crest, which in this case rolls down the front of the wave, is at first smooth and even, while the back of the wave is also smooth and unfurrowed, but the edge of the crest suddenly becomes crenated, and almost simultaneously the combing appears on the back of the wave, travelling rapidly backwards from the crenated edge. Moreover a considerable length of the wave appears to be similarly affected almost at the same instant. With larger waves, whose crest falls rather than rolls upon the concave front, I have observed that the edge is at first smooth and even, but that it suddenly becomes uneven, and often fringed with a row or rows of drops, and that at the same instant the combing appears. In both cases, if there is much wind, the regularity of the phenomenon is disturbed, and observation is in other ways rendered difficult. The action is so exactly parallel to something which takes place in the splash of drops, and which I have described in detail in a paper recently read before the Royal Society (see *Proc. Roy. Soc.*, No. 218), that I think your readers may be interested in a brief statement, with special reference to this more familiar case of waves, of the explanation there put forward. The explanation amounts to this:—It is well known that a long cylinder of liquid is unstable, and will, if left to itself, at once tend to split into a row of equal, equidistant drops; the splitting being effected by a constriction of the cylinder in certain places, and a bulging out in others. Again, if a mass of liquid is bounded by an edge whose surface is approximately a portion of a long cylinder, there is good reason for supposing that this cylindrical edge will be subject to similar laws of stability, and that it will tend to cleave in the same way, the surface being forced in in certain places, and out in others. Now a wave's crest presents such a cylindrical edge.

---

[1] In his work, "Ueber die Beziehungen der Sonnen flecken-periode zu den Meteorologischen und Magnetischen Erscheinungen," p. 175.

It will, therefore, of itself, cleave in the way described, and the flow of water will thereby be hindered at the constrictions, and aided at the places of bulging out. Thus lines of easiest flow will be set up, which in their turn will determine the furrows on the back of the wave. The fringe of drops is due to the splitting in a similar manner of the cylindrical jets shot out from the places of bulging, where the flow is aided. Indeed, much of the seething at the edge of a wave is, I think, attributable to the breaking up of such jets in this manner. In the case of the minute phenomenon of a drop-splash, I have been able, in some degree, to bring this explanation to the test of measurements, which, so far as they go, quite confirm it. The regularly-toothed edge of a spot of candle-wax that has fallen on a cold object, affords in a permanent form a familiar illustration of the same action.

Clifton College, Bristol, June 20

THE SEAL ISLANDS OF ALASKA[1]

TEN years have only just elapsed since the Government of the United States of America obtained by treaty the territory of Alaska, including the seal islands situated off its coast in the Bering Sea, and at that time although the sealskin trade occupied thousands of hands, and had done so for at least a century previous, yet next to nothing was known of the animal producing the skins, and there was not, even in the museum of the Smithsonian Institution, a perfect skin and skeleton thereof. This state of things has happily now vanished, and through the joint action of Prof. Spencer Baird and the Secretary of the Treasury of the United States, Mr. Henry W. Elliott, was enabled to visit the Pribylov Islands in 1872, and we cannot but admire the zeal and energy which enabled him to reside in these dreary and desolate places all through the seasons of 1872 to 1874 inclusive. While a brief digest of Mr. Elliot's notes were published in 1874, it is only now that he has been enabled to publish a complete monograph on the subject, an emended copy of which, reprinted from the Report on the Fishery Industries of the Tenth Census at Washington in this year, is now before us. It forms a quarto volume of some 176 pages, and is illustrated by two maps and twenty-nine plates of subjects from the author's pencil. The writer's opportunities for observation, it will be noticed, were especially good. The previous observations of Stellar and others left much to be desired. The geographical distribution of the Arctic fur seal (Callorhinus) is very peculiar. In the Arctic waters of the Atlantic they have not been found, in the corresponding waters of the Pacific they are virtually confined to four islands in Bering's Sea, namely St. Paul and St. George of the tiny Pribylov group, and Bering and Copper Islands of the Commander group. On the former two they swarm. On the latter two, though the larger in area, the seals do not occur in such quantities. It seems impossible to avoid the reflection here as to the waste of fur seal life in the Antarctic regions, and along the coasts of South America, from which, as a centre, the Arctic forms, probably, originally came. Not a century ago the fur seals rested on the Falkland Islands in millions for hundreds that are to be found there now, and it seems hopeless to expect that a British parliament could, with all its many labours, trouble itself to frame regulations, such as the Russians and Americans have done, with the object of repeopling, even in time, these splendid breeding-grounds which, on the Falklands, lie in the very track of commerce, and which, unlike the Alaskan Islands, have beautiful and safe harbours.

The Pribylov Islands were discovered by the hardy navigator whose name they bear, in 1786, and one of the islands is called after his sloop, the *St. George*. He took possession in the name of Russia. Almost striking against the island in a fog, the sweet music to his ears of numerous seal rookeries was wafted towards him. For a little time he kept his secret; but he was soon watched, and his treasure had to be shared with others. These islands lie in the heart of Bering Sea; they are just far enough south to be beyond the reach of permanent ice-floes, upon which the Polar bears could have reached them. Fog banks shut out the sun nine days out of ten during summer, and the breeding season. By the middle of October strong, cold winds from the Siberian Steppes sweep across them. By the end of January great fields of sludgy, broken ice bear down on them; and from December to May, or June, they lie ice-bound. It is owing to this constant, cold, moist, shady, gray weather, that these islands are frequented by such millions of the fur seals. Let the sun but shine out, and the temperature rise to 60° F., or 64° F. in the shade, and both seals and natives are at once incommoded by the glare and heat. During the winter of 1872-73 Mr. Elliott, while watching with all the impatience which a man in full health and tired of confinement can possess, to seize every opportunity upon quiet intervals between the storms of sleet, in order to make a short trip for exercise, only got out *three* times, and then only by the exertion of great physical energy. On one occasion the temperature sank to –4°, and the wind velocity, as recorded by one of the Signal Service anemometers, was at the rate of 88 miles per hour. This storm lasted for six days. The average summer temperature is between 46° and 50° F. in ordinary seasons. The cloud effects are, as might be anticipated, something wonderful, but the aurora is scarcely to be seen. The islands are of volcanic formation; their vegetation seems interesting, and algæ (seaweeds) seem to abound. This is the weakest part of the author's report, and it would be well worthy of the Smithsonian Institute to have the whole flora of these islands carefully investigated. Only a few very hardy vegetables are raised on St. Paul's. As yet, rats seem not to have landed on the islands, though mice have become troublesome, and the cats brought to keep the mice in order, have by inordinate indulgence in meat (seal) eating, become wonderfully altered; they are described as "stubby balls," having become thickened, short, losing the greater portion of their tails (in the second and third generations), and their voices are altered into a prolonged, fearful cry, that surpasses anything ever heard in these countries. So bad is this caterwauling, that it even at times arouses the wrath of the sluggish Aleutians. Foxes and lemmings abound on St. George; the latter are not found at St. Paul's. Birds abound, and though fishes are scarce, invertebrate life in the waters of the group seems abundant. The "natives" of the island were about 400 in number in 1880, of whom some eighteen were whites (Russian), and the rest Aleutians. The births never equalled the deaths, but they are constantly being recruited by the Alaskan Commercial Company. Now-a-days the people are comfortably housed and well clothed. Seal meat is their staple food; and by the regulation of the Treasury they can kill, every autumn, an average of twenty-three to thirty young seals for each man, woman, and child in the settlement. As each pup averages ten pounds of good meat, this would show an average of about 600 pounds of flesh meat for each. To this diet they add butter, sweet crackers, and sugar. They are passionately fond of butter. No epicure could appreciate good butter more than these people, and the sweetest of all sweet teeth are to be found in the jaws of an Aleut. The Company allows them fairly liberal supplies of these, also rice and tobacco. As an illustration of the working ability of the natives on the seal grounds, the following shows the actual time occupied by them in finishing up the three seasons' work which Mr. Elliott personally supervised on St. Paul's Island.

In 1872, 50	days' work of	71	men secured	75,000	skins.
In 1873, 40	,,	71	,,	75,000	,,
In 1874, 36	,,	84	,,	90,000	,,

---

[1] "A Monograph of the Seal Islands of Alaska," by Henry W. Elliott. Reprinted, with Additions, from the Report on the Fishery Industries of the Tenth Census (U.S. Commission of Fish and Fisheries). Washington, February, 1882.

This shows the increased ability and consequent celerity of action among the natives.

Here it may be mentioned that by an Act of Congress the exclusive right of taking a certain number of fur seals every year for a period of twenty years on these islands was granted to the Alaskan Commercial Company of San Francisco, subject to certain reservations and conditions. The Company seem to have done far more than they were actually by law required, and the benefit to the people has been no less great than to the Company ; and where it was simply impossible under the old state of things to collect the lawful quota of 100 000 seals' skins annually in less than from three to four working months, it is now done by the same amount of hands in less than thirty days, and so the whole of the skins are preserved at their prime, and it is rare that any of them are unfit to be sent to London, whereas in comparatively recent years, often as many as three-fourths were rejected ; comment on such an altered state of things is needless. Here it may be interesting to note that almost all the raw seal hides are sent to London, from whence, when dressed, they are distributed all over the civilised world where furs are worn. Our reader will surely know that the sealskins as worn by the seals and as offered for sale by the furrier are very different-looking objects. Instead of the sleak, glossy coats familiar to us, the sealskin when on its own owner's back is a very unattractive thing, the fur not being visible, but hidden away under a coat of stiff overhair, which is of a dark gray brown or grizzled colour. Not only is this hair removed, but the whole fur is dyed.

The seal life on the Pribylov group consists not only of the fur seal (*Callorhinus ursinus*), but also of the sea lion *Eumetopias Stelleri*, the hair seal (*Phoca vitulina*). and the walrus (*Odobænus obesus*). Of these it is only the first that is of any commercial value ; but in this work we have some very interesting sketches of the life and manners of the others, and some very characteristic portraits. As our space will not allow us to refer in detail to these, we may here mention the fine figure of an old male walrus, being a life study, forming Plate 21, and the figures of the sea lions on Plate 16. The life studies of the common hair seal on Plate 4 are also very excellent ; this animal, so common in the Atlantic, would appear to be rare in the North Pacific. Although the skin of the sea-lion has little or no commercial value, yet to the natives it is most valuable ; it supplies them not only with its hide and flesh, but they also utilise its fat, sinews, and intestines ; its very lip bristles are in great demand in China for pickers to the opium pipes, and for several ceremonies peculiar to the joss houses. The walruses are of little value unless for their hides ; these are used for covering the frames of boats, and when the latter are thoroughly and constantly attended to they form the best species of lighter that can be used on the islands, standing more thumping and pounding than any sort of a wooden boat or even than a corrugated iron lighter.

It is, however, the history of the fur seal that will chiefly interest the readers of this volume. It repairs to these islands to breed and to shed its hair and fur, in numbers that seem almost fabulous. It seems to be an animal of wonderful instinct ; indeed, our author thinks that few, if any, creatures in the animal kingdom exhibit a higher order of instinct. A male, when in his prime, about 6 or 7 years of age, will measure 6½ to 7¼ feet in length from the tip of his nose to the end of his little tail, and will weigh from 400 to 600 pounds. Its muzzle and jaws are about the same size and form as those of a full blooded Newfoundland dog, only the lips are pressed against one another as in man ; on either side of the muzzle are an expressive pair of large bluish hazel eyes. In one of the plates there is a very excellent portrait by the author, of an old male. When the fur seal moves on land, it may be almost said to step with its fore feet, but it brings up the rear of its body in a quite different style, for after every second step ahead with the anterior limbs, it will arch its spine, and in arching it drags and lifts up and brings forward the hind feet to a fit position under its body, giving it, in this manner, fresh leverage for another movement forward by the fore feet, in which movement the spine is again straightened out. If it be frightened, its abandons this method. "It launches into a lope, and actually gallops so fast, that the best powers of a man in running are taxed to head it." This rapid progress it can only keep up for some thirty or forty yards at most, then it sinks to the earth, gasping and breathless. The adult males are always the first to arrive on the seal-ground, which has been deserted by all of them since the close of the preceding year. These arrivals begin about May 1. Not the oldest, but the most ambitious, land first. Up to June 1 more seals arrive, but about this period the seal weather begins—foggy and moist ; and as the gray banks roll up and shroud the islands, the bull seals swarm out of the depths by thousands, and take up advantageous positions. The labour of locating and maintaining a position on the rookery is a terribly serious business for the late-coming males, as it is throughout all the time to those males that occupy the water-line of the breeding-grounds. A constantly sustained fight between the new comers and the occupants goes on morning, noon, and night without cessation, frequently resulting in death to one, and even to both the combatants. This fighting is done with the mouth. The sharp, canine teeth, tear out great masses of the skin and blubber. One old veteran, specially watched, took up his position on the water-line early in May. He had to fight from forty to fifty desperate battles ; and when the fighting season was over he was there, covered with scars, and frightfully gashed, raw, festering, and bloody, with one eye gouged out, but lording it still bravely over his harem of some fifteen or twenty females. These seals are profound sleepers, so much so that one, cautiously keeping to the leeward, and stepping softly, would find it easy to approach near enough to pull the whiskers of any old male ; but on the first touch the trifler must be prepared to jump back with electrical celerity, if he has any regard for the sharp teeth and tremendous shaking which would await him. On young seals the trick may be played with impunity, but to the great terror and confusion of the little sleepers. While the females and young have but one note, a hollow prolonged bla-a-ting call, addressed to their young : the bulls have the power of uttering four distinct calls or notes. They seem to suffer misery from a comparatively low degree of heat. From the time of the males landing, until the close of the season—about three months—they never leave the stations they have secured for a single moment, and of necessity they abstain during all this time from food of any kind, or water. It is no wonder, therefore, that after such a fast they return to the sea mere bony shadows of what they were.

About the middle of June the females arrive, and, bad as the fighting among the males has been up to this to secure good stations on the land, it is now ever so much worse for the possession of the cows. These latter are much smaller and more lithesome than the males, seldom over 4 to 4½ feet in length. Their heads and eyes are exceedingly beautiful ; their expression is gentle, intelligent, and attractive. The females land on the "rookeries" for the purpose of gestation, and the young are born very soon after the arrival of the females. The females are received by the males on the water-line stations with attention ; they are alternately coaxed and asked up on the rocks, as far as these beach-masters can do so, by chuckling, whistling and roaring, and once up they are immediately under the most jealous supervision ; but owing to the covetous and ambitious nature of the bulls which occupy those stations to the rear of the water-line ones and some way back, the little cows have a hard time of it at the first and when they are few, for no sooner is one pretty creature fairly established in the station of male number one, who has got her there, than he perhaps sees another of her style in the water from whence she has come, and he devotes himself to coaxing the later arrival by the same winning methods so successful before; whereupon bull number two, one station in the rear, observing bull number one to be off guard, reaches out with his long, strong neck, picks up the passive cow by the scruff of her neck, just as a cat does a kitten, and deposits her upon his ground; and this will happen again and again until the little cow will finally find herself several stations back. Her last lord not being exposed to the same temptations as lie on the water level, gives her such care that not only could she not leave if she wished, but no other bull gets a chance of seizing her. When the females have all landed and the harems are full, it would seem that those nearest the water may contain on an average from fifteen to twenty females, those in the rear from five to twelve. The courage of the fur seal is of the highest order. As regards man, it is invariably of a defensive character. Though always on the defensive, he never retreats, but he will not attack; the cows, however, are easily frightened and are timorous. Shortly after the females are landed, the young are born; they are for the first three months of a jet black colour, are about fourteen inches long, and weigh about four pounds. It would seem that they are nursed only every second day, the mothers going off to the fish grounds to get a supply of food, but they may also return to suckle their young at night. When returning in the daytime, each mother at once recognises her own young, though there may be thousands upon thouands all together blaating at once. Before entering into such a crowd, the mother stops and calls out, just as a sheep does for a lamp, and out of all the din she then recognises her offspring's voice, and makes direct for it; but it would seem that the young ones do not often know their own mothers.

Early in August the young seals, now about six weeks old, are taught to swim. If dropped into deep water about this period down goes their bullet-like head, and they are drowned; at first they try their skill in the shallow pools, for a week or two they only flounder about, thrashing the water as little dogs will do. When for the first time they are well launched out they soon turn to the shore, and if by some receding wave they should be left high and dry, they will crawl away for a little distance and, quite exhausted, will coil themselves up to take a short recuperative nap, and then to the swimming lesson again. Once boldly swimming they seem to fairly revel in it. The parents do not in the slightest degree supervise or direct the young in swimming. The young shed their black coat about the middle of October; the second or sea-going jacket, does not at first vary in colour between the sexes, nor does a pronounced difference take place until after the third year. The females bear their first young when they are three years old, and the period of gestation lacks only a few days of a year.

The great herds of "bachelor" seals, numbering perhaps one-third to one-half of the whole aggregate of the 5,000,000 seals known to the Pribylov group, are never allowed under the pain of death to put their flippers on or near the rookeries. These are the seals of most importance to commerce, for with the exception of a few thousand young ones and an odd old male, these are the only ones slaughtered for their hides. They locate them in immense tracts, mostly away from the rookeries, but sometimes the road to these will pass along or through a rookery, where, as long as the bachelors keep to the main road, they are never molested; but if they pry about, it is all over with them, for they are literally torn to pieces. These bachelors are wonderfully gentle, but they are possibly the most restless animals in creation, they never seem quiet, not even in their sleep, they do not fast, as they constantly leave the land for the sea, though this at irregular periods depending a good deal on the weather; on land they sport and roll about as if in perfect enjoyment, curling and uncurling themselves, in fact they seem to be surcharged with a quite joyous life, but when in play they never grovel or bite or seem to show even an angry feeling. It is we have seen very different with them when they are a little older and begin to take upon themselves the cares of a harem. These seals pass a deal of their time in the water, where their gambols are truly wonderful, and the time they can remain under water is, Mr. Elliott writes, "past belief." They are readily, when on land, classified as to age. They shed their fur and hair during August. Passing over a detailed and well illustrated account of the various rookeries, carefully calculated as containing some 3,193,042 breeding seals and their young in 1873, and of non-breeding seals over 1,500,000, and the speculations as to the vast amount of fish consumed by this immense army, we have to notice briefly the chapter on the taking of the seals. Except for food, none but the "bachelors" are slaughtered when their furs are in good trim: the natives get between a herd and the sea, and then gently drive it up to a slaughtering station. In cool and moist weather the seals can be safely moved along at the rate of half a mile an hour; on firm grassy ground three or four men can secure and guide as many as a thousand seals at the same time. They are permitted frequently to halt, rest, and cool, as over heating injures their fur, and so on they go to death, and to supply with their hides the markets of the world. They never show fight, and are as docile as a flock of sheep; the bull seals on the contrary will fight rather than endure the panting torture of travel, so that if any of them get mixed up with a herd of bachelors they are easily let drop out; their fur is of no value. On arriving at the slaughter places the herd is allowed to cool, and then the killing begins; the labour of skinning is severe and trying even to experts; the hide has to be taken off at once. The skins are taken from the field to the salt-house, where they stay for two or three weeks, being pickled; after this they are taken and rolled into bundles of two skins in each package, with the hairy sides out and lightly corded. In this state they go by steamer to San Francisco, where they are counted for the tax, and from thence they are shipped to London.

In a series of illustrative and supplemental notes to this volume, there are a number of very interesting details as to the Russian Seal Islands; as to the Fauna and Flora of the Priblyov Group; a digest of the data in regard to the fur seal rookeries of the South Atlantic and Pacific, and the number of skins taken therefrom. There is a translation of Veniaminov's account of the Russian seal industry at the Priblyovs, 1842; a meteorological abstract for the months from September, 1872, to April, 1873, which was an unusually severe winter; and a history of the organisation and regulations of the Alaskan Commercial Company, under whose excellent management the sealskin trade is now carried on. In concluding a necessarily somewhat brief notice of this excellent monograph, we would congratulate Mr Commissioner Spencer Baird on being the means of obtaining for men of science and of commerce so much valuable information, and we can scarcely give too much praise to Mr. Henry M. Elliott for his most artistic and praiseworthy history of the most interesting of all Pinnipeds.

A DYNAMOMETER FOR ALTERNATING CURRENTS OF MODERATE STRENGTH

THE object of this instrument, which I had the pleasure of bringing before the Physical Society at their Oxford meeting, is chiefly medical. But it occurred to me that a few details, mainly constructive, might prove of interest. It was suggested by Mr. Preece, in consequence of a statement made by me in a paper on "Measurement in the Medical Application of Electricity," read before the Society of Telegraph Engineers. This statement was to the effect that some difficulty still existed in the trustworthy estimation of induction currents of medium strength, such as are habitually used for physiological and therapeutical purposes. The French International Commission had only imperfectly remedied the deficiency by recommending the universal adoption of a particular pattern of induction coil made by a single German firm, and arbitrarily graduated to a "sledge" apparatus. Mr. Preece thought that a dynamometer, which may be regarded as a galvanometer of which the moving magnet is replaced by a suspended coil introduced into the circuit, would answer the purpose; since the deflection of the coil is in one uniform direction, although the currents traversing the circuit are alternate. This very practical hint seemed to offer a prospect of obtaining accuracy in a department of science in which it is much needed. But on examining existing dynamometers I found only Weber's original instrument, which, in spite of its immense value, is fitted only for a well-appointed laboratory, and another, made by Messrs. Siemens for the measurement of very intense electric light currents, which erred on the opposite side of deficient delicacy. The dynamometer of Messrs. Siemens, shown at the French International Exhibition, by means of which the alternating currents of telephones were demonstrated, was probably in the same category, though neither I, nor the president of the Physical Society could obtain any exact details of its internal arrangements.

An electrodynamic balance, described in the *Annalen der Physik* in 1881 by Helmholtz, comes somewhat closer to the requirements of the case, but this, like that of Weber, is a delicate apparatus, difficult of transportation. It might, however, prove excellent as a means of calibrating a less perfect and absolute, but more handy instrument, such as that I was in search of.

Another form of dynamometer had been incidentally named to me by Mr. Ayrton, of his invention, in which the moving coil is replaced by a piece of soft iron which becomes magnetic during the passage of the current. Of this also further details were wanting.

I therefore attempted to make one for myself by the usual method of suspending a coil of wire from two silk fibres within a fixed coil, bringing its two ends to mercury contacts at the lower part, and joining all up in one circuit. Two defects at once appeared. 1. The coil of copper wire was far too heavy to move with the small currents at my disposal; and when it did swing, it continued to oscillate slowly for an unlimited time, giving no satisfactory reading. 2. The mercury contacts caused so much friction as absolutely to stop all motion whatever.

It was therefore obvious that (1) a light coil, and (2) a sensitive bifilar suspension were needed. Both of these must have a fairly high electrical conductivity. The second of these desiderata may be dismissed first. I found at the gold lace shops bobbins of silver-gilt wire, in which the gold is drawn over the silver in manufacture; not merely plated on. These two combined have a diameter of $\frac{1}{500}$ of an inch; which is exactly that of the finest platinum wire commercially made. But whereas the resistance of 1 metre of the latter is 62·2 ohms, that of the former is only 9·8 ohms. An induction shock from Dubois-Reymond's apparatus passed through a metre of this wire has such strength, that I do not wish to try it again, nor should I venture to administer it to an invalid.

It occurred to me that (1) the light coil might be obtained by using fine aluminium wire covered with silk. Messrs. Johnson and Matthey, with their usual courtesy, drew this for me specially, to a diameter of 1-100th of an inch, or even less,[1] and Mr. Rickards, of Derby, completed the operation.

By winding this on a mandril, tying the ring thus obtained with silk threads, and immersing in photographic amber varnish, which I find much less dense, and as good an insulator as Shellac, I obtain a coil composed entirely of metal and silk, which is at once rigid, light, and conductive. One of these, of 1·25 inches internal diamater, not of very fine wire, contains forty-two turns of wire in five layers, its length thus being over four yards. It weighs 6·25 grammes, less than 100 grains, its resistance is about half an ohm.

On suspending this light coil from two threads of the silver-gold wire named above, I found its deflections considerable, and easily measured, even with moderate currents. It could easily be made "dead-beat." The bifilar couple was varied by giving the suspending points a sliding motion to and from each other. By also fashioning the suspensions in the form of light vertical springs, the two threads were kept at an approximately equal tension.

Aluminium appears to offer great advantages for employment in such functions as these. It is said in Watt's "Dictionary," that "the electric conducting power of aluminium is eight times as great as that of iron, and about equal to that of silver," where probably the comparison is intended to be made with equal weights, and not volumes. But even if it were lower, it would be abundantly sufficient for the purpose named, as the currents are of high tension, and as the resistance need not be materially less than that of the suspending wires given above. Its specific heat is very great, so that moderate changes of temperature affect it but little. This property might render it valuable for the fabrication of resistance coils.

It was stated at the meeting that this metal had been tried by Messrs. Siemens, but given up in consequence of the failure of connection in the ends of the aluminium wire. This difficulty I have not found, probably in consequence of the high tension, and also from the fact that the contacts are between gold and aluminium, both stable substances. In any case the difficulty could be overcome by making a gripping contact with a light clamp, such as is already used in watchwork. Nor can Messrs. Siemens' unsuccessful attempt for other purposes be, I think, considered as a distinct anticipation of this. The mechanical advantage of such a light coil in diminishing moment of inertia, and in reducing the force of the bifilar couple, can hardly be denied on theoretical grounds, and is, indeed, borne out by experiment. W. H. STONE

MATHEMATICS AT THE JOHNS HOPKINS UNIVERSITY

FROM time to time we receive copies of the *University Circular*. From two now before us, we make a few extracts, which will serve to show what this young but promising University has done (or attempted to do) in the session 1881-82. The students have been thirty-two in number; of these, twenty followed advanced and University courses, and twelve pursued collegiate courses.

Supreme over the department presides Prof. Sylvester, F.R.S., who, besides editing the *American Journal of Mathematics* and reading papers at the Mathematical Seminary (similar in its character to our own London Mathematical Society), has delivered two courses of lectures—one on the Theory of Numbers (and in especial on an extension of Tchebycheff's theory concerning Prime Numbers), the other on a new theory of universal multiple algebra.

This session on the invitation of the Trustees, Prof. Cayley was called in as *amicus curiæ*, and arrived at

---

[1] The finest wire has not yet been measured in the microscope; it passes through the smallest hole of the B.W.G., No. 80.

Baltimore in December last. At the January meeting of the Seminary, he read a paper "On Two Cases of the Quadric Transformation between two Planes," and has subsequently read other papers, and been a contributor to the *Journal*. But the result of his visit has been the delivery of "a systematic and highly original course of lectures upon Algebraical Geometry, in connection with the Abelian and Theta Functions."

These lectures, we hope, will be given, in book form, to a more extended audience. Besides the ordinary class lectures, given by the able staff of assistant professors, some of whom are well known to mathematicians here, short courses of lectures have been delivered by Mr. C. S. Peirce (who has recently annotated and published in the *American Journal* his father's fine work on "Linear Associative Algebra"), on the Logic of Relatives, by Dr. Story; on the Clebsch-Gordan invariantive theory; and by Dr. Craig, on the Construction and Direction of a Riemann's surface (how these two last courses recall to our minds a departed master.)

Leibnitz somewhere says "Les mathématiques sont l'honneur de l'esprit humain;" if this be so, then the University has done well in assigning so great a part of its time and resources to the study of the higher branches of this department of knowledge. But indeed Johns Hopkins is a true university, for it is catholic in its sympathies, and enfolds in its wide embrace all branches of culture and learning.

In No. 13 is an abstract of a lecture before the students by Dr. James Bryce, M.P., on our English universities.

R. T.

KŒNIG'S EXPERIMENTS IN ACOUSTICS

I.

IN the volume mentioned below[1] Dr. Kœnig has collected the valuable series of researches in experimental acoustics that have been published by him chiefly in the *Annalen* of Poggendorff and of Wiedemann during the past twenty years. Many of these researches are well known in England, having attained to "classic" importance, and their main results are to be found embodied in all the best text-books of acoustics. Other researches of more recent date are yet known only to the few, but will doubtless win their way to general knowledge before long. The most novel points in the book are the late researches of its author with the ingenious instrument known as the wave-siren. This invention Dr. Kœnig has applied to support his views upon the origin of the beats of imperfect consonances, and also to investigate the influence of differences of phase upon the quality of tones. The general nature of the wave-siren has already been explained in the pages of NATURE, but in the sequel we will attempt to describe fully its most recent forms, as applied in the last investigation. In addition to these deeply interesting matters of recent research, there is a mine of wealth contained in the volume. The first chapter deals with the application of the graphic method in acoustics; an equally interesting chapter on manometric flames and their applications occur a little further on. Dr. Kœnig's researches on the standard tuning-fork or "*diapason normal*" are too well known to need comment. The reader will find the whole series of papers collected in Chapter XIII. He will also find notices of an adjustible tuning-fork capable of giving a variety of tones, of a curious tuning-fork clock, of new stethoscopes, of instruments for producing continuous beats audible to a large company of persons, together with researches on the phase of vibration of two associated telephones, on the fixed notes charcteristic of the different vowel sounds, and on several other matters of great importance. He must not, indeed, expect to find deep mathematical insight nor folios of analytical equations. But he will find a perspicuous and fascinating record of experiments planned with rare ingenuity, carried out with honesty, patience, and consummate skill, by the man whose exceptional abilities as experimentalist and constructor have done more than those of any other physicist to make the science of experimental acoustics what it is to-day.

In the present article we shall refer in some detail to Dr. Kœnig's researches on the influence of phase upon the quality of sound.

It has long been an accepted doctrine of acoustics that every continuous sound possesses three recognizable characteristics, viz., *pitch*, *intensity* and *quality*, and that these three characteristics depend respectively upon the frequency, the amplitude, and the degree of complexity of the sonorous vibrations. The third of these characteristics, the *quality* of a sound, has also been denominated "*timbre*" or "*clang-tint*" by those who affect Gallic or Teutonic proclivities in scientific nomenclature. Everyone now knows that, by whatever name this third characteristic is called, it constitutes the almost indefinable yet perfectly recognizable difference which exists between a note as played on one musical instrument and the same note as played upon another. The notes may be the same in pitch and in intensity, but there is a residual difference in quality that the dullest ear cannot mistake.

It was by one of the finest pieces of scientific research by Germany's greatest living physicist, that the true cause of this mysterious "quality" was established. Helmholtz's great work on *The Sensations of Tone* takes for its basis the fact that with every fundamental "tone" or perfectly simple sound there co-exists a whole series of "partial tones," which together with the fundamental make up the mass of sound that we usually call a "note." All our musical instruments yield us complex sounds in which every fundamental is accompanied by a variety of upper partial tones (sometimes called by mistranslation "overtones"; and also, by a far more serious mistake, "harmonics), the number of such upper partials and their relative intensity being a consequence of the conditions of vibration in the instrument. Hence instruments having different kinds of vibrating parts—strings in one, reeds in another, columns of air in another—will emit tones that vary in number and intensity of accompanying partial tones; and the ear taking the mass of complex vibration as a whole will pronounce that there is a difference *in quality*. Helmholtz's theory, in short, asserts that the quality of a tone depends on the following points: firstly, whether there were any upper partials present; secondly, what those upper partials were; thirdly, what their relative intensity toward one another and toward the fundamental note might be. Thus, for example, the thin quality of the notes of wide, stopped organ-pipes, which contrasts both with the full rich quality of the pianoforte notes, and with the harsh, strident, irrepressible notes of the harmonium, becomes intelligible when it is rendered plain that in the first case there is an almost complete absence of upper partials, that in the second the partials, though numerous, are loud only for such partial tones as are concordant with the fundamental, while in the third discordant partials, loud and shrill mingle with the fundamental.

But there is a negative proviso in Helmholtz's theory of a very important kind, namely, that differences in quality of tone depend "*in no respect on the differences in phase under which these partial tones enter into composition.*"[1]

This negative law, which Helmholtz has sought to confirm by various experimental proofs, is a consequence of the hypothesis that the ear unconsciously analyzes complex sounds into their simple elements—the partial tones—each simple (partial) tone actuating a separate part of the nerve-structures of the ear. Before Helm-

---

[1] "Quelques Expériences d'Acoustique." Par Rudolf Kœnig. (Paris: R. Kœnig, 27, Quai d'Anjou, 1882.)

[1] *Helmholtz.* Sensations of Tone (Ellis's Translation) p. 186.

holtz's time, the theory had been propounded that quality depended on the *form* of the vibrations of the wave of sound; but since differences of phase greatly affect the form of the vibration, Helmholtz was forced either to abandon the new hypothesis that the ear thus decomposes complex tones into simple ones, or else to establish by experiment that no difference of phase affected the perception of quality by the ear.

Fig. 1.—Resultant curves formed by compounding together the wave-forms of a harmonic series of simple tones of equal intensity but differing in phase.

The difference of form introduced into a complex vibration by a difference of phase between its components is already known; but Kœnig has brought forward some very striking examples. Fig. 1*a*, for example, gives the curves which result from compounding together the wave-forms of a note and its first eight upper partials, each of the nine tones being of equal intensity. Of the four curves ranged in line the first corresponds to the resultant when the components start at similar phases, each component beginning from zero with descending ordinates. In the second of the row, each of the separate component waves begins with a negative ordinate of maximum amplitude, or differing in phase by one quarter from the first case. In the third the difference is half a wave-length, and in the fourth case three-quarters of a wave-length. It will be noticed how very different these curves are to the eye, though compounded of the same elements. It will also be observed that the curves for

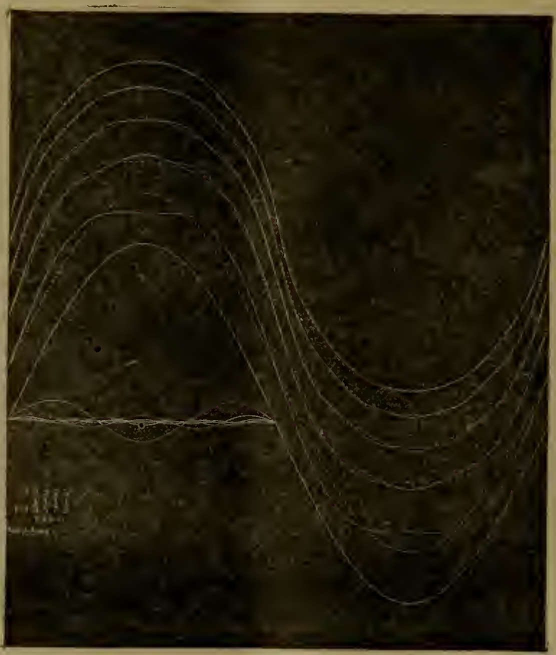

Fig. 2.—Resultant wave-form for odd members of series of upper partial tones when there is no difference of phase.

difference of phase $= \frac{1}{2}$ is a reversed copy of that for which the difference of phase $= 0$; while the curves for phase-difference $\frac{1}{4}$ and $\frac{3}{4}$ are reversed copies of one another Now, according to Helmholtz's theory. all these forms of vibration should yield identical sounds in the ear. Kœnig finds, on the contrary, the startling result that the sounds are perceptibly different in quality. His proof is extremely simple. The curve, calculated graphically with great care, is set off upon the circumference of a cylindrical band of thin metal, the edge being then cut away leaving the shaded portion, the curve being repeated half a dozen times, and meeting itself after passing round the circumference. For convenience the four curves to be compared are set out upon separate rims of metal, all of which are mounted upon one axis to which a rapid motion of rotation can be imparted. Against the indented edges of these rims wind can be blown through an appropriate slit; the whole combination forming a variety of the Wave-Siren described a few months ago in the columns of NATURE (p. 358, vol. xxiv.). It will be obvious that as these indented curves pass in front of the slit the maximum condensation will result when the slit is least covered, or when the point of greatest depression of the curve crosses the front of the slit. The negative ordinates of the curves correspond therefore to condensations, the positive ordinates to rarefactions. Now, according to Kœnig's experiment, the sound is louder and more forcible, with a difference of phase of $\frac{1}{4}$, than in any other case, that with $\frac{3}{4}$ difference being the most gentle and soft in tone; whilst the curves of phase 0 and $\frac{1}{2}$ yield intermediate qualities of tone. Kœnig also finds that by combining simply a note and its octave, the loudest resultant sound occurs when the phase of combination is $\frac{1}{4}$, a difference of phase of $\frac{3}{4}$ again yielding the feeblest resultant. In Fig. 1, *b*, four curves are shown corresponding to the combination of the odd members, 1, 3, 5, 7, 9, of the harmonic series, taken as before as of equal intensity. In this case the form of the waves is identical for the phases 0 and $\frac{1}{2}$ and also for the phases $\frac{1}{4}$ and $\frac{3}{4}$. The latter yield a loud and strident tone as com-

FIG. 3.—Resultant wave-form for odd members of series of upper partial tones when the difference of phase is a $\frac{1}{4}$.

pared with the former, though according to Helmholtz's theory their tones should be alike. It may be objected to these illustrations that in all natural sources of tone one never finds a whole series of partial tones every member of which is equally loud as the fundamental tone. It is more nearly true for most musical instruments that the higher up one goes in the series of partial tones the feebler are they in comparison with the fundamental tone.

Accordingly, Kœnig has combined, as in Fig. 2, a series of partial tones corresponding to the respective frequencies 1, 3, 5, 7, 9, making the amplitude of each partial tone inversely proportional to its frequency. The separate curves are shown in Fig. 2, both grouped about a horizontal line, and also as successively superposed upon the fundamental. The uppermost of the set of curves exhibits the final resultant; which, in this case, where the difference of phase is taken as *nil*, and all the components rise from zero together, is seen to consist of bold, well-rounded sinuosities. In Fig. 3, curves identical in wave-length and amplitude, but differing in phase by $\frac{1}{4}$, are compounded together; but the final resultant shows a wave-form that is practically a zig-zag. Now if these bold sinuosities and zig-zags be cut out in thin metal and curled up into circumferences so as to adapt them to use as wave-sirens in the manner before-mentioned, it is again found that the zig-zags corresponding to differences of phase $\frac{1}{4}$ and $\frac{3}{4}$ yield always harsher and louder tones than the rounded sinuosities that correspond to 0 and $\frac{1}{2}$.

These observations are very remarkable, and have important bearings that must be left for discussion in the next article on Kœnig's work.

For the present we will conclude by observing that more than once it has been pointed out that a certain perception of difference of phase did exist. Sir W. Thomson has suggested that there is evidence of this in the phenomenon of slow beats which by a curious acoustic illusion almost always suggest the idea of something revolving. The writer of this notice had also previously pointed out that in certain cases where a compound sound was led separately to the two ears a difference of phase between the components could be detected.

It may not be generally known that Dr. Kœnig has quite recently republished under the title of "*Quelques Expériences d'Acoustique*" the most important of his recent researches, including those on the Wave-Siren and on the Beats of Imperfect Consonances. The figures herewith presented, and those which will accompany the continuation of this notice, are taken by Dr. Kœnig's courteous permission from this his very valuable contribution to experimental acoustics. S. P. T.

THE RAINFALL OF THE GLOBE

PROF. LOOMIS has recently contributed a paper on this subject to the *American Journal of Science* of no small interest and value. The paper gives the mean annual rainfall at 713 places in all parts of the globe, and the results are graphically represented on a map of the world as closely as can be done by five tints of one colour. These tints represent respectively annual amounts of rain under 10 inches, from 10 to 25 inches, 25 to 50 inches, 50 to 75 inches, and above 75 inches. It is stated that the map is merely a provisional one, it being Prof. Loomis's expressed intention to publish a list of additional observations with a revised edition of the map; and in the meantime he invites the assistance and criticism of meteorologists in furtherance of the work.

The map shows unquestionably the broad features of the geographical distribution of the rainfall of the globe, so that any changes that will be made in a future issue, however interesting and important these may be locally, will only be rectifications of the iso-hyetal lines in some of their subordinate details.

Leaving out of consideration all exceptionally heavy rainfalls confined to limited spots, such as those of Cherapunji, in Assam, which amounts to 492 inches annually, and the Stye, in Cumberland, which is about 190 inches, the heaviest rainfall is met with in the rain-belt which surrounds nearly the whole globe lying between the north-east and south-east trade-winds. Absolutely the largest rainfalls over large regions are to be found where the trade-winds, after having traversed a great breadth of ocean, are forced against and over a breadth of land, of some elevation and extent which lie across their path. Of these the best examples are the highlands of Java, Sumatra, and Assam, in the Old World, and parts of the north of South America, and of the steep slopes of Mexico facing the Gulf of Mexico in the New World, over which the trades or monsoons discharge their moisture so copiously as to raise the rainfall over large tracts up to, and in cases considerably above 200 inches annually. The influence of height is well illustrated by the rainfall of Mauritius; thus, while at the observatory it is 46 inches, it amounts at Cluny to 149 inches on a mean of the same 19 years. Similarly in St. Helena, while near the sea-level it is only 5 inches, at a height of 1764 feet it is 48 inches. In Ascension, no part of which rises to any considerable height, the annual rainfall is only 3 inches, and the whole island is little else than a burned-up desert.

The rainfall is particularly large in mountainous regions in both hemispheres above lat 40°, situated on the eastern shores of the great oceans, and consequently in the full sweep of the strong westerly winds of these high latitudes. Thus large portions of Scotland north of the Clyde, one or two small patches in England, a few spots in Ireland, large tracts between California and Alaska, the south of Chile, and the west coast of the south island of New Zealand have an annual rainfall exceeding 80 inches. Nay, even at Bergen, lat. 60° 23′ N., bathed in the warm, moist, westerly winds of the Atlantic, the rainfall is 73 inches annually, which is the largest rainfall yet observed anywhere at so high a latitude. Those headlands, even though of comparatively small height, which ran out into the sea, meeting the moist oceanic winds, have rainfalls very considerably above the average—owing doubtless largely to the greater friction of land than water on the winds, thus partially arresting their progress, and inducing a more copious precipitation.

As causes of deficient rainfall, Prof. Loomis enumerates five, viz.: (1) a uniform direction of the winds during the year, such as prevails within the regions of the trades, illustrated by the rainfall of Ascension, Sahara, and South California; (2) the prevailing wind having crossed a mountain range, thence descends on the leeside, illustrated by desert of Gobi, Chili, and large tracts in Spain; (3) ranges of mountains so high as to obstruct the free movement of the surface-winds towards the interior, as parts of Central Asia and California; (4) remoteness from the ocean measured in the direction from which the wind proceeds, illustrated by the gradual diminution of the rainfall on advancing eastward into Europe; and (5) high latitudes, since beyond lat. 60°, at a little distance from the ocean, it seldom exceeds 10 inches, and there are apparently large tracts in North America and Asia, where the rainfall is less than 10 inches. As regards this last statement, observation scarcely bears it out, since in Europeo-Asiatic continent, only two stations in latitude the above 60°, viz. Kola in Russian Finland, on the Arctic Sea, and Yakutsk, show rainfalls less than 10 inches, and these are doubtful owing to the short periods over which the observations extend.

The truth is there are other causes powerfully influencing the distribution of the rainfall than these, which an examination of the rainfall of the individual months, notably January and July, best discloses. These causes have their explanation in the systems of low and high pressures, which appear and disappear with season. Of these the most prominent are the low pressures which occupy the centres of continents in the summer months, and the northern portions of the Atlantic and Pacific Oceans in the winter months; and on the other hand, the high pressures which fill the centres of the continents in the winter months, and the high pressures in the oceans immediately to the west sides of the great continents, about lat. 36°, as shown by the Admiralty's physical charts of the Atlantic, Pacific, and Indian Oceans.

To take, as an example, the great summer barometric depression of Central Asia with the winds, flowing in upon it on all sides vortically, carrying with them the moisture of the ocean from which they come. Thus East Siberia is then swept by south-east and east winds, which distribute to westward as far as Irkutsk, in July, a monthly rainfall of 3 inches and upwards. Now since the annual rainfall of this region is all but wholly determined by the rains of the summer months, the extension of these rains inland wholly determines the position of the annual iso-hyetal lines. Again, to westward of long. 100° in Siberia, the rains have their origin in the Atlantic and Arctic seas, and since west and north-west winds prevail from Archangel to Central Asia, they bring with them comparatively so large a share of moisture from the ocean, as to raise the annual rainfall over the greater part of these northern regions to about 20 inches, or even more. On the other hand, on the east side of the Ural Mountains, which drain these winds of much of their moisture, the summer rainfall is much less. From north of the Caspian and Aral Seas, southward to the Persian Gulf, and eastward to the Indus, the summer winds are north-west, and since they thus advance over regions rapidly rising in temperature, little if any moisture is deposited in their train, thus rendering this extensive region one of the largest arid tracts of the globe.

These, with other considerations, indicate that the courses of several of the iso-hyetal lines, where observations are sparse, should be regulated to a greater extent than has been done in the map before us, by the positions of river-basins and mountain ranges in their relations to those seasonal winds, which really determine the annual amounts of the rainfall.

One of the most important points to which attention is drawn by Prof. Loomis, is that more rain falls on the eastern than on the western sides of continents. This remark holds good everywhere, until we reach the higher latitudes of both hemispheres, where the predominating winds become westerly. Thus the rainfall at San Francisco is only from a half to a third of the amount which falls on the coast of Pennsylvania in the same latitude; and about the same proportions, or even proportions still more striking, are seen on comparing Morocco with the Chinese coast, and the west with the east coasts of South Africa, Australia, and South America. The explanation is to be found in the portions of the areas of low and high pressures, with their accompanying winds, during the season whose rainfall determines the annual amounts. On the east side of the continents the prevailing summer winds are south-west, south, or south-east, which having traversed a large extent of ocean, and constantly advancing into higher and colder latitudes, spread a copious rainfall over the regions they traverse. But on the other hand, since the west side of continents in the same latitude lies between the region of abnormally high pressure in the ocean immediately to westward, and the low pressure of the interior, north-west winds in the northern, and south-west winds in the southern hemisphere prevail there; and as they advance into lower latitudes or over regions of a constantly increasing temperature, they deposit little or no rain in their course. Hence, owing to the failure, more or less complete, of the summer rains, it follows that the annual rainfall of these portions of the continents is small.

In preparing the second issue of the map, attention should be directed, in addition to the regions already indicated, to the rectification of the lines of equal rainfall over Iceland, the south-east of Norway, the Gulf of Guinea, the temperate regions of South America, and Northern, Central, and Western Australia, and we feel assured meteorologists will heartily co-operate with Prof. Loomis, and give him all possible assistance in completing the important work he has so successfully begun.

NOTES

The name of Prince Leopold (Duke of Albany) has been added to the General Committee of the Darwin Memorial Fund, subscriptions to which, we may remind our readers, are still being received at the Royal Society, Burlington House, by the Hon. Secretaries, Prof. T. G. Bonney and Mr. P. Edward Dove.

The communication from Greenwich which appeared in our last number, p. 175, showed that in the double magnetic storms of April, the Greenwich times of commencement of disturbance were, for Greenwich, April 16, 11h. 32m., and April 19, 15h. 35m.; and for Toronto, Canada, April 16, 11h. 34m., and April 19, 15h. 34m. The communication in question was followed by one from M. Dechevrens, reporting the magnetic disturbance as commencing suddenly also at Zi-ka-wei, China, at 7h. 36m. on the morning of April 17, and as being as suddenly renewed at 11h. 40m. on the morning of April 20; equivalent to April 16—11h. 30m., and April 19, 15h. 34m. Greenwich time. The outbursts thus occurred at the same absolute time at Toronto, Greenwich, and Zi-ka-wei.

The Prince and Princess of Wales opened the handsome new Technical School at Bradford on Friday. The Prince, in the various speeches he gave showed that he has a real appreciation of the necessity for scientific training in this country, if we are to keep on a level with the other great nations in our industry and commerce.

The Commission appointed by M. Ferry to report on the construction of the rotating dome for the large refractor of the Paris Observatory, has held numerous meetings at the Conservatoire des Arts et Métiers, Col. Laussedat, director of the establishment, being in the chair. Only two projects have been reserved for final choice. M. Eiffel proposes to use a saline solution in a horizontal circular channel placed on the wall to diminish the weight of the rotary roof.

We are glad to learn that owing to the exertions of Admiral Mouchez, magnetical observations will soon be resumed at the Paris Observatory, in subterranean chambers which have been excavated in the newly annexed grounds. These observations will be self-registering by photography, in conformity with the instruments established by M. Mascart at the Collège de France. Direct observations will also be conducted with the old instruments which were used by Arago, which were famous for his prognostications of Auroræ, at a period when, the electric telegraph not having been invented, many days must elapse before the arrival in Paris of news from the northern parts of Europe.

In the course of a few weeks all the International circumpolar observatory parties will have arrived at their different destinations, or be on their way thereto, and on August 1 the observations will commence simultaneously on the common plan framed by the different conferences held in Hamburg in 1879, in Bern in 1880, and in St. Petersburg in 1881. By the present arrangement Russia has three stations, the United States and Germany two each, whilst England, Austria, Sweden, Norway, Denmark, France, Holland, Italy, and Finland maintain one each, of which three—the French, the Italian, and one German—will be established in the Antarctic regions. The total number of stations will thus be sixteen, with a complement of some 150 men. The work will be carried on continuously for thirteen months, and the expeditions will leave their quarters on September 1, 1883. On their return an International Conference will assemble—it is suggested in London—in order to examine the material collected, which will, it is hoped, give important results, particularly as regards meteorology.

"LA LAMPE SOLEIL," or the sun lamp as it is called, from the likeness of its rays to solar light, was successfully tried on Saturday last in the vaults of the Royal Exchange. This lamp is the invention of MM. Clerc and Bureau of Brussels, and is so simple in its action as to require no regulating mechanism. It consists of a square block of marble or dry limestone, having two holes pierced into it from above. The holes slant together until they nearly meet just within the base of the block. Into these holes are inserted the two carbon rods forming the poles of the arc, and the current traversing the partition of calcareous stone between their points heats it to incandescence, and thus a soft white light is emitted from the bottom of the block. This light is remarkably steady, and is very suitable for picture gal-galleries. It was used to light the picture gallery in the recent Paris Electrical Exhibition, and is now employed in the *foyer* of the Grand Opera House, Paris. The limestone is calcined by the current, and the carbons feed themselves by gravity as they are consumed. The ugly shape of the lamp is certainly against its use, unless it be sufficiently well screened from view, but its simplicity is decidedly in its favour.

THE new Report (1880) of the Smithsonian Institution contains among other valuable material, a Bibliography of Sir W. Herschel's writings, a list of his published portraits, and a long and very careful synopsis of his scientific writings. This last occupies nearly 100 pages, and its value to the student is evident. Appended there is a subject-index to the scientific writings of Herschel. The same volume contains the first results of the attempt of the Institute to issue a yearly report of the work done at observatories all the world over; the report covers upwards of 100 pages.

OF the Smithsonian Report, upwards of 200 pages are occupied with a Record of Recent Scientific Progress, in which Prof. Baird writes the Introduction, Prof. Holden, Astronomy, Dr. G. W. Hawes, Geology and Mineralogy, Prof. G. F. Barker, Physics and Chemistry, Prof. Barlow, Botany, Prof. Theodore Gill, Zoology, and Mr. O. T. Mason, Anthropology. Mr. Mason also contributes a separate Bibliography of Anthropology, in which (p. 412) we find the following curious entry—"Vikin's (A.) ship."

ON the recommendation of the Agricultural Chamber in Stockholm the Swedish Government has accepted the invitation to participate in the International Fishery Exhibition to be held in London next year, and granted a sum of about 3000*l.* towards the expenses of representation. The Norwegian Government has also accepted the invitation, and a small sum has been voted by the Storthing.

AT a recent meeting of the Smoke Abatement Committee, held at 44, Berners Street, Mr. Ernest Hart in the chair, jurors' reports were handed in from Col. Festing, C.B., Prof. Chandler Roberts, F.R.S., Mr. Atchison, Mr. D. Kinnear Clark, Mr. Harris, and others, on behalf of the various juries, discussing the results obtained and tabulating the figures shown by the various tests. Great satisfaction was expressed at the excellent results which these reports show to have been achieved by some of the leading exhibits in the economy of fuel and abatement of smoke in open grates, as well as the satisfactory action of open grates and kitcheners intended for burning anthracite or smokeless coal. The hon. secretary (Mr. W. R. E. Coles) announced that the Manchester Exhibition of Smoke-Abating Apparatus, carried out partly under the auspices of this Society, had proved highly successful, and had attracted great interest among the practical men in the Lancashire district, and would, it was believed, be fruitful in good results. The arrangements were discussed for converting this committee into a permanent institution for smoke abatement, under the provisions of the law. It was announced that the Duke of Westminster would preside at a meeting to be held at Grosvenor House on Friday, July 14, for the purpose of distributing the awards, when it was expected that all the reports and tabulations would be ready in the form of a volume for public information.

THE President of the Italian Antarctic Expedition has received, at Genoa, a letter from Lieut. Bove, announcing the arrival of the expedition at Punta Arenas, on April 24 from Staten Island. Staten Island has been thoroughly examined as to its fauna, flora, topography, hydrography, and commercial utility.

THE *Hope*, commanded by Sir Allen Young, left the Thames last week to search for and succour the *Eira*, under Mr. Leigh Smith, missing in the Arctic regions for about a year. The *Hope* is 450 tons register, is fortified for ice work, well equipped, and with provisions for two years, and a year's supply for the *Eira*. Sir Allen, while he will doubtless use his discretion, has been instructed to avoid entering the ice, if possible. It has certainly been a peculiar Arctic season, so far as ice condition are concerned, and Sir Allen may find when he gets on the ground that all his calculations and arrangements are at fault.

MR. C. HOLCOTT BROOKS, Secretary of the Californian Academy of Sciences, sends us the following note on a meteor in Wyoming, which he states is "well authenticated in all respects." "May 11, at 4 p.m., in Weber Cañon, Wyoming Territory, while the sun was shining brightly, a sudden and steady glow in the sky attracted attention to an immense meteor, whose brilliant colours were beautiful beyond description. Its track across the heavens was marked by a large red belt, which after its brightness had died out, left a column of clearly defined white smoke in its place. It fell in a south-easterly direction, and was observed by a scientist who recently arrived in this city, and who attended the meeting of the California Academy of Sciences last evening."

NEW seismic apparatus for indication of earthquake-motions on Etna have been devised by the brothers Brassart, at the instance of Prof. Tacchini. From an illustrated account in the *Rivista Scientifica Industriale*, we gather that the indicator for undulatory shocks is in form as follows: a funnel grooved interiorly (and looking like a small inverted umbrella) is fixed at one end of a pivoted horizontal bar having a counterpoise; it has an aperture at the bottom, which allows of its oscillating a little way with the bar on a vertical column, on which is placed a vertical style with weight at top (this latter act being facilitated by a sliding brass tube). This weight, by its fall (contrary to the direction whence the shock comes), into one of the eight lettered grooves of the funnel (N, E, &c.), indicates the direction, and, depressing the bar, closes a circuit, making an electro-magnet, the result being that the pendulum of a small clock on the base-board is liberated. Thus if the clock had been set at 12, and it indicated 5 when looked at, this would show that the liberating shock had occurred five hours before. An electric bell may be introduced; also the liberation of the pendulum may be effected without electricity. In an arrangement for vertical shocks, a spiral of fine wire, with platina-tipped weight, is suspended vertically over a cup of mercury;

the circuit being closed when the weight dips in the mercury, with effects as above.

The Société Nationale d'Acclimatation de France, at its Annual General Meeting, lately held in Paris, awarded a medal of the first class to Mr. J. E. Harting, F.L.S., for his monograph on "Ostriches," and his recently-published work on "Extinct British Animals."

We are glad to learn that the Geographical Society have finally resolved to make further use of the services of Mr. Joseph Thomson in the work of African exploration. The region to be explored by Mr. Thomson is that around Mount Kilimanjaro, about which our knowledge is so meagre. Mr. Thomson will set out in the beginning of next year.

We have received a copy of an interesting address by Prof. F. W. Hutton of Canterbury College, New Zealand, on "Biology in an Arts Curriculum." The author takes as his subject the principle of selection, and after briefly explaining its importance in biology, proceeds to argue that it is of not less importance in psychology and sociology. The analogues, or rather parallels, which he draws are thoughtful and interesting, as the following examples will show:—"Either from transmission, or from early association, every man has a number of opinions common to the nation and to the class in life to which he belongs, which may be called his inherited opinions; but as his reasoning powers develop, these opinions are subject to variation. The variations may be owing to original ideas arising in his mind we know not how, like the variations of structure in animals; or they may be due to education, that is, to coming into contact with other minds, either personally or through books; and it must be noticed that, unlike structural variations, these mental variations may be produced at any time in a man's life, and may or may not remain constant. Physical transmission is not necessary; mental transmission from mind to mind diffuses a variation rapidly through all the individuals, and consequently it is not necessary for the action of selection that the originator of an improved mental variation should have any bodily offspring. When mental variations compete with one another, selection constantly acts on them through the agency either of utility or of sympathy." Similarly in Sociology Prof. Hutton shows that the principle of selection is all-important, and therefore that the political constitution which best admits of variation within due limits, or is most flexible, is most likely to survive in a struggle with other political constitutions. Hence, he maintains, the growing tendency of Monarchies to supplant Despotisms, and of Republics to supplant Monarchies; also of the progress of parliamentary forms of government—parliamentary discussion being but the principle of selection applied to political ideas. The parallels thus drawn between the principle of selection in biology and its operation in psychology and sociology, are well presented; but they are clearly in no way closely analogous to the survival of the fittest among organisms. There is just such a resemblance as there is in the case to which Prof. Hutton alludes of the analogy between the biological and the social organism, and which, as he truly observes, is incomplete and apt to be misleading. "Indeed, it would not be difficult to find in this analogy as many discrepancies as likenesses. What, for instance, in the organisation of an animal answers to the professors of theology, medicine, or law? What to prisons and reformatories?" &c. So, we think, in the principle of selection, although there is a general resemblance in its operation in biology and in psychology or sociology, the resemblance is nevertheless only general, and may not be pressed too far. Thus, the single fact noticed by the author that variations of ideas may propagate themselves without the aid of heredity, is alone sufficient to constitute an immense difference between the two classes of cases—the biological and the sociological—and it is further evident that in biology there is nothing corresponding to individual judgment, which is the most important agent in selecting variations of ideas.

In the current number of the *Journal of Forestry* is an excellent article on Epping Forest, in which the natural beauties of this well-known resort are faithfully portrayed. It is to be hoped that in the discussion that has raged and is still raging as to the management of Epping Forest under its new superintendent, the aim of Parliament for its preservation "in its natural aspect as a forest" will not be lost sight of. In the words of the writer of a paragraph on the subject in the same number of the *Journal of Forestry*, we repeat that "it is a forest that the public want, and not a gigantic park or tea garden."

It is well known that of late a good deal of attention has been devoted in America to the manufacture of sugar from the Sorghum. In connection with this subject a letter has recently been published in the *New York Daily Tribune* from Prof. Silliman, in which he gives a detailed account of the value of the most important varieties. There seems to be a great future in America for the Sorghum as a sugar producer.

The discussion of diurnal ranges of temperature having shown to Dr. Woeikof (*Izvestia* of the Moscow Society of Naturalists for 1881) how much they depend upon the topographical conditions of different stations, he discusses in the last number of the *Journal* of the Russian Chemical and Physical Society the influence of the same conditions on the average temperatures of winter and on the deviation from average temperatures, especially during anti-cyclones. Comparing the observations at different Swiss stations, he finds that the annual range of temperatures does not always diminish with the height of the station; it is less on isolated mountains, but it is greater in high valleys when they are wide. Discussing further the differences of temperature in valleys and on isolated mountains, he shows how the temperature of the air in the former is often much colder than on the mountains, as well in Switzerland as on the Caucasus, and in Eastern Siberia; and he concludes that the map of isotherms, recently published by Dr. Wild in his great work "On the Temperatures in the Russian Empire," does not give a true idea of the distribution of winter-temperatures, especially in Siberia; most of the stations of this country being situated in valleys, where the temperature is lowered during the winter by typographical conditions, the isotherms for January occupy altogether a too southern position on this map. Thus, for instance, the January isotherm of – 31° which passes through the Voznesensky gold-mine, is lower by 7°·2 than the true temperature for this place, and by 10°·1 if the necessary reduction to the sea-level be taken into account.

On the 14th inst., at 2 p.m., a severe earthquake was felt at the town of Luleå in Sweden (65° 40′ N., 22° 7′ E.). The shocks, which were several, were felt within a radius of thirty-six miles, doors being thrown open, flower-pots turned over, &c., through the tremor of the earth.

M. Brazza has delivered in the large hall of the Sorbonne a lecture on his discoveries in the Ogowe, and his efforts to establish a regular communication between the Ogowe and Congo through a land district. These efforts have proved successful.

The frequent observations of the mirage in the south and central part of Sweden is very remarkable. From time to time we are told that whole landscapes, cities, and castles, with moving objects, have been observed reflected on the sky for hours, and we again learn that a similar display of the forces of Nature was seen one afternoon last month over the lake of Orsa, in a remote part of Dalcarlia, lat. 61°, which is stated to have reflected a number of large and small steamers, as if plying on the lake, and from whose funnels even the smoke could be observed to rise. Later on the scene changed to a landscape, the vessels now taking the form of islands in the lake, covered with more or less vegetation, and at last the mirage dissolved itself in a haze. The phenomenon, which lasted from 4 to 7 o'clock p.m., is said to have furnished a most magnificent spectacle.

THE additions to the Zoological Society's Gardens during the past week include a Yellow Baboon (*Cynocephalus babouin* ♀) from West Africa, presented by Mr. A. Collison; a Slender Loris (*Loris gracilis* ♂) from Ceylon, presented by Mrs. A. H. Jamrach; a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Mr. E. Meek; a Burmese Tortoise (*Testudo elongata*) from the Western Dooars of Bhotan, presented by Mr. B. H. Carew; a —— Tree Snake (*Ahætulla liocercus*) from Pernambuco, presented by Mr. C. A. Craven; a Common Adder (*Vipera berus*), British, presented by Mr. F. W. Elliott; a Rude Fox (*Canis rudis*), a Common Rhea (*Rhea americana*) from South America, deposited; a Yellow Baboon (*Cynocephalus babouin*) from West Africa, received on approval; a Burrhel Wild Sheep (*Ovis burrhel*), born in the Gardens, eight Summer Ducks (*Aix sponsa*), six Swinhoe's Pheasants (*Euplocamus swinhoii*), bred in the Gardens. The following insects having emerged during the past week:—Silk Moths: *Actias selene, Samia cecropia, Attacus mylitta*; Moths: *Hypochera io, Deilephila euphorbiæ, Deilephila vespertilis, Trochilium apiformis, Sciapteron tabaniformis, Sesia muscæiformis, Callimorpha dominula*; Butterflies: *Apatura iris, Vanessa xanthomelas, Vanessa urticæ, Aporia crabægi.*

OUR ASTRONOMICAL COLUMN

MASKELYNE'S VALUE OF THE SOLAR PARALLAX.—Mr. Dunkin has consulted the first edition of Vince's "System of Astronomy," published in 1797, and finds therein Maskelyne's article on a new method of determining the solar parallax, the same as in the second edition which appeared in 1814.

Mr. W. J. Davies, writing from Tyglyn, Cilian Aeron, Cardigan, asks, with reference to this value of the parallax, Is it not probable that this was first published in the *Philosophical Transactions?* Prof. Ball, in his "Elements of Astronomy" (Longmans, 1880), page 361, gives the value $8''{\cdot}723$, and the authority for it, viz., *Phil. Trans.*, vol. lxi. p. 574, year 1771. On this point we may remark that Prof. Ball, according to the statement in his preface, has mainly relied for his numerical data upon Houzeau's "Répertoire des Constantes Astronomiques"—a work which, though excellently designed, would, according to our experience of it, benefit by a careful revision. There are a number of errors in the first edition, which are likely to be copied into more popular works, unless attention be drawn to them. In the present case, where reference is made for Maskelyne's parallax to the *Phil. Trans.*, 1771, p. 574, we find at that page a paper by Dr. Hornsby, entitled "The Quantity of the Sun's Parallax as deduced from the Observation of the Transit of Venus, on June 3, 1769, by Thomas Hornsby, M.A., Savilian Professor of Astronomy in the University of Oxford, and F.R.S.," in which the parallax from a number of combinations is found to be $8''{\cdot}78$. Maskelyne's name is not mentioned in the paper, which appears to relate exclusively to Hornsby's own deductions.

Mr. Dunkin having traced the publication of Maskelyne's note to 1797, the only earlier work of Vince in which it would be likely to be found, is the first edition of his text-book, the "Elements of Astronomy," 1790. Mr. Davies remarks that Olinthus Gregory, in his "Treatise on Astronomy," published in 1803, refers to Maskelyne's method, and considered it the best that had been given; he explains it almost in the same words as in Vince, adding that the assumed value $8''{\cdot}83$ was taken "agreeably to the result of observations on the transit in 1761."

THE COMET OF MAY 17.—M. Trépied, in an account of his observations made in Egypt during the total solar eclipse of May 17, which was communicated to the Academy of Sciences on the 19th inst., has the following interesting note:—"Vers le milieu de la totalité, j'aperçus à droite du Soleil, par un angle zénith de environ 90°, un trait légèrement courbé vers le bas, d'un effet singulier, et en discordance évidente avec le reste de la couronne. Je n'ai pas eu un seul instant l'idée que ce pouvait être une comète; je n'en ai reconnu la nature qu' une heure après l'eclipse, en comparant mon croquis à l'une des photographies obtenues par le Dr. Schuster. Cette photographie montrait nettement le noyau à une distance du bord du Soleil un peu supérieure au diamètre de cet astre; l'angle zénith et la direction de la queue s'accordaient bien avec ce que j'avais dessiné, mais j'avais arrêté le trait à une distance beaucoup trop faible du bord. Je n'ai pas cru cependant qu'il me fût permis de rien changer à mon dessin." The sketch referred to is copied in the *Comptes rendus* of the above sitting of the Academy. M. Trepied further remarks: "L'eclat de la comète m'a paru du même ordre que celui des parties extérieures de la couronne." The position of the observing station, as provisionally determined by M. Trépied, is in longitude 1h. 57m. 40s. east of Paris, and latitude 26° 33′ 21″, where the middle of totality occurred at 8h. 31m. 53s. a.m. local mean time. M. Trépied says in the week following the eclipse he searched for the comet many times before sunrise and after sunset, but without detecting it.

The comet has doubtless been sought for elsewhere, though unfortunately without success. The object notified as having become visible some ten days since in the Cape Colony, near the sun in the evenings, would be the comet 1882 *a* (Wells), March 17).

DAYLIGHT OBSERVATION OF COMET 1882 *a*.—Prof. Julius Schmidt writes to the *Astronomische Nachrichten* that on June 10 after 3 p.m., in an exceptionally clear sky at Athens, he observed the comet, though with difficulty, in the 6-feet refractor of that observatory. By ten observations (the instrumental corrections from previous determination) the approximate position was found to be—

June 10, at $3^{\text{h.}}\ 59^{\text{m.}}{\cdot}7$ M.T. Athens, R.A. $5^{\text{h.}}\ 0^{\text{m.}}\ 40^{\text{s.}}$, Decl. $+23^{\circ}\ 19'{\cdot}4$.

This place differs from that inferred from the last orbit given in this column (on observations to May 21) by $-5'{\cdot}5$ in R.A. and $+3'.2$ in declination. The comet's distance from the nearest limb of the sun was about $2^{\circ}{\cdot}8$.

PHYSICAL NOTES

PROFESSORS BELLATI AND NACCARI, of the University of Padua, have recently sent to the Academy of Sciences at Turin, a memoir on the heat developed in solid and liquid dielectrics by successive electrostatic polarisations. They find that when a dielectric, placed between two metal armatures, is subjected to successive polarisations by means of a Ruhmkorff's coil, the dielectric is warmed. This result had already been obtained by Siemens and Righi in the case of glass; the authors of the memoir have experimented also on liquid dielectrics. They have employed two methods: in one of these the heating was indicated by the dilatation of the liquid dielectric (or, in the case of a solid dielectric, of another liquid) observed in a capillary tube. In the other method, the liquid dielectric was contained in a glass vessel, in which were two concentric metallic cylinders serving as the armatures of a condenser. The outer one of these two cylinders was open above and below; the other was closed, and communicated with a horizontal capillary tube containing benzine. This cylinder, therefore, acted as the bulb of an air-thermometer, the heating of the dielectric being indicated by the displacement of the benzine in the capillary tube. This phenomenon must not be confounded with the electric expansion discovered by Fontana more than a century ago, and more recently studied by Govi, Duter, and Quincke. The true electric expansion is instantaneous, and ceases when the polarisation ceases; but the expansion due to the heat developed in the dielectric by repeated charges and discharges is progressive, and increases by prolonging the action of the induction coil. Professors Bellati and Naccari found no electrolytic decomposition in the dielectric, nor was the heating due to the passage of a feeble current through the dielectric.

THE utilisation of the earth's internal heat is a subject which is attracting the attention of scientific men in Japan just now. At a recent meeting of the Seismological Society, Mr. Milne introduced the subject for the consideration of the members. He first drew attention to the fact that philosophers have told us the whole available energy upon the surface of the earth had in some way or other its action and its existence traceable to the sun. That there was an unlimited supply of energy in the interior of the earth was a circumstance which had, he said, been overlooked. In speaking of this energy, Mr. Milne first referred to that portion of it which crops out upon the surface in countries like Japan, Iceland, and New Zealand, in the form of hot springs, solfataras, volcanoes, &c. He stated that there was an unlimited supply of water in hot springs within a radius of one hundred miles around Tokio, and that the heat of these springs could be converted into an electric current, and the energy transmitted to the town. The second part of the paper referred to the possibility of obtaining access to the heat which did not crop out in the surface.

THE whole behaviour of homogeneous colours is explained (according to Herr Albert, *Wied. Ann.*, No. 5), on the Young-Helmholtz theory, by this assumption: To a lessening of the intensity of vari-coloured light correspond various lessening of the strength of sensation, such that for rays of less wave-length, to whatever part of the spectrum they belong, it decreases more slowly than for rays of greater wave-length.

GEOGRAPHY IN RUSSIA

THE just issued "Annual Report of the Russian Geographical Society for 1881" shows that during last year the Society has again accomplished a good deal of useful scientific work. A subject to which much attention was given was the establishment of polar meteorological stations. The station at Novaya Zemlya has already been in operation, as is known, for two years, and a new one, which will be established at the mouth of the Lena, is provided with the best instruments, and is intrusted to persons who will be able to make of it a first-class meteorological observatory. During the summer the expedition will reach the shores of the Arctic Ocean, and begin the meteorological observations. The Dutch station will be erected at Port Dickson, at the mouth of the Yenisei.

Among the scientific expeditions undertaken by the Society, that of M. Polakoff, to Sakhalin, promises to give very interesting results. The rich ornithological collections made in the Alexandrovsk Valley, on the western coast, proved that the birds of Western Sakhalin have a remarkable likeness with those of Siberia and Northern Russia. The same is true with regard to the former inhabitants of Sakhalin, whose stone implements and remains of earthenware, discovered in great masses, are much like, or even identical to, those of European Russia; the presence of obsidian implements, however, originally from Kamschatka, or from the islands of the Pacific, hints that the inhabitants were in intercourse with these countries. M. Polakkoff has also discovered dwellings of the same period, which were holes, like those of the Kamtchadales, the numerous stone pieces which were used to be attached to the nets, show that the nets of the prehistoric man were very large, and that fishing was carried on to a great extent at that period.

The result of M. Polakoff's explorations of the eastern shores of the island, as well as in its middle parts, are not yet known. M. Adrianoff's journey in very little known parts of the Tormsk and Sayan Mountains, during which the explorer crossed Lake Teletzekoye and the Shapshal Mountains, have given rich materials for the geology, zoology, and botany of these countries. The travels of A. E. Regel to the Pamir, M. Hedroitz's explorations of the alluvial deposits of the Amu-daria, M. Lessar's travel to Saraks, and M. Moushketoff's researches on Caucasus, have already been mentioned in NATURE.

A very interesting journey, mentioned in the "Report," was made by A. W. Eliseeff, who tried to follow the same route to Palestine which was followed by the Jews during their exode from Egypt. M. Eliseeff discovered during the journey numerous traces of man of the Palæolithic and of the Neolithic periods in Arabia Petrea, as well as in Egypt and in Palestine. The prehistoric man of the Sinai peninsula belonged to two different types: one, with light bones, of the Semitic type, and the other, with massive bones, of the Berber type; dolichocephalic skulls are predominant. Both had the custom of burning corpses, and did not neglect anthropophagy; however, their chief food consisted of wild animals, fishes, and molluscs. The disposition of these remains confirms the hypothesis of Owen, that the Sinai peninsular and lower Egypt were under water, excepting the higher terraces, after man inhabited the banks of the Nile. As to the present inhabitants, the Arabs of the peninsula afford two different types: a western one, more akin to the Fellah and Egyptian type, and the eastern one, which is of a purer Arabian origin. The nomad Bedouins belong to different sub-types, and there are in the Bedouin desert, traces of a fair-haired people, as well as representatives of Berberian and Ethiopian blood. Some very interesting material for a knowledge of prehistoric man was also discovered by M. W. Malakhoff, during his journey on the western slopes of the Middle Ural. The remains of this epoch are very numerous, especially on the shores of lakes, and they are the more interesting, as we find here the first vestiges of an epoch when the Neolithic man began to discover the properties of metals, and to manufacture metallic implements from the rich ores he found on the Ural. The skeletons of men of this period discovered, together with mixed implements of stone, bone, and copper, are most interesting, especially with regard to the skulls, which represent a very low stage of human development. The remains of a later epoch (implements and rock hieroglyphics) are also very numerous. M. Malakhoff concluded his researches by ethnographical observations on the present Permyaks, whom he considers as very nearly akin to the primary prehistoric inhabitants of this region. G. N. Potanin's exploration of the Votyaks, of their migrations, mythology, and customs, and an excursion of S. K. Kouznetzoff to the Tcherenisses of the Vyatka government promises to yield interesting results.

Among the new publications of the Society we notice the following:—The Anthropology of Mordvinians, by W. N. Mainoff, is printing, and will appear in the eleventh volume of the Ethnographical Memoirs of the Society; the anthropological researches of K. S. Mereshkovsky in the Crimea, preliminary reports of which have appeared in the *Izvestia*, will soon be ready to print; G. N. Potanin's work, "Sketches of North-Western Mongolia," being a report, in two volumes, of his first journey in Mongolia, is an important acquisition for the geography of Asia; the first volume contains abundance of valuable geographical information, and the second contains the ethnographical results, with twenty-six tables of drawings. Volumes iii. and iv. of this work, the third already being under press, will contain the results of the second journey of M. Potanin in Mongolia; the work of N. M. Przhevalsky, "Travels in the Deserts of Central Asia" will consist of six volumes, with more than 120 drawings and maps, four volumes being devoted to the zoology, botany, and geology of these countries; the first volume is already finished by the author, as well as several parts of the following volumes:—An interesting map of Jungaria, drawn up by the Swedish Lieutenant Renat in the eighteenth century, after several months' imprisonment by Kalmuks, was published last year by A. S. Maksheef. Finally, the "Report" mentions also a series of pamphlets, in French, published for the Geographical Exhibition at Venice, which contains very good reviews of scientific work done in Russia in hydrography, zoo-geography, botanical geography, geology, and statistics during the last five years.

The ninth volume of the Memoirs of the Society for the Physico-Geographical Section contains an excellent work by A. W. Kaulbars on the delta of the Amu-daria—unhappily without the atlas of maps and drawings, which the Society was unable to publish. The tenth volume will contain the materials collected by the expedition of Karelin in 1830, which are not yet published.

PRELIMINARY NOTICE OF THE RESULTS ACCOMPLISHED IN THE MANUFACTURE AND THEORY OF GRATINGS FOR OPTICAL PURPOSES[1]

IT is not many years since physicists considered that a spectroscope constructed of a large number of prisms was the best and only instrument for viewing the spectrum, where great power was required. These instruments were large and expensive, so that few physicists could possess them. Prof. Young was the first to discover that some of the gratings of Mr. Rutherfurd showed more than any prism spectroscope which had then been constructed. But all the gratings which had been made up to that time were quite small, say 1 inch square, whereas the power of a grating in resolving the line of the spectrum increases with the size. Mr. Rutherfurd then attempted to make as large gratings as his machine would allow,

---

[1] By Prof. H. A. Rowland. (Extract from Johns Hopkins University Circular, No. 16.) Communicated by the Author.

and produced some which were nearly 2 inches square, though he was rarely successful above 1¾ inches, having about 30,000 lines. These gratings were on speculum metal, and showed more of the spectrum than had ever before been seen, and have, in the hands of Young, Rutherfurd, Lockyer, and others, done much good work for science. Many mechanics in this country, and in France and Germany, have sought to equal Mr. Rutherfurd's gratings, but without success.

Under these circumstances, I have taken up the subject with the resources at command in the physical laboratory of the Johns Hopkins University.

One of the problems to be solved in making a machine is to make a perfect screw, and this, mechanics of all countries have sought to do for over a hundred years and have failed. On thinking over the matter, I devised a plan whose details I shall soon publish, by which I hope to make a practically perfect screw, and so important did the problem seem, that I immediately set Mr. Schneider, the instrument maker of the university, at work at one. The operation seemed so successful, that I immediately designed the remainder of the machine, and have now had the pleasure since Christmas of trying it. The screw is practically perfect, not by accident, but because of the new process for making it, and I have not yet been able to detect an error so great as 1·100,000th part of an inch at any part. Neither has it any appreciable periodic error. By means of this machine I have been able to make gratings with 43,000 lines to the inch, and have made a ruled surface with 160,000 lines on it, having about 29,000 lines to the inch. The capacity of the machine is to rule a surface 6¼ × 4¼ inches, with any required number of lines to the inch, the number only being limited by the wear of the diamond. The machine can be set to almost any number of lines to the inch, but I have not hitherto attempted more than 43,000 lines to the inch. It ruled so perfectly at this figure that I see no reason to doubt that at least two or three times that number might be ruled in one inch, though it would be useless for making gratings.

All gratings hitherto made have been ruled on flat surfaces. Such gratings require a pair of telescopes for viewing the spectrum; these telescopes interfere with many experiments, absorbing the extremities of the spectrum strongly; besides, two telescopes of sufficient size to use with 6-inch gratings would be very expensive and clumsy affairs. In thinking over what would happen were the grating ruled on a surface not flat, I thought of a new method of attacking the problem, and soon found that if the lines were ruled on a spherical surface, the spectrum would be brought to a focus without any telescope. This discovery of concave gratings is important for many physical investigations, such as the photographing of the spectrum both in the ultra-violet and the ultra-red, the determination of the heating effect of the different rays, and the determination of the relative wave-lengths of the lines of the spectrum. Furthermore, it reduces the spectroscope to its simplest proportions, so that spectroscopes of the highest power may be made at a cost which can place them in the hands of all observers. With one of my new concave gratings I have been able to detect double lines in the spectrum which were never before seen.

The laws of the concave grating are very beautiful, on account of their simplicity, especially in the case where it will be used most. Draw the radius of curvature of the mirror to the centre of the mirror, and from its central point with a radius equal to half the radius of curvature draw a circle; this circle thus passes through the centre of curvature of the mirror, and touches the mirror at its centre. Now if the source of light is anywhere in this circle, the image of this source and the different orders of the spectra are all brought to focus on this circle. The word focus is hardly applicable to the case, however, for if the source of light is a point, the light is not brought to a single point on the circle, but is drawn out into a straight line with its length parallel to the axis of the circle. As the object is to see lines in the spectrum only, this fact is of little consequence, provided the slit, which is the source of light, is parallel to the axis of the circle. Indeed, it adds to the beauty of the spectra, as the horizontal lines due to dust in the slit are never present, as the dust has a different focal length from the lines of the spectrum. This action of the concave grating, however, somewhat impairs the light, especially of the higher orders, but the introduction of a cylindrical lens greatly obviates this inconvenience.

The beautiful simplicity of the fact that the line of foci of the different orders of the spectra are on the circle described above, leads immediately to a mechanical contrivance by which we can move from one spectrum to the next, and yet have the apparatus always in focus; for we have only to attach the slit, the eye-piece, and the grating to three arms of equal length, which are pivoted together at their other ends, and the conditions are satisfied. However we move the three arms, the spectra are always in focus. The most interesting case of this contrivance is when the bars carrying the eye-piece and grating are attached end to end, thus forming a diameter of the circle with the eye-piece at the centre of curvature of the mirror, and the rod carrying the slit alone movable. In this case the spectrum as viewed by the eye-piece is normal, and when a micrometer is used, the value of a division of its head in wave-lengths does not depend on the position of the slit, but is simply proportional to the order of the spectrum, so that it need be determined once only. Furthermore, if the eye-piece is replaced by a photographic camera, the photographic spectrum is a normal one. The mechanical means of keeping the focus is especially important when investigating the ultra-violet and ultra-red portions of the solar spectrum.

Another important property of the concave grating is that all the superimposed spectra are in exactly the same focus. When viewing such superimposed spectra it is a most beautiful sight to see the lines appear coloured on a nearly white ground. By micrometric measurement of such superimposed spectra we have a most beautiful method of determining the relative wave-lengths of the different portions of the spectrum, which far exceeds in accuracy any other method yet devised. In working in the ultra-violet or ultra-red portions of the spectrum we can also focus on the superimposed spectrum, and so get the focus for the portion experimented on.

The fact that the light has to pass through no glass in the concave grating makes it important in the examination of the extremities of the spectrum where the glass might absorb very much. There is one important research in which the concave grating in its present form does not seem to be of much use, and that is in the examination of the solar protuberances; an instrument can only be used for this purpose in which the dust in the slit and the lines of the spectrum are in focus at once. It might be possible to introduce a cylindrical lens in such a way as to obviate this difficulty. But for other work on the sun the concave grating will be found very useful. But its principal use will be to get the relative wave-lengths of the lines of the spectrum, and so to map the spectrum; to divide lines of the spectrum which are very near together, and so to see as much as possible of the spectrum; to photograph the spectrum so that it shall be normal; to investigate the portions of the spectrum beyond the range of vision; and lastly to put in the hands of any physicist at a moderate cost such a powerful instrument as could only hitherto be purchased by wealthy individuals or institutions.

To give further information of what can be done in the way of gratings I will state the following particulars:—

The dividing engine can rule a space 6¼ inches long, and 4¼ inches wide. The lines, which can be 4¼ inches long, do not depart from a straight line so much as 1-100,000th of an inch, and the carriage moves forward in an equally straight line. The screw is practically perfect, and has been tested to 1-100,000th of an inch, without showing error. Neither does it have any appreciable periodic error, and the periodic error due to the mounting and graduated head can be entirely eliminated by a suitable attachment. For showing the production of ghosts by a periodic error, such an error can be introduced to any reasonable amount. Every grating made by the machine is a good one, dividing the 1474 line with ease, but some are better than others. Rutherfurd's machine only made one in every four good, and only one in a long time which might be called first-class. One division of the head of the screw makes 14,438 lines to the inch. Any fraction of this number in which the numerator is not greater than say 20 or 30 can be ruled. Some exact numbers to the millimetre, such as 400, 800, 1200, &c., can also be ruled. For the finest definition either 14,438 or 28,876 lines to the inch are recommended, the first for ordinary use, and the second for examining the extremities of the spectrum. Extremely brilliant gratings have been made with 43,314 lines to the inch, and there is little difficulty in ruling more if desired. The following show some results obtained:—

Flat grating, 1 inch square, 43,000 lines to the inch. Divides the 1474 line in the first spectrum.

Flat grating, 2 × 3 inches, 14,438 lines to the inch, total 43,314. Divides 1474 in the first spectrum, the E line (Angström 5269·4) in the second, and is good in the fourth and even fifth spectrum.

Flat grating, 2 × 3 inches, 1200 lines to one millimetre. Shows very many more lines in the B and A groups than were ever before seen.

Flat grating, 2 × 3¼ inches, 14,438 lines to the inch. This has most wonderful brilliancy in one of the first spectra, so that I have seen the Z line, wave-length 8420 (see Abney's map of the ultra-red region), and determined its wave length roughly, and have seen much further below the A line than the B line is above the A line. The same may be said of the violet end of the spectrum. But such gratings are only obtained by accident.

Concave grating, 2 × 3 inches, 7 feet radius of curvature, 4818 lines to the inch. The coincidences of the spectra can be observed to the tenth or twelfth spectrum.

Concave grating, 2 × 3 inches, 14,438 lines to the inch, radius of curvature 8 feet. Divides the 1474 line in the first spectrum, the E line in the second, and is good in the third or fourth.

Concave grating, 3 × 5½ inches, 17 feet radius of curvature, 28,876 lines to the inch, and thus nearly 160,000 lines in all. This shows more in the first spectrum than was ever seen before. Divides 1474 and E very widely, and shows the stronger component of Angström 5275 double. Second spectrum not tried.

Concave grating, 4 × 5¾ inches, 3610 lines to the inch, radius of curvature 5 feet 4 inches. This grating was made for Prof. Langley's experiments on the ultra-red portion of the spectrum, and was thus made very bright in the first spectrum. The definition seems to be very fine, notwithstanding the short focus, and divides the 1474 line with ease. But it is difficult to rule so concave a grating, as the diamond marks differently on the different parts of the plate.

These give illustrations of the results accomplished, but of course many other experiments have been made. I have not yet been able to decide whether the definition of the concave grating fully comes up to that of a flat grating, but it evidently does so very nearly.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

Cambridge.—The following awards have been made at St. John's College for proficiency in natural science:—Foundation Scholarships to Bateson, Goodman; Exhibitions to Edmunds, Love, T. Roberts (already scholars), and to Acton, Andrews, Clementson. T. Roberts also received a Wright's Prize, with augmentation of scholarship to 100*l.* for the year. In the Open Exhibition Examination at Easter, H. Stroud (Owens College) was awarded a a Foundation Scholarship of 100, and Fuller (Perse School, Cambridge), 50*l.* for three years.

In the long list of lectures on Natural Science for the ensuing academical year, lately published, we note as new courses or features of special interest, Mr. Shaw's lectures on some Applications of the Higher Mathematics to Physics (Michelmas Term); Dr. Roberts's lectures on Physiography (Michaelmas Term); Prof. Hughes's Course of Dynamical Geology (Lent Term); Dr. Vines's complete course of advanced Botanical Study, extending through the year; Prof. Newton's lectures on the Evidence of Evolution in the Animal Kingdom, in the Michaelmas Term, and on the Geographical Distribution of Animals, in the Easter Term; and Prof. Balfour's announcement of his lectures and practical work, as Professor of Animal Morphology.

The annual report of the Botanic Gardens Syndicate details work done in improving the Gardens, and amongst valuable additions to the collection, the Tonga plant, recently introduced from the Fiji Islands. A special collection of medical plants has been formed, which already contains the most important hardy plants, and some of considerable rarity. About 8000 labels have been written during the year.

With regard to the recent Mathematical Tripos (in which Messrs. Welsh of Jesus College, and Turner of Trinity College, were respectively Senior and Second Wranglers), although the twenty-nine Wranglers may enter for a further advanced examination in January next, they are by no means compelled to do so. The examination, so far as it has already proceeded, includes very many of the subjects of the old Mathematical Tripos, and we anticipate that unless the colleges decline to elect to Fellowships Wranglers who do not proceed to the higher examination, many will rest content with the test already undergone. The recent talk about the "abolition of the Senior Wrangler" has not a very valid basis.

The eighth annual meeting of the Yorkshire College was held at Leeds on Saturday, Sir Edward Baines in the chair. Prof. Marshall, the principal, made a satisfactory report, and a resolution of the council was confirmed to proceed with the completion of the new college buildings. On the proposition of the Mayor of Leeds (Alderman Tatham) it was resolved that, in memory of the late Lord F. Cavendish, M.P., the late president of the college, who for twelve years had been one of its foremost promoters, a fund be established for the endowment ot a Cavendish Professorship of Physics or for such other purpose as the council should deem best.

SCIENTIFIC SERIALS

Notes from the Leyden Museum, vol. iv. No. 2, April, 1882, contain: On American Diptera, by F. M. van der Wulf.—On new species of Lycidæ, Lampyridæ, and Telephoridæ, and on a new Sumatran species of Callimerus, by Rev. H. S. Gorham.—On new species of Pedilidæ and Anthicidæ, and on a new African species of Hister, by S. de Marseul.—On the Holothurians in the Leyden Museum, by Dr. H. Ludwig.—On some British Indian reptiles and amphibia, by Dr. A. Hubrecht.—On the Pselaphidæ and Scydmænidæ of the Sunda Islands by Dr. L. W. Schaufuss.—Description of a new species of Apogonia, by Dr. D. Sharp.—On a new species of Pantolamprus from Liberia, by Dr. E. Candèze.

Bulletin de la Soc. Imp. des Naturalistes de Moscou, tome lvi. No. 3, 1882, contains; V. Kiprijanoff, on fish remains in the Siwerischen Osteoliths (2 plates).—Dr. Max Schmidt, on *Bolborhynchus monachus.*—Prof. K. Lindeman, on *Coleophora tritici*, a new injurious Russian insect.—Dr. J. v. Bedriaga.—On the Amphibia and Reptiles of Greenland.—F. v. Thumen, contributions to the fungal-flora of Siberia.—N. Vischniakoff, on the *Ammonites distractus* of Quensted.—Prof. Bredichen, report on the tails of comets 1881 *b* and *c*.—Dr. E. Kern, on a new milk ferment from the Caucasus (2 plates).—Th. A. Sludski, on two inequalities taking place in the movement of the solar system (in Russian).—A. Becker, journey to Southern Daguestan.—M. Menzbier, comparative review of the ornithological fauna of Moscow and Toula.—A. Regel, Correspondence.

Zeitschrift für wissenschaftliche Zoologie, vol. xxxvi., part 4, 1882, contains J. Brock, on the anatomy and systematic position of the Cephalopoda (with plates 34 to 37).—O. Katz, contribution to a knowledge of the tegumentary system of the pouch and its several accompanying organs in the marsupials (with plates 38-40).—R. Rössler, contribution to the anatomy of the Phalangidæ (with plates 41 and 42).

Archives des Sciences Physiques et Naturelles, May 15.—Study on the chemical composition of albuminoid substances (continued), by A. Danilewsky.—Mean diurnal heights of Lake Leman, at Secheron, from 1874 to 1881, by P. Plantamour.—The rheolyser, by E. Hartmann.—Darwin considered as regards the causes of his success and the importance of his works, by Alph. de Candolle.

Sitzungsberichte und Abhandlungen der naturwissenschaftlichen Gesellschaft Isis in Dresden, July to December, 1881.—On some lime-spar crystals, by A. Pungold.—Flora of Dresden and its environs, by C. F. Schulze.—On the oldest traces of fossil plants in Saxony, by H. B. Geinitz.—On the progress of Geological researches in North America, by the same.—On the occurrence of Cenomanian petrefactions at Dohne, by J. v. Deichmüller. On the occurrence of the Riesengebirge races of *Pinus Montana*, Müll., in the Saxon-Bohemian Oberlausitz, by O. Drude.

SOCIETIES AND ACADEMIES

London

Royal Society, June 15.—"On an Arrangement of the Electric Arc for the Study of the Radiation of Vapours, together with the Preliminary Results." By Professors Liveing and Dewar.

By the arrangement described, the authors are able to make observations as the temperature rises and as it falls, and so to trace the influence of temperature in many cases in which the extent of that influence was before doubtful. The temperature attainable is doubtless far below that of the arc, but still it is quite sufficient to maintain iron and aluminium in the state of vapour, and show the reversal of the lines of these elements with singular sharpness. The temperature of the interior is sufficiently high to transform the diamond into coke, even in a current of hydrogen, and the result may be taken as proving that the temperature is above that of the oxyhydrogen flame.

The apparatus is thus constructed:—A rod of carbon, 15 millims. in diameter, perforated down its axis with a cylindrical hole 4 millims. in diameter, is passed through a hole in a lime block, and is connected with the positive electrode of a Siemens' dynamo electric machine; another carbon rod, unperforated, is passed into the lime block through a second hole at right angles to the first, so that its end meets the middle of the other rod inside the block of lime. The second rod is connected with the negative electrode of the dynamo-machine, and after contact is made between the two rods, is raised a little, so that the arc discharge continues between the two carbon rods within the block of lime. In this way, the outside of the perforated rod or tube becomes intensely heated, the heat is retained by the jacket of lime, and the interior of the tube gradually rises in temperature, and attains in the central part a very high point. By stopping the arc it can be made to pass through the same stages of temperature in the inverse order. Observations are made by looking down the perforation. When the light issuing from the tube is projected by a lens on to the slit of a spectroscope, the heated walls of the tube give at top and bottom a continuous spectrum, against which various metallic lines are seen reversed, while in the central part, when the tube is open at the further end, the spectrum is discontinuous, and the metallic lines seen reversed against the walls at top and bottom, appear as bright lines.

By passing a small rod of carbon into the perforation from the further end, a luminous background can be obtained all across the field, and then, as the walls of the tube are hotter than the metallic vapours between them and the eye, the metallic lines are only seen reversed. A very slight alteration in the position of the carbon rod makes the lines disappear, or reappear, or show reversal, and as the core is adjusted by eye-observation before photographs are taken, all the conditions of the experiments are thoroughly known and are under easy control. The authors have taken photographs of the violet and lower part of the ultra-violet spectrum given by the tube at successive intervals while the temperature was rising, and noted the following results. When commercial carbons were used the first lines to be seen as the temperature rose were the potassium lines, wave-length 4044-6, next the two aluminium lines between H and K became conspicuous, then the manganese triplet about wave-length 4034, and the calcium line, wave-length 4226, then the calcium lines near M and an iron line, probably M, between them, and then gradually a multitude of lines which seem to be all the conspicuous iron lines between O and *h*. At this stage, when the small rod is used to give a background, the bright continuous spectrum is crossed by a multitude of sharp dark lines, vividly recalling the general appearance of the solar spectrum. In the higher region the continuous spectrum extends beyond the solar spectrum, and the magnesium line, wave-length 2852, is a diffuse dark band, while all the strong iron lines about T, and the aluminium pair near S, are seen as dark lines. The behaviour of the calcium lines H and K is peculiar. These lines are often absent altogether, when the line wave-length 4226 and the two near M are well seen, and when the two aluminium lines between them and many of the iron lines are sharply reversed. Even the introduction of a small quantity of metallic calcium or calcium chloride into the tube did not bring them out reversed. They were only seen as bright lines, not very strong, when the small rod was removed.

In some of the photographs H is visible as a bright line without K. The authors have formerly observed that K shows reversal in the electric arc spectrum taken in a lime crucible on the addition of aluminium, when H remains bright, and such a condition as that shown by the hollow carbon tube when H is present without K, might legitimately have been predicted. The lithium lines at 4603 and 4131 are often bright when many other lines in the neighbourhood are reversed, and must therefore be regarded as relatively difficult of reversal. As a rule, the lines less refrangible than 4226 are balanced as to their emissive and absorptive power and therefore disappear, while the more refrangible are reversed. The cyanogen group at 3883 remain bright when the iron lines on either side are reversed; they often, however, disappear on the continuous spectrum. Many lines about P end Q of the solar spectrum are reversed. The cyanogen band above K is generally to be found in the photographs of the spectrum when only air is in the tube. It is then very faint, and is the only cyanogen group visible. If ammonia is passed into the tube the fine set above K, the N group, and, although less plainly marked, the set at 4218 appear. In one plate the thin lines at 4380 and the group of seven at 4600 appear along with the blue hydrocarbon set. It is well known that ammonia reacts on carbon at a white heat, producing cyanide of ammonium and hydrogen, so that the genesis of the cyanogen spectrum under the present conditions is a crucial test of the validity of the author's former observations on this subject.

Both the indium lines 4101 and 4509 are persistently reversed, together with several lead lines. Tin gives lines partly reversed in highly refrangible portions of the spectrum, and silver gives a fine fluted-looking spectrum in the blue. Chloride of calcium gives a striking set of six or seven bands about M, which may be seen both bright and reversed.

When the small rod is removed, it is easy at any moment to sweep out the vapours in the tube by blowing through it; it is equally easy to pass in reducing or other gases. Ammonia introduced seems to facilitate the appearance of reversed lines. On passing this gas through a tube containing magnesia, the set of lines just below *b*, which the authors have always found to be associated with the presence of magnesium and hydrogen, and is most probably due to some compound, instantly appear. When the authors can command several electric arcs to heat a considerable length of carbon tube, and are enabled to examine the radiation of a powerful arc passing through the vapour in the tube, valuable results may be anticipated.

Linnean Society, June 15.—Sir J. Lubbock, Bart., M.P., F.R.S., in the chair.—The following gentlemen were elected Fellows of the Society:—The Rev. R. Collie, Chas. A. Ferrier, J. D. Gibson-Carmichael, Sir J. R. Gibson-Maitland, Bart., W. D. Gooch, M. Murphy, Rev. H. A. Soames, H. C. Stephens, H. G. W. Stephens, and James Turner.—Mr. W. T. Thiselton Dyer exhibited specimens of *Equisetum giganteum* from Brazil, which is said to have aërial stems attaining 30 feet.—Mr. C. B. Clarke drew attention to a bundle of Hampshire *Orchis*, in support of his view regarding the *O. incarnata*, L.—Mr. H. N. Ridley showed a *Carex glauca* with two pediceled spikes and lower male spike, each arising from a complex utricle; and he also showed a specimen of *Lolium perenne* exemplifying transition from plumes to carpellary leaves.—Mr. G. J. Fookes exhibited and explained peculiarities of malformation in specimens of wallflower and *Clematis lanuginosa*, var. *alba*.—Sir John Kirk gave information concerning specimens of fruit leaves and the rubber of *Landolphia florida* obtained from the island of Pemba, North Zanzibar; and he showed native bells and rubber beaters from East Central Africa, pointing out the beaters were the only application of the rubber made use of by the negroes.—Sir J. D. Hooker read a paper on "*Dyera*," a new genus of rubber-producing plants belonging to the natural order Apocyneæ, from the Malayan Archipelago. The nearest affinity is with *Alstonia*, from which it differs in the sessile stigmas and singular pistils. Its flower is very minute, scarcely 1-8th of an inch long, and ovules of 1-200th of an inch diameter, yet these are succeeded by fruits of immense size.—The next communication was on the caoutchouc-yielding Apocynaceæ of Malaya and Tropical Africa, by W. T. Thiselton Dyer (for which see science notes).—Prof. E. Ray Lankester afterwards read notes on some habits of Scorpions. Of *Androctonus funestris*, Ehr., he referred to their manner of burrowing in the sand, making horizontal tunnels occasionally 8 inches long. The process of exuviation was described, the scorpion then pushing its large chelæ into the sand and scraping rapidly backwards with the three anterior pairs of walking legs. *Androctonus* in walking raises its body well from the ground, and carries the tail and sting arched over the back, thus differing from *Euscorpius*, which keeps the body low, and drags the tail behind, with only the very tip bent. *Androctonus* feeds at dusk, seizing its prey with the left chela, and, swinging the tail overhead, pierces its victim, and, afterwards grasping the body by the short cheliceræ, sucks the nutrient substances. The comb ordinarily is not sensitive, though it may be more so during the breeding season. Specimens of *Euscorpius* fought with each other, then using the chelæ, and not the sting.—Mr. G. Brook read a paper on a new genus of Collembola (*Sinella*), allied to

Degeeria, Nic. The former differs from the latter in possessing four, and not sixteen eyes, in the absence of the long abdominal hairs, and in the different construction of the claws and mucrones.—Mr. McLachlan made a communication on a Marine caddis-fly from New Zealand. Material for examination of this curious discovery having been received by the author from Prof. Hutton of Canterbury, New Zealand, who found larvæ, &c., in rock pools between high and low water-mark in Lyttleton Harbour. The small pupa case is surrounded with and strengthened by portions of a coralline. Mr. McLachlan finds that the caddis-fly in question has been referred to as a new genus, *Philanisus*, by Walker, and apparently the same form described by Brauer under the name of *Anomalostoma*, but neither of these entomologists seem to have known anything regarding the development or habits of the insect.—Prof. P. M. Duncan, in a paper on the genus *Pleurochinus*, L. Agass., now shows that the linking it with the fossil forms from Gand, as described by D'Archiac and Haime, is erroneous. The minute anatomy of its test corresponds closely with that of *Temnopleurus*, with which he places it as a sub-genus; it being distinct from *Temnochinus*, and the Nummulitic so-called Temnopleuridæ of D'Archiac and Haime.—Mr. F. M. Campbell gave his observations on a probable case of parthenogenesis in the house spider (*Tegeneria*). He submits that the fertility of one of the spiders he kept in confinement for 11 months, during which time she twice moulted and afterwards laid eggs, which were duly hatched, can only be explained by one of the two alternatives—(1) either impregnation must have occurred prior to the casting of the two exuviæ, and therefore in an immature stage; or (2) parthenogenesis takes place in the Aracnidea, of which no case (virgin reproduction) has hitherto been recorded in the true spiders.—A paper was read, on the indication of the sense of smell in Actiniæ, by Messrs. W. H. Pollock and G. J. Romanes. From their experiments, it appears probable that a kind of diffused olfactory sense is possessed by these lowly organised creatures.—Thereafter the following papers were read:—On the fungi of Queensland, Australia, by Messrs. M. J. Berkley and C. E. Broome; on a new Infusorian allied to *Pleuronema*, by F. W. Phillips; on *Teredo utriculus*, Gm., and other ship-worms, by S. Hanley; on a collection of ferns from the Solomon Islands, by J. G. Baker; and the fifteenth contribution to the Mollusca of the *Challenger* expedition, by the Rev. R. Boog Watson.—With a few remarks from the President, concluding the session, the meeting adjourned till November 2.

Meteorological Society, June 21.—Mr. J. K. Laughton, F.R.A.S., president, in the chair.—The following papers were read:—A new metal screen for thermometers, by the Rev. F. W. Stow, M.A., F.M.S. This screen differs from the ordinary Stevenson in the following respects:—(1) It is somewhat larger. (2) It has a single set of double zinc louvres. (3) It is partially closed at the bottom to cut off radiation from the ground. The advantages claimed for the use of zinc louvres are:—(1) The conductivity of metal causes the heat derived from the sun's rays to be distributed over every part of the louvres. (2) The louvres being much thinner than those of wood, the circulation of air through the screen is not only much greater absolutely, but much greater also in proportion to the bulk of the louvres. (3) The zinc louvres, therefore, are much more sensitive to changes of temperature than wooden ones. Comparative readings of thermometers in this screen, along with those in an ordinary Stevenson screen, were made during the summer of 1881. From these, the author is of opinion that the Stevenson becomes unduly heated when the sun shines, but this may be as much due to its small size as to the material of which the louvres are made. The thermometers in it are only three to five inches from the louvres at the back of the screen, against seven to eight inches in the zinc screen. The roof, too, is single, and the box is open at the bottom. The author also says that there is no need to condemn all wooden screens, but there does seem to be some reason to think that screens with metal louvres might be better.—On the effect of different kinds of thermometer cribs, and of different exposures in estimating the diurnal range of temperature at the Royal Observatory, Cape of Good Hope, by David Gill, LL.D., F.R.A.S. Meteorological observations were commenced at the Cape Observatory in 1841, when the thermometers were placed in a well-ventilated crib, before a south window, through which they could be read. The buildings were, unfortunately, burnt in 1852. A small wooden house with double roof, and affording a free passage of air, was then erected on the site of the old meteorological observatory. The instruments were placed in the middle of this building, and observations were recommenced on the same plan as before, and continued until the end of August, 1858. On September 1 the thermometers were transferred to a crib erected in front of the south-west window of the transit-circle room. This crib is well ventilated, except on the side next the transit-room window, but the great mass of solid masonry in the immediate neighbourhood of the thermometers appears seriously to affect the range of temperature. For many years a Glaisher stand has been in use, and at the end of 1880 the author caused a Stevenson screen to be erected in its immediate neighbourhood. In this paper the author gives results of observations made in the window, Stevenson and Glaisher screens, during the year 1881, from which it is evident that the exposure of the thermometers in the window crib gives a distinctly smaller, and on the Glaisher stand a larger, daily range of temperature than in the Stevenson screen.—Some account of a cyclone in the Mozambique Channel, January 14–19, 1880, by C. S. Hudson.—Rainfall of Frere Town, Mombassa, East Coast of Africa, 1875–1881, by R. H. Twigg, M.Inst.C.E., F.M.S.

Anthropological Institute, June 13.—General Pitt-Rivers, F.R.S., president, in the chair.—Mr. Mann S. Valentine, of Richmond, Virginia, exhibited a series of figures carved in steatite and mica schist, forming part of a large collection found by him in Virginia and North Carolina. The whole collection consists of some 2000 specimens, consisting of various animals and household utensils, cups, &c.; the human beings are all clothed, and are represented riding on animals and sitting on chairs, and indicating a remarkably advanced state of civilisation; and in some instances, obvious traces of contact with Europeans. Mr. A. H. Keane describ d the district in which the objects had been found, and the tribes that were known to have inhabited that country.—The following papers were read: Nepotism in Travancore, by the Rev. S. Mateer; the Laws of Madagascar, by Dr. W. G. Parker; and Cummer Co., Wexford, by G. H. Kinahan, Esq.

Berlin

Physical Society, June 9.—Prof. Roeber in the chair.—Prof. Neesen described experiments on the relation between specific heat and temperature; and first, in the case of distilled water. In these, he used the method of cooling, and the ice-calorimeter; the manipulation of which he indicated. Each time, after filling the calorimeter, and before the heated substance was introduced, the mercury-column, whose displacement, due to the melting ice, was to be observed, showed spontaneous movements, first back and then forwards; which source of error could be partly avoided by using glass for the external envelope of the calorimeter, instead of the zinc-vessel. It further appeared, that the first two measurements always gave too small values, and were useless, probably because the ice, which was to be melted by the cooling body, was not at 0° C. at the beginning of the experiment, but at a lower temperature, and therefore a part of the communicated heat was used in heating to 0° C. The carefully purified distilled water, whose specific heat was to be ascertained, was in a platinum or glass capsule; in the former the soldering occasioned great difficulties, so that most experiments were made with glass. The measurements already made (they will be extended next winter) range in temperature from 2° to 30° C. (by a normal air-thermometer). If the directly observed changes of volume be taken as ordinates, and the temperatures as abscissæ, a curve is obtained, differing little from a straight line. A close examination of the numerical values shows that the mean specific heat of distilled water from 2° C. slowly increases to a maximum between 20° and 21°, beyond which, to 30°, it slowly decreases; but the divergences from the mean value are always very slight. According to the mercury-thermometer, the maximum of the specific heat is about 12° C., instead of 20°. Prof. Neesen does not regard the numerical values as absolute, but merely, for the present, indicative (*orientirende*); and he hopes to verify them by further measurements.—Dr. Hertz reported on experiments which he had made on the vapour-tension of mercury, by a different method from that lately described by Dr. Hagen. The vapour-tension was measured at high temperatures, and values were obtained which likewise were smaller than Regnault's, but greater than those found by Dr. Hagen. From his values, Dr. Hertz calculated a formula, according to which he produced a curve of the vapour-tension of mercury with varying temperature; its zero point being at absolute zero (– 273° C.). For low temperatures 0° C., 10°, and 20°

the values he deduces from his formula, are under those obtained experimentally by Dr. Hagen for the same temperatures.

Berlin

Physiological Society, June 2.—President, Prof. du Bois-Reymond.—Prof. Kronecker reported upon the experiments which Dr. Melzer made to determine the action of the vagus and superior laryngeal nerves upon respiration. The idea that the action of the vagus in respiration has already been definitely determined, proved to be unwarranted by the facts of the case. It is known that stimulation of the nerve can both suspend inspiration and expiration; but the conditions of the opposed effects are still to be investigated. Now the experiments of Dr. Melzer have shown that these conditions are very manifold and complicated. In a succession of cases, it is the strength of the electric current that determines a particular effect; slight stimulation of the vagus, producing a cessation of respiration in inspiration, great stimulation producing the cessation in the position of expiration, whereas stimulation of medium intensities produced cessation in an intermediate position. Further, the condition in which the respiratory apparatus was at the moment of stimulation of the vagus, determined the results of the stimulation; the effect of an equal degree of stimulation during inspiration being exactly the reverse of what it would have been if applied during expiration. Simultaneous stimulation of the vagus and the superior laryngeal had likewise very diverse effects. If one nerve was more strongly stimulated than the other, the effects of the more strongly stimulated nerve overcame those of the other. If the stimulation in both was equally strong, the results were cessation, either in the position of deep expiration (this taking place when the vagus assisted the action of the superior laryngeal), or in an intermediate position when the two nerves acted antagonistically. Dr. Melzer has also had opportunities of observing individual differences in the action of the vagus, and supposes that the sex of the animal experimented upon may have some influence. Since Hunter's time there have been very few attempts to count the pillars in the electric organs of the Torpedoes, and his view as to their number was universally received as accurate. By the numerous careful countings of Prof. Fritsch, on the contrary, it was discovered that the number of the pillars only differed slightly in large and small specimens of the same species, being often even greater in small specimens than in large ones; embryos of Torpedoes were examined by him, and these already exhibited the same number of pillars as are to be met with in adult specimens of the same species. On the whole the number of pillars in several species of Torpedoes, which are to be regarded as "good species," is pretty nearly the same. It varies between 400 and 600; very large differences in the number of the pillars are to be regarded as "species-characters," and are to be taken into consideration in diagnosis. And from this point of view Hunter's results admitted of an explanation. For Herr Fritsch had an opportunity of seeing two preserved specimens of the American *Torpedo occidentalis* in Vienna. These were, in spite of their shrinking in the spirit, one metre long, and they turned out, when a calculation was made of the number in their electrical organ, to have more than 1000 pillars; it is hence probable that Hunter's giant electric rays were specimens of *Torpedo occidentalis* that were washed upon the English coasts by the Gulf-stream, and that Hunter's enumerations do not in the least contradict the doctrine of preformation.

Paris

Academy of Sciences, June 19.—M. Jamin in the chair.—The following papers were read:—On the reaction-current of the electric arc, by MM. Jamin and Maneuvrier. With a Gramme machine and an arc between unequal carbons, or between some metal and carbon, there is a differential current, by which a galvanometer is affected—largely when copper, zinc, or mercury is used; little (and about equally) with lead, iron, and carbon: these latter show the greatest resistance. The current is explained, not by a difference of resistance, but by an inequality in the inverse reactions of the arc in the two directions. With a mercury arc, the differential current wholly changes the working of the machine, one system of currents being greatly weakened, while the other grows in strength.—On the reciprocal displacements of halogen substances, and on the secondary compounds which rule them, by M. Berthelot.—Separation of gallium, by M. Lecoq de Boisbaudran. He describes the separation from zirconium, manganese, and zinc.—M. du Moncel presented his work, "On the Microphone, Radiophone, and Phonograph."—Total eclipse of the sun observed at Souhag (Upper Egypt), May 17 (civil time), 1882, by M. Thollon.—Same subject: Observations of M. Trépied. He concludes as follows: The position of the green line of the corona corresponds exactly with that of 1474 (Kirchhoff). The relative intensities of dark lines do not seem to be preserved in the spectrum of bright lines. There seems to be a relation between the frequency of the spots and the structure of the corona. There was undoubtedly an increase of intensity of absorption lines in the group B, on the moon's contour; but the author cannot confidently infer a lunar atmosphere.—Same subject, by M. Pinseux.—The President, on a proposal by M. Dumas, asked the Astronomical and Navigation Sections to prepare a programme of observation for the solar eclipse in 1883.—A letter from M. Ferry announced the opening of the Volta competition for a second period of five years.—On a linear equation, by M. Darboux. The displacements through small dilatation or condensations produced in any indefinite homogeneous and isotropic medium, are calculable like a Newtonian attraction, by M. Boussinesq.—On the determination of carbonic acid in the air at Cape Horn, by MM. Müntz and Aubin. They describe apparatus for their method, furnished to Dr. Hyades, who has been familiarised with its use.—On the products of distillation of colophany, by M. Renard.—On microzymas as cause of the decomposition of oxygenated water, by the tissues of animals and plants, by M. Béchemp. He shows that the microzymas of different organs and tissues show unequal energy in action on oxygenated water. Numerical results are given in a table. The microzymas of the lung have the greatest activity; it is as great at first as that of bioxide of manganese, but soon diminishes. Microzymas of the blood and the liver rank next.—On various properties of hydrocyanic acid, by M. Brame. The bodies of animals poisoned with the acid remained in good preservation after a year, though sometimes exposed to 38° C. Preserved in closed vessels, they lose the smell of the acid, and acquire that of formiate of ammonia, which is found in the serous liquid. To embalm with the acid, a little of some substance which absorbs water while hardening (chloride of zinc) should be introduced after the acid.—Chemical composition of different layers of a lava current of Etna, by M. Ricciardi. There is more sesquioxide of iron in the parts in contact with aqueous vapour and atmospheric air.—Lithological determination of the meteorite of Estherville, Emmet County, Iowa (May 10, 1879), by M. Meunier.—On the branchia and circulatory apparatus of *Ciona intestinalis*, by M. Roule.—Comparison of alkaline chlorides as regards toxical power or minimum fatal dose, by M. Richet. These experiments, with chlorides of lithium, sodium, potassium, rubidium, and cæsium, were on guinea-pigs, and by injection under the skin. There seems to be no relation between atomic weight and toxical power.—M. Neujean, in a note, proposed manufacture of manures from the basic scoriæ (containing 10 to 15 per cent. of phosphoric acid) from Bessemer retorts, Martin furnaces, and others.

CLIFFORD'S MATHEMATICAL PAPERS

Mathematical Papers. By William Kingdon Clifford. Edited by Robert Tucker, with an Introduction by H. J. Stephen Smith. (London: Macmillan and Co., 1882.)

Mathematical Fragments; being Facsimiles of his Unfinished Papers Relating to the Theory of Graphs. By the late W. K. Clifford. (London: Macmillan and Co., 1881.)

ONLY those who wander much through the aridities of modern English mathematical text-books, whose duty compels them daily to read such literature, and who know

> "The mispent tyme, the service vaine,
> Whilk to considder is ane pane,"

can understand the pleasure of reviewing a book like Clifford's Papers. Here there is no occasion to yawn over page after page of commonplace, to mark with wonder the hundredth iteration of an ill-founded inference, to trace with languid amusement the method and arrangement of our ancestors, nay, the hereditary dots and dashes decrepid in the fourth generation. On the contrary, the novelty and variety alike of subject and of treatment is almost confusing, every page shadows forth some new idea, every line is informed with the personality and with the genius of its author.

Clifford was one of the bright spirits, all too few in number, who, in a generation, whose educational system is devoted to the encouragement of mediocrity and the cultivation of sciolism, saved the English school from the reproach of inability to follow their leaders. He was one of the select few who sat at the feet of Cayley and Sylvester, and shared their genius. When we compare him with the former of his great masters, he appears at first to want the steadfast purpose and rugged strength of our mathematical giant. The extreme, almost boyish vivacity of his style, and the refined elegance and studied variety of his methods give an impression of this kind which a nearer acquaintance with his work speedily dispels. Apart from his great originality, this elegance, popularity in the best sense, of style gave Clifford a specially important place among the leaders of the English School of Mathematicians, a place which there seems to be none left to fill. It was by his assistance that many were led to scale the almost inaccessible heights on which stand the structures of modern mathematics.

In some respects the exuberant philosophy of his popular works, especially his lectures, in which the more striking conclusions of modern mathematical science were presented to the uninitiated, must have harmed his reputation for solidity of thought. We are also inclined to doubt whether some of the enthusiastic non-mathematical souls that thought they had assimilated his teaching, really after all rose to the conception of Riemann's finite space of uniform positive curvature, in which the problem is solved of

> "Einer dem's zu Herzen ging
> Dass ihm sein Zopf so hinten hing,
> Der wollt' es anders haben."

Such a flight is given only to the sons of Genius, and to those who have in the first place painfully exercised their pinions in less ambitious journeys. Still these lectures of Clifford did good service in drawing the attention of the rising generation to the revolution that is taking place in the very elements of exact science. If every physical discovery of permanent or passing importance is to have its day in the drawing-room and the lecture-hall, why should the trumpet of mathematical progress not be blown occasionally in the streets of Gath and Ascalon? If too many be *called* in this way, some few may still be *chosen*. To these few the volume of Mathematical Papers will furnish the best help available in the English language to enable them to follow their calling. To our mind the popular lectures are cut too much after the passing fashion of the present day; and we should be surprised if the majority of those best qualified to judge of Clifford's work did not agree with us that it will be on the present volume that his future fame will rest. In our poor judgment there is ample foundation.

It would scarcely be proper here to criticise the papers in detail, with the view of pointing out the exact amount of originality in each. Besides, even if the reviewer felt more confident of his judgment in such a matter, the task were a needless one, for it has been done already, in the admirable introduction, by an authority to whom every English mathematician will at once bow.

The Papers have a somewhat fragmentary aspect. This is due in part to the immense range of Clifford's mathematical sympathy, which led him to write on a great variety of subjects; but mainly to the fact that many of the papers are actually unfinished, some of the most important being indeed mere sketches. Clifford seems to have cared, comparatively speaking, but little for the mere mathematical *Art;* his interest was reserved mainly for methods and principles. Accordingly we find him much occupied with new and far-reaching theories; and many of the memoirs in this volume are merely the outlines of vast schemes of work, which life and leisure were denied him to accomplish.

Besides advances in the Theory of Algebraic Integrals, the development of Projective Geometry, and the enormous extension of analysis that is included under the title of Higher Algebra, two great generalisations have marked the progress of modern mathematical science. The first of these is the extension of the axioms of geometry, which originated with Gauss, Bolyai, and Lobatschewsky, and was perfected by Riemann, and the theory of an n-fold manifoldness (Mannigfaltigkeitslehre) of which tridimensional geometry in this extended sense is only a particular case, Euclidian geometry a more particular case still. The second consists in a somewhat similar extension of the Axioms, or more strictly speaking, of the Laws of Operation, of Algebra, begun independently by Hamilton and Grassmann, and resulting in the first instance in the Quaternions of the one and the Ausdehnungslehre of the other. Both these generalisations have been progressive, and both appear to be pregnant with mighty results for the future. Clifford seized upon them with the instinct of genius. They pervade and colour the whole of his work, and the student who wishes clearly to understand the tendency of much that he has done must begin by attaining some mastery over these fundamental novelties. Great assistance will be obtained

VOL. XXVI.—NO. 662

from the elementary exposition of them given by Prof. Smith in his introduction to the Papers, pp. xl. *et seqq.* We should like, however, if we might venture to differ from so great an authority, to take exception to his definition of *flatness* by means of the notion of *planeness*, and to the introduction of the idea and the word *curvature* into an elementary exposition of the properties of space. This seems at best an explanation of the less by the more difficult; and, after all, the use in this case of the word *curvature* is of questionable propriety (although sanctioned by the highest authority), inasmuch as it suggests not only true but also false analogies. It is very well in the hands of a mathematician, to whom it suggests merely that a certain common apparatus of mathematical formulæ is applicable to a particular class of manifoldness and to a particular kind of surface; but to the mathematically untrained or half-trained reader the word suggests the paradox that portions of space on the two sides of a plane in elliptic space both are and are not congruent. Much harm has, we are persuaded, been done by this unfortunate usage of words. A similar piece of mystery making has been practised with n-dimensional space; the language of mathematicians concerning which has been retailed to ordinary simple-minded people as if it had the literal sense they naturally attach to it.

Clifford's papers on the geometry of hyper-space began with his translation of Riemann's famous Habilitationsschrift on the hypotheses which lie at the basis of geometry. He establishes a close connection between the generalised geometry and the generalised algebra in the Preliminary Sketch of Biquaternions, to our mind one of the ablest of his papers. He farther develops the subject in the memoirs "On the Motion of a Solid in Elliptic Space," "On the Theory of Screws in a Space of Constant Positive Curvature," "On the Free Motion under no forces of a Rigid System in an n-fold Homaloid." The kinematic of elliptic space as given by Clifford, and developed quite recently by Dr. Ball, forms one of the most elegant and attractive of modern geometrical theories. The starting point may be said to be the finding of the analogue in elliptic space to Euclid's parallel. In the modern geometrical sense a parallel (*i.e.* a line intersecting another at an infinite distance) cannot of course exist in elliptic space except as an imaginary line. If, however, we define a parallel as the straight equidistant from a given straight line, then through every point in space two parallels (a right and a left parallel as Clifford calls them) can be drawn to a given straight line. This appears at once by drawing at the given point a tangent plane to the equidistant surface of the given straight line, which it will be remembered is, in elliptic space, an anticlastic surface of revolution of the second degree, every zone of which is congruent with every other of the same breadth. This tangent plane meets the surface in two rectilinear generators, which intersect at the given point and have the property of equidistance from the given line. Parallels in this sense are of course imaginary in hyperbolic space, Euclid's parallel being the transition case for parallels in both senses. It seems a pity that a new word has not been used for this species of parallel.

It follows at once by synthetic reasoning of the simplest kind (in which we may in fact dispense with the aid of biquaternions or analytical aid of any kind) that almost all the properties of Euclidian parallels and parallelograms have their counterpart in the theory of Clifford's parallels, due attention being paid to the distinction of right and left. It is shown that a motion of a rigid body is possible in elliptic space such that every point moves in a right parallel, or every point in a left parallel, to a given straight line. A motion of the first kind is called a right vector, a motion of the second kind a left vector. The composition of two right vectors gives a right vector, and two left vectors a left vector; whereas the composition of a right vector with a left vector gives the most general motion of a rigid body, which Clifford calls a motor. It was to represent the ratio of two such displacements that Clifford invented his Biquaternion. Translation, strictly analogous to that in Euclidian space, *i.e.* rotation about the line at infinity does not exist in elliptic space. We may, of course, cause a body so to move that every point of it remains equidistant from a given line, and *in the same initial plane with that line.* Such a displacement is the same as a rotation about the polar of the given line, and is hence called by Clifford a Rotor. We have then the fundamental proposition, that every motor can be represented in an infinite number of ways as the sum of two rotors, but uniquely as the sum of two rotors whose axes are polar conjugates. It is the abolition of the line at infinity, whereby duality is made perfect, that gives the peculiar completeness and elegance to the properties of elliptic space, and fit it to be the paradise of geometers, where no proposition needs to wander disconsolate, bereft of its reciprocal.

To the second great branch of mathematical theory above alluded to, Clifford made exceedingly important contributions in his memoirs on the "Applications of Grassmann's Extensive Algebra," and "On the Classification of Geometric Algebras." Following, to some extent, in the footsteps of B. Peirce, whose epoch-making memoir has been given to the public at last in the *American Journal of Mathematics* for the current year, Clifford treats the subject with an incisive vigour all his own. The point of view (indicated by the word *geometric*) is no doubt limited, just as Peirce's is in another way; and there may be some doubt, as yet, as to the exact nature of the foundations upon which the reasoning rests. There is a lingering trace of the old sophistry in Peirce's work, here and there, at least so it appears to us; a reliance still upon ideas *a priori*, and a reluctance to abandon the restrictions imposed upon algebra by its arithmetical origin. Yet there can be no question as to the great value of the results already obtained and the immense extension of the mathematical horizon thereby effected. Already the attention of mathematical workers has been powerfully drawn to the matter, and there is hope that ere long another great theory equal in importance to the Mannigfaltigkeitslehre will drive its roots through the mathematical soil.

We have dwelt on two of the subjects touched upon in the "Papers," because they seem to us to be of the greatest immediate importance, and to show Clifford at his best as an original mathematician. But it must not be supposed that there is no other food for the mind mathematical in this volume. On the contrary, not one of these papers but is full of delight and edification, even for the most highly educated reader. The charming simplicity of their style, the omission of everything like superfluous detail, and the great variety and importance of the subjects treated, will make the book an indispensable *vade mecum* for the tyro in pure mathematics. We think with regret of the infinite use it would have been to us in our learning years; from it we could have gathered, easily and pleasantly, in the pliant hours of youthful leisure, what we are now constrained to glean, in the intervals of ordinary drudgery, from partial treatises, and articles in foreign periodicals often the driest of the dry.

We must not conclude this notice without alluding to the appendix to the volume of papers, the most important parts of which are the fragment of a treatise called "The Algebraic Introduction to Elliptic Functions," the Notes of Clifford's Mathematical Lectures, and the problems and solutions contributed to the *Educational Times*. The fragment on elliptic functions, which deals with the Theta functions, has great value, as it gives a treatment of the subject not to be found in any English text-book. The lecture notes will be most useful to such teachers of mathematics as are sufficiently alive to the need of some modification of our traditional methods to take advantage of them. They remind us of the irreparable loss we have sustained by Clifford's early death of a doughty champion in the reformation of our degenerate system of mathematical education, which strangles the youthful mathematician ere he is born. It is, perhaps, too much to expect that the veteran chiefs of mathematical science should enter into the work of the drill-sergeant of mathematical recruits. They cannot be asked to devote their time to the petty work of reorganising the teaching of geometry and algebra in our schools and colleges. The more reason that we should mourn the departure of one who was able to take his place with the gods immortal, and yet disdained not to mingle with us mortals in the dusty fray of the Trojan Plain.

The handsome folio of lithographed manuscripts relating to the Theory of Graphs, forms one more monument of Clifford's genius, and affords us one more reason to lament our loss. Fully as we appreciate what he has actually done for us, and much as we are grateful for it, we cordially sympathise with the feeling that prompted the editor of the papers to put on the title-page the saying of Newton concerning Cotes: "If he had lived, we might have known something;" for, if we measure Clifford's promise by his actual performance, we see that he certainly died before his work was well begun.

G. CHRYSTAL

OUR BOOK SHELF

Winters Abroad. Some Information respecting Places visited by the Author on account of his own Health. Intended for the use of Invalids. By R. H. Otter, M.A. 8vo., pp. 236. (London: John Murray, 1882.)

THE places visited by the author are Australia, including Melbourne, Sydney, Queensland, and the Riverina, Tasmania, Algiers, Egypt, Cape of Good Hope, and Davos. He gives a short account of the places in the order in which he visited them, written in an easy readable style. The author's object in writing is to give invalids an idea of the easiest routes by which to reach health resorts, the kind of accommodation they may expect, the weather they must be prepared for, and the occupations and amusements which the several places afford. He has kept this object constantly before him, and has consequently produced a book which, notwithstanding its moderate size, clear, large type, and easy style, yet contains a great quantity of solid information which is quite trustworthy as far as it goes. From the nature of the work, embodying as it does the author's personal experience only, it is not complete, and might possibly mislead invalids who decided to follow the author without reference to the exact condition of their own lungs. For example, the author prefers the route to Egypt by the P. and O. steamers, and for many persons this may be excellent, but it involves a passage through the Bay of Biscay, with the possibility of rough weather, which to many invalids might be exceedingly dangerous. He has done good service to invalids by warning them of the necessity for warm clothing everywhere, but he speaks of throwing his coat on his bed as an additional covering, and so appears not to have had with him that greatest of all comforts to an invalid, an eider down quilt, which keeps him warm in bed, sofa, or chair, and when packed in a waterproof cover, is easily carried and serves at need for a pillow or footstool. In his remarks on Davos, the author observes, that through want of knowledge of the kind of cases for which the climate is suitable, many persons are sent there who would be much better elsewhere, and makes a most sensible suggestion that the authorities of Brompton Hospital should send thither a certain number of test cases. Proper accommodation and medical attendance would have to be provided for them, but the expense would not be very great, and might be met by special subscriptions for the purpose, while "the benefit to many of the sufferers and to the world at large might be incalculable." The origin of tubercle from germs, which has recently received such confirmation from Koch's experiments, as well as the increasing probability that under certain conditions these germs may be inoculated, afford a hope that consumption may ere long be brought, like typhoid fever, into the category of preventible diseases. But even after its causation is known as well as that of typhoid, cases will continue to occur from ignorance, stupidity, or negligence; but we may trust that it will no longer be the awful scourge which it is at present. To those who suffer from it, and who require to winter abroad, the present work will be a useful adviser and companion, and we would also strongly recommend its perusal to medical men who are personally unacquainted with the health-resorts to which they recommend their patients.

A Sequel to the First Six Books of the Elements of Euclid. By John Casey, LL.D., F.R.S. (Dublin: Hodges, 1882.)

THIS handy book has deservedly soon reached a second edition. In this way it will be seen that it has met a want. "The principles of modern geometry contained in the work are, in the present state of science, indispensable in Pure and Applied Mathematics and in Mathematical Physics; and it is important that the student should become early acquainted with them." The author appears to have thoroughly revised the text, and he has added many notes of interest, a few figures, we believe, and several problems: the enunciations occupy more space; that is, such terms as parallelogram are given in full, instead of being symbolically represented; but in the demonstrations the symbols are retained. An index has been added at the end.

We have noted a few errata: in the list of errata, for 4 read 74; p. 39, l. 15, "AB" should be "A C," as in first edition; on pp. 95, 157, the names of Sir W. Thomson and M. Mannheim are incorrectly printed; p. 110, the reference to *Educational Times* should be to the "reprint" from that journal; but these are very slight slips. We recommend Dr. Casey's book with increased confidence for use in the higher forms of our schools.

Il Telefono, il Microfono, la Bussola, Istrumenti Rivelatori delle variazioni atmosferiche. Di A. V. G. Mocenigo. 131 pp. (Vicenza, 1882.)

THIS little work deals with the physics of the earth as revealed by the telephone, the microphone, and the compass. Amongst the subjects dealt with are the perturbations of the earth's magnetism, atmospheric electricity, earth-currents, particularly in relation to their study by the aid of the telephone, and seismological movements of the earth's crust as revealed by the microphone. For the study of the latter class of phenomena the author has devised an earthquake-pendulum-microphone. In this instrument one piece of carbon is hung by a long wire vertically above another attached to a rigid frame, the upper carbon resting with very light pressure against the approximately flat top of the lower. Any disturbance of the verticality of the apparatus causes a variation in the contact, and gives rise to grating sounds in a receiving telephone. The author appears to attribute earth-currents to the rotation of the magnetic mass of the earth; and he proposes to utilise them for working telephones in regular fashion. A large part of the book is taken up with correspondence between the author and Signor de Rossi.

S. P. T.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

An Observatory for Auroræ

J'AI l'honneur de vous annoncer que, dans le cours de l'automne prochain, j'ai l'intention de faire proposer au gouvernement norvégien la création d'un établissement ayant pour but l'investigation et l'observation de l'aurore boréale et des autres phénomènes du magnétisme terrestre.

En me permettant, M. l'Editeur, de vous communiquer ce projet pour vous en demander votre avis j'indiquerai en peu de mots les motifs qui m'ont porté à chercher la réalisation de cette idée, nouvelle encore sous bien des rapports.

La théorie du magnétisme terrestre est un des problèmes qui présentent à la science naturelle moderne les plus fortes demandes d'être examinés. Si la science n'a pu résoudre, jusqu'à présent, qu'une petite partie des nombreux problèmes noués à ce terrain de recherche—pourtant, à chaque progrès elle a pu prouver, de plus en plus clairement, l'énorme importance des phénomènes du magnétisme terrestre pour les relations physiques de la terre. Par la découverte de la connexion existant entre ces phénomènes et des évènements sur la surface du soleil, la question a gagné une portée cosmique.

Il sera inutile, M. l'Editeur, de vous rappeler le grand et important rôle joué dans toute la vie physique de la terre par les forces du magnétisme terrestre, par leur état changeant et par leurs périodes, soit qu'elles se présentent dans le jeu énigmatique de la lumière polaire, soit qu'elles se prononcent dans les mouvements changeants de l'aiguille aimantée, ou par leur influence sur le réseau télégraphique de pays entiers.

Aucun pays en Europe, peut-être même pas sur toute la terre, n'offre à l'investigation de ces phénomènes des conditions si favorables que la Norvége. Ayant une étendue de presque 2000 kilomètres —du 58me au 71me° N.—elle s'étend plus loin vers le Nord qu'aucun autre pays habité. Elle est plus rapprochée du foyer des perturbations magnétiques, qu'aucune autre partie du continent européen. La zone maximale de l'aurore boréale traverse la partie Nord et Nord—Ouest du pays. Un réseau continu de fils télégraphiques s'étend de son extrémité Nord à celle du Sud. Les lignes téléphoniques de Drontheim et de Bergen sont celles de toute la terre, qui sont le plus rapprochées du pôle.

A aucun autre pays ne s'adresse donc plus directement la demande de prendre l'initiative énergique de l'investigation des mystères du magnétisme terrestre.

Ayant reconnu ces nombreux avantages, si négligès jusqu'à présent, j'ai tâché, pendant ces dernières années, d'entreprendre, de ma propre initiative, et avec les ressources d'un seul individu, une partie de la grande œuvre qui nous reste encore sur ce terrain relativement si peu exploité. Dans l'automne de 1878 je fis, pour la première fois, répandre dans toutes les parties de la Norvége l'invitation à contribuer (Actes de la société des sciences de Christiania, 1880, No. 6) 839 observations de 154 aurores prises de Sept. 1878—Avril 1879 de 132 stations, principalement en Norvége.

Ce résultat me mit à même de prouver, que l'aurore boréale est un phénomène beaucoup plus fréquent, même hors des régions polaires, qu'on ne l'a supposé jusqu'à présent, et que, dans un territoire comme celui de la Norvége, il n'en manque presque jamais, même dans une année de minimum.

A compter de ce modeste début, l'entreprise s'est développée bien rapidement; non seulement la Suède et le Danemark, la Finlande, l'Angleterre, le Groenland et l'Islande sont aujourd'hui comprises dans le réseau d'observation. Le travail complémentaire à l'égard des observations de l'hiver de 1879-80, quoique fini depuis longtemps, n'a pas encore été publié; cette série est bien plus considérable et plus complète que celle du premier hiver, et contient 1600 observations de 249 aurores boréales prises de 357 stations. Le matériel de l'hiver de 1880-81 est bien plus riche encore que celue de l'hiver passé; il contient jusqu'à 5200 observations d'environ 300 aurores boréales, prises de 675 stations. Le résultat de l'hiver de 1881-82 sera probablement encore plus vaste; je suis en correspondance, dans ce moment avec 1000-1500 observateurs dans tous les pays de l'Europe septentrionale.

Comme supplément à ces observations des aurores boréales je suis parvenu à faire noter, à ca. 50 stations télégraphiques, suédoises et norvégiennes, toutes les perturbations ayant lieu dans les fils, avec indication de l'heure, de la force, de la direction etc. Il résulte de ce travail un matérial aussi vaste, aussi étonnant que celui des observations des aurores boréales, les perturbations télégraphiques se montrant aussi fréquentes que les aurores elles-mêmes, et presqu'aucun jour ne passe en Norvége, que les lignes n'éprouvent une perturbation quelconque. Dès que j'aurai reçu les observations d'une année entière, je pourrai les publier et les faire accompagner d'un atlas, montrant carto-graphiquement les perturbations télégraphiques de chaque jour, les aurores boréales et les orages observés le même jour, avec indication de l'heure et de l'endroit, ainsi que la quantité de nuages le soir sur tout le terrain d'observation.

J'ai réussi à construire un appareil qui, mis en communication avec un fil télégraphique, note graphiquement tous les courants perturbateurs selon l'heure, la force et la direction. Ce rhéographe sera bientôt mis en communication chaque nuit avec une ligne télégraphique (direction N.—S., longueur de ca. 1400 kilomètres) qui n'est pas employée pendant la nuit pour le service télégraphique; pendant la journée il sera mis en communication avec une ligne téléphonique spéciale.

A côté de cette activité, j'ai rendu compte des résultats déjà gagnés dans plusieurs traités qui sont, ou publiés ou en état de préparation. Sans compter les ouvrages déja cités, j'ai pu contribuer, d'après des observations prises en Groenland, à l'explication des périodes journalières, annuelles et celles d'onze ans de l'aurore boréale (voir "Sur les périodes de l'aurore boréale"—extrait de l'annuaire 1880 de l'institut météorologique danois). Dans un traité qui sera publié dans les actes de la société des sciences de Christiania, j'ai discuté la période dépendant du clair de la lune; dans "Archiv for Mathematik og Naturvidenskab 1881" j'ai publié une monographie assez détaillée de l'aurore boréale du 17 mars 1880. Je prépare enfin un catalogue de toutes les aurores boréales observées en Norvége depuis la période la plus reculée jusqu'a nos temps, dont le travail préparatoire est presque fini.

Je peux encore ajouter que je passerai l'hiver prochain (Septembre-Avril) à Kautokeino dans le Finmark (69° 1′ lat. N., 21° 0′ long. E. P.) pour y faire, en commun avec la station polaire norvégienne Bosekop, située à 100 kilomêtres plus loin vers le Nord, des observations surtout à l'égard de la parallaxe de l'aurore boréale.

Quoique j'aie trouvé tout appui et encouragement possible chez les gouvernements et les institutions scientifiques des royaumes du Nord, il est évident, qu'une organisation si étendue et si compliquée doit finir par épuiser les forces d'un seul homme, surtout comme je suis obligé de vouer la plus grande partie de mon temps à une activité différente. Il est également clair, qu'une entreprise, n'ayant pour appui que l'initiative individuelle, ne peut être poursuivie avec autant d'exactitude et de perfection, qu'étant basée sur une institution publique. Il me semble, enfin, que ces recherches sont d'une telle importance, qu'il est à désirer, qu'elles soient continuées si énergiquement et sur une échelle si complète que possible. Cela ne peut se faire, selon mon avis, que par la création, par l'état, d'un établissement spécial pour ces recherches. Les principes sur lesquels je voudrais voir basé un tel institut, les voici :

(*a*) L'institut sera établi à Drontheim (63° 27′ lat. N., 8° 5′ long. E.P.), endroit à peu près central dans le pays et mis en vive communication avec l'étranger par des bateaux-à-vapeur et des chemin-de-fer. Situé à 30° S. seulement du cercle polaire, il est assez rapproché de la zone le plus active des forces du magnétisme terrestre, ce qui, entre autres choses, est aussi prouvé par le fait que, pendant l'hiver de 1880–81, non moins de 62 aurores boréales ont été observées par un de mes observateurs, et que les perturbations télégraphiques y sont aussi très-fréquentes; dans la période 1 Julliet 1881–30, Avril 1881 on en a compté a pas moins de 122 jours (plus de 40$_{0}$/^{0}) dont une partie insignifiante provenant des orages.

(*b*) Il sera construit pour l'institut, sur un emplacement à l'horizon libre, un édifice spécial, situé de manière à ne pas être gêné par la lumière artificielle. Sans compter l'appartement du directeur, l'édifice doit contenir une salle de travail, des cabinets pour les instruments, une tour, contenant une chambre à vue libre dans tous les sens et une plateforme.

(*c*) L'institut tâchera de devenir le point central des observations des aurores boréales en Europe. Tout en faisant lui-même toutes les observations possibles, il veillera sur la régularité des observations dans toute l'Europe septentrionale, dans l'Islande et dans le Groenland, il en chargera les navires navigant les mers arctiques etc.

(*d*) L'institut se fera également le centre des observations des perturbations télégraphiques, recues de toutes les lignes télégraphiques de Norvége et de Suède. Le rhéographe cité plus-haut sera employé à des observations nocturnes sur une ligne longue. De semblables recherches seront faites à l'aide des lignes téléphoniques de Drontheim.

(*e*) Sans compter les spectroscopes, les théodolites pour les aurores etc., l'institut sera pourvu d'une série d'instruments de variation, à l'action spontanée, placés dans un pavillon particulier.

(*f*) L'institut publie tous les ans les observations recueillies et classifiées par lui, ainsi que leurs résultats.

Je suis persuadé qu'un observatoire, basé sur ces principes, pourra rendre d'importants services à la science, et j'espère que la réalisation de cette idée sera accueillie avec joie par le monde scientifique.

J'adresse cette communication à vous, M. l'Editeur, et à d'autres autorités reconnues sur ce terrain de la science, pour que cette question soit soumise à votre jugement. Je vous prie de vouloir bien me communiquer votre opinion sur les mérites d'un tel institut, afin que le poids de votre nom me serve d'appui dans mes efforts pour la réalisation de mon projet—si toutefois l'idée gagne votre approbation, ce dont je ne doute pas. Si vous y ajoutiez encore la bonté de formuler des propositions eventuelles et des conseils pour l'organisation de l'institut, pour son plan de travail etc., je vous serais également très reconnaissant.

Dans l'espoir d'être honoré d'une prompte réponse, qui pourra être conçue dans quelque langue que vous deviez désirer, j'ai l'honneur, M. l'Editeur de vous prier d'agréer l'expression de mes sentiments les plus distingués.

Bergen en Norvége, Juin SOPHUS TROMHOLT

Hydrophobia and Snake-bite

IT has been the fashion of late, in newspaper and other commentaries on the numerous experiments in search of an antidote for serpent-venom, which are now attracting general notice in different parts of the world, to compare snake-bites with hydrophobia, and to raise hypotheses and suggestions that the remedy, when it is discovered, for the one, will be found also to effect the cure of the other. Such a surmise, one would imagine, must be based on a very superficial knowledge, even of the rough outlines of the two affections, and in total ignorance of their pathological characteristics. What are their points of similarity and distinction, dismissing all rhodomontade involving such terms as "ferments" and "active principles," "germs," and "vibriones"—expressions which are very convenient to make use of as signifying an *unknown something*, but which, in their literal meaning, indicate definite actualities, the existence of which has certainly never been shown by tangible demonstration in the present instances? Hydrophobia and blood-poisoning by a venomous snake-bite are alike, then, in being produced by an animal poison, commonly conveyed by the living animal; in being of intense virulence, accompanied by many parallel symptoms denoting violent constitutional disturbance, and great prostration of the vital powers; and, *in some cases*, in leaving certain post-mortem lesions which are identical. But there all likeness ceases; and even without considering the grand differences which exist between them, however viewed, I think we shall find these items of resemblance when analysed a very insufficient foundation for the theory of the probability of a common antidote. To begin with, the poison in one is a natural secretion, provided for the distinct physiological purpose of enabling the reptile to secure its prey; in the other, a new and morbid product generated by disease in a secretion naturally innoxious—whether by chemical decomposition or by the formation of new compounds from materials pre-existent there or from others specially eliminated from the blood, we cannot say. For it is to be observed that neither the microscope nor chemical examination has afforded us any clue to the mysterious ingredient which constitutes the toxæmic property of these fluids as yet. Then, in the second place, as to the acuteness of the symptoms of vital disturbance; neither the symptoms themselves nor their severity are specific to these affections, but are such as might be produced by any grave interference with the relation of tissues or function—a deadly mineral or vegetable poison, the rapid course of a zymotic disorder, violent concussion, or the rupture of an internal organ. Lastly, the occasional identity of the appearances after death from snake-bite with those which are constant in hydrophobia (notably those observed in the spinal cord) are little to be relied upon, partly on account of their comparative infrequency, and partly because they are not in themselves primary evidences of the introduction of the poison, but *tertiary* to it—secondary to the effects which result from the altered blood and its new and vital function on other tissues. One is compelled to attribute such phenomena to something more than passive contamination (as the idea giving rise to some recent experiments would seem to be), and to recognise a defined potential agency in the new formation.

The fact that the hydrophobic poison is located, and undergoes a period of incubation at the seat of the original wound, even long after cicatrisation, and is not diffused in what we vaguely call the "system," draws a broad line of separation between the pathology of this disease and snake-poisoning, and renders it perfectly unique in the category of ills known to medical science. The constitutional symptoms never appear in less than three weeks after the bite, rarely under six, and may be delayed for twelve months. Could there be a greater contrast to the *impetuosity* of the changes sequent on inoculation with the poison of a serpent? Both the latter fluid and the saliva of a mad dog are incapable of producing their characteristic effects when absorbed through mucous membrane, but that is a circumstance common to most animal viruses.

There is a far greater similarity between the course of some of the rapidly fatal tropical fevers and a snake-bite, than there is between that injury and hydrophobia. The inception of a morbific agent—though of what nature, or through what channel, is uncertain; the almost *instant* development of acute symptoms—for, if there is any period of latency, it must be a very brief one; the intense disorganisation of the economy produced within a few hours; the nearly inevitable termination in death—all suggest a comparison which will not be thought strained or far-fetched by those who have witnessed the progress of these appalling diseases. My friend Dr. Fairbairn, of Rio de Janeiro, who has probably seen more of yellow fever than any man alive, and who has certainly met with greater success in his treatment of it than any other physician whose experience has been placed on record, called my attention to this resemblance, with which he had long been impressed, living in a region which afforded plenty of opportunities for observing both; so much so, that be expressed a conviction that many points of identity of process and morbid anatomy would eventually be revealed. His last words to me at parting were: "Now, mind—if you ever discover the antidote for snake-bites, you'll have a cure for yellow jack!" ARTHUR STRADLING

The Rainfall of the Globe

IN reference to a paragraph in an article on the rainfall of the globe in NATURE, vol. xxvi. p. 206, Prof. Loomis states that the heaviest rainfall is met with in the rain-belt, which surrounds nearly the whole globe lying between the north-east and south-east trade-winds.

Having been engaged in collecting records of rainfall at sea for some time back, I may take the opportunity of saying that I have received data enough to enable me to give an estimation of rates per annum for this rain-belt.

That for the Atlantic Ocean is calculated at 133·37 inches per annum, that for the Indian Ocean at 80·55 inches per annum, that for the Austro-Chinese Seas at 107·96 inches; but none has yet been made out for the Pacific Ocean, owing to absence of observation altogether from that quarter.

In physical atlases the rain-belt is continued across this ocean in the same latitudes as it is found to exist in the Atlantic and Indian Oceans, but as yet it is only conjectural, and it may probably be found to cross in other spaces by direct observations taken at sea. The observance of rainfall on islands in the open oceans would appear to afford but imperfect means of judging of the rainfall at sea surrounding them. It is frequently found that they differ very materially, as at St. Helena, the island may be covered with mists, invisible, while the ship outside is sailing under a clear sky and fresh breeze.

The ocean rainfall, therefore, can only be made out by observations on board ships, and these are not easy to get, and also take up a long time in effecting. W. J. BLACK

The Recent Unseasonable Weather

MR. ARCHIBALD's letter on this subject displays great ability, and is deserving of much attention by meteorologists. Nothing can be, I think, more interesting and important than a proper interpretation of the meaning of the facts of the weather of the late extraordinary and contrasted seasons. Will you, therefore, allow me shortly to make a few remarks regarding the comparison pointed out by Mr. Arcbibald as existing between the weather of India and that of North Europe.

In the "Report on the Meteorology of India," 1877, the reporter, referring to the Himalayan regions, says: "There are two periods of cold, (1) when the snow is accumulating; and (2) when it is dissolving; and the first occurs in January and February, the latter in April and May." Again, he says: "The conclusion appears to be very strong that during the early months of the year, one very important factor in determining the peculiar features of the season is, the amount of snowfall and of snow accumulation in the Himalayan regions during the winter."

For six years past I have observed the same thing hold *generally* in the north of Europe, a cold winter being followed by a late spring and an ungenial summer, and *vice versa.* This I would therefore be inclined to regard as a general law. The weather of June, however, serves to indicate the difference between the meteorological conditions of India and North Europe. It has been ungenial, I think, solely, on account of the exceptional force and warmth of the winds of winter causing a vast detachment of the ice in the polar regions. This ice has floated into lower latitudes—has come much nearer to us—and has produced, in melting, icy winds. These commingling with the warmer tropical winds, have produced in their turn the recent changeable weather.

Our cold spring winds usually come from the east of north, but the prolongation of cold winds which we experienced in the middle of June, came from the west of north, indicating their origin to be in the masses of ice floating for the most part probably between Iceland and the American coast. Thus the movable ice has caused a high atmospheric pressure and a low temperature. The fixed ice, however, which forms by far the largest area within the Arctic Circle, has been during this winter relatively diminished, and from it, therefore, we should expect less incursion of cold winds; therefore a finer summer.

While, then, the chief influence of warm westerly winds in winter is, as I believe, to produce a fine summer, their minor influence must be, particularly when strongly developed, as they have been during the past winter, by detaching an unusual quantity of Arctic ice, to produce unseasonable weather in early summer.

The same exception would take place in India, if we could suppose some part of the winter's accumulation on the Himalayas to be carried at the close of a severe winter down into the northern plains so as to distribute in melting, volumes of cold air throughout the otherwise warm atmosphere.

Dundee, July 3 DAVID CUNNINGHAM

Is the Axis of a Cyclone Vertical?

I AM not aware if it has ever been suggested, in explanation of the frequent (or rather, usual) incompleteness of cyclonic disturbances, that the axis of the cyclone may be inclined, and consequently only one side of the disturbance affect the earth's surface, the other half being at a greater or less elevation, according to the amount of the inclination, and thus (so far as wind currents are concerned at least) lost to us.

My own observations of storms in this country point to a southerly inclination of the cyclonic axis. I should be glad to know if observers in the southern hemisphere have traced any indications of a *northern* inclination in the cyclones there.

J. A. WESTWOOD OLIVER

Belle Vue, Springburn, Glasgow, June 25

THE idea propounded by Mr. Oliver, that the axes of cyclones are inclined, is no new one, nor is it the first time that a *southerly* inclination has been inferred to exist, to account for the preponderance of winds belonging to the southerly quadrants, and the comparative absence of those belonging to the northerly quadrants of cyclones in our latitudes.

The value of Mr. Oliver's opinion on this point must depend to a great extent on the nature of the observations on which he relies.

This supposed southerly inclination was formerly attributed by Andrau and other Dutch writers (according to Réclus), to the fact that a cyclone, starting from some point near the equator, must have its rotation-axis initially inclined to the terrestrial axis nearly at right angles, and that as it moves from thence polewards, the direction of its rotation-axis remaining fixed in space, it must *apparently* become gradually more and more inclined to the local horizon in a southerly direction. This explanation is ingenious, but there are many considerations, both theoretical and practical, which militate powerfully against it.

Another view—that of the Rev. W. Clement Ley, derived from observation (principally of the upper clouds)—makes the axis of a cyclone incline backwards as regards its direction of translation, and in favour of this notion, the retardation in the occurrence of the barometric maxima and minima on the summits of Mount Washington, Pike's Peak, and Mount Michell, noticed by Prof. Loomis, has been cited.

Ferrel, however, remarks that "a retardation of just about the same amount is observable in the occurrence of the times of maxima and minima in the diurnal changes of the barometric pressure at the summits of these same mountains, which cannot be explained by means of cyclones with reclining axes," so that in all probability the same cause acts in both cases, and is independent of any such special quality of cyclones as that inferred by Mr. Ley.

The hypothesis of Mr. Ley is, moreover, so much at variance with mechanical principles and with what we should naturally infer would take place, that, as Mr. Ferrel says, "we must hesitate to adopt it, without seeking further for some more plausible hypothesis to explain the observations."

The theory of cyclones, as developed by Ferrel and others, makes it far more probable that if there is any inclination at all, it will be *small*, and *forwards*, not backwards.

Ferrel thinks it possible that the elliptical form of the isobars and rain-areas is partly due to this forward inclination of the axis.

Moreover, the preponderance of southerly and westerly winds in our cyclones cannot correctly be adduced as an argument in favour of the southerly inclination of their axes, since it is mainly due to the fact that our cyclones are for the most part secondaries, moving within the periphery of a large, nearly permanent cyclone, whose centre generally lies not far from Iceland, and thus those winds and gradients predominate, which would tend to occur in that part of the large cyclone where we happen to be situated. E. DOUGLAS ARCHIBALD

OUR ASTRONOMICAL COLUMN

The Transit of Venus in New South Wales, &c.—In his address as president of the Royal Society of New South Wales, read May 3, Mr. H. C. Russell, the director of the Observatory at Sydney, gave some account of his arrangements for the observation of the approaching transit of Venus in that colony. Provision was liberally made last year by the legislature, and a sum of 500*l*. has been placed at Mr. Russell's disposal for this purpose. With this he states he will be able to provide four high-class 6-inch equatorials, exactly similar to those which are to be used by European observers, and two of 4½ inches. There are remaining from the last transit one equatorial of 11½ inches, one of 7¼, one of 5 inches, one of 4¾, and one of 4¼ inches. He hopes to be able to take up four stations, in addition to the Observatory, with two observers and two telescopes at each point. In order to make the best of the chances of favourable atmospheric conditions, elevated points on the east coast of New South Wales, have been selected, which, it may be fairly anticipated, will have a clearer view an hour after sunrise than could be looked for near the sea-level. Mr. Russell remarks that in observing the transit of Mercury last November, the observers were stationed at Bathurst, Katoomba, and Sydney, places which he had thought were far enough apart to secure different weather; but the result showed that the weather was practically the same at the three stations. This induced the unpleasant reflection that it may prove cloudy all along the coast on December 6, and he had therefore gladly taken advantage of the recent commission to Lord Howe Island to make some inquiry as to its suitability as a station. It is found that an elevated spot is easy of access, and the weather at the hour and season is almost sure to be fine.

We have also received from the Imperial Observatory of Rio de Janeiro a report on the proposed arrangements to be made by the Brazilian Government for securing observations of the Transit. In addition to Rio, it is intended to establish a station at Pernambuco and to equip an expedition to Santiago de Cuba. The details are in charge of M. Cruls, acting director of the Observatory at Rio.

Solar Parallax from Observations of Minor Planets.—Mr. David Gill, H.M. Astronomer at the Royal Observatory, Cape of Good Hope, has arranged with a number of observatories in both hemispheres for corresponding observations of the minor planets, *Victoria* and *Sappho*, about the times of their oppositions in the present year. Victoria, in opposition on August 24, will be distant from the earth 0·89 of the earth's mean distance from the sun; and Sappho, which comes into opposition in R.A. on September 24, will be within 0·85, so that we have in each case a favourable opportunity of applying the method of determining the sun's parallax, which was advocated and also applied by Prof. Galle, the director of the Observatory at Breslau. In a communication to the *Astronomische Nachrichten*, Mr. Gill states that the necessary extra-meridian observations will be made in the southern hemisphere at the Cape, Natal, Melbourne, and Rio de Janeiro, and in the northern hemisphere at Dunsink (Dublin), Strasburg, Berlin, Bothkamp, Leipsic, Upsala, Moscow, Clinton, U.S., and probably at Kiel. From the clearer skies of the southern hemisphere, he believes that a fully corresponding number of observations will be secured there, notwithstanding the smaller number of observatories, and he invites co-operation from other establishments in the northern hemisphere, on this ground. A list of the proposed stars of comparison is given in his letter.

Comet 1882*a* (Wells).—The Emperor of Brazil, telegraphing to the Paris Academy of Sciences (of which body his Majesty is a member), reports the visibility of this comet at Rio de Janeiro, on June 17, and that three days later the nucleus was very bright, and the tail 45° long. If there be no error in the telegram, the development of the tail must have been rapid after the perihelion passage.

Prof. Zona has made a communication to the Società di Scienze Naturali of Palermo, in which he describes the undulations in the tail observed there in the week following April 14. On the 17th, in a fine sky, it is remarked of the phenomenon—"Sembra che la luce della coda vada a poco a poco diminuendo stringendosi attorno il nucleo come se venisse da questo attratta, poi ad un tratto si spande di nuovo."

EDUCATION IN THE UNITED STATES[1]

THE great work of the American Bureau of Education continues, like that of a large Reference Library among men who know its value. About 100 inquiries a day are addressed to it, and 150 letters of information are sent out on subjects varying from the Semitic language to dress-making, and including everything that comes within the limits of education. Its latest report, in which everything is tabulated, down to the opening of a normal summer school only kept open for four weeks, and in which attention is called to many matters of special interest, cannot be gone through without advantage to educationists in any civilised country, and most of all to those in our own.

If we are accustomed to think that Americans look upon their country with complete satisfaction, and as standing ahead of the Old World, more particularly in the matter of education, we shall not find such self-praise in the Government reports. A very interesting *résumé* is given of what foreign countries are doing. Attention is called to the more thorough manner in which young persons aiming at commercial pursuits are instructed on the Continent, while England is quoted as an example to be followed of the higher education of women. It is satisfactory to find, in this Report also, that the province of Ontario, in Canada, stands at the head of educating countries. There a system of free schools and compulsory attendance was established in 1871; and while the number of children within the school ages of five and sixteen was 492,460, there were actually attending schools 489,015! On the other hand, it is surprising to find the illiteracy of a very large proportion of the population of Prussia, where of 40,000,000 persons (including infants, &c.), 25,000,000 were unable to read or write!

The schools requisite to supply education to so widely spread a population as that of America are far more numerous than in our crowded country. Naturally, therefore, it is a great difficulty to find sufficient teachers properly educated and qualified for this important work. It might seem, at first, that, in a country where, on an average, each individual is better educated than in England, there would be no lack of able teachers; but teaching is an art requiring a technical education as much as any other art; and the work of those who have not had this technical training is as clumsy as most amateur work is, and is found to have the fault of superficiality. The Bureau of Education is simply an office of information and reference; it has no central control over the various States; and one result of this is, that no uniform standard of capacity is required of those who present themselves as teachers, and two standards are to be found, not only in the same State, but in the same city. A more unsatisfactory difficulty still is the favouritism and even corruption, not unfrequent in appointing and dismissing teachers, who, in many cases, seem to go in and out of office like the nominees of a government. The picture of corruption on page xxii. must surely be an extreme case; but its possibility must add greatly to the difficulty of the situation. Pennsylvania's is called a proud record, there dishonesty among school-board officials is *almost* unknown; "a few thousand dollars would cover all the losses." These things tell greatly against the business of a teacher being an attractive one, and, to add to them, in many States, as in Virginia, diminished public funds have been allotted to the common schools; the number of schools has been reduced, and the salaries of the remaining teachers lowered. In some countries in that State the local boards determined to open no schools, and to use the income for paying off debts.

The small pay of teachers, in the lowest standards especially leads them to throw up that branch on the first

---

[1] United States Report of the Commissioner of Education for the year 1879. (Washington Government Printing Office, 1881.)

opportunity—a very mischievous thing in its results—for in nothing is it more true than in the case of education that what is well begun is half done. Hence a good infant school is an immense help to all subsequent stages, and *vice versâ*. So much is this deterioration felt in Michigan, where salaries of schoolmistresses have been reduced to the level of those of domestic servants, that the attendance at the primary schools has absolutely fallen off; and the explanation of it seems to be that these faults are well known to the intelligent public of the United States, and accordingly the children are being removed to private schools. The Commissioner very aptly quotes Roger Ascham's words:

"It is a pity that commonly more care is had, yea, and that among very wise men, to find out rather a cunning man for their horse, than a cunning man for their children. . . . To one they will gladly give a stipend of 200 crowns by the year, and loath to offer to the other 200 shillings. God that sitteth in heaven laugheth their choice to scorn, and rewardeth their liberality as it should. For he suffereth them to have tame and well-ordered horses, but wild and unfortunate children; and therefore, in the end, they find more pleasure in their horse than comfort in their children."

This is not a bright picture of the work of education in America. It certainly seems an indication that our brethren there are losing faith in the old rule, that what is worth doing at all is worth doing well, but it does not go very deep below the surface of so vast a work. On the whole there continues a steady rise in numbers of both schools and pupils, though not so large since 1875, as we should have expected in such a progressive country. This rise also is almost wholly in cities, again pointing to the difficulty of supplying the *number* of schools required in so wide-spread a country. In one of the most flourishing of these cities also, Chicago, it sounds more like the Old World to read that more than 2000 children are taught in underground rooms, where the light is so bad as to expose their eyes to serious injury! In New York and New Jersey, where population in its extremes of rich and poor keeps crowding together as in older countries, the school attendance is actually falling off. In Maine, New Hampshire, and Rhode Island the population is, curiously enough, at the present time decreasing, but school attendance is increasing; not quite one-third of the population attend daily; nearly two-thirds are on the books. In nearly all Southern States there is considerably increased attendance. The administration of the Peabody Fund has had a remarkable influence in developing the school spirit in the south, in awakening the people to a sense of their obligation with reference to the support of public schools and in maintaining a high standard for such schools. This last result has been accomplished by the wise policy pursued by Dr. Sears in insisting upon a certain degree of excellence in a school as the condition of receiving aid from the fund.

An increase of more than 50 per cent. in the number of students in the Schools of Science in 1878 led to the number of these schools being raised from 809 to 884; but this increase of pupils hardly kept up in 1879. Still science, though a long way behind theology in number of schools, is rapidly gaining ground upon it, and has already far outstripped it in number of students. In 1870 there were 80 schools of theology with 3254 pupils, which numbers have grown respectively to 133 and 4738; but the corresponding numbers for science are 17, increasing to 81, and 1413, increasing to 10,914! This has called for a large increase of teachers; and, accordingly, while in secondary schools the proportion of those receiving a scientific, to those receiving a classical, education is as 2 to 5, in the preparatory department of colleges the proportion is as 4 to 5. At some of these colleges there are workshops, where the use of tools is taught to students by their being used in the production of other tools and things useful to the establishment. The Massachusetts Institute of Technology has one of these workshops upon a plan designed at the Imperial Technical School of Moscow, Russia. The income of these scientific colleges is partly derived from the sale of lands allotted to them in each state; 30*l*. a year is charged to each pupil for tuition, but it represents but a small percentage of the income. The Cooper Union Free Night Schools of Science are well described as "an intelligent application of a great charity. Their purpose is the technical instruction of the labouring classes, and the means used are a free library and reading-room, free lectures, and two classes of schools, viz. the Evening Schools of Science and Art, and the Art School for Women. All money earned in the schools belongs to the pupil, and a number are thus enabled to support themselves while studying. A Telegraph Company has appointed a teacher in this school, who trains the pupils in their methods of working their instruments, and they have employed many of its graduates on their lines. Still the Report endorses the doctrine that even in technical schools, principles, not practice, must be the leading object of a school, and that even to those following a special business, a broad general culture is very important, and a want of it very much felt. After reviewing the various schools and institutions of this class in the United States, the Commissioner of Education is led to the conclusion that "the present condition of scientific and technical schools in our country is thus seen to be very promising. . . . Already they have excited the people to an appreciation of scientific methods and processes in their application to agriculture and the mechanic arts; and as the results of such methods are more widely known and more fully comprehended, the institutions rise in favour and influence, and the demand for their graduates increases."

Drawing is highly eulogised, and its importance insisted upon. In Massachusetts any town *may*, and every city and town having more than 10,000 inhabitants *shall*, provide for instruction therein; and a training school for teachers has been organised to meet their wants, with the result also of supplying designers to many manufacturers who were in want of them.

On the law schools in America, our Report observes that it is surprising that a profession which requires such thorough preparation, and which has in it so large a number of men of wealth, and one which occupies so important a place in the public affairs of the country, has done so little to endow its schools in the most substantial manner.

Medical men are very plentiful in the United States compared with other countries: 1 to every 600 inhabitants, while Canada has only 1 to 1200 inhabitants, Great Britain 1 to 1672, Germany 1 to 3000. A higher standard of examination is recommended, and an all-round education insisted upon. Only five schools at present require the highest amount of study to qualify a full practitioner.

A valuable branch of education is the training schools for nurses, which adopt a very high standard as to whom they receive for their important functions. A small sum, however, is *paid* to students, besides board and lodging, the latter of which is carefully provided them at a bright, cheerful home away from the hospitals where their duties are inculcated.

More than 30,000 blind people are among the population of the United States, and their education is considered, like other education, a duty and not a charity, and is provided out of national funds. Again, the education of the feeble-minded is systematically provided for, as being necessary for the prevention of crime, and useful to individuals of all classes. This leads on to the most important question in a country where population is thickening even as much as in America, of Reform Schools. There, under the Michigan system especially, which all should investigate, it seems fully realised that prevention is better than cure; and that while these inindustrial homes are indubitably powerful in preventing the formation of criminals, prisons, on the other hand, are just as indubitably powerful in carrying it on!

Evening High Schools have been worked in several American cities, but hardly with results lending much encouragement to increase. One would think, however, that the knowledge gained at elementary schools by the age of fourteen would lead to a wish for more on the part of many, to whom a library only could not supply it. But free libraries are a great power in the United States. Forty-nine new ones were opened in 1879, containing 86,779 volumes, making a total of 3842 public libraries of all classes. The correspondence with the Bureau of Education on the subject of public libraries far exceeds that on any other subject; academies standing next, and art and science standing curiously low for a country like America. Yet local feeling varies even on a favourite subject like free libraries, the large manufacturing town of Paterson being without one like so many populous English towns.

Like free libraries also, agricultural education is a department in which England, notwithstanding the height to which husbandry has been brought there, stands lower than in any other country.

One can hardly, nevertheless, read this Report without feeling that spite of our shortcomings the advantages are not all on the side of America. Our compactness, plentiful supply of thoroughly-trained teachers, and, we must add, higher sense of honour in political transactions, perhaps owing in part also to the close inspection to which the works of every man are subjected here, entitle us to feel how far better we are placed, as far as meeting educational requirements goes, than the thin and scattered families of the United States.

MALAYO-POLYNESIAN LINGUISTICS[1]

THE learned authors have earned the thanks of linguistic students by issuing, in a separate form, this important contribution to a better knowledge of the Melanesian and Papuan languages, which was first published in the eighth volume of the *Philological Transactions* of the Royal Saxon Scientific Institute. It forms the first instalment of a series of papers intended to supplement the comprehensive and well-known treatise of H. C. von der Gabelentz, published at Leipzig in 1860 and 1873. To the languages dealt with in that work are now added two others: that of Mafór (Núfór), Geelvinck Bay, and a dialect current on the Astrolabe Bay Coast, North-East New Guinea, from materials supplied by Van Hasselt and Miklucho-Maclay respectively. To these notices are added the Papuan idioms spoken in the islands of Errúb and Maer, Torres Strait, and in Segaar Bay, near Cluer Gulf, South-West Coast of New Guinea, the former by Herr Grube, the latter from data supplied by H. Strausch to the *Zeitschrift für Ethnologie*, viii., pp. 405-18.

In the introduction, the question of the relations of the Papuan and Malayo-Polynesian linguistic groups is discussed at some length. It is satisfactory to find that the authors seem at last disposed entirely to abandon the views held by the elder von der Gabelentz regarding a possible, if not probable, fundamental unity of these families. The key-note of the objection to this theory is struck in the following paragraph, at p. 4:—"Assuming that the linguistic affinity were fully established, we should have at once a direct antagonism between anthropology and philology. Two linguistic groups are related; of the corresponding ethnical groups, one belongs to one, the other to another race of mankind. How is this possible?"

To many this may seem merely an old-fashioned *a priori* argument, of no value in itself unless supported by the evidence of facts, which have hitherto pointed at an opposite conclusion. But one of the most firmly established and universally accepted principles of anthropology maintains the evanescent character of human speech as compared with the relative fixity of physical types. Ethnologists are of accord as to the substantial unity of the Iranian, Semites, Berbers, Basques, Georgians, and other members of the so-called Caucasic ethnical stock. Philologists are, on the other hand, equally of accord as to the essential difference of the Iranic, Semitic, Hamitic, Basque, Georgian, and other linguistic groups spoken within this common Caucasian ethnical group. Here we have fundamental racial unity combined with organic divergence of speech, and the apparent contradiction is readily reconciled by the doctrine of the far greater permanence of physical, as compared with linguistic types. The race, even notwithstanding the intrusion of foreign elemenrs, remains essentially one; the speech, presumably one originally, owing to its greater evanescence diverges in various directions to such an extent, that all traces of this original unity have long been effaced.

Coming now to the Oceanic area, where the Papuan and Malayo-Polynesian forms of speech, shown to be fundamentally one, while the physical forms are confessedly distinct, the case would be entirely reversed. Instead ot physical unity, combined with linguistic disparity, we should have the opposite phenomenon of linguistic unity combined with physical disparity. Such a phenomenon is certainly neither intrinsically impossible nor altogether unknown to science, as appears, from the Persian-speaking Házérahs and Aimaks of North Afghanistan, or the French and English-speaking negroes of the New World. But where they occur, such cases are easily accounted for by political supremacy, social contact, superior culture, and other obvious influences. These influences have also been to some extent at work probably for many ages in the oceanic world. The Malays in the west, and the brown Polynesians in the east, both of kindred speech, and both of roving or piratical habits, have in this way influenced numerous Papuan and Melanesian peoples in their respective domains. Hence we find the Tagalas, Bisayans, and even some of the Negrito Aetas of the Philippines, as well as some of the Negrito Samangs of the Malay Peninsula, and most of the Formosan wild tribes speaking various more or less divergent dialects of the organic Malay speech. In the same way the Papuan Motu tribe of the south-east coast of New Guinea, many of the Melanesian Fijians, New Hebrides, and Solomon Islanders are found to be now speaking various more or less divergent dialects of the organic Polynesian speech.

It was precisely from these misunderstood facts that philologists had generally arrived at the surprising conclusion that, in point of fact, the Polynesian and Melanesian languages were essentially one, thus placing anthropology and philology in antagonism. The Melanesian and Papuan dialects selected by Hans Conon von der Gabelentz, and again quite recently by the Rev. Mr. Codrington, as the subjects of comparison, were not, properly speaking, Melanesian languages at all, but Polynesian forms of speech imposed by the restless Samoans and other Polynesians on these Papuan and Melanesian populations. Obvious instances are the almost pure Papuan Motu people speaking a tolerably correct Samoan dialect (Rev. W. G. Lawes), and the mixed Melanesians of Fotuna, in the New Hebrides, speaking idioms closely related to the same group.

But it is remarkable that the reverse phenomenon has not yet been recorded. At least no instance is known to the writer of a distinctly Malay or Polynesian tribe speaking a distinctly Papuan or Melanesian tongue. It is more than doubtful whether such a case will ever be discovered in this watery domain, where the Malays and Polynesians

---

[1] "Beiträge zur Kentniss der Melanesischen, Mikronesischen und Papuanischen Sprachen," von G. von der Gabelentz und A. B. Meyer. (Leipzig, 1882.)

have always been the aggressors, where the dark populations have always represented the passive or recipient element. On the other hand, wherever it has escaped from Malayo-Polynesian influences, or wherever it has been able to preserve its original speech in spite of those influences, this dark element will certainly be found speaking languages organically distinct from the Malayo-Polynesian. Mr. Man's recently published account of the Andamanese dialects shows that they differ in their morphology, in their glottology—in fact, in every respect, from those of Malaysia.

Mr. Lawes makes the same remark respecting the Koiari people, who occupy the highlands back of Moresby Bay in South-East New Guinea. And the authors of the work under review now find that the Mafór of Geelvinck Bay betrays, with many striking resemblances to the Malayo-Polynesian, "an astounding peculiarity of structure."[1] The "resemblances" are of a verbal character, due to known contact with the Malays, who have long frequented the waters along the north-west coast of New Guinea. The "peculiarity of structure," involving root modifications and something even approaching to inflection ("Quasiflexion"), as understood in the Aryan family, belongs to the organic Papuan linguistic type. This type is thus demonstrated to be fundamentally distinct from the Malayo-Polynesian, which shows no trace of these peculiarities. And thus also disappears the fancied antagonism hitherto supposed to exist between the linguistic and anthropological elements in the Oceanic regions.

A. H. KEANE

THE SOLAR-COMMERCIAL CYCLE

IN an article printed in NATURE (vol. xix., pp. 588-90) I gave a table of the prices of wheat at Delhi, from 1763 to 1835, quoted, or rather calculated from data given in a brief paper of the Rev. Robert Everest, contained in the *Journal* of the (London) Statistical Society for 1843, vol. vi. pp. 246-8. Between the years 1763 and 1803 there was evidence of wonderful periodicity in the recurrent famine and abundance at that part of India. When recently engaged in examining more minutely the relation between these prices and the variations of solar activity, as indicated by Prof. Wolf's numbers, it has occurred to me that an inference may be drawn which I overlooked on the previous occasion.

In the accompanying diagram I have exhibited the prices in question together with Wolf's numbers as stated in the *Monthly Notices* of the Royal Ast. Soc. vol. xxi. pp. 77, 78. I have also indicated the dates of the Commercial Crises of the time according to the article on the subject in Mr. H. D. Macleod's "Dictionary of Political Economy," vol. i. pp. 627-8. It need hardly be said that the coincidence between the three classes of recurrent phenomena is of a very remarkable character, and goes far in supporting the relation of cause and effect which I had inferred to exist, both on empirical grounds and from the well-known fact that it is the cheapness of food in India, which to a great extent governs the export trade from England to India. But although the coincidence of commercial Crises in Western Europe with high corn prices at Delhi is almost perfect, it will be noticed that after 1790, the correspondence of the solar curve with that of prices is broken. Wolf does not recognise the existence of any sun-spot maximum between 1788 and 1804, and he believes that there was a minimum at 1798. According to Wolf's later researches (*Memoirs* Roy. Ast. Soc., vol. xliii. p. 302), these dates are respectively, maximum 1788·1, minimum 1798·3, and maximum, 1804·2.

But now arises the question to which I wish to draw attention. If the eleven-year solar periodicity was really interrupted in this long interval of 16·1 years, how comes it that the meteorological periodicity, as manifested in the corn prices at Delhi, was not interrupted. It is true that the price maximum of 1803 was a comparatively small one; but this was quite to be expected, considering that if there were an intervening solar maximum, it must have been a small one. May we not reverse the argument and infer that the evident relation between the previous sun-spot maxima and the succeeding scarcities at Delhi, would lead us to expect a minor solar maximum about the year 1797?

Standing alone, the presumption thus created would, doubtless, be of a somewhat slight character. But it is in the first place well known, that the data upon which Wolf based his numbers about this time, are less conclusive than in other parts of his series. His results, too, from 1801 to 1807 are expressly marked as doubtful, so that extrinsic information which might have little weight where there was abundance of reliable solar or magnetic observations may come in very usefully where doubts already exist. Now it happens that the late Mr. J. A. Broun inquired very carefully into the facts known about the solar variation at this time, his results being given in the *Transactions* of the Royal Society of Edinburgh, vol. xxvii. pp. 563-594, and in his article printed in NATURE (vol. xvi. pp. 62-64). Broun inferred from the observations of Gilpin, and from other data, that there was a small maximum about 1797, and that there were grounds for believing that the subsequent maximum "may really have occurred after 1806, when Gilpin's series terminated." Now, what Broun deduced from totally different data, is exactly what we should infer from the Delhi prices. If we are to believe that Indian meteorology depends upon solar variations, then it almost follows that there was a solar maximum about 1797. The consequence of this inference, however, is very important, because it goes to support the views of Lamont, Broun and others, that the solar period is about 10½ (10·45) years and not 11·1 as calculated by Wolf. It should also be pointed out that the temperature observations of Prof. Piazzi Smyth lead to a like result. The epochs of the heat waves are, according to him (NATURE, vol. xxi., p. 248), 1826·5, 1834·5, 1846·4, 1857·9, and 1868·8, giving an average interval of 10·57 years.

I may take this opportunity of asserting that the progress of events confirms belief in the eastern origin of the great commercial Crises.[1] In his important work, the "Précis du Cours d'Economie Politique" (vol. i. pp. 604-5), M. Cauwès while partially accepting the doctrine of periodicity criticises the particular views here advocated. He says:—

"Depuis longtemps les économistes ont signalé la périodicité de ces évolutions : MM. Juglar et Jevons prétendent même pouvoir la calculer d'une manière précise. Selon M. Jevons, l'ensemble des phénomènes serait renfermé dans un cycle de dix années et demie. De fait, les grandes crises économiques du siècle (1806, 1817, 1825-7, 1836-37, 1847, 1857,) s'échelonnent à dix années d'intervalle ou à peu près, mais les dernières, 1866 et 1873, seraient venues un peu avant l'heure, et celle de 1873 s'est prolongée au delà de toute attente." M. Cauwès in short accepts the six earliest crises of this century as sufficiently agreeing with the theory. The crisis of 1866 no doubt came about a year before it would be expected, which is a divergence of reasonable amount. The year 1873, however, is one which it would be impossible to introduce into the series. Now there doubtless were both in America and England in that year, a state of commercial stringency, a relapse of prices and other disturbances which might be mistaken for the signs of a

---

[1] "Gerade das Mafoor'sche aber wird in seinem Baue bei manchen auffälligen Aenlichkeiten eine erstaunliche Eigenthümlichkeit im Bildungsprinzipe aufweisen," p. 4.

[1] As it is impossible to reproduce the explanations and qualifications contained in the article quoted above, or that at pp. 33-37 of the same volume of NATURE (vol. xix.), it is assumed that this article is read subject to those qualifications and explanations. In p. 588 col. *b* of the same volume, a *seer* of wheat was by a typographical oversight stated to be equal to 21 lbs. instead of the true weight 2 lbs.

true crisis. But such as it was, this crisis turned out to be just one of those exceptions which prove the rule. The following statistics of bankruptcy in the United Kingdom, as collected by Messrs. Kemp, and published in the *Mercantile Gazette*, show conclusively that the real collapse came in exact accordance with the decennial theory in the autumn of 1878 or early in 1879:—

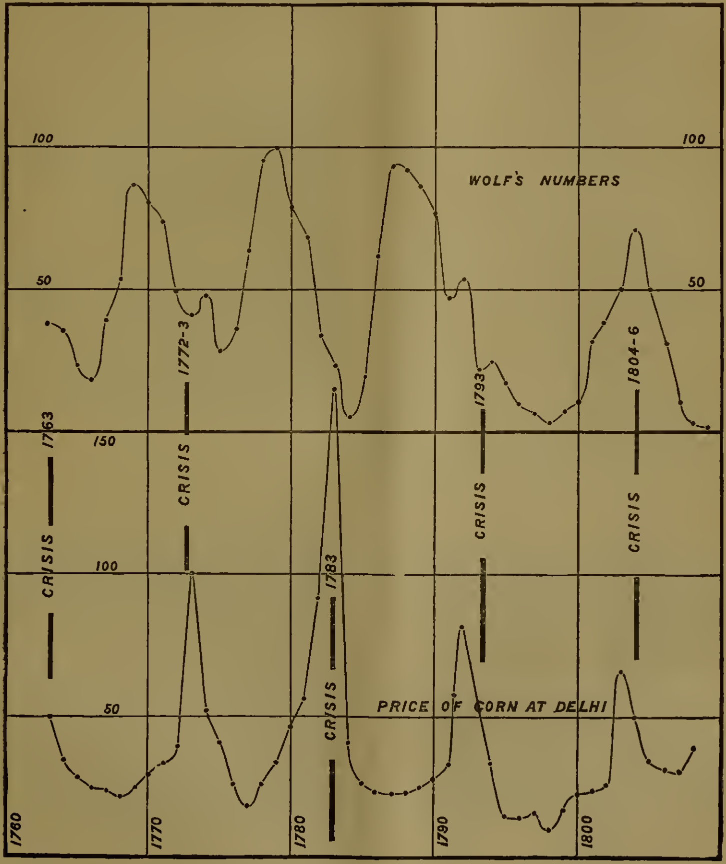
Year.	Number of bankruptcies.	Year.	Number of bankruptcies.
1870	8,151	1876	10,848
1871	8,164	1877	11,247
1872	8,112	1878	13,630
1873	9,064	1879	15,732
1874	9,250	1880	12,471
1875	9,194	1881	11,632

It will be remembered that the crisis of 1878 was precipitated by the failure of the City of Glasgow Bank owing to great losses of their customers in the Indian trade, the depression of that trade being caused by the recent famine in India.

As a good deal of misapprehension has arisen concerning the American Crisis of 1873, it is well to quote the following valuable statistics from the Annual Circulars of Messrs. R. G. Dun's mercantile agency:—

Year.	Number of failures.	Amount of liabilities in dollars.
1873	5,163	228,589,000
1874	5,830	155,239,000
1875	7,740	201,060,353
1876	9,092	191,117,786
1877	8,872	190,669,936
1878	10,478	234,383,132
1879	6,658	98,149,053
1880	4,735	65,752,000
1881	5,582	81,155,932

Although the amount of liabilities involved in the failures of 1873 was larger than in any subsequent year except 1878, the number of failures was less than in any year named except 1880. The average liability of each failure in 1873 was $44,274 compared with $22,369 in 1878. It is thus apparent that the crises differed entirely in character, and I believe that the collapse of 1873 was mainly due to the breakdown of values of properties necessarily following sooner or later upon the contraction of the paper



currency. In any case there was a very distinct maximum of failures in 1878, succeeded by a sudden reduction, and it occurred at a time differing by less than a year from the corresponding collapse in England. In the Dominion of Canada there was a very strongly marked maximum of failures at the same time as in England, namely, in 1879.

The theory of the solar-commercial cycle and of the partially oriental origin of decennial crises has received such confirmation as time yet admits of. I am, however, fully alive to the weight of some of the difficulties and objections which have been brought forward against the theory. These objections are far from being conclusive, and I may hope to give them in due time a satisfactory answer. But such answer must involve more detail than can be put into a brief article.

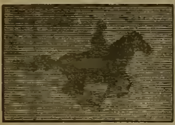
W. STANLEY JEVONS

CONVENTIONAL REPRESENTATION OF THE HORSE IN MOTION

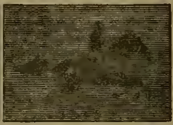
IT is of interest to analyse the reason why artists represent a galloping horse in a way unlike any of its real attitudes, as they have been photographed by Mr. Muybridge, and why the critical public have so long acquiesced in these incorrect representations without remonstrance. Partly, no doubt, it is owing to prevalent errors of conception which govern the judgment in its interpretation of a movement that is hard to follow. An excellent instance of this is to be seen in the Academy, in the diploma picture of Mr. Riviere, R A., entitled "The King drinks." It is a lion lapping water in the wrong way, by spooning his tongue outwards and upwards instead of curling it backwards, like the fingers of the half-closed hand when the knuckles are to the front, an action that may be conveniently studied in the kitten. The error of preconceived ideas partly explains the conventionally extended figure of the galloping horse; but I find the latter to be largely justified by the shape of the blur made on the eye by his rapid and various movements. I wish I could reproduce on a scale, however small, any one of the many plates published in "The Horse in Motion;" but it appears that the copyright of the photographs is disputed, and there are difficulties in the way of doing so, and I must make shift without them.

I find that taking the attitudes of the galloping horse, Phryne, as an example, published in Plate XVI. of the book just mentioned, that her stride has the duration of about six-tenths of a second, and that it has been photographically analysed into twenty momentary attitudes. Also, that these may be arranged in four groups, which I will call A, B, C, and D. I have made photographic composites of each of these groups, and copies of them by the wood engraver are annexed.

A



B



C

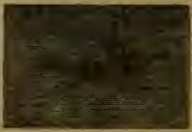
D

A contains six attitudes, in which the legs are crumpled below the body.

B contains four attitudes, in which one or both of the hind legs are on the ground, and the fore legs are pawing in the air.

C contains five attitudes, in which both the fore and hind legs are extended.

D also contains five attitudes; the hind legs are flung back and the fore legs are on the ground.



G

G is the general composite of all the attitudes.

FIG. 1.

FIG. 2.

It will be observed that in the general composite the blur somewhat justifies the conventional representation, because though the lower parts of the limbs leave no definite image at all (less so in the photograph than in the engraving), the upper portions have a distinctly outflung look, and as the artist lies under the same unhappy necessity that plagues the geographer, who, when he has to put down a lake or river on the map must put it *somewhere*, although its real position may be uncertain, so the artist thinks he must put the lower parts of the four legs of the horse somewhere, and he is guided in his decision as to the exact place by the direction of their upper portions.

I find, however, on trial that another cause of confusion lies in the difficulty of watching closely both the fore and the hind halves of the animal simultaneously. The eye wanders from one to the other and seizes the most characteristic attitudes of each, and combines them into a hybrid monster.

The accompanying composites, Figs. 1 and 2, each from four successive attitudes, will explain the process; it certainly tends to go on in my mind, and probably does so in that of others. The first composite shows the hind legs distinctly; the second shows the fore legs distinctly; and if duplicates of the first and second woodcuts are each divided in two halves and the best defined half of each are united (in a way that might have occurred to Baron Munchausen if a second rider's horse had suffered as his own, and there had been a mistake in piecing them), a result, Fig. 3, is produced that shows a very fair correspondence with a not uncommon representation in sculpture.

FIG. 3.

FRANCIS GALTON

THE CHANNEL TUNNEL

AT the meeting of the Paris Academy of June 26, M. Daubrée read a note on the geological conditions of the Channel tunnel. The works connected with the tunnel comprise three phases:—(1) Scientific researches; (2) preparatory works; (3) execution of the tunnel itself. The first phase was devoted to purely geological investigation, in the form of minute exploration of the French and English coasts, exact and detailed investigation of the sea-bottom in the Strait, borings made on *terra firma* which verified the nature, thickness, and inclination of the strata, and gave an approximate idea of the hydrological condition. Since 1879 the second phase has been entered on by verifying the previous scientific data, and preparing for the execution of the tunnel itself, experimenting in small galleries with machines and tools capable of being ultimately used in a work of exceptional importance. On the French coast, the geological investigation established a slight bulging of the beds at the place known as the *Quenocs*. On account of this bulging the inclination of the strata, which, in the strait is towards the north-north-east, is found, along the cliffs of Blanc Nez, turned towards the south-east, and the slope which, according to the first orientation, in the neighbourhood of the Quenocs, is about 0·05 m. per metre, is found, in the second, to be nearly 0·09 m. It is important then, to find in what conditions this bulging may modify the physical conditions of the banks forming the base of the Rouen chalk. For this purpose the French Association had dug, near Sangatte, two shafts of a depth of 86 m., which met the gault at 59 m. below the hydrographic zero, adopted in the maps in which the geological explorations of 1875-6 are recorded. The digging of these shafts, one of them 5·40 m. in diameter, showed that all the white chalk and the upper part of the Rouen chalk are water-bearing. These strata had thus to be abandoned.

On the other hand, the base of the Rouen chalk allowed only a very small portion of water to pass. There, then, the tunnel should be pierced, as the stratum appeared to proceed without interruption from France to England. The water penetrating the works is fresh, and of good quality; at the upper part only some slightly salt veins were found. Nevertheless, the communication of the water-bearing strata with the sea is proved by the oscillation of the water-level in the shafts according to the tide, and by the invariable increase at high water. M. Daubrée then refers to further galleries dug on the French and on the English sides, and excavations made with the machines of Col. Beaumont and Mr. Brunton On the Dover side, the chalk, which on the French side was but little permeable, was, on the English side, quite impermeable. Owing to this circumstance, they were able to begin at the bottom of the shafts, at 29 m. below the French hydrographic zero, a gallery advancing under the sea by following in the stratum an almost regular descending slope of 1-80th, or 12·5 mm. per metre. The bed on the English side, somewhat more powerful than on the French side, presents a very great regularity. Thus the Beaumont machine, which has been used in the perforation, has been easily able to trace a perfectly cylindrical gallery, which has now reached 1800 metres from the shafts, of which 1400 metres are under the sea. So far there has been no access of water. In the banks which form the base of the Rouen chalk, the rock in mass is almost completely dry; the access of water which has been observed has entirely the character of small springs issuing from the joints of fracture or cleavage. The perfectly cylindrical form produced by the Beaumont machine renders the gallery where such leakage occurs easily isolated by means of cast-iron rings prepared in segments easily united, the rings themselves being clamped together to form a tube of any length. When the water spurts out in considerable force, a sort of mastic or minium is successfully employed, which is placed between the segments of the rock, and compressed in the manner of a water-joint by the pressure of the rings against the rock. The mastic also seems to render the joints of the neighbouring rings water-tight. Owing to the excellent make of these rings, they can be rapidly put in position; a complete ring can be placed in half-an-hour, and several experiments in the Shakespere Cliff Gallery have proved that by this simple process the springs encountered can be completely blocked. On account of the slope on which the English gallery descends, its extremity recently reached 51 m. below the hydrographic zero, at a point where the depth of the sea at low water is 5 m.; there is thus 46 m. of chalk between the floor of the gallery and the bottom of the sea.

NOTES

MR. GEORGE GRAY, Honorary Secretary of the Philosophical Institute of Canterbury, Christchurch, New Zealand, writes under date May 20:—"I have been requested to forward you the inclosed resolution passed at a meeting of this Institute May 4, 1882, and to ask if you would kindly insert the same in the Notes of your valuable journal. Resolution proposed by C. Chilton, M.A., seconded by G. Gray and carried:—'That this Institute desires to place on record its high appreciation of the great services that have been rendered to science by the late Dr. Charles Darwin, and its deep sense of the loss that science has sustained through his death.'"

AT a meeting of the Executive Committee of the Darwin Memorial Fund, held on June 30 at the Royal Society's Rooms, Burlington House, it was announced that the total subscriptions already promised or received amounted to £2487 13*s*. It was decided that the memorial should take the form of a marble statue; and a sub-committee was appointed to make the necessary arrangements. It was agreed to ask the trustees of the British Museum for permission to place the statue in the large hall of the British Museum (Natural History), South Kensington. The sub-committee consists of the following:—Mr. W. Bowman, Sir J. D. Hooker, Prof. Huxley, Mr. C. T. Newton, and Sir F. P. Pollock, with the Chairman, Mr. W. Spottiswoode, Pres. R.S., the Treasurer, Mr. John Evans, Treas. R.S., and the Hon. Secretaries, Prof. Bouney and Mr. P. Edward Dove.

WE would draw the attention of our readers to a letter which we print this week from Dr. Sophus Tromholt, relative to the establishment of an observatory in Sweden for the Aurora Borealis "and other phenomena of Terrestrial Magnetism." Dr. Tromholt, it will be seen, is anxious to obtain for his proposal the opinion and advice of those familiar with the subject. Doubtless some of our readers might in this matter render useful help.

IN the sitting of the Paris Academy of Science of July 2, M. Berthelot, who had crossed the Channel with M. de Lesseps to visit the English works of the Channel Tunnel, gave an enthusiastic description of the galleries excavated at Dover, and the working of the Beaumont machine.

DR. ZIEGLER of Freiburg has recently prepared five wax models illustrating the development of the head of *Sinedon pisciformis*, *Salmo salar*, and *Rana temporaria*, founded upon the investigations of Dr. Ph. Stöhr of Wurzburg. These models are likely to be of great service to students in mastering the development of the skull, being greatly superior for this purpose to the best diagrams. The price of the series, conveniently packed in two boxes is 55 marks.

THE splendid dining-room and picture-gallery, together with the grand staircase of Stafford House, the residence of the Duke of Sutherland in Mayfair, have now been fitted up with the incandescent electric light. The lamps are those of Lane-Fox, as supplied by the British Electric Light Company, and the arrangements have been made by Mr. W. Mackie, who has been entirely successful in producing a fine effect. There are about 250 lamps displacing 8000 wax candles, and they are fed by the current from six Gramme machines of B type. The field magnets of these machines are excited by the current from two E Gramme machines, it being found preferable to adopt this plan. The power is derived from a 20 H.P. (nominal) steam-engine built by Marshall. The lamps are all in parallel circuit, so that the total resistance of the lighting circuit, including leading-wires of copper, is only 0·6 ohms. The leads consist of copper strand wires ⅞th of an inch in diameter, properly insulated and protected. The pure character of the incandescent light, together with its sanitary and artistic advantages, is causing it to make its way in West-End mansions.

A SPECIAL meeting of the Anthropological Institute will be held at No. 4, Grosvenor Gardens, S.W., the residence of Gen. Pitt Rivers, F.R.S., the President of the Institute, on Tuesday, July 11, at half past eight o'clock, p.m., when the following papers will be read:—1. Note on the Egyptian Boomerang, by General Pitt Rivers, F.R.S., President. 2. On the Longevity of the Romans in North Africa, by the Right Hon. Lord Talbot de Malahide, F.R.S., President of the Royal Archæological Institute. 3. On Neolithic Stone Implements, &c., from Wásá on the Gold Coast, by Capt. R. F. Burton and Commander V. L. Cameron, R.N., C.B. 4. Exhibition of Bushman Drawings, by Mr. M. Hutchinson, with Note by Mr. W. L. Distant.

THE Anniversary Meeting of the Sanitary Institute will be held in the Royal Institution Theatre, Albemarle Street, on Thursday, July 13, at 3 p.m. An address will be delivered by Edward C. Robins, F.S.A., F.R.I.B.A., entitled: "The Work of the Sanitary Institute of Great Britain." The chair will be taken by His Grace the Duke of Northumberland, K.G., President of the Institute.

THE late Dr. Karl Remeis has left a sum of 20,000*l*. to found an astronomical observatory in his native town of Bamberg, Germany. He has besides given the future observatory a 10-inch refractor and several other instruments.

THE great summer excursion of the Geologists' Association will be this year to the West Riding of Yorkshire, on July 17 and five following days.

FROM the *Scotsman* we learn that H.M. ship *Triton* arrived at Granton on Sunday week from Sheerness, where she had been fitted up for the prosecution of deep-sea investigations. The steamer is commanded by Staff-Commander Tizard. At the request of the Royal Society, the *Triton* has been detached for two months to investigate certain questions of physical geography in the Faroe Channel, which have a bearing on the results of the *Challenger* Expedition. On Monday week the vessel was supplied from the *Challenger* office in Edinburgh with dredging and sounding gear, deep-sea thermometers, and other apparatus. Mr. Murray and his assistants are to join the vessel at Stornaway in the course of three weeks; and she will be engaged for about six weeks in investigating the Faroe Channel. After completing this work, the *Triton* is to come into Oban to take on board Prof. Tait, and convey him to the North Atlantic, where, in a depth of 2000 fathoms, he proposes to test certain experiments which he has been performing on the *Challenger* deep-sea thermometers. (See NATURE, vol. xxv., pp. 90, 127.) In regard to the proposed Faroe expedition, it may be remembered that an exploration of the channel in question was made by Staff-Commander Tizard and Mr. John Murray, during the summer of 1880, in H.M.S, *Knight Errant*, the results of which were recently submitted by Mr. Murray to a meeting of the Edinburgh Royal Society. On that occasion Mr. Murray referred to the discovery by the *Lightning* and *Porcupine*, in 1868-9, of two contiguous areas having widely different bottom-temperatures, called by Dr. Carpenter the cold and warm areas respectively. At that time, he said, there was no suspicion of the existence of a sub-marine ridge separating those two areas. Certain theoretical considerations, however, based on some of the general results of the *Challenger* expedition, induced Commander Tizard to express the opinion that these two areas were separated by a ridge rising to within 200 or 250 fathoms of the surface. When a divergence of temperature was observed at some distance above the bottom in adjoining areas, it was inferred that a ridge intervened, and that the point of divergence indicated the height of the ridge. It was to make soundings in reference to this question that the *Knight Errant* was detached (see NATURE, vol. xxii. p. 405). Referring to the probable limitation of the British fauna, Mr. Murray remarked that since the depth limit had been disproved by the finding of animals at all depths, an artificial limitation must be substituted, and he thought it would be a temperature limit, for Arctic, British, and deep-sea species were obtained by the *Knight Errant*. There were climates on the surface of the sea, as well as on land, each having its peculiar fauna, and this surface fauna could be traced on the bottom by the dead shells found in the deposit.

FROM the Cape of Good Hope we receive the Report for 1881 of the South African Museum, which, under the superintendence of Mr. Trimen, is prospering and increasing. The following paragraph is of some interest:—"Upon trustworthy information that in a part of the Beaufort West district some unusually fine and perfect remains of extinct Saurians were accessible, the Trustees in October last despatched the Acting Curator to make an examination on the spot. Mr. Oakley reported that he had met with a large quantity of fragmentary remains of the *Dicynodon* group (some of which he brought with him), and that he had reason to believe, from the best local information obtainable, that in the bed of the Klein Leeuw River there existed an almost perfect fossil skeleton of a Saurian of great size, which, though recently visible, had become hidden by alluvial deposits. In transmitting this report to Government on November 1, the Trustees strongly recommended that a sum of 200*l.* should be placed on the estimates for 1882-83, for the purpose of defraying the cost of procuring for the Museum the more perfect of these fossil remains, and of conducting further investigations into South African palæontology; and they were informed in reply that every consideration would be given to their proposal when the time for framing the estimates should arrive. In reference to their subsequent communication on the subject, dated February 9, they now desire respectfully to renew their recommendation, as it is most desirable that the extinct *Dicynodontia* and allied reptilian forms, so characteristic of the past life of South Africa, should be as completely represented as possible in the Colonial Museum." We trust the necessary funds have been granted, and that the Trustees will see that it is for the best interests of the Colony that such an institution as this be maintained in complete efficiency.

THE surveyor to the Finnish Government, Herr Rodas, states that on June 25 this year he carefully measured the height of a hole, bored according to authentic records 2 inches above the level of the sea on the coast of Österbotten on June 25, 1755, and discovered that that part of the coast had risen, in 127 years, 6 feet 4 inches, or more than half an inch per year.

A SECOND earthquake of a far more violent character than the previous one, was felt at the town of Luleå in Sweden on June 23 at 7.30 a.m., the shock extending as far as the towns of Haparanda and Pitia. It lasted fully a minute, and went from south-west to north-east. People awoke from their sleep, and those about could only stand with difficulty, and that no accident occurred is due to the circumstance that all houses are constructed of wood. Whilst the tremor lasted subterranean noises could be heard similar to the rapid movement of heavy artillery on a hard road. There was no disturbance of the sea, the weather was clear and no wind, the temperature being 20° C., barometer high.

THE Parkes Museum, which was first instituted in 1876 as a memorial to the late Dr. Edmund Parkes, and in order to promote the health of the community for which Dr. Parkes so successfully devoted the best years of his life, was incorporated on June 28. The museum has been temporarily located in University College, Gower Street, since its establishment, and a proposal for permanently keeping it in connection with the College has been under consideration for some time, but the probability is that those who desire to see the Parkes Museum established as an independent institution in a building of its own will have their wishes gratified. Negotiations are now being made for acquiring such a building in a more central position than University College. The Museum is not rich pecuniarily, but its objects are of such growing importance that the necessary funds will no doubt be forthcoming. The objects of the Museum are "to aid, promote, and encourage the acquisition and diffusion of knowledge of hygiene in all its branches, and of all matters relating thereto, especially in connection with personal *régime*, food, domestic sanitation, means of safety and rescue, architecture, engineering, naval and military hygiene, and State medicine.

WE regret to notice that the Austrian Polar Meteorological Expedition has not been able, on account of the state of the ice, to land on Jan Mayen Island. The *Pola* put back to Tromsö, and was to make another attempt after fourteen days; we hope she will be successful.

AN International Geographical Exhibition is being held at Copenhagen.

THE French expedition to Cape Horn will leave this week without any further delay.

LIEUTENANT SCHWATKA is organising an expedition for the exploration of Northern Alaska.

THE Report of the Imperial Mint, Ôsaka, Japan, for the year ending June 30, 1881, being the eleventh report of the Mint, shows that during the financial year gold coins to the value of 490,585 yen (dollars) was struck, this being rather more than during the previous year. In the silver coinage there has been great activity, 5,089,113 one yen pieces having been struck, this being a larger number than ever before finished in a year. Nearly 74 millions of copper coins were struck during the year, their aggregate nominal value being over one million yen. The total value of coin issued by the Imperial Mint since its commencement in 1871, to July, 1881, amounted to yen 97,596,529,·79. The reports of the Assayers to the Imperial Japanese Mint, of the Royal Mint, and of the United States Mint, testify to the highly satisfactory manner in which the standards of weight and fineness are kept up. The soda-works within the Mint-ground are now in operation, and small quantities of sulphate and carbonate of soda have been turned out. The sulphuric acid-works did not produce so large a quantity of acid as in former years, but another works has been established in Osaka by a private company, showing that chemical industry in Japan is not standing still. The work carried on at the Osaka Mint, both as regards quantity and quality, is in the highest degree creditable to the two foreign *employés*, Mr. Gowland, the chemist, assayer, and technical adviser, and Mr. McLagan, the engineer, as well as to the staff of native officials and workmen.

CAPTAIN CONDER and Lieutenant Mantell, R.E., have returned from their first campaign in Eastern Palestine, bringing with them the results of their work. These include the map of a large district, covering 500 square miles of country, with a very large quantity of notes, plans, drawings, and photographs concerning the antiquities of Moab and Gilead. Captain Conder will proceed at once to arrange these materials for publication. He has also brought with him a considerable quantity of notes, and additional information made by himself and his party in Western Palestine. These will be included in the next volume of the Society's great work, which will be delayed a month or two on their account.

THE Municipal Council of Paris has voted a sum of 40*l.* as a subsidy to the Academy of Aërostation for the purpose of trying to photograph Paris with the help of captive balloons.

THE July number of the *Proceedings* of the Royal Geographical Society is of unusual interest. Along with excellent maps we have Mr. D. D. Daly's account of the surveys and explorations in the native States of the Malayan Peninsula, 1875-82; a translation of Dr. Albert Regel's account of his journey in Karateghin and Darwaz; and some interesting details as to Capt. P. de Andrada's journeys to Masinga and the Mazoe on the Lower Zambese. This number contains the report of the anniversary meeting.

A WELL-ATTENDED meeting was held last week to consider the desirability of presenting a testimonial to Mr. Ernest Hart in recognition of his eminent public and professional services. It was unanimously resolved that an appeal for subscriptions should be made to the medical profession and the general public in support of this movement. It was agreed that the testimonial should take the form of a portrait of Mr. Ernest Hart, to be presented to Mrs. Ernest Hart. It was announced that already over 100 influential members of the medical profession had expressed their desire to contribute to the fund. Mr. Spencer Wells was appointed treasurer, Mr. Arthur Myers, surgeon to the Coldstream Guards, and Mr. Noble Smith (24, Queen Anne Street, W.), were appointed hon. secs., and an executive committee, with power to add to their number, was appointed.

IN a recent communication to the Vienna Academy, Dr. Paulsen has described a singular series of experiments with reference to the course of air in the nasal cavity in breathing. Conclusions as to this path have been drawn from structure, but Dr. Paulsen adopted the method of lining the nasal cavity in the head of a dead body with small pieces of red litmus paper, and then causing ammoniacal air to be inhaled and exhaled through the windpipe. The changes of colour in the paper proved that the expiratory and inspiratory currents take nearly the same course, and that the main portion passes, not through one of the nasal passages, but along the septum in an arching course, convex above. The course of air-currents was investigated under varying conditions of ventilation, &c., also the behaviour of secondary cavities. Some old and new experiments on the act of smelling are explained on the basis of the facts elicited.

FROM the woody tissue of some plants (according to recent researches by Herr Max Singer, Vienna) four substances can be extracted by means of hot water: 1. Vanillin, which seems to be one of the most widely distributed plant-substances; it is found even in decayed wood and in brown coal. 2. A substance which shows the reactions of coniferin. 3. A species of gum soluble in water. 4. A substance soluble in water, and coloured yellow with muriatic acid, not identical with any of those already specified. Moreover, woody tissues (also elder pith) contain the wood gum discovered by Thomson. In what relation these substances stand to the hypothetical lignine is not determined, but the way in which they can be separated from the wood, one after another, by water, renders it probable that what is called lignine is a mixture of several chemical entities.

THE Academy of Sciences has nominated M. Bertrand as its representative at the inauguration of the Fermat statue, which will take place on August 20 next, in a small country town of Tarn-et-Garonne, where this illustrious mathematician was born, at the beginning of the 17th century.

THE additions to the Zoological Society's Gardens during the past week include a Diana Monkey (*Cercopithecus diana*) from West Africa, presented by Messrs. L. and J. Boljhon; a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mrs. Norris; two Tovi Parrakeets (*Brotogerys tovi*) from Columbia, presented by Major Langford Brooke; two Uvean Parrakeets (*Nymphicus uvæensis*) from Uvea, Loyalty Isles, a New Zealand Parrakeet (*Cyanorhamphus novæ-zealandiæ*) from New Zealand, presented by Mr. E. L. Layard, H.B.M. Consul, New Caledonia; an American Robin (*Turdus migratorius*) from North America, presented by Col. Verner; a Yellow Wagtail (*Motacilla flava*), a Marsh Tit (*Parus palustris*), British, presented by Mr. H. Grant; four Speckled Terrapins (*Clemmys guttata*) from North America, presented by Mr. C. D. Ekman; a Common Snake (*Tropidonotus natrix*), British, presented by Mr. Poyer Poyer; nine Fire-bellied Toads (*Bombinator igneus*), a Lacertine Snake (*Cœlopeltis lacertina*), a Back-marked Snake (*Rhinechis scalaris*), European, presented by Mr. G. A. Boulenger; a —— Newt (*Notopthalmus viridescens*), from America, presented by Messrs. Sargent; an Undulated Grass Parrakeet (*Melopsittacus undulatus*) from Australia, deposited; a Canada Goose (*Bernicla canadensis*), British, a Sharp-nosed Crocodile (*Crocodilus acutus*) from Central America, purchased; two Geoffroy's Doves (*Peristera geoffroii*), bred in the Gardens. The following insects have emerged during the past week:—Silk Moths: *Actias selene*; Moths: *Hypochera io*, *Ceratocampa imperialis*, *Deilephila vespertilis*, *Deilephila euphorbiæ*, *Sciapteron tabaniformis*, *Sesia museæiformis*, *Sesia empiformis*, *Zygæna filipendulæ*, *Plusia concha*; Butterflies: *Apatura iris*, *Vanessa polychlorus*, *Lycænia iolas*, *Aporis erabægi*.

DISTRIBUTION OF AWARDS, NORMAL SCHOOL OF SCIENCE AND ROYAL SCHOOL OF MINES

THIS took place in the Lecture Theatre of the South Kensington Museum on Saturday, June 24. The Vice-President of the Committee of Council on Education, the Right Hon. A. J. Mundella, M.P., took the chair.

Col. Donnelly, after some introductory remarks, said:—In the report of the school, which you have before you, Sir, there is a paragraph from which some people might possibly imagine that the necessity for training teachers in science was not thought of when the general scheme of aid to science instruction was considered and promulgated in 1859, and that it was not until that scheme had been in operation for a few years that the necessity for training science teachers came to light. Now, Sir, I was present at the deliberations which took place on the framing of that Minute of 1859, and although it is a long time ago I have a very distinct recollection of all that occurred.

But I would here wish for one moment to digress, and recall the memory of a remarkable man who was deeply connected with those deliberations, and to whom they owe so much. He has but recently been taken from us, and though Sir Henry Cole had for several years ceased his connection with this institution, I am sure it needs no excuse from me that on this, the first public ceremony which has taken place since his death, I recall to you for one moment his memory. We cannot but all remember how much this place, and science and art instruction, I mean of course elementary science and art instruction, owe to Sir Henry Cole. No one would be so foolish as to suppose that even if Sir Henry Cole had not lived and worked we should not at the present time have had a system of elementary science and art instruction in the country; but it is given to a few men here and there, now and then, to have a clear view before them, and to have that energy and indomitable perseverance, which enables them, as it were, to put on the hands of the clock, and to impress a form and reality on what in the hands of other men would probably have remained vain imaginings. Sir Henry Cole was such a man; and no one who, like myself, worked for some fifteen or sixteen years under him, could fail to be impressed with that remarkable personality; with his boundless sympathy in all progress and work; and with his extraordinary *vis viva* which communicated some at least of his zeal and devotion to all who came in contact, and were working, with him.

Well, Sir, to recur to the deliberations with regard to the Minute of 1859; numbers of educational doctors were consulted; they all proposed, and I believe it was about the only suggestion in which they all agreed, that the first thing to be done was to establish a system of training teachers at some central institution, such as the School of Mines in Jermyn Street, which when it was first established had that object in contemplation. Fortunately—most fortunately—that advice was not followed. You will remember, Sir, that a noble lord, your predecessor in the office you now hold, has been somewhat twitted with prophesying something with regard to the steam-ploughs in Asia Minor. The day will no doubt come, when his lordship will have the laugh of the scoffers. But a cargo of steam-ploughs in Asia Minor at the present moment would be a no more hopeful consignment than a number of trained teachers issued from a central establishment, to make their living by science instruction, would have been in 1859. We had to trust to a much ruder implement, if I may say so, and we had to trust to that local implement being brought out and set in motion by a system of payments by results, and right well many of those local teachers have done their work. I should remind you, sir, that the system of paying on results, which has had so large a development since in various directions, was first tried here. This is not, however, the occasion for discussing the general system of science instruction, and science payments, and I only advert to it at the present moment to call attention to what has grown out of it to supplement it, and that is the arrangement for bringing science teachers from the country up to London for short courses of instruction in the summer. That is a system which I believe obtains in no other place or country; I believe it is most invaluable. This point also illustrates another fact, and that is that the Normal School of Science is not the outcome of some cut and dry report of a commission, founded possibly on a foreign example, but it is the natural outgrowth of what has been found to be required. It has grown so as to suit its environment, and so far is a thoroughly English institution; and now that it has in the fulness of time—I will not say that the time may not have been a little too full—now that it has come out in its full plumage, I think the country may be congratulated on this. It has a scientific educational institution fairly provided with apparatus and appliances; but it has what is far more valuable. It has a staff of professors whose position in the scientific world for the work they have done, whose power of teaching and imparting knowledge, and whose zeal in the cause will, I believe, bear comparison with the staff of any other similar institution, or seat of learning in this or any other country at the present time.

The Chairman:—I have now the pleasure of calling on Prof. Huxley, the Dean of our re-organised institution.

Prof. Huxley:—Mr. Mundella, under ordinary circumstances the address the Dean of the School is called upon to make on occasions of this kind is confined to a statement of the condition of the school, and to an account of the manner in which the various departments of instruction are thriving or otherwise. But as this institution, the Normal School of Science and Royal School of Mines, is extremely young—in fact has not yet completed the first year of its existence—I think, with your permission, it may be well that I should call the attention of those who have honoured us by their presence to facts with which your official mind is perfectly familiar, but of which they cannot be expected to have cognisance.

As Col. Donnelly has just remarked, this institution has not been so much made as it has grown; it is therefore a particularly English institution, inasmuch as in that respect it resembles the British constitution, which, from an abstract and logical point of view is probably not the most symmetrical and reasonable fabric that ever was raised, but which has the great merit of having grown out of the actual conditions of life, and of possessing the power of adapting itself to the incessant changes of our social state. The school is not, as might be judged from its title, a dual institution like the Austro-Hungarian monarchy; but it has grown out of the growth, development, and eventual coalescence of two perfectly distinct and independent organisations, which have at different times, and quite independently of one another been set on foot by the Government of this country for the purpose of giving science—by which I mean physical science—that influence upon the industries and arts of the country which, as every one now recognises, is absolutely essential to their sound and rapid progress. The Royal School of Mines was practically established, or rather the foundations of it were laid, so far back as the year 1851, at which time a very staunch and kind friend of mine, at a time when friends were not quite so plentiful as they are now, the late Sir Henry De la Beche, one of the most sagacious and able men it was ever my good fortune to meet with, having set agoing, chiefly by his own energy, the Geological Survey of Great Britain, obtained the attachment to that service, and to the Museum of Practical Geology, which was connected with it, of an institution which I think may be described as the first technical school which was ever established in this country by the influence of Government; I do not know if private enterprise had done anything of the kind before. This institution was termed "the Government School of Mines, and of Science applied to the Arts"; and you will observe, and I call your attention to the fact, that in that title there is a duality of precisely the same nature as that which exists in our present name. No doubt one of the objects most dear to Sir Henry de la Beche and his associates, was the establishment of a technical school for those branches of science of which the applications are more or less direct to mining and metallurgy; and no doubt a considerable proportion of the influence which was brought to bear in establishing the school arose from the fact that the mining and metallurgical industries of the country were largely interested in it. But you will also observe that the school took upon itself the teaching of "science applied to the arts," and we had therein a germ, for it was no more than a germ, of what may be termed a general technical school.

Now it was about the same time that the Great Exhibition of 1851 directed the attention of people in this country, far more strongly than it had been directed before, to the extreme importance of giving our industries some better foundation than the mere rule of thumb, which up to that time had too largely obtained. That movement grew and became more important until it resulted in the creation of the Science and Art Department, the effects of which upon the art side, are unmistakeable, for you have them in this vast museum in which you now meet, which I believe is without its parallel in the civilised world. That side of the activity of the Science and Art Department grew rapidly; but the other side of it, the development of the technical application of science, was indeed attempted, but got very little further than the attempt. That attempt was made in this wise: the course of instruction in the Government School of Mines and Science applied to the Arts, then lodged in Jermyn Street, was enlarged so as to include an addition to its mining and metallurgical division, which was called a general division—a general training in physical science—and a technical division, that is to say, what we now understand as a technical school. Moreover, the Royal College of Chemistry was combined with the School of Mines; and in order, as it were, to emphasise the development of the general technical school side of the institution, its title was altered into that of the "Metropolitan School of Science applied to Mining and the Arts." That was in the year 1853, very nearly thirty years ago—a generation of men; and I have no hesitation in saying that if the idea which at that time obtained in the minds of the heads of the Department of Science and Art had been developed and carried out, it would not have been left for this generation to make the efforts which it now seems prepared to make in various ways for the establishment of a thorough and effectual system of technical education throughout the country. Whether it was that the time was not ripe for such an effort, or from what other cause, it is not worth while to inquire; but this course of development was more or less nipped in the bud. The instruction in Jermyn Street narrowed instead of widening; the general and technical divisions were gradually abolished, and the institution restricted itself as far as it could, to being a school of mining and metallurgy, pure and simple; with this difference, however, that the very large and efficient organisation for teaching chemistry under Prof. Hofmann, which existed at that time, retained a certain amount of *quasi* autonomy, and did specially profess to teach the applications of chemistry to industry. The change of policy was signalised in the year 1859 by another change of name; the institution was then called the "Government School of Mines," and so it remained for a few years, until in 1863 the title was altered once more, by way of giving the institution extra dignity, to the "Royal School of Mines," which title it has retained ever since.

I had the honour to be appointed one of the professors of the School of Mines in the year 1854. I have now, therefore, completed twenty-eight years' connection with it. I estimate that connection as one of the happiest and most honourable events of my life, having always been associated with colleagues with whom any man might have been proud to act. Moreover, let me say, in respect of such change of policy as has taken place, I am just as much responsible as anybody else, so that you must not think that I have the smallest intention of saying a word which could militate against the estimation which the School of Mines, I am happy to say, always has held, and which I profoundly trust it always will hold, if I point out to you that there were, from the very beginning, certain extremely grave defects in its constitution. I cannot say that they arose from the fault of any body concerned, but from the fact that the necessities of scientific training were understood a quarter of a century ago in a totally different way to that in which they are now understood. The only provision which was made for that practical instruction, which is the heart and soul of all efficient scientific education, in the original School of Mines, consisted in the laboratories for chemistry and for metallurgy. For no other branch of science was there any efficient practical teaching provided, and even the accommodation for chemistry and metallurgy was so imperfect, that within a very few years after the foundation of the school, laboratories for these purposes had to be sought elsewhere. For eighteen years I did my duty as well as I could towards that institution, lecturing about natural history, and I am sorry to say, all the time, with the more or less definite consciousness, that I was an involuntary impostor, and that it was not possible for me to teach in any genuine fashion, because I had no room in which practical instruction could be given. I do not know whether my colleagues would be inclined to make the same confession, but the same want must have been felt in the teaching of physics, and in the other kinds of instruction given in the school. Moreover, we had no mathematical instruction, and, in spite of our repeated representations, it was not provided.

Now that state of things obtained up to the year 1872. By that time some of us had got extremely tired of it, and I was one of those who were so tired, my chemical colleague was another, my colleague the Professor of Physics was a third, and we got up a sort of little pronunciamento to say that we really could not go on teaching in that way any longer; that at South Kensington there was a large building which was standing perfectly empty, and might we be allowed to do our business in a more efficient way by being transferred to this empty building? With the assent and consent of our colleagues, and with the sanction of the Department of Science and Art, the desired transference took place, and the result of that was, that all the professors who were moved were able at once to institute a more or less adequate system of practical instruction, and to make the teaching in the school in their own departments something like what it ought to be. Subsequently the Professors of Geology and Metallurgy and Applied Mechanics were similarly moved, until now only the Professor of Mining remains in Jermyn Street, simply because he has there the admirable collection of models which are so important for his work.

That, Sir, is the history so far as it can be told, in a few words, of the origin and growth of the Royal School of Mines. The only change that has taken place in consequence of the new organisation in that institution is that it has been made more efficient. Mathematical instruction has been added; practical teaching has been supplied in all branches of science which the Associates of the Royal School of Mines are required to study, and I cannot doubt, seeing the respect which has for many years been paid to the title of Associate of the Royal School of Mines, that that respect will simply grow and increase with the knowledge of the public, that the only alteration which has taken place here of late years is to make the title represent a very much larger value than hitherto it has been possible it should represent.

Now, sir, I turn to the Normal School of Mines, about which my task will be easier, because Col. Donnelly has said something about it. I have spoken of my respect and affection for the older institution, the Royal School of Mines, with which I have been so long connected, but I am not quite sure that, looking at the matter from a broad and general point of view with reference to the influence of our school upon the country, that I may not have taken an even greater interest in the series of steps which have led to the organisation of the Normal School of Science. It is very hard for those whom I address, and who have not the advantage or disadvantage of being as old as I am, to believe that there was a time, hardly more than a score of years ago, when it was almost impossible for any one who was not connected either with the universities, with the medical schools, with the School of Mines, or with one or two institutions in London, to obtain the slightest tincture of practical scientific instruction in this country. When, therefore, those conferences and deliberations, to which Col. Donnelly referred just now, came to my knowledge in the year 1859, I felt profoundly interested, and I thought the plan proposed extremely well devised, and that it was the only one, whatever its imperfections may be, which at that time was adapted to meet the wants of the time. I confess that when I heard of the establishment of these science classes, I made the same sort of reflection as the man who said let him make the songs, and he did not mind who made the laws. I said to myself, I do not care in the slightest degree from this time forth what the universities, or what the public schools may do in the way [of teaching science to the non-professional classes; they are bound now *se soumettre ou se demettre*; either they will follow in the wake of this movement towards general scientific education of the country, or they will pass out of the stream of progress of modern culture. You may think that was a very large anticipation to base upon a small foundation, and undoubtedly it was; but the immense development of this system of scientific teaching has, I think, entirely verified my anticipation, and I am happy to say that the public schools and the Universities have followed suit, until now it is as easy to obtain a fair general scientific training in this country, as a quarter of a century ago it was difficult.

Well then, this system of science classes having spread over the country, it soon became apparent that the greatest obstacle to its efficiency lay in the want of knowledge of proper modes of teaching on the part of teachers. It is lamentable how much the ordinary mode of education in what is often called literature, but commonly is not, tends not only not to help a man to become a learner or a teacher of physical science, but rather to impede his becoming one. Nothing is more surprising to me than to find a number of instructed persons coming up here for scientific education, and to discover that they cannot observe. They have been so accustomed to take statements on credit from books and word of mouth that they have almost lost the faculty of seeing things for themselves. I remember after having given a lecture, accompanied in my ordinary way by drawings on the blackboard, that I went to look through the microscope, and see what one of the students who had heard this lecture was drawing. To my astonishment, I saw that his drawing was the thing I had drawn on the blackboard, not the thing under the microscope. I said to him, What is this? this is not at all like what is under the microscope. No, he said, that is what was on the blackboard. He did not believe nature, he believed me; and the great lesson I have tried to teach, which is the fundamental basis of scientific teaching is, do not put too much faith in your teacher, but do believe nature. The only way of remedying this evil habit of taking science on trust, is to give the science teachers the opportunity of obtaining a discipline in the methods and a practical acquaintance with the most important facts of the particular branches of science which they profess to teach. That has been done partly by bringing up teachers from the country for short courses such as are now going on, or will shortly be going on in this institution, and partly by giving them the opportunity individually of attending the courses of the Royal School of Mines during its separate existence. What happened last year was that this system of bringing up teachers for scientific training, for training, that is to say, in special branches of science, was made systematic and thorough. By adding to the staff of the Royal School of Mines a chair of Mathematics and Mechanics, a lectureship on Astronomy, a lectureship on Agriculture, in addition to lectureships on some other subjects, and by providing full means of practical instruction, the institution is now able to provide for a tolerably efficient training, extending over a considerable number of months, of teachers of the science classes in those matters of elementary science which it is needful for them to understand thoroughly in order to teach properly.

Having been practically interested in the administration of the great measure of education for the masses of the people, which was set on foot a dozen years ago, it is particularly gratifying to me to see this last step taken, because it appears to me that so far as science is concerned, it is the crowning of all the organisations which a Government may and should undertake in regard to the education of the masses of the population. The result is this: At this present time, if there be anybody in the remotest district of England in which these science classes are established, if there be any child who has a faculty for science, which is a thing inborn, and as much a genius as the faculty for art; that child, boy or girl, as the case may be, has open to him or her the means of instruction in one of the science classes. To those who have not any special faculty, science certainly will not do any more harm than learning anything else that they learn without understanding, as most boys do learn so many things at all schools. But if the scholar possesses this scientific faculty which I just now spoke of, it is open to him to distinguish himself at the May examinations. If he distinguishes himself at the May examinations, scholarships are open to him at various institutions, among the rest in this Normal School. If under the instruction which is offered to him, he shows a higher kind of scientific capacity, I do not know that there is any limit to the point which he may eventually reach. If he has in him the making of a Davy or a Faraday—and once in thirty or forty years men of that kind are born in the most out of the way and unlikely places—if he have that faculty, there is no longer a need that he should hopelessly struggle with adverse obstacles, but the path to reach that position in which he may serve his country most effectually is laid open to him by the organisation which I have described. And in order to make that organisation complete, we are endeavouring to give such instruction to the teachers as will enable them to aid in this business of picking out from the mass of youth under instruction those who are most likely to attain scientific distinction, and to train and inform those who are likely to profit by scientific instruction.

I am sorry, Sir, that I have detained you so long. It now only remains for me to report to you that, at present, the number of students in the Institution amounts to 198. I may say, that in only one or two classes is there a slight falling off in numbers. In several the numbers are enlarged, particularly in the metallurgical class, and in the geological class, in which latter the demand for a system of instruction which has been established here by my colleague, Prof. Judd, has been so considerable, that several have had to be turned away for want of accommodation. You will be glad to know that this system is so thorough and so efficient, that from abroad men are sent to study its working. The whole school is at present in a very healthy condition. Some little difficulties attended its birth, as is very often the case with strong and lusty infants; but I think our infantile complaints have all now subsided, and I hope that the institution may look forward to a vigorous manhood.

General Martin was then called upon to read the names of the successful students. He said: The ceremony to-day of necessity came so closely on to the heels of the examinations, that the general lists could not possibly be made up. Only those awards, therefore, would appear to-day which could be ascertained in time. For this same reason we may hope that some other gentlemen, in addition to those who receive the Associateship to-day, will be found to be qualified, and receive it hereafter.

The following names were then read, and the certificates and prizes were delivered by the Chairman:—

List of Students who are to receive Associateships, June, 1882

A. W. Day	1st Class	Mining
F. W. Harbord	1st Class	Metallurgy
G. Kamensky	1st Class	,,
F. L. Cepero	2nd Class	Mining
G. Ross Divett	1st Class	,,
J. E. Green	2nd Class	Metallurgy
J. P. Walton	1st Class	,,
F. L. I'Anson	2nd Class	Mining
M. Staniland	1st Class	Metallurgy
	2nd Class	Mining
F. T. Barnett	1st Class	Metallurgy
J. H. White	1st Class	,,

Award of Prizes, Scholarships, &c., June, 1882

2nd Year's Scholarships	H. F. Collins R. T. Bodey
1st Year's Scholarships	A. Sutton H. W. Hughes T. Mather H. G. Graves

Medals, &c.

"Forbes"	C. J. Gahan
"Murchison"	H. F. Collins
"Tyndall"	W. T. Burgess
"De la Beche"	C. H. Powell
"Bessemer"	J. J. Hood (1880–81) F. W. Harbord
Chemistry Prize, "Hodgkinson"	C. A. White

The Chairman:—Mr. Dean, ladies and gentlemen, in the discharge of the duties of my office I have seldom had to perform a more interesting duty than the one I have just fulfilled, of distributing the awards to the successful students on this occasion. I am not going to detain you at this hour with a speech, especially as you have had a most excellent address from that master of science and oratory, the Dean of our Normal School. It would not only be bad taste, but it would be a great indiscretion on my part, if surrounded by men so eminent in science, I ventured to talk to this audience on any scientific question. All I have to express is my great gratification in being in the humblest degree instrumental in bringing the Normal School to its last phase, and to its present position. I am sorry that my noble friend, the Lord President of the Council, who is at this moment discharging also the arduous duties of Lord Lieutenant of Ireland, is not here to day to preside over this interesting ceremony, for he took the greatest possible interest in the reorganisation of the school, and of bringing it into the position which fulfils so admirably the conditions of usefulness which Prof. Huxley has so well described to you.

We have all felt in the words which fell from Col. Donnelly how much science and art in this country and in this place owe to the late Sir Henry Cole, and I should not feel satisfied to address this audience without expressing my own deep conviction of the great service which he rendered to his country, services which will endure for generations and centuries, the value of which we only yet very imperfectly realise. Prof. Huxley pointed out how slow the growth of science teaching in this country had been as compared with the success of art-teaching. It is hardly to be wondered at how much more easy it is to appreciate beauty and art as applied to industry than to see at once the advantages which science confers on industry. Even the most superficial of us who have lived for the last thirty years cannot walk through the streets of London, cannot look into any ordinary shop, or look into a shop window, without being struck with the marvellous change which has come over the textile and metallic productions of this country in the way of their artistic character. There is nothing so remarkable as the change which has taken place in our curtains, or carpets, or hangings, or furniture, or decorations, in everything admitting of the application of art to our common life. There is nothing more charming or more agreeable to realise, but it is not so easy to understand the enormous value and importance of scientific instruction, as it is to appreciate at once the advantages of art training. The influence which art has had on the industry of this country through the instrumentality, I think, in the first instance, of the late Prince Consort, and the men who surrounded him thirty years ago at the exhibition of 1851—that influence is something incalculable, I believe, not only in its advantages to those of us who enjoy the pleasure of these more interesting surroundings, but also in the industry of the country, and in the extent of its employment and manufacture, and the hundreds and thousands of people who are benefited by an increase of our export trade. But we have, and I am glad to know that the manufacturers of this country are beginning to realise it, been far behind in science-teaching. We have been behind our neighbours in France and Germany, and other countries. They have within the last twenty or thirty years made prodigious efforts, and are still making prodigious efforts to apply science to individual industry, and to avail themselves of the resources of science in order to improve their manufactures and to develop the resources of their country in order that they may successfully compete with us in the markets of the world. I know nothing so astonishing as the lavish expenditure and the prodigious efforts that France and Germany have made within the last ten years to increase science teaching in those countries. However, if we have been slow in our growth, I am not at all disheartened, because I believe it has been sure, and, as Prof. Huxley has told you, it is better fitted to the circumstances and wants of our country, probably, than the Government-created institutions which have prevailed abroad. I do not want for one moment to anticipate the report of the Royal Commission on technical education which is now pursuing its investigations. I am quite sure that Commission will lay before Parliament and the country not only a most interesting, but a most startling report; but at the same time I am not at all afraid that we are so behind that we cannot adapt ourselves to the circumstances of the case, and that we shall not continue to hold our own in the industrial progress of the future as we have in the past.

Prof. Huxley told you that, twenty-five years ago, in our provincial towns, and even in London, there was hardly any opportunity for scientific instruction. I know in my own early days the only opportunity an inquiring young man had was to be found in the classes of Mechanics' Institutions, where some amateur student of science was willing to convey to his fellows some share of the little knowledge which he himself possessed. But anything like systematic scientific instruction was utterly unknown in the great centre of industries of this kingdom thirty years ago. To-day, in connection with the Science and Art Department, there are 1760 teachers, at least, principal teachers, I am excluding assistants. There are 60,000 students in schools receiving grants from the Government, in connection with the Science and Art Department. There are about 200 students that we have here in this institution, 50 of whom are in training as teachers, and there are 200 science teachers who come from the provinces ever year to receive short courses of instruction, with their travelling expenses paid, and an allowance made to them whilst they are pursuing their studies in this institution. We have also twelve exhibitions of 50*l.*, four of 15*l.*, and two of 25*l.*, which are awarded annually by the Government. These are only the nucleus, so to speak, of numbers of exhibitions which are given in various localities, and that bring to this institution for training, the men who have the faculty for science teaching, and who will be the future teachers for science in this country. I am sure no one can have been present to-day, and have seen those young men advance to the table, and have seen them receive their certificates of associateship, and their honourable awards for their successful studies, without feeling that those men are going to carry to all the centres of industry an amount of light and knowledge which will be of immense advantage, not only to themselves, but to the industry with which they are associated. In every part of England there is a demand for technical instruction, and that demand is very much groping in the dark, for our people hardly understand what they mean by it yet. It means they want to know the *rationale* of the work which they are doing. They are tired of working by rule of thumb, that when, as I have heard a Dyer explain how he got certain results, he tried his alkalies and acids by dipping his thumb into them and tasting them, and when he found the components for some particular dye, he took a shovelful of this and a shovelful of the other, and so arrived at certain results which he could rarely arrive at with precision again, but which was mere guesswork, rule of thumb, chance, and accident; all that is passing away, and I believe, as the result of the good work that is doing in this institution. I am sure you will all join with me in expressing the hope that our Dean, who holds that title for the first time during the last year, will long remain at the head of this institution, to carry it to that success to which he aspires, and which he has done his utmost, by his noble effort and by his constant and eloquent advocacy, to secure.

DUNSINK OBSERVATORY[1]

MR. DREYER, having been appointed to succeed the late Dr. T. Romney Robinson as director of the Armagh Observatory, will vacate his post here next September. An advertisement has been inserted in NATURE inviting applications for the post of assistant. I have received a number of replies, but I am not yet in a position to make a definite recommendation. I do not like to allow Mr. Dreyer's resignation to pass without expressing the high opinion I have of the manner in which his duties here were discharged.

The meridian circle has been as before in the entire charge of Mr. Dreyer. During the past year Part IV. of the Dunsink Observations and Researches has been issued, in which is contained an account of the meridian circle and a catalogue of the red stars whose places have been determined. In July and August many nights were spent observing the two bright comets, but the weather was so unsettled that only four observations of Comet III. and two of Comet IV. could be secured on the meridian.

In September a series of observations of stars between − 2° and − 23° declination were commenced. In all there have been made 713 observations of transits, and 582 observations of declination; the reductions to apparent place are completed for R.A. up to December 11, and for decl. up to March 10.

The meantime clock service has been continued throughout the year. The circuit has been tested on 349 days—from July 1 up to June 14—with the following results:—

265 days'	error not greater than 1 sec.
56 ,,	between 1 sec. and 2 secs.
28 ,,	greater than 2 secs.

I referred in my last report to the chronograph which Mr. Grubb has had in hand. From a great press of other work, the instrument has not yet been quite finished, but I think we may now regard the chief difficulties as conquered, and I look forward very shortly to having a chronograph which will enable us to do real justice to the meridian circle.

The South Equatorial has, as before, been chiefly employed by myself in the observations of stars for annual parallax. The number of the observations made altogether amount to 186. This number is less than that in former years, because several series of observations have been brought to a close during the present year, and the results have been discussed and prepared for publication. I now submit the manuscript which is ready for the press as Part V. of our publications. The work will be considerably larger than the parts formerly issued, and will contain 200 pages or somewhat more. It consists entirely of the parallax researches made by myself at the South Equatorial in the last four years, and brief abstracts have occasionally appeared elsewhere. I now only glance at the portions completed since the last visitation.

In my last report I stated that the measures of the position angle of + 50°, 1724, from Groombridge, 1618, required further discussion: that discussion they have since received, and the result is very satisfactory. From the distances I had obtained from Gr. 1618 a parallax of

0″·334 ± ·036.

From the position angles the discussion now submitted gives a parallax of

0″·314 ± ·031.

By combining these results, we find as the result of 106 nights of observation the mean value

0″·322 ± ·0″·028.

Considering the smallness of the probable error, it can hardly be doubted that this object has a parallax of a third of a second.

I also submit the completely discussed observations of 368 stars which have been examined in the manner already described as reconnoitring for annual parallax. In the great majority of cases the results are negative, yet even in these cases I believe the work is of value as a part of the general survey of the heavens. It is also, I believe, the only systematic effort which has yet been made to search for the nearest neighbours of the sun.

I am, however, glad to say that all the results of this work are not purely negative, but that certainly in one instance, and probably in others, results of considerable interest have arisen. At the present moment I am only in a position to speak definitely as to one object, viz. this star 6 Cygni B = Σ2486.

My attention was directed to the star from the circumstance that the reconnoitring observations indicated a probable parallax, and I determined to observe it systematically. The observations were made on 33 nights, the first being November 30, 1879, and the last being December 22, 1881, observations of the distance and of the position angle now submitted. The mean value of the parallax from the distances is—

+ 0″·504 ± ·060,

and from the positions

+ 0″·383 ± ·130,

the mean being

+ 0″·482 ± 0″·054.

It is a matter of considerable interest to observe that this is about the same parallax as that of 61 Cygni, another object in the same constellation, and a double of the same character.

The proposed part v. will consist of five papers, as follows:—(1) Reconnoitring observations of 368 stars, with a view of finding whether they have a large parallax; (2) on the annual parallax of Groombridge 1618; (3) further researches on the annual parallax of 61 Cygni; (4) on the annual parallax of P. III., 242; (5) on the annual parallax of 6 Cygni B.

Brief accounts of the results of 2, 3, 4 have already appeared in the *Proceedings* of the Royal Irish Academy or in the special astronomical journals. It is now proposed that they shall be issued fully and with all the information necessary to enable astronomers to judge them adequately.

Besides this work, which I now submit as completed, there is a large mass of other work which is in a partially completed state. The red star Sch 249 (*a*) seems to have a parallax, and I have completed two sets of observations thereon. These have indeed been finished for some time, but I have not yet been able to complete the discussion, and further observations will probably be necessary. I have also completed two sets which will give four independent determinations of the parallax of μ Cephei. There are also some hundreds of the reconnoitring observations in a half-completed condition, most of which I hope to observe during the autumn.

Up to the present I have almost entirely confined my work with the South Equatorial to the researches on annual parallax with which Dunsink is historically associated. I have, however, after some hesitation, decided to co-operate in the proposal of Mr. Gill, her Majesty's Astronomer at the Cape, to determine

---

[1] Report on the Work of the Dunsink Observatory between July 6, 1881, and June 26, 1882, made to the Board of Trinity College, Dublin, at the Annual Visitation on June 27, 1882. By Prof. Robert S. Ball, LL.D., F.R.S., Royal Astronomer of Ireland.

the sun's parallax by observation of Victoria and Sappho. I have already commenced the preliminary work, and I anticipate that much time will be devoted thereto in the ensuing autumn.

ROBERT S. BALL

SCIENCE IN BOHEMIA

A CORRESPONDENT, who was present at the recent meeting of the Bohemian Naturalists, sends us the following brief report:—

The second meeting of Bohemian Naturalists and Physicians was held during May 24–30 in Prague (NATURE, vol. xxvi. p. 66). This meeting, in which over 600 members (some of them coming from Poland) took part, seems to have proved sufficiently that the above-named Slavic tribe (counting only something over six millions of souls) is not less successful in cultivating and promoting science in its own language, than other small nations (Dutch, Swedes, &c.).

In the two general meetings the following addresses were given:—By Dr. Schafarik, Professor in the Bohemian University, on the aims of chemical investigation, in which the subject was treated from an unusually deep and philosophic point of view; and by Dr. Holub, on the importance of the medical profession in transatlantic countries. In this address the essayist pointed out that the great power which had been obtained by the English in transatlantic countries is especially due to the investigations made by them from the scientific, commercial, economical, and strategical point of view. Dr. Holub further referred to other experiences of that kind, which he made in his travels in South Africa, already known to the readers of NATURE (vol. xxiv. pp. 35–38).

In the Section for Medicine, papers were read by the following gentlemen:—Doctors Eiselt, Janovsky, Maixner, Drozda, Thomayer, Chodounsky, Hlava, Wiktor, Zahor, Pelc, Böhm, Belohradsky, Ehrmann, Carda, Krasinski, Chudoba, Mayzel, Steffal, Wach.

In the Section for Surgery, papers were read by Doctors Schoebel, Obtulowicz, Janovsky, Janda, Kuniewicz, Michl, Medal, Talko, Weiss, Bastyr, Jerzykowski, Ostrcil, Carda, Michl, Matlakowski, Spott, Maixner, Skalicka.

In the Section for Pharmacy, papers were read by Doctors Belohoubek, Jandous, Fragner, and Stepanek.

In the Section for Mathematics and Physics, Dr. E. Weyr read a paper on the construction of a hyperboloid of osculation; J. Vanecek, on general inversion; V. Jaeger, on the solution of equations of 4th degree; K. V. Zenger, on a dispersive parallelopipedon, and on microscopes with endomersic lenses; Dr. Doubrava, on sensitive flames; Dr. Becka, on comets; F. Machovec, on the construction of certain curves; Dr. Weyr, on the construction of rational curves in space, of third, fourth, fifth, and sixth degrees; B. Prochazka, generalisation of stereographic sections of planes of second degree; A. Sucharda, on movements of curved planes; F. Toms, construction of section lines of two conic sections; F. Cecbac, contributions to electrotechnics; Dr. A. Seydler, on the use of quaternions for the solution of a certain mechanical problem; Dr. V. Strouhal, on the peculiarities of magnetic and galvanic steel; E. Dziewulski, electric conductivity of mixtures of alcohol and water.

In the Section for Natural Science, papers were read by Dr. Celakovsky, on the sympodial constitution of vine-branches; J. Szyszylowicz, on the influence of light upon the transformation of matter in plants; F. Bayer, on the asymmetry in the shoulder-blade circle of frogs and some birds; V. T. Velenovsky, on the flora of Bohemian chalk-formation; Dr. Palacky, on the relations of the American and Bohemian flora; F. Sitensky, on the turfs from the giant mountains; K. Cermak, on the stratification of the alluvium and diluvium in certain parts of Bohemia, the fauna of these strata, and their deposition over older formations; Dr. Mayzl, on the division of cells; Dr. Fric, on the Sauria found in the permic formation of Bohemia; F. Safranek, on a new rock found near Tabor (Bohemia); J. Korensky, on the diluvial fauna from the rock-cave near Tetin; J. Kafka, on Bohemian bryozoa; Dr. Woldrich, on the diluvial system of Central Europe; G. Ossowski, geology of Wolonia; Dr. Novak, contributions to the fauna of Bohemian Siluric formation; J. Fric, contribution to the ontogeny of Copepoda; Dr. Kamienski, contribution to the morphology of the urticularii; J. Ssyszylowicz, conservation of spores of plants during the winter; K. Taranek, on rhizopoda and diatomacæa of South Bohemian turfs; S. [Klnava, criteria of modern petrology; Dr. Celakovsky, comparison of indusia of ferns and oval integumenta; F. Safranek, on a new find of opals and chalcedons near Tabor; Dr. Vejdovsky, on the male of *Lernæpoda selachiorum*, and on Bohemian Planariæ; Dr. Hansgirg, on Bohemian Algæ, and on the movements of Oscillariæ; J. Ulicny, on Moravian Molusca; Dr. Zulinski, on mineralogical symbolics; Dr. Palacky, on the flora in the Bohemian chalk formation; C. Zahalka, geological map of the environments of Jicin; Dr. Kamienski, growth of plants in an atmosphere not containing carbon dioxide; F. Posepny, on the disintegration of rocks; Dr. Rostafinski, on the distribution of Galician fishes, and on the formation of hormogonia.

In the Chemical Section papers were read by Prof. Butleroff, on the oxidation of isodibutylene by potassium permanganate (presented); Dr. Radziszewski, on physiological oxidation; F. Stolba, application of aluminium-metal in laboratories; A. Belohoubek, on crystallised hydrates of potassium; Dr. B. Brauner (Manchester), on the atomic weight of didymium and other researches, regarding the chemistry of rare earth-metals (presented); F. Chodounsky, on fermentation; Prof. Preis, on sodium sulfarsenite; Dr. Janecek, on the electrolysis of saline solutions; Dr. Wasowicz, on crotaconic acid; Farsky, on superphosphates; K. Kruis, fermentation in spirit-refineries; M. Fischer, on the decomposition of collagenous substances; J. Stoklasa, on the geochemical conditions of Bohemian chalk-formation; Jal, on the estimation of hypophosphorous acid; J. Wiesner, on potassium-uranic chromates; K. Sykora, on certain coloured clays found in Bohemia, B. Rayman, on a new synthesis of methyl-phenyles; Farsky, chlorine as a nutriment of plants.

In the Section for Archæology and Anthropology, papers were read by Dr. Woldrich, on the skulls of prehistoric domestic dogs; J. Ossowski, on the objects found in caves near Cracow; Dr. Berger, on fibulæ found in Bohemia; Dr. Kopernicki, on the trepanation of prehistoric skulls in Bohemia; B. Jelinek, on the environments of Plesivec.

In the Section for Pædagogy the following papers were read or subjects discussed:—Dr. Hejzlar, how to teach physics and astronomy; F. Nekut, how to teach mineralogy; J. Mrazik, on the services rendered to pædagogy by medicine and natural science; J. Vanecek, necessity of teaching new geometry in middle schools; Dr. Kotal, on the treatises of natural science used in middle schools; J. Klika, how to popularise natural science; Pokorny, on teaching of gymnastics.

In an exhibition connected with the meeting many interesting objects touching upon [Medicine and Natural Science were exhibited. From the scientific excursions by which the meeting was concluded only that into the well-known mine of Pribram, under the direction of Prof. Krejci, may be mentioned.

Only within recent years Natural Science began to be cultivated in Bohemia in the Slav language, and this is especially due to the establishment of a Bohemian Polytechnic School and recently of a corresponding division in the University of Prague though the last-named high school was founded already in 1348.

INDIA-RUBBER PLANTS

MR. W. T. THISELTON DYER brought before the Linnean Society, June 15, an important communication on the caoutchouc-yielding Apocynaceæ of Malaya and Tropical Africa. After giving a general sketch of the structural and physiological conditions of the occurrence of caoutchouc in plants, the author pointed out that the plants which appeared to yield it in commercial quantity in three widely-separated regions all belonged to one tribe of Apocynaceæ, the *Carisseæ*. In the East Indies the "gutta singgarip" of the Malay Peninsula, the "gutta soosoo" of Borneo, was the produce of a new species *Willughbeia*, *W. Burbidgei*. Many other species of this and allied genera also seemed to produce caoutchouc in quantity, worth collection. In Central Africa *Landolphia*, which was closely allied to *Willughbeia*, but differed in possessing terminal instead of axillary flowers, was the most important source. On the East Coast caoutchouc was yielded by *L. owariensis* and *L. florida*, the latter a very ornamental plant. As the rubber exuded from the cut stems, it was plastered by the collectors on the breast and arms, and the thick layer, when peeled off and cut up into squares, was called "thimble rubber." On the west coast the most important species was *L. Kirkii*, the rubber of which could be wound off into balls or small rolls from the cut stems, like silk from a cocoon; this species was called "Matere." *L. florida* also occurred, and was called "m'bunga"; its rubber was worked up into balls, but was inferior in value. The rubber of *L. Petersiana* was of little importance. In South America *Hancornia speciosa* yielded what was called "mangabeira rubber."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

At the summer commencements of the University of Dublin, held on June 29 last, the degree of LL.D. Honoris causâ was conferred on Dr. Siemens and on Mr. Alfred Russel Wallace.

At a special meeting of the Council of the University of Dublin, held on June 30, Mr. Robert Crauford was nominated for the important post of Professor of Engineering in the University. Mr. Craufurd is well known for his many fine engineering works successfully carried out in North and South America, and in Europe.

UNIVERSITY COLLEGE, BRISTOL.—The new wing of the permanent buildings of University College, Bristol, is now rising rapidly. The portion devoted to physical and engineering laboratories and lecture-rooms will be ready for occupancy in October; the new chemical laboratories and lecture-rooms will be completed before Christmas. This greatly-needed extension will not, however, meet all the requirements of the growing institution, and additional buildings to accommodate the medical faculty are greatly wanted. One of the laboratories of the Physical Department is to be fitted up as an electrical laboratory. Prof. Thompson is actively endeavouring to raise funds for its complete outfit. Mr. C. C. Starling has been appointed Demonstrator in Physics.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 15.—"On the Specific Heat, and Heat of Transformation, of the Iodide of Silver, AgI, and of the Alloys $Cu_2I_2.AgI$; $Cu_2I_2.2AgI$; $Cu_2I_2.3AgI$; $Cu_2I_2.4AgI$; $Cu_2I_2.12AgI$; $PbI_2.AgI$." By Sigr. Manfredo Bellati and Dr. R. Romauese, Professors in the University of Padua.

The authors have determined the specific heat, and heat of transformation, of iodide of silver, and of five alloys or compounds of that substance with iodide of copper, and one with iodide of lead. The substances have already been studied by Mr. G. F. Rodwell as regards their expansion and contraction on heating, and the results communicated to the Royal Society; the same specimens were transmitted to Padua for the experiments of Prof. Bellati and Romanese. The following results were obtained. θ_1 and θ_2 are the temperatures at which change of molecular structure respectively commences and finishes; c the mean specific heat between t and T for temperatures below θ_1; c_1 specific heat for temperatures above θ_2; and λ the heat absorbed by the unit weight of the substance in consequence of change of structure.

Composition of the substance.	Percentage of AgI.	θ_1.	θ_2.	c.	c_1.	λ
		C.	C.			
AgI	100·0	142°	156°·5	0·054389+0·0000372(T+t)	0·0577	6·25
$Cu_2I_2.12AgI$	88·1	95	228	0·05882 (from 16° to 89°)...	0·0580	8·31
$Cu_2I_2.4AgI$	71·2	180	282	0·056526+0·0000410(T+t)	0·0702	7·95
$Cu_2I_2.3AgI$	65·0	194	280	0·059624+0·0000280(T+t)	0·0726	7·74
$Cu_2I_2.2AgI$	55·3	221	298	0·061035+0·0000295(T+t)	...	7·88
$Cu_2I_2.AgI$ ...	38·2	256	324	0·063099+0·0000260 T+t)	...	8·67
$PbI_2.AgI$ ...	33·8	118	144	0·047458+0·0000026(T+t)	0·0567	2·556

The results are compared and discussed, and inferences are drawn therefrom as to the constitution of the bodies experimented upon.

Geological Society, June 7.—J. W. Hulke, F.R.S., president, in the chair.—Alfred Morris, C.E., and William Henry Watson were elected Fellows of the Society. Prof. Louis Lartet of Toulouse was proposed as a Foreign Correspondent of the Society. The following communications were read:—The President read the following note, forwarded by Don Manuel F. de Castro, Director of the Geological Survey of Spain:—"On the Discovery of Triassic fossils in the Sierra de Gador, Province of Almeria, Spain. The metalliferous limestone of the Sierra de Gador, owing to no fossil remains having been found prior to this occasion, has been a perfect puzzle to all geologists for the last fifty years. MM. Maestre, Amar de la Torre, Pernolet, Ansted, and Cooke considered these limestones to belong to the Transition series, the former taking it as a representative of the Mountain Limestones of other parts of Europe. M. Prado hinted that they might be Devonian; whilst M. Willkomm, in the geological map published to accompany his botanical researches in Spain, considered them Silurian. Lately MM. Botella and Vilanova, in their respective maps, have marked them as belonging to the Permian series, whilst M. de Verneuil, coming nearer to the truth, took the whole of the limestones to the south of Granada and the Sierra de Gador as Triassic, though in doubt ('Trias incertain') Under these circumstances I was commissioned by the Director of the Geological Survey of Spain to investigate the south-west portion of the Province of Almeria, which comprises the Sierra de Gador. In February last I had the good fortune of discovering abundant fossil remains in different parts of the Sierra de Gador, which perfectly fix the age of the metalliferous limestones of this part of Spain. The whole series of rocks forming this *sierra*, resting on the mica-schists and slates of the Sierra Nevada, is a succession of black, white, and purple talcose schists at the base, which alternate with some beds of yellowish and porous limestone, and which pass through a considerable thickness of grey limestones and slates, and precisely where the fossils have been found, to the metalliferous limestone of Sierra de Gador, which appears to form the top of this interesting formation. The fossils found belong to the following genera:—*Myophoria* (*M. lævigata* and *M. Goldfussi*), *Hinnites*, *Monotis*, *Avicula* (*A. Bronni*), *Myacites*, *Rissoa*, and many others difficult to determine. The places where the fossils have been found are the following:—On the southern slopes of the Sierra de Gador, in the Rambla del Cañuelo, midway on the road from Felix to Marchal, and in the place named La Solana del Fondon, to the left of the River Andarax, following the track between the mine Sebastopol and the town of El Fondon.—Joaquin Gonzalo Y Xavier."—The Girvan Succession.—Part I. Stratigraphical, by Charles Lapworth, F.G.S., Professor of Geology in the Mason Science College, Birmingham. The Lower Palæozoic rocks of the neighbourhood of Girvan, in the south of Ayrshire, have long been famous for the remarkable variety of their petrological features and for the abundance and beauty of their organic remains; but the strata are so intermingled and confused by faults, folds, and inversions, that it has hitherto been found impossible to give a satisfactory account of the geological structure of the region. The most remarkable formation in this Girwan area is a massive boulder-conglomerate, several hundreds of feet in thickness, which forms the high ground of Benan Hill, and ranges throughout the district from end to end. Employing this formation as a definite horizon of reference, the author showed, by numerous plans and sections, that it was possible for the geologist to work out the natural order of the strata both above and below this horizon, and to construct a complete stratigraphical and palæontological scheme of the entire Girvan Succession. The development of the palæontological features of the several zones of life in this succession, and the demonstration of their correspondence with the zones already recognised in the synchronous Lower Palæozoic strata of Moffatt, the Lake District, Scandinavia, and elsewhere were reserved by the author for a second part of this memoir.—Notes on the *Annelida tubicola* of the Wenlock Shales, from the washings of Mr. George Maw, F.G.S., by Mr. George Vine. Communicated by Prof. P. Martin Duncan, M.B., F.R.S., V.P.G.S.—Description of part of the femur of *Nototherium Mitchelli*, by Prof. Owen, C.B., F.R.S., F.G.S. The specimen described consisted of the distal portion, probably about one-half, of a femur obtained from Darling Downs, Queensland, and received by the author from Dr. George Bennett. Its principal differences from *Diprotodon* are that it has no depression above the outer condyle, but in its place a rough longitudinal rising for the attachment of the same or of a homologous muscle; and the hinder surface of the condyle is transversely convex. The relative width of the post-condylar fossa resembles that in *Phascolomys*; and a further resemblance to the Wombats consists in the more equal prominence of the lateral boundaries of the rotular surface than in *Diprotodon* and *Macropus*. The bone differs from the corresponding part in the

Wombats by several subordinate characters, and the animal to which it belonged would seem to have been intermediate between *Phascolomys* and *Macropus*. From the size and characters of the bone, the author referred it to *Notctherium Mitchelli*; its breadth across the condyles is 5¾ inches.—On *Helicopora latispiralis*, a new spiral Fenestellid from the Upper Silurian beds of Ohio, U.S., by Mr. E. W. Claypole, B.A., B.Sc. (Lond.), F.G.S.

Chemical Society, June 15.—Dr. Gilbert, president, in the chair.—The following papers were read:—Note on β naphthaquinone, by C. E. Groves. The author has repeated the experiments of Liebermann (*Ber.* xiv. 1310) as to the preparation of the above substance from β napthol-orange, and fully corroborates the results of that chemist, but disagrees with him as to the economical value of the process. He has somewhat improved Liebermann's method by using less stannous chloride, but finds that even then it is more troublesome and tedious than the conversion of β napthol into the amidonapthol through the nitroso-compound, &c. The cost of Liebermann's process is four times as great as the one originally proposed by Stenhouse and Groves. In preparing either α or β naphthaquinone from the corresponding amido-compounds, the author prefers to use ferric chloride as the oxidising agent.—On some new compounds of Brazilein and Hæmatein, by J. F. Hummel and A. G. Perkin. Extract of logwood is dissolved in hot water and when cool, ammonia is added in slight excess. This solution, by exposure to the air, deposits a dark purplish precipitate of hæmatein, which, on purification, gave numbers indicating the formula $C_{16}H_{12}O_6$; by the action of cold sulphuric acid, an orange crystalline substance, $C_{16}H_{12}O_6SO_3$ was obtained. By the action of hydrochloric acid in sealed tubes, hydroxyl is replaced by Cl: $C_{16}H_{11}O_5Cl$), a similar body is produced by hydrobromic acid. Brazilein was prepared in a similar way from Brazil extract. It forms compounds which resemble those of hæmatein.—On the determination of nitric acid as nitric oxide by means of its reaction with ferrous salts, Part II., by R. Warington. The method is founded on that proposed by Schlœsing, but the nitric oxide is collected and determined by gas analysis, the gas being absorbed by caustic potash after successive treatments with oxygen and pyrogallol; great care was also taken to exclude all oxygen from the carbonic acid used.—On a new process of bleaching, by J. J. Dobbie and J. Hutcheson. The authors have investigated various methods of liberating chlorine by decomposing hydrochloric acid and chlorides with a weak electric current. The best results were obtained by moistening the goods with sea-water and passing them between two slowly-revolving carbon rollers, which were connected with opposite poles of a battery; sodium hypochlorite was formed in the fabric, and on immersion in acid the bleaching was effected. Results were also obtained with dilute hydrochloric acid. Pure hydrofluoric acid also bleaches when thus decomposed.

Physical Society June 17.—The Physical Society met in Oxford by invitation of the president, and after luncheon in the hall of Merton College, by kind permission of the Warden and Fellows, the health of the Society was proposed by the president, and responded to by Lord Rayleigh. The usual meeting was then held in the Clarendon Laboratory, Prof. Clifton, president, in the chair.—Dr. W. H. Stone exhibited and described an electro-dynamometer specially designed for measuring the currents used in the medical applications of electricity (NATURE, vol. xxvi. p. 201). Mr. Varley, Prof. Perry, and others, offered some remarks.—Mr. Bosanquet then described his application of the Faure accumulator charged by a dynamo-electric generator to the working of laboratory apparatus instead of the usual Grove, or other battery. The net result of his experiments is that the accumulators charged for two hours have sufficient energy to keep the apparatus employed running for a week, and hence it is unnecessary for him, as heretofore, to put up thirty Grove cells each day. Prof. Perry observed that a well-made Faure cell, having the minium laid on in a uniform coat, does not lose its charge nor develop local action, as is done by those accumulators in which the minium is put into holes in the plates.—Prof. W. G. Adams then took the chair while Prof. Clifton described some ingenious devices adopted by him in lecture experiments on electrostatics. These consisted of insulating glass stems with glass cups to hold sulphuric acid formed on the stems; also a form of key which, by rapidly succeeding contacts, brings the spot of light on the electrometer scale to rest without tedious swinging. He also described a form of lecture-galvanometer, sine or tangent, which could be readily shown in all its working to a large class, and exhibited a simple and inexpensive apparatus for measuring the focal length of a lens in six different ways, according to what is known about the lens. The results showed that the apparatus was very accurate in its indications.

SYDNEY, N.S.W.

Royal Society, May 3.—Annual Meeting.—The number of new members elected during the year is 46, making the total number of ordinary members upon the roll to date 475.—At the Council Meeting held on March 22 it was unanimously resolved to award the Clarke Memorial medal for the year 1882 to Prof. James Dwight Dana, LL.D., of Yale College, Newhaven, Conn., in recognition of his eminent work as a naturalist, and especially in reference to his geological and other labours in Australia, when with the United States Exploring Expedition round the world in 1836 to 1842.—During the year the Society has held eight meetings, at which thirteen papers were read, and three of the sections held regular monthly meetings.—At a meeting held by the Council on October 26, it was resolved that the Society should offer prizes of 25*l*. each for the best communication containing the results of original research or observation upon certain subjects to be set forth from time to time.—The Bill for incorporating the Society was approved by the Parliament of New South Wales on December 16, 1881.

BERLIN

Physiological Society, June 16.—Prof. Du Bois-Reymond in the chair.—Prof. Zuntz read a paper upon the value of amid bodies as animal nutriment, based on experiments which he made upon a number of rabbits. In each experiment he divided the animals that he was experimenting on, into two groups. One of these groups was fed with food-stuffs containing no nitrogen (starch and oil) and with various nutritive salts, while the other rabbits received, in addition to this food, a supply of amid bodies. The object of the experiments was to determine which, if any, of the amid bodies could replace the albumen of the food. Herr Zuntz managed to overcome the distaste of the animals for the monotonous, unstimulating diet (a difficulty which has often to be combated in a disagreeable manner in experiments of this kird), by also giving them small quantities of an alcoholic infusion of hay, and by giving the food that had been refused by the animal as pap or powder, in a firm friable form. The results of the experiments may be shortly summed up thus: Extract of meat, when added to the non-nitrogeneous food-stuffs, produced no effect upon the nutrition; the animals died in exactly the same time as without the extract. Asparagine likewise could not take the place of the albumen of the food, but the loss of albumen was about 20 per cent. less in the animals that were fed with the asparagine, in addition to their other food, than in those who were fed on non-nitrogenous food alone. An addition of a mixture of asparagine and some other amid bodies, *i.e.* leucine, tyrosine, and others, of which one might have presumed that they would together form an albumin-material during the process of digestion, had, as a fact, the exactly opposite effect of producing a remarkably larger loss of albumen than the non-nitrogenous diet of the other group of animals that were kept for purposes of comparison. In the same way the addition of the crystallising decomposition-products of albumen which were got by the action of pepsin, had a prejudicial influence, producing a greater loss of albumen. Probably an ammoniate was the active principle in both cases, as it is known to work destructively in the body upon albumen; but it is possible that the amid bodies themselves behaved like ammoniate. These experiments are to be pursued with other amid bodies and with decomposition-products of albumen.—Prof. du Bois-Reymond made some remarks upon Prof. Fritsch's late investigations as to the homology of the torpedo-electrical organ with muscles and mucous-cells, and on the development of the Torpedinea, the relative weights and the nerve-endings in the electric plates, and made some observations upon the question of the immunity of the electric fish against their own shocks. He especially drew attention to the fact that there are to be found in the intestines of electric fish, certain entozoa, which must either have an immunity against the shocks of their hosts, or, a question that has not yet been investigated, be altogether insensible to electricity.

Physical Society, June 23.—Prof. du Bois-Reymond in the chair.—Prof. Neesen showed a new mercury air-pump, made on the principle of the Topler air-pump, but with several alterations to facilitate the working.—Dr. Braun exhibited a somewhat modified Huyghens barometer, which had, both at the upper and at the lower meniscus of mercury, points for exact measurement, and which served to measure not only the variations, but also the amount of the air pressure.—Dr. Kaiser showed a moment-shutter for instantaneous photographs, in which, on pressing a small capsule with the hand, two pendant valves before the aperture are raised, and meet one over the other. The time during which the light can penetrate by the aperture into the apparatus, is 1-20th second. By a simple replacement in the apparatus, the mechanism can be so altered, that the light coming from above—that of the sky and clouds—acts a much shorter time than that from other objects, so that, with 1-20th second of illumination, the exposure for the sky is not excessive.—Prof. Neesen remarked, *à propos* of a former communication by Dr. Thiesen, on the deflection of projectiles, that in the case of the best German guns, this deflection amounts to one degree; thus, with a distance of 3000 metres, it is about 128 metres, a value which cannot be explained by the hypothesis of Dr. Thiesen.—The next meeting of the Society takes place after the holidays, on October 20.

VIENNA

Imperial Academy of Sciences, June 9.—E. Mach, on A. Guebhard's statement on equipotential curves.—L. Boltzmann, on the theory of gas-diffusion.—E. Heller and C. Della-Torre, on the distribution of the fauna in the high mountains of Tyrol.—E. Ratbay, Researches on the spermagonia of the Æcidiomycetes.—R. Andreasch, on mixed alloxantins.—On cyamidomalonic acid, by the same.—On dimethylglyoxylcarbamide, a product of reduction of Cholestrophæne, by the same.—W. Pscheidl, on determination of the coefficient of elasticity by bending of a rod.—G. Schmidt, on analogies.—C. Braun, a sealed packet, with the inscription, some suggestions to the technics and praxis of astronomical instruments.—L. Psæczolka, a sealed packet with the inscription, on the action of silicon on carbonic oxide in the recarburation in the Siemens-Martin process.—C. Natterer, on monochloraldehyde.—E. Lecher, on the absorption of radiant heat by steam of water and carbonic acid.—V. Uhlig, on the cephalopoda fauna of the strata of Wernsdorf.—On the strata of Wernsdorf and their equivalents, by the same.

June 15.—K. Fulkowsky, on the constituents of corallin.—B. Brauner, contributiou to the chemistry of the cerite metals.—E. v. Haerdtl, computation of the orbit of the planet Adria.

June 22.—Ph. Knoll, contributions to the theory of respiratory innervation (part 2); on respiration with artificial stimulation of the cervical part of vagus.—G. Stach, on the fossils collected in the Western Sahara, by O. Lenz during his journey to Timbuctu. They belong all to the carboniferous, and show analogies with the fossils of the Belgian limestone.—F. Steindachner, ichthyological contributions (part 12) on a new Ezemias species, *E. Holubi*, from the valley of the Limpopo River (Transvaal).—Th. Weinzweig, on the anatomy of laryngeal nerves.

PARIS

Academy of Sciences, June 26.—M. Jamin in the chair.—The president reported on the presentation of a commemoration medal to M. Pasteur on June 25, by a committee of friends and admirers. M. Dumas' address and M. Pasteur's reply are given in *Comptes rendus*.—A telegram from the Emperor of Brazil stated that comet Wells was visible on the 17th (June). On the 20th the tail measured 45°, and the nucleus was very bright.—On the reciprocal displacements of acids combined with oxide of mercury, by M. Berthelot.—Note on the preparatory works of the submarine railway between France and England, and on the geological conditions under which they are executed, by M. Daubrée.—On *débris* of mammoth found in the heart of Paris, by M. Gaudry. The locality is in the Rue Pagevin, the foundations of the new Hôtel des Postes. M. Gaudry showed a molar. Since Cuvier's time numerous remains of large quaternary mammals have been found in Paris, and human remains contemporary with the mammoth.—Mobile tableau of the different attitudes of the horse in any pace, by M. Marey. He describes a device of M. Cuyer, in which a jointed figure of a horse is fixed on a board; the hoofs are painted different colours; and placed on corresponding coloured and numbered spaces on sheets of paste-board, so that different phases of a pace can be represented. Direction is also given in placing the head, neck, body, and tail.—Action of low temperatures on the vitality of trichinæ in meat, by MM. Bouley and Gibier. Exposure of meat to a temperature of − 20° and even − 15° is sufficient to kill the trichinæ in it.—On the second comet of the year 1784, by M. Gyldén.—On the photographic spectrum of Comet I, 1882 (Wells), by Dr. Huggins.—On *Laminaritez Lagrangei*, Sap. and Mar., by M. de Saporta.—Experimental study of the conditions that allow of rendering usual the employment of the method of M. Toussaint for weakening the virus of charbon and vaccinating animal species subject to splenic fever, by M. Chauveau. Heating (according to certain rules) blood infected with bacteria, makes it a vaccinating liquid quite as sure as that of M. Pasteur. The temperature 43°-44° suffices. In an hour enough vaccine matter for 500 sheep can be prepared from one guinea-pig.—M. Lallemand was elected Correspondent in Physics in room of the late M. Billet.—On Eulerian integrals, by M. Tannery.—On Abelian functions, by M. Appell.—On the reduction of Abelian integrals to elliptic integrals, by M. Picard.—On the perforating machine of Col. Beaumont employed on the submarine railway, by M. Duval.—On the employment of zinc-carbon couples in electrolytes, by M. Tommasi. A reply to M. Berthelot.—On silicium, by MM. Schützenberger and Colson. Platinum plate or wire, heated to a white red within a thick layer of non-siliciferous lamp-black, gains weight, and has its fusibility increased, through fixation of silicium, which can only have come from the crucible. From various experiments, the authors infer that nitrogen, and probably also oxygen, have a *rôle* in the transport of silicium.—Action of bimolybdate of potash on some oxides; production of corundum and specular iron ore, by M. Parmentier.—Action of sulphuretted hydrogen on sulphate of nickel in acetic solution, by M. Baubigny.—On the supposed compound NH_2, by M. Combes. Having repeated M. Maumené's experiments, he gets only ammonia and carbonic acid.—On didymium, by M. Brauner.—Action of oxygenated water on the red colouring matter of blood and on hematosin, by M. Béchamp. Hemoglobin and hematosin behave, in contact with oxygenated water, as oxidable bodies. The blood contains two causes of decomposition as regards oxygenated water, viz. microzymas and hemoglobin.—On gastric juice, by M. Chapoteaut. Pepsine seems to him to be a combination of an albuminoid matter with an organic acid; (he hopes to prove this shortly).—On the differentiation of protoplasm in the nerve-fibres of Unionides, by M. Chatin.—On the sexual organs of *Ciona intestinalis*, by M. Roule.—The eye of *Proteus*, by M. Desfosses. It has retinal development, but no crystalline lens, nor any refractive organ; thus it cannot be compared with the eye of any vertebrate.—New example of alternating generations; œcidium of creeping Ranunculus [*Œc. Ranuncuacearum* (*pro parte*)] and Puccinia of roses (*Puccinia arundinacea*, Dc.), by M. Cornu.—On the disease of saffrons called "Death," by M. Prillieux.—On the petioles of Alethopteris, by M. Renault.—On the marine carboniferous of Upper Alsace; discovery of its relations with the culm or the plant carboniferous, by MM. Bleicher and Mieg.

THE GEOLOGY OF CHINA

China: Ergebnisse eigener Reisen und darauf gegründeter Studien. Von F. Freiherrn von Richthofen. Zweiter Band. (Berlin: Reimer, 1882.)

THE second volume of Baron Ferdinand von Richthofen's great work on China has just appeared. Five years have elapsed since the publication of the first volume, and two additional volumes are promised to complete the work, which when its maps and full index have been supplied, will be a great storehouse of observations in almost every department of Geology. Few geologists have enjoyed such opportunities of extended travel as have fallen to the Baron's lot. Already familiar with the rocks of a large part of Central Europe, he carried his knowledge and experience to the far west of North America, and did admirable service theie as a pioneer to those who have [come after him. Subsequently he set himself to explore the geological structure of the Chinese Empire, and he is now laboriously collecting and arranging the vast materials which he amassed in his wanderings through the almost unknown geological formations of that wide region.

His chapters are arranged in the chronological order of his journeys, and bristle with local details, which, however, are illustrated and made more readily intelligible by numerous sections interspersed through the text, as well as by sheets of coloured profiles. One of the most valuable features of the book for general readers consists in the clear summaries of geological data which for each great district are given in larger type. From these the salient points in the geological structure of the different provinces and their bearing on systematic geology may be gathered by those who have not time to read the voluminous narrative of details. The author confers a further and most welcome boon upon students by appending to his volume a final chapter of "Geological Results," wherein he gives a succinct but clear and interesting outline of what he conceives to have been the leading events in the geological history of China. As this outline is accompanied throughout by references to the pages where each subject will be found treated in ample detail, the reader sees at once where to turn for fuller information.

Baron von Richthofen divides the story of the geological evolution of China into three chief periods. (1) That of the formation and plication of the Archæan rocks; (2) that of the Palæozoic rocks to the end of the Carboniferous epoch; and (3) a vast continental period lasting from Palæozoic time up to the present day. The Archæan gneiss, in highly inclined beds with a persistent N.N.W. strike, is separated from all younger formations by a great abrasion and discordance. It is succeeded by a younger gneiss and by mica-schist, hornblende-schist, quartzite, marble, coarse conglomerate, sandstone, and green slates, some of which can be seen to lie unconformably upon it. These various crystalline masses underwent enormous plication and subsequent denudation before the deposition of the Palæozoic series upon them. They are succeeded by a vast mass of sedimentary material (12,000 to 20,000 feet thick) constituting the "Sinesian Series," in which arenaceous rocks predominate in the lower and calcareous in the upper portions. The occurrence of some forms of *Dikellocephalus* and *Conocephalus* and numerous brachiopods at the top of this series indicates that in part it represents the period of the Primordial Fauna of Europe, and the Potsdam Sandstone of North America. These interesting and important fossils will be fully described in a future volume of the work. It would appear that the denudation of the elevated area of crystalline rocks continued through the Silurian and Devonian periods. In the latter period, or at its close, considerable terrestrial disturbance took place, whereby a general upheaval of the whole area was effected, with plication and fracture in certain tracts. Next came the deposit of the Carboniferous Limestone and of the coal-bearing sandstones shales and marine calcareous bands (with *Productus semi-reticulatus*) which overlie the limestone. The existence of coal in China was known many years ago, and English steamboats have been in the habit of coaling in Chinese ports from the produce of native workings. But the vast extent and geological relations of the coal-fields have first been made known by our author. One of his maps gives a graphic representation of the enormous area of undisturbed country over which the nearly horizontal coal-bearing measures extend. There are at least two series of coals, one belonging to the true Carboniferous and the other to the Jurassic system.

The close of the Carboniferous period was marked by an equable uprise of the land towards the north and plication in the south, with the outbreak of volcanic eruptions. The result of these movements was the final and persistent transformation of the greater part of China into land. Among the oldest deposits of that ancient terrestrial area are the coal-bearing beds in the northern tracts of Chili and Shansi, which contain land-plants referable to the age of the Upper Jurassic rocks of Europe, and the coal-basin of Ta-tung-fu, the flora of which appears to be of Lower Jurassic age. Among the events of Mesozoic time was the outburst of porphyritic eruptive rocks, with which are associated masses of breccia and tuff.

Some of the most generally interesting portions of the volume are those that deal with the origin of the present surface-features and superficial deposits of China. The author traces the history of the vast depression forming the great plain or basin of China, and of the volcanic activity which took place there and in other parts of the empire during Tertiary and Post-Tertiary time. Those who have seen his first volume will be prepared to find that he ascribes much of the existing configuration of the Chinese Empire to prolonged denudation since the Post-Carboniferous elevation of the region into dry land. He distinguishes three great climatic periods during which the denudation proceeded:—(1) The period of Erosion, in which the existing contours of the firm surface under the Loess were carved out; (2) the period of the Steppes, when the peculiar conditions of the Central Asiatic steppes spread over Northern China; and (3) the period of the Loess, or the duration of the existing meteorological conditions, whereby the former steppe-land is desiccated and converted into loess-land. He is disposed to regard the steppe-period as contemporaneous with the Ice-Age in Europe; but no traces of glaciation occur in Northern China. He reiterates his well-known views regarding the origin of the Loess, and cites a number of authors who have elsewhere been led to the same conclusion, that the deposit is essentially a subaërial one, formed by long-continued wind-drift with the help of vegetation. That this conclusion is true for the high arid regions of Asia and Western America cannot be doubted by any attentive observer who has watched what is now daily going on in either of these regions. In his first volume the Loess was spoken of as "subaërial"—a term altered in the present volume into "æolian," which the author noticed for the first time employed geologically in Mr. Clarence King's Report on the "Exploration of the Fortieth Parallel." It is a very good term, but of much older date than the Baron supposes, for he will find it in Captain Nelson's suggestive paper on the Bahamas, published as far back as 1852.

In a section "Upon Abrasion and Transgression," the author insists upon the paramount influence of the sea as an agent in planing down the surface of the land. "Regional abrasion," he affirms, "can only be accomplished by the advance of the breakers." This used to be also the opinion of geologists in Britain, who from their insular position and stormy climate had exceptional advantages in studying marine denudation. But there is now a wide-spread conviction among them that the part played by the sea in the levelling of land has been much exaggerated. For the production of a plain of erosion the co-operation of the sea is no doubt necessary. But the abrasion of the land down to the level of the sea is the work of the subaërial agents, and only the final touches are given by the breakers. A "plain of marine denudation" is the surface down to which a terrestrial area has been reduced. Its position and form were mainly determined by the lower limit of breaker action. But by far the greatest amount of abrasion was done by wind, rain, frost, rivers, glaciers, and other subaërial forces, which in fact reduce the land to the level at which breaker action could take effect. Oscillations of level might doubtless assist the sea, but any such help would be of comparatively trifling value.

In a final section the author gives a sketch of the coal-fields of Northern China, and analyses of sixty varieties of coal which will be found of some economic interest. He must be congratulated on the appearance of this second volume. The task he has undertaken is a most laborious one; but the method he follows is well suited to combine scrupulous attention to details and general intelligibility and interest. Without ample details his work would be of comparatively little value to those who shall hereafter travel over the same ground to verify, modify, or extend his observations. On the other hand, mere details would repel ordinary readers; but Baron von Richthofen skilfully caters for them in his large print summaries, where they find the points so well put before them as to induce probably not a few to attack the voluminous detail. It is to be hoped that the Baron may find leisure enough to enable him soon to complete the work.

ARCH. GEIKIE

OLD ENGLISH PLANT-NAMES

Sinonoma Bartholomei. A Glossary from a Fourteenth Century Manuscript in the Library of Pembroke College, Oxford. Edited by J. L. G. Mowat, M.A. (Oxford: Clarendon Press, 1882.)

IT is announced that "under the general title of 'Anecdota Oxoniensia,' it is proposed to publish materials, chiefly inedited, taken directly from MSS., those preserved in the Bodleian and other Oxford Libraries to have the first claim to publication." The materials will be issued in four series—(1) Classical, (2) Semitic, (3) Aryan, (4) Mediæval and Modern; and the work named at the head of this notice is the first of the fourth series.

Of the general value of these mediæval glossaries it is of course unnecessary to speak. The "Promptorium Parvulorum" (c. 1440), issued by the Camden Society in 1865, and the Early English Text Society's "Manipulus Vocabulorum" (1570) and "Catholicon Anglicum" (1483)—the latter one of the most recent as it is one of the most useful of their publications—may well be styled priceless records of the English language. Our only regret is that the whole work from which the "Sinonoma" is taken has not been made accessible, as Mr. Mowat's brief preface renders it abundantly evident that it contains much which would be useful, and probably also amusing—if we may judge from the few sample extracts which he gives, one of which refers to the "pulvis pro instrumento illo bellico sive diabolico quod vulgaliter dicitur *gunne*."

The editor tells us that "it was in the plant-names chiefly that [his] interest lay"; and this is easily accounted for when we see how large a proportion words of that class bear to the whole glossary. We have lately had from Prof. Earle an interesting little volume on "English Plant-Names from the Tenth to the Fifteenth Century"; while the "Dictionary of English Plant-Names" by Mr. Holland and myself, of which the third and last part is nearly ready for issue by the English Dialect Society, is, I hope, fairly complete for such names from the days of William Turner downwards. Some day it will, I trust, be found practicable to combine these two, adding to them the names found in "Promptorium Parvulorum" and in other early glossaries, both published and unpublished; and the "Sinonoma" will form a useful adjunct to such a work. There can be no doubt that Mr. Earle's book and the "Dictionary of English Plant-Names" will be found to supplement one another to an extent hardly suspected by Mr. Mowat, who, in spite of his interest in plant-names, does not seem to have consulted the latter work. For instance, he gives "Allium agreste, *i.* crawegarlek," and adds in a footnote "probably meadow-saffron." A *meadow* plant would hardly be termed *agreste;* and a reference to the "Dictionary" would have identified the crowgarlic with *Allium vineale*, which is so called by Turner ("Names of Hebes"), and is, or was, sometimes—*fide* Lisle's "Husbandry" (1757)—as troublesome a weed among corn in England as it is in the continental vineyard from which it took its specific name. Later on (p. 38) we find Mr. Mowat saying of "Allium sylveste" [sylvestre] that it "can be no other than meadow saffron." Here again the designation *sylvestre* should have put the editor on his guard; the reference to Fuchs which he gives shows clearly that some *Allium* was intended, and tracing the synonymy through Bauhin to Linnæus, we find that *A. vineale* is the species meant. Even apart from this evidence, it is obvious that the "sellers of simples" who substituted another herb for *Teucrium Scordium* would have selected one that had a similar smell, and not one like the *Colchicum*, which has no such odour. Mr. Mowat rightly identifies the "gosegresse" of the "Sinonoma" (p. 41) with *Potentilla Anserina;* but it is hardly accurate to say that it is "generally cleavers" (*Galium Aparine*). The "Dictionary of English Plant-Names" shows that the *Potentilla* is at least as frequently called goosegrass nowadays; and it is the "Gosgres" of the Old English Medical MS. printed in Archæologia, vol. xxx. (p. 408)—a glossary containing many plant-names which have been too little noticed. "Caputpurgium, *i.* stafisagria," is not *Pedicularis,* as glossed by Mr. Mowat—a plant supposed to favour the growth of lice—but the Stavesacre, which has been used for destroying them since the days of Pliny. Similarly "Calendula, *i.* solsequium," is not Caltha, but the Marigold, *Calendula officinalis;* this is made quite clear by the description under Kalendula, which may be cited as an example of the capital diagnoses which the glossary contains. "Kalendula est herba crescens in hortis portans florem rubeum vel croceum de quibus floribus faciunt sibi juvenculæ coronas, solsequium idem."

To make a glossary of this kind useful to other than English-speaking students, the plants should be identified with their Latin as well as by their English names. Even in America, the mention of the cowslip would suggest, not *Primula veris* but *Caltha palustris.* Mr. Mowat says (quite correctly) that "pigle, pagle, paigle seems to be the regular old name for cowslip"; and he seems to imply that the entry "pigle, *i.* stichewort," may also refer to *Primula veris.* But a previous entry, "Lingua avis, *i.* stichewort, *i.* pigle," is quite sufficient to confirm the natural conclusion that by stitchwort *Stellaria Holostea* (which is still commonly so called) was intended; and this plant is called pigle by Gerard in his appendix of "names gathered out of ancient written and printed copies, and from the mouthes of plaine and simple countrie people." Under "Serpillum" we find the name "pelestre," which Mr. Mowat queries "palustre?" but this is a form of Pellitory, already given on p. 34—"Piretrum, pelestre idem"—the name "Piretrum" showing that *Anacyclus Pyrethrum,* not *Parietaria,* was intended; the Anacyclus also figures in the Glossary under the name of "Dentaria," in allusion to its former use in toothache. An instance of the insufficiency of English names is given in the gloss of "Umbilicus veneris, *i.* penigresse," as "penny-grass, pennywort"; it is of course *Cotyledon,* not *Hydrocotyle,* which is here meant, though the vernacular names are common to the two plants.

In most cases, however, where Mr. Mowat has given a modern synonym, it is correct; but I do not quite understand why only comparatively few plants are identified, as the identifications are by no means confined to cases of special difficulty. Some very obvious explanations are duly set forward, while in more doubtful cases help is often not forthcoming.

In the volume of Plant-Names which I hope to prepare for the Early English Text Society, I shall try to identify as far as possible all the plant-names, both English and Latin, with their modern scientific equivalents. This will be a tedious work, and one in which mistakes are certain to occur; but a foundation will then have been laid for the future production of a comprehensive work on English plant-names which shall take in all, from the earliest to the most recent. When such a work comes to be done, the great value of collections like this of Mr. Mowat will become apparent.

JAMES BRITTEN

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Analysis of the Tuning Fork

MR. HERMANN SMITH, in a letter in NATURE last week, commenting upon my paper read before the Physical Society on June 10, of which you gave a short report, offers some very cogent experiments in support of the evidence I have endeavoured to give, that the tuning-fork does not communicate its sonorous vibrations to a sounding-board through a *ventroid,* as we find generally accepted upon the theory of Chladni. In remarks upon my paper at the Physical Society, Lord Rayleigh suggested that this matter could be demonstrated by cutting a tuning-fork out in both ends of a long steel bar in the manner I had done, for an experiment, in one end only; we might then observe if sonorous vibrations would be communicated through either of the prongs of the double fork, at the opposite end to that set in vibration. In the following week I constructed such a fork, and I found that either of the non-vibrating prongs, when the opposite ones were set in vibration, would form a perfect stem to the fork, and communicate sonorous vibrations just as well as a single stem. In this case it will be seen that the prongs, which may be considered to form the stem, lead directly to the places on the fork pointed out as its nodes by Chladni. It appears, therefore, evident that a node may communicate sonorous vibration to a sounding-board.

After reading my paper Dr. Stone told me in conversation that he had constructed a tuning-fork with a rod projecting at right angles to the open space between the prongs, and directly from its stem, and that this rod communicated sonorous vibrations from the fork to a sounding-board nearly as perfectly as the direct stem. This modified form of fork I also made by screwing a stem into my experimental fork, which was made in the end of a flat steel bar. I found it to act as Dr. Stone had stated. These experiments appear further to show that sonorous vibrations are communicated through nodes to sounding-boards. If we may apply this principle to stringed instruments, we must look rather to the bridge than the transverse motion of the string, as the communicator of the sonorous vibrations which produces the note. I may say that the discussion of Chladni's theory was not the object of my paper, the purpose of which was to show that the sonorous vibrations forming a note are possibly compounded of vibrations of much smaller amplitude than generally assumed, which was perhaps better demonstrated by other experiments.

W. F. STANLEY

The Mount Pisgah (U.S.) Stone Carvings

THE number of NATURE dated June 15 (p. 160) contains some statements relating to the curious stone carvings discovered by Mr. M. S. Valentine in the neighbourhood of Mount Pisgah, North Carolina, and now exhibited by him in Europe. Before leaving the United States, Mr. Valentine brought his specimens to Washington, in order to have them examined by Prof. Baird, the Director of the United States National Museum, and by myself. I am therefore enabled to express an opinion concerning them. Having been for many years in charge of the largest existing collection of North American antiquities, I can safely assert that they are totally abnormal in character, that is, unlike any pre-Columbian stone carvings thus far found in the United States. They neither show the characteristics of the stone sculptures discovered in mounds, nor do they resemble the well-known specimens of modern Indian art. In short, they are not typical at all, unless, indeed, we deem them sufficiently important to form a type for themselves. Such an importance, however, I cannot concede to them, believing that they originated in comparatively modern, certainly in post-Columbian, times, and were made by a few individuals of the Indian, or, perhaps, even of the Caucasian, race. The rude attempts at imitating animals of the Old World are conclusive evidences that the makers either had seen such animals, or knew at least that they existed.

The carvings, it should further be taken into account, are executed in soft potstone, a material easily yielding to the effects of exposure, and hence a short lapse of time would have sufficed to give them the appearance of real antiquities. In fine, I consider these carvings as a modern intrusion, and would deem it an extremely hazardous attempt to make them the basis for speculations bearing on the ethnology of North America.

The Influence of Light on the Development of Bacteria

IN NATURE for July 12, 1877, there appeared a short communication from Messrs. Downes and Blunt summarising the conclusions at which they had arrived as the result of investigations on the influence of light on the development of lower organisms. The experiments were described in detail in the *Proceedings* of the Royal Society for 1877 (vol. xxvi. p. 488), and were considered by them to show that light is inimical to the development of bacteria in Pasteur's solution; but that for the full effect direct insolation is needed. Exposure to the sun's rays, according to them, may simply retard development, or it may completely sterilise the solution, by killing bacteria or their germs contained in it. In a second paper read before the Royal Society (*Proceedings*, vol. xxviii. p. 199), some further experiments were detailed, which, however, did not, I venture to think, do much towards settling the difficulties of the question. In the same volume of the *Proceedings* (p. 212) Prof. Tyndall supplied observations of his own, which confirmed the conclusions of Messrs. Downes and Blunt, in so far as the retardation of development was concerned, but differed on the point of sterilisation by bacterial destruction being attainable by insolation. At the last meeting of the British Association, Prof. Tyndall returned to the subject (NATURE, September 15, 1881), and related some further experiments confirming what he had previously stated.

I have recently made a considerable series of experiments, with the hope that under our bright Australian sun I might get results decisive on the point of difference between these inquirers and also confirming or negativing the result on which they were agreed. I made use of Cohn's solution as the cultivation fluid and common one-ounce phials as the vessels. The solution was inoculated with a small quantity of fluid swarming with bacteria (*B. termo*), the bottles plugged with cotton wadding and exposed fully to the sun. Some of the experiments were made in the hottest weather of February and March, and the later in April. To begin with, I simply placed the bottles on the outside of a window-sill, on which the sun shone during the greater part of the day, a temperature of 124° F. being noted on one occasion, and that probably not the highest reached. My first results seemed fully to confirm the conclusions of Messrs. Downes and Blunt, complete sterilisation apparently being sometimes attained, at least as far as bacterial growth was concerned, the destruction of mould spores, as also noted by them, not being so easily accomplished. Suspecting at last that the effect might possibly be due as much to elevation of temperature as to any special chemical or other action of the sun's rays, I varied my procedure. I was led to do this in part by the circumstance that I had not seen diffused light check in any way the bacterial growth, when the solution exposed to it was kept at the same temperature approximately as that in other bottles closely wrapped in brown paper. It did happen, indeed, that the exposed solution became opalescent *sooner* than that which had been guarded. The method ultimately adopted was, to suspend the bottle outside of a window, and the particulars of one experiment will make clear what resulted, and show the general method. On April 6, at 2 p.m., the weather being bright but cool, these bottles, containing each two drachms of inoculated solution, were suspended outside of a window. The 7th was cloudy, the 8th bright and cool; and on the 9th, which was bright and warm, all were still found transparent, and, at 9 a.m., one was brought in out of the sun. On the 10th, which was also bright, another was taken in at 9 a.m., the one which was left out showing, at that time, faint signs of cloudiness. A thermometer hung up beside it marked a temperature of 98° F. Next day, the 11th, at 9 a.m., the exposed solution was quite milky, the others just beginning to show traces of opalescence, the one removed on the 9th being least advanced. This experiment, even by itself, was almost decisive. It established the fact that insolation by itself does not prevent the growth of bacteria in a perfectly transparent medium, and does not even retard it, relatively to the time needed in solution less exposed, but kept at a rather lower temperature. In another experiment I found two bottles continuously exposed to the sun during two bright days, become milky, the bacterial growth, in fact, only beginning then, no trace of cloudiness having shown itself during five previous days which were dark and cold.

The conclusion I came to of necessity was, that the bacterial development was mainly, if not wholly, dependent on temperature. On referring to a paper by Dr. Ed. Eidam, in Cohn's *Beiträge zur Biologie der Pflanzen*, Heft iii., I found that he had proved that the *bacterium termo* passes into a torpid condition (Wärmestarre), when exposed to a temperature of between 40° and 45° C. (104°–113° F.); is killed by seven days exposure at 45° C., by fourteen hours at 47° C. (116°·3 F.), by three to four hours at 50°–52° C. (122°–125·6° F.), and by one hour at 60° C. (140° F.). In this country there need be no difficulty in getting a heat in the sun, greater than even the highest of these; and I should think it possible enough in England, on a hot summer day, to get a temperature in exposed situations considerably over 104° F., sufficient to paralyse the bacteria, or even to kill them, if the exposure was long enough continued. Any explanation of the difference between the results of Messrs. Downes and Blunt, and those of Prof. Tyndall, on the point of complete sterilisation, is simply that, while they used small test-tubes, his solutions were contained in flasks, and that the larger body of fluid less easily reached the highest temperature attainable under the conditions. The different results, with very small and larger tubes, observed by the former, and to them evidently inexplicable, if not simply accidental, is best explained on the same principle.

It is true that Prof. Tyndall agrees with the other inquirers in disclaiming the notion that the apparently inimical influence of light can be ascribed to difference of temperature; but it is evident that it had not occurred to them, that any possible elevation of temperature could act otherwise than by favouring bacterial growth and multiplication. This is plain, from the words used by Messrs. Downes and Blunt (*Proceedings*, vol. xxvi. p. 491), when, trying to account for some anomaly, they remark that "external conditions—notably temperature—may retard or counteract the preservative quality of the solar rays. It must be understood, however, that the putrefactive tendency of warmth does not, in our experience, with this solution at least, override what we termed the preservative quality of light; for, provided that there was the full amount of sunlight, we have preserved tubes exposed *continuously* from day to day as readily in hot weather as in cool." Prof. Tyndall, in his recent paper, speaks of his flasks having been exposed to strong sunshine for a whole summer's day; and, with reference to the more rapid occurrence of turbidity in those which had been shaded, adds: "This result is not due to mere difference of temperature between the infusions. On many occasions the temperature of the exposed flasks was far more favourable to the development of life than that of the shaded ones."

I feel the boldness of criticising the conclusions aimed at by such a famous investigator as Tyndall, and all the more when these are in accord, in the main, with those of other inquirers, the joint results having hitherto, to all appearance, been accepted as unimpeachable. I do so only after careful observation and consideration, and with the hope that further investigations, made with due precautions, will establish the correctness of what I have here stated. My researches in detail will be brought before the Royal Society of Victoria at the next meeting, and I will take the liberty of forwarding you a copy of the paper when printed, and of distributing a few others. It contains an account of experiments for the purpose of testing the action of sun and air on dried bacteria, which have some interest, but which the fear of trespassing unduly on your space prevents me from entering on here. JAMES JAMIESON

Melbourne, May 22

Fireballs observed in the Netherlands

IN the well-known "Meteoric Astronomy" of Dr. D. Kirkman, p. 67, is to be found the following note, on the occasion of the interesting shower of dust and aërolites in Calabria on the 13th and 14th of March, 1813. "The date of this remarkable occurrence is worthy of note, as a probable aërolite epoch. From the 12th to the 15th of March we have the following falls of meteoric stones. . . ." &c. (7 cases).

In reference to this note it may interest your readers that on the night of 12-13 March last two great meteors were observed in two different places in the Netherlands. The first observation, made near the village of Haren (four and a half kilom. S. of Groningen), by the schoolmaster, Mr. H. Bos, at 1 a.m., refers to a bright fireball, shining with a splendid "bluish red" light, illuminating the night, leaving a violet train, which lasted some moments. The path seems to have been from a point not far beneath the zenith, in an azimuth of 115° to another at 108° azimuth, and had a length of 45°, which was traversed by the phenomenon in 4 or 5 seconds. After 85 seconds—measured afterwards by means of a watch and by the distance of the objects which the observer had passed, going with a known velocity—a full detonation, like a distant cannon-shot, was heard in the same direction.

On the same night, and at the same hour, another fireball was seen near the village of Bergen, in North Holland. The schoolmaster, J. Francken, gives me the following indications of its path, found by him after having interviewed the observer. It went from N.E. in altitude of 50° to S.E. in an altitude of a little less than 40° It is therefore impossible that this phenomenon should be the same as the former, the direction of the course being opposite. A second observer gave nearly the same direction.

It is worthy of remark that another violet meteor had been seen near Haren on March 12 at 8 p.m. in the S.W.[1]

A fourth meteor of the greatest size, described as being as great as the full moon, was seen by three policemen, from whom I have received tolerably harmonising records, though they were standing in different positions in the town. The time of appearance was May 1, at 4 a.m. precisely, or perhaps three minutes afterwards, and the direction of the course was S.S.E. to N.N.E. It was described by one of the observers as beginning like a shooting star (though already lightening the sky), falling downwards and rising again in a curve from S.S.E. to N.N.E., increasing in the meanwhile to a great ball of a splendid purple light, and showing a train of a silvery colour. The phenomenon lasted 50 seconds (?) measured by a watch. No sound was heard. The disappearance was instantaneous. It is uncertain if an explosion was really observed. The altitude seems to have been at the beginning, and at the end point perhaps 10°, somewhat higher in the middle, as I have attempted to determine *in loco*. The second observer estimated the duration of the phenomenon to be 13 seconds. Even when this is accepted, the body must have been very distant, and of a great volume, though increased apparently by irradiation.

The same morning, at 3h. 45m. a.m. there was also seen a great meteor, going from W. to E. near Enumatil (8 kilom. W.), and at Assen (S. from Groningen). It seems not to be identical with the former. At Assen there was heard a buzzing sound. The Enumatil observers compare the phenomenon, whose colour was white with a red train, to a drum-major's staff. The Assen observers speak of a bluish train or tail, which seemed to be smoke. The same was seen by the sluice-keeper, G. Mulder, at Veenhuizen (W. of Assen), who heard also the buzzing sound, and gives also the direction, W.—E. The ball passed S. of the zenith (Assen).

Still another great fireball was observed at Bourtange (S.E. of Groningen) at 5h. 12m. (local time) a.m. on the same morning. It had a quick motion from S.W. to E. It gave the impression of being very near the earth, only some meters above the houses. It seems to me uncertain whether it was a globulous lightning or a true fireball. The phenomenon showed a fiery tail and exploded without any sound.

Recapitulating, there seems to have been observed the following fireballs of great size :—

March 12, 8 p.m. (Groningen M.T.) at Haren.
,, 13, 1 a.m. ,, ,, ,,
,, 13, ,, ,, Bergen (N. Holland).
May 1, 3.45 ,, ,, ,, Enumatil.
,, ,, ,, ,, Assen } Probably
,, ,, ,, ,, Veenhuizen } the same.
,, 4, ,, ,, ,, Groningen.

Finally a fireball or a globulous lightning.

May 1, 3 45 a.m. (Groningen M.T.) at Bourtange.

Groningen, June 19 H. J. H. GRONEMAN

---

[1] In the German journal, *Sirius*, edited by Dr. H. J. Klein, Bd. x. (1882), p. 40, is mentioned likewise a fireball of the full moon size, from March 13, 1875, by Mr. T. Köhl.

Aluminium for Movable Coils

AT the Oxford meeting of the Physical Society, after Dr. W. H. Stone's interesting description of an electrodynamometer designed for medical purposes with the movable coil, made of aluminium wire for the sake of lightness, I took the liberty to remark that about eight years ago Dr. Werner Siemens had made use of aluminium wire for the movable bobbin of his *dynamo-relay*.

I was then under the impression that this fact was probably not known in this country; a friend has, however, since called my attention to a short paragraph in the *Telegraphic Journal* of 1878, p. 53, in which it is already mentioned.

One of these dynamo-relays was shown working at the Paris Electrical Exhibition, and Messrs. Siemens and Halske have made use of the same principle in their so-called *soot-recorder* (see *Telegraphic Journal*, 1878, p. 90), an instrument well suited for the registration of currents of varying direction and strength.

At the meeting I further said that in some of the coils made of very thin aluminium wire, I had found an increase of resistance after the lapse of some time, and that this increase was proved to exist at the place where two lengths of wire had been joined by twisting them round each other.

Some experiments were afterwards made to coat the ends of the wire with an electrolytic deposit of copper, and then solder them together; but the best and most natural way to overcome the difficulty is to make the coil all of one length of wire, and thereby dispense with all internal joints.

A similar increase of resistance at the place of contact between aluminium wire and mercury I had already observed several years previously; the cause of it seems to be the formation of a very thin film of aluminium oxide on the surface of the wire.

I have been led to make the above remarks after perusing the closing paragraph of Dr. Stone's article in NATURE, vol. xxvi. p. 201. EUGENE OBACH

Woolwich, July 3

The Recent Weather

THE article published in NATURE, vol. xxv. p. 225, entitled "Recent Weather," attracted attention from meteorologists in China from the fact that the extraordinary character of the season therein discussed was observable in China also In my Report on the Health of Wenchau, I referred to the unprecedentedly high reading of the barometer in this part of the world, at the same time that a like phenomenon was observed in Western Europe.

NATURE records that November last showed the highest thermometrical range that has been known since thermometers came into use. On referring to the tables of Dr. Zrightsche (director of the Belgian Observatory at Peking), I find that the mean temperature at Shanghai of that month for a period of twelve years falls considerably below that of the record for November last; and finally we learn from NATURE that the winter of 1881-82 in Western Europe was an "open one," which was the case in Eastern Asia; the port of Tientsin, for example, having been closed by ice later, and opened to navigation earlier than usual. When the meteorological reports are all gathered in, it will be found that the abnormalities which characterised last winter were coincident with like phenomena in this part of the world. D. J. MACGOWAN

Wenchau, May 17

"Megaceros Hibernicus" in Peat

My friend, Dr. Leith Adams, has given it as his opinion that the Irish elk is only found in the clay or marl under the peat, while I contended that some of them occur in the peat, this opinion being formed from reports of finds in the counties of Limerick, Carlow, and Wexford, also from the colour and appearance of the bones; still I could not be positive, as I had not myself seen the bones raised out of the peat. Last week, however, I heard from Capt. Woodrift, Kilowen Inch, Co. Wexford, that he had found an elk's head in the peat, and I went to see it. It was lying on its back altogether in the peat, except some of the points of the horns. The portions in the clay under the peat were quite hard, while those in the peat were soft, but became quite hard a short time after they were taken out.

The "Elk Hole" at Kilowen is a very remarkable place, because, although very small, not 200 yards in diameter, yet at the present time the remains of over ten skeletons of elks have been taken out of it; while in the undisturbed portion of the bog there are probably other skeletons. A few miles to the south-west of Kilowen there is the small bog of Axe, in which the remains of the *C. megaceros* has also been found.

Ovoca, July 8 G. H. Kinahan

Perception of Colour

Happening to be reading out of doors, while the sun was shining on my book, I noticed that patches of weed on the lawn appeared peculiarly conspicuous in their difference of tint from the grass. The same patches of weed close-cropped to the level of the grass were ordinarily scarcely observable from difference of colour. Now, as I looked up from my book—my eyes dazzled with the glare—they appeared to me to have a strong blue tint. My attention thus being drawn to the point, I extended my observations, with the following results, which, if new, will doubtless prove interesting to some of your readers. I found that if the eye was exposed for two or three minutes to the action of a very strong light, *by looking at a sheet of white paper*, while bright sunshine fell on it, the capacity of the eye for perception of colour was curiously modified, under certain conditions. For example: if, on the instant after the exposure of the eye to strong light, as described—solarisation I will call it—flowers of various colours, placed in a shady part of a room were examined, a pink rose appeared the colour of lavender; dark crimson Sweet William, almost black; magenta Snapdragon, indigo; scarlet Poppy, orange; the eye was, in fact, red-blind. After a minute or two, the eye recovered its normal sensibility to red, and the flowers assumed their natural colour.

In order to ascertain that the mal-perception of colour, under the conditions described, was due to the action of strong light on the eye, and not to any other circumstance, I repeated the experiment, allowing the solarisation to take place on one eye only, the other eye being kept shut until the moment of making the observation. I then found, as before, that the solarised eye was red-blind to objects in a subdued light for a minute or two after solarisation, but sensitive to blue, and in less degree to yellow, while the non-solarised eye was perfectly normal in its perception of all the colours. By alternately closing and opening the solarised and non-solarised eye, the difference in colours perceived by the two eyes was extremely striking—the rose was, as seen by one eye, pink, by the other eye, blue. It must be remembered that the effects described were produced when the flowers were observed in a room not strongly lighted.

When a corresponding experiment was made with the flowers *in the sunshine* instead of in the shade, it was found that a reverse effect was produced—that every colour, and red particular, was intenser to the solarised eye than to the non-solarised eye—as was readily seen by alternately shutting and opening them. To the solarised eye a red rose-bud was deep red, to the other eye light red. The red of the poppy was deeper and more vivid to the solarised eye. A calceolaria was orange chrome to the solarised eye, lemon chrome to the non-solarised eye. A viola was dark violet to the solarised eye, a colder tone of blue to the non-solarised eye.

I found that after the insensibility to dimly lighted red and orange (the effect of solarisation) had worn off, a reverse condition succeeded, for example, venetian red, which was a dirty brown, as seen the instant after solarisation, appeared gradually to change to a full vermillion. I found also that portions of the solarised eye that had escaped the solarising action behaved like the non-solarised eye. I leave the explanation of these slight observations to those within whose special field of study they naturally fall, only remarking that the power of the eye, fatigued by solarisation to perceive blue light, and light of no other colour, under the conditions described, seems to suggest that the eye, like almost all matter sensitive to light, is more sensitive to blue rays than rays of lower refrangibility.

Lancing, July 10 J. W. Swan

WATER-JET PROPELLERS

Very early in the history of steam navigation, attempts were made to employ the "hydraulic" or "water-jet" propeller. About 1782 Rumsey began to work in this direction, using a steam-engine to force water out at the stern of a boat, the inlet being at the bow. His experiments are said to have extended over twenty years, but led to no practical result. Another American, named Livingston, applied the same principle of propulsion in a different manner. A horizontal wheel, or turbine, was placed in the bottom of the boat, near the middle of the length, the water was admitted from beneath it, and expelled from the periphery of the wheel through an opening at the after part of the boat. In 1798 a monopoly was granted to Livingston for twenty years by the State of New York, on condition that within a given period he produced a vessel capable of attaining the speed of four miles an hour. This condition was not fulfilled, and, as is well known, the first successful steamers built in this country or abroad were propelled by paddle wheels. This form of propeller alone was employed for nearly forty years, during which period steam-ships increased greatly in numbers, size, and speed, proving themselves well adapted not merely for service on inland and coasting navigation, but also for ocean voyages. Just when the Transatlantic steam service had been successfully commenced by the *Great Western* and *Sirius*, both paddle steamers, the screw-propeller began to threaten the supremacy of the paddle-wheel; and the success of the *Archimedes* in 1840 led to the adoption of the screw in the *Great Britain*, as well as the construction of the screw sloop *Rattler* for the Royal Navy. Soon after came a revival of the water-jet propeller by the Messrs. Ruthven of Edinburgh. In 1843 their first vessel was tried, attaining a speed of about seven miles an hour. Ten years later a fishing-vessel was built on the same principle, and exceeded nine miles an hour. Several other river steamers and small craft were constructed with jet-propellers in the period 1853-65, but they were all comparatively slow, and the plan did not grow into favour either as a substitute for the paddle-wheel or the screw.

There were certain features in the jet-propeller which recommended it to the judgment of many naval officers who had witnessed the trials of vessels so fitted; their influence led the Admiralty in 1865 to order the construction of a small armoured vessel, appropriately named the *Waterwitch*, which was to be fitted with Ruthven's propeller. Admiral Sir George Eliot was one of the principal advocates of a trial of the new system, in which he has always continued to take a great interest. In the German navy, trials of the Ruthven system have also been made on a small vessel named the *Rival*, and experiments of a similar nature have been made in Sweden. At the present time Messrs. Thornycroft are building for the Admiralty a torpedo-boat, to be propelled by water-jets, the trials of which are awaited with interest, since they will furnish another comparison between the performances of the hydraulic propeller and the screw.

The Ruthven system agrees in its main features with the proposal made by Livingston forty years earlier. As an example the arrangements of the *Waterwitch* may be briefly described. Openings are made in the bottom of the ship amidships, to admit the water into a powerful centrifugal pump or turbine, the axis of which is vertical.

The main engines drive the turbine, expelling the water with considerable velocity through curved pipes or passages leading to "nozzles" placed on each side at the level of the water-surface. When the vessel is going ahead the jets are delivered sternwards; if it is desired to move astern the engines are not reversed, but valves are operated in the outlet pipes, and the jets are delivered through the forward ends of the nozzles. These motions of the valves can be made from the deck by an officer in command. If desired, the jet on one side can be delivered ahead, and that on the other side astern, the vessel then turning without headway. This power of control over the movements of the vessel, without reversing the engines, is one of the chief advantages claimed for the system; and it is undoubtedly of value, especially in war-ships. Another advantage claimed for the jet-propeller is the power of turning it on an emergency, into a powerful pump, by which large quantities of water can be discharged from the interior of a ship that has been damaged in action. This latter feature cannot be regarded as of primary importance, however, seeing that modern war-ships are minutely sub-divided into water-tight compartments, and must depend for their flotation upon the integrity of the bulkheads and other partitions, if their skins have been broken through by ramming or torpedo-explosions. A further claim on behalf of the jet-propeller for war-ships is based upon the less risk of disablement in action, as compared with screws or paddle-wheels; and this claim may be admitted. On the other side must be set the fact that all the trials made hitherto in vessels fitted on the Ruthven system have shown a less speed for a given amount of engine-power than would have been obtained with the screw-propeller. It may be urged, of course, that the decrease in speed should be accepted, at least in special cases, in order to secure the undoubted benefit of the hydraulic system. But the general feeling of naval architects and marine engineers is in favour of the use of twin-screws rather than water-jets for war-ships, the duplication of machinery and propellers decreasing the risk of disablement, giving great manœuvring power, and securing higher speed than could be obtained with the jet propeller.

Recently further trials have been made with a vessel built in Germany, from the designs of Dr. Fleischer, who claims to have devised a novel and more efficient system of hydraulic propulsion. A brief notice of the invention appeared in NATURE, vol. xxvi., p. 18; fuller details are to be found in two pamphlets published by the inventor: "Der Hydromotor," and "Die Physik des Hydromotors" (Kiel, 1881). The first of these pamphlets contains a general description of the system, as applied in the *Hydromotor* (a vessel of 110 feet in length, and about 100 tons displacement), a summary of her trials, compared with those of earlier vessels engined on Ruthven's system, and an enumeration of the advantages to be obtained by using jet-propellers instead of screws or paddles. The second pamphlet contains a statement of the experimental and mathematical investigations conducted by Dr. Fleischer in working out his system.

Dr. Fleischer dispenses with a turbine, and allows the steam to act directly upon the water in two large vertical cylinders placed amidships. These two cylinders communicate with the ejecting nozzles which are situated on either side of the keel. In each cylinder there is a "float" or piston of nearly the same diameter as the cylinder, with a closed spherical top; when this float is in its extreme upper position, the cylinder is full of water. Steam is then admitted into the upper part of the cylinder above the float, the latter is pressed down, and the water is expelled through the nozzle-pipe with great velocity. At a certain portion of the stroke, the admission of steam is shut off automatically, the remainder of the stroke being performed during the expansion of the steam, and the velocity of ejection of the water gradually diminishing. At the conclusion of the stroke, the exhaust-valve from the steam space to the condenser is opened, the steam rushes out, forming a partial vacuum above the float, and the water enters, pressing the float up. The entry of the water at this stage is partly through the nozzle, and partly from a separate valve communicating with the water-space of the surface condenser. In order to utilise the vacuum as much as possible, and to increase the effective "head" of water during the down stroke, the cylinders are placed as high as convenient in the vessel. Two cylinders acting alternately were used in the *Hydromotor*, for larger or swifter vessels it is proposed to use a greater number of similar cylinders. As in other jet-propelled vessels valves operated from the deck enable the commanding officer to reverse the direction of outflow of either or both jets, making the vessel move ahead or astern, or turn on her centre. The position of the nozzles in the *Hydromotor* is not so favourable to manœuvring power as in the *Waterwitch*, and the difference in behaviour is likely to be appreciable.

Greater interest attaches to the trials of speed than to those of turning. Unfortunately the records are too meagre to enable a decisive opinion to be formed on the merits of the new system as compared with that of Ruthven. Dr. Fleischer claims that the *Hydromotor* attained a speed of 9 knots with 100 indicated horse-power; but the conditions under which this speed was attained may have differed considerably from those under which measured-mile speed trials are conducted in this country. Any exact comparison of the performances of two steam-ships with either similar or different systems of propulsion, demands as its basis the elimination of all varying conditions, the determination of the true mean speed, and the calculation of the engine-power corresponding to that speed. Dr. Fleischer may have done all this, but it does not clearly appear in his publications whether he has or not. He distinctly claims for his system a very high "efficiency" as compared with that of Ruthven, but it will be shown hereafter that the formula which he uses is not absolutely correct; and what is more important to note is the circumstance that Dr. Fleischer clearly does not possess the experimental data respecting the resistance offered by the water to the motion of the *Hydromotor* when towed at various speeds, which would enable him to express the true efficiency of the propelling apparatus. On this point a few further remarks may be permittted.

Supposing a vessel to be towed at any speed, and her resistance to be ascertained by a dynamometer, the horse-power expended in overcoming that resistance can be calculated, and. in the terminology of the late Mr. Froude, is styled the "effective horse-power." Next let it be supposed that the vessel is driven at the same speed by her own machinery, and that the "indicated horse-power" in the cylinders is ascertained. The ratio of the "effective" to the "indicated" horse-power expresses the true efficiency of the propelling apparatus, excluding from the account, of course, the efficiency of the boilers. Now what has been said above respecting Dr. Fleischer's figures simply amounts to this: he does not appear to have ascertained the effective horse-power of the *Hydromotor*, and consequently cannot express the true efficiency except as an estimate.

The excess of the indicated horse-power over the effective in any steam-ship is to be accounted for by the waste-work of the mechanism, the waste-work of the propellers, and the "augment" of the tow-rope resistance produced by the action of the propellers. In good examples of screw-steamers the effective horse-power at full speed has been found to vary from 40 to 60 per cent. of the indicated power. Dr. Fleischer claims for the *Hydromotor* a corresponding efficiency of about 34 per cent. at full speed; but not, it would seem, with any certainty.

Passing by this comparison with screw-propelled ships, the *Hydromotor* may be compared with the *Waterwitch.* She gains upon the latter obviously in the avoidance of much waste-work in the mechanism In the Ruthven system there is necessarily more waste-work in the engines which drive the turbines, and in the friction of the water in the turbines and passages to the nozzles, than has to be incurred in the Fleischer system. On the other hand, in the latter system, there must be some loss from condensation of steam in the cylinders, and the high mean velocity of ejection must be a disadvantage. The considerable variations in the velocity of ejection at different parts of the stroke must also be a disadvantage, as compared with the uniform velocity of delivery from a turbine. Respecting the condensation it is asserted, as the result of experiment, that the losses are exceedingly small, the cylinders being wood-lined, and a layer of hot water being formed below the float. Experienced engineers were scarcely prepared for this satisfactory result, anticipating that more serious losses would occur from the alternate heating and cooling of the cylinders. Of course, experience in such a matter is the true test; but it is to be observed that the *Hydromotor* appears to have very ample boiler-power in relation to the indicated horse-power assigned to her maximum speed. Losses from condensation cannot be estimated from the statement of indicated horse-power. The indicator diagrams which have been published, show a very good performance.

The varying rate of outflow through the nozzles must be a source of disadvantage in the Fleischer system. For the hydromotor it is stated that the *mean* velocity of outflow was about 66 feet per second when the speed of the vessel was about 15 feet per second. We are not informed what was the maximum velocity of outflow; the minimum velocity is said to have exceeded the speed of the vessel. This varying velocity, of course, carries with it a varying thrust, and the hydromotor in this respect must be less favourable to uniform motion of the ship than the screw or paddle or Ruthven propeller, where the thrust can be kept practically constant. With two cylinders this might be more felt than with four or more cylinders, but in all cases the drawback must exist.

The high mean rate of outflow involved in the Fleischer system is contrary to the generally accepted view as to the condition most favourable to efficiency. For a given speed of ship, neglecting the augment of tow-rope resistance which may be caused by the action of the propeller, there must be a certain thrust developed, which will overcome the resistance of the water to the advance of the ship. This thrust in the jet-propeller is measured by the sternward momentum generated in the jets. No matter how the mechanism may be arranged, what has to be done by it is to impart to water which has entered the ship and acquired her forward velocity, a sternward momentum which shall have a reaction equal and opposite to the fluid resistance. Momentum, it need hardly be explained, involves the consideration both of the weight of the water acted upon and of the velocity imparted to it in each unit of time. Nor is it possible to create this momentum in the water expelled from the nozzles without doing waste-work in overcoming frictional and other resistances. The magnitude of this waste work may vary greatly in different examples, and it is difficult to estimate its value apart from experiment. Hence in theoretical investigations, this waste-work is usually neglected, although in practice it is of great importance.

Leaving out of account for the moment this waste-work, and the possible influence upon the efficiency of the propeller exercised by the disturbance produced in the surrounding water by the passage of the ship, it may be well to explain briefly the accepted theory of the action of jet-propellers. This is done in the following equations:—

Let V = the speed of outflow of the jets from the nozzles in feet per second, v = the speed of advance of the ship, A = the joint sectional area of the nozzles in square feet, w = weight in lbs. of a cubic foot of water. Then—

Cubic feet of water acted upon per second $= A \,.\, V.$

Sternward velocity of jets in relation to still water $\} = V - v.$

Thrust, or momentum created per second $\} = \frac{w}{g} \,.\, A \,.\, V \,.\, (V - v),$

where g is the accelerating force of gravity—say 32 feet per second. For sea-water $w = 64$; so that $w \div g = 2$ (nearly) Hence

$$\text{Thrust (in sea-water)} = 2\,A \,.\, V \,.\, (V - v).$$

Under the foregoing assumptions, we also have

U = Useful work of propeller (in unit of time) $\}$ = work done in propelling ship.
= Thrust × speed of ship.
$= 2\,A\,V\,(V - v) \,.\, v.$

W = waste work in race $= \frac{1}{2}$ *vis viva.*
$= A\,V \,.\, (V - v)^2.$

$U + W$ = total work of propeller $= 2\,A\,V\,(V - v)\,v$
$+ A\,V\,(V - v)^2$
$= A\,V\,(V^2 - v^2).$

$$\text{Efficiency} = \frac{U}{U + W} = \frac{2\,v}{V + v}.$$

From the last of these equations it is seen that the more nearly the velocity of outflow V approaches the speed of the ship v, the nearer will the efficiency approach its maximum value, or unity. Moreover, for given values of speed of ship and *thrust,* if the difference $(V - v)$ between the speeds of outflow and advance is diminished, the area of the outlets must be correspondingly increased. That is to say, if the value of $V - v$ is diminished, the *quantity of water* $(A \,.\, V)$ operated upon must be increased. Now, in general, it has been supposed that the inferior performance of jet-propelled vessels, as compared with screw steamers was due to the small quantities of water acted upon, In the *Waterwitch,* for example, about 150 cubic feet of water were expelled per second, whereas in the rival twin-screw vessel *Viper* more than 2000 cubic feet of water were operated upon per second. In the *Waterwitch* $V = 30$ feet per second, and $v = 15{\cdot}7$ feet per second; so that according to the foregoing formula

$$\text{Efficiency} = \frac{2 \times 15{\cdot}7}{15{\cdot}7 + 30} = \frac{31{\cdot}4}{45{\cdot}7} = 68{\cdot}7 \text{ per cent.}$$

In the *Hydromotor* $V = 66$ feet (mean velocity) $v = 15{\cdot}2.$

$$\text{Efficiency} = \frac{2 \times 15{\cdot}2}{15{\cdot}2 + 66} = \frac{30{\cdot}4}{81{\cdot}2} = 37{\cdot}4 \text{ per cent.}$$

Dr. Fleischer adopts the foregoing equations, so far as they relate to *thrust* and *useful work*, but for the *total work* he uses another formula, and it is here that we venture to think he goes wrong. According to his investigation—

Total work $= \frac{1}{2}$ *vis viva* of issuing streams.
$= \frac{1}{2} \times$ Mass of water delivered per second × (speed of outflow)².
$= \frac{1}{2} \times 2\,A\,V \times V^2.$

Hence he writes—

$$\text{Efficiency} = \frac{\text{Useful work}}{\text{Total work}} = \frac{2\,A\,V\,(V - v)}{2\,A\,V \times \frac{1}{2}V^2}$$
$$= \frac{2\,V}{v^2}\,(V - v).$$

In thus dealing with the total work, instead of using the expression given above, Dr. Fleischer virtually ignores the fact that the vessel is in motion ahead; and that the streams issuing from the nozzles have the velocity V only relatively to her. It is upon this questionable formula for the efficiency that his estimates above-mentioned are based. For example, in the hydromotor at 9 knots, according to Dr. Fleischer—

$$\text{Efficiency} = \frac{2 \times 15{\cdot}2}{(66)^2}(66 - 15{\cdot}2) = 35{\cdot}4 \text{ per cent.}$$

If the same formula is applied to the *Waterwitch*, at 9·3 knots—

$$\text{Efficiency} = \frac{2 \times 15{\cdot}7}{(30)^2}(30 - 15{\cdot}7) = 49{\cdot}9 \text{ per cent.,}$$

giving about 20 per cent. less efficiency to that vessel, than is given by the accepted formula first stated.

It has been explained that the assumptions upon which the first formula rests are not fairly representative of the conditions of practice. For example, the deduction therefrom (stated above), that it is advantageous to operate upon larger quantities of water, and to reduce the excess in speed of outflow above the speed of the ship requires an important qualification in practice This deduction would be absolutely correct were it not for the waste-work which has to be done in giving the motion to the water; but in actual practice the growth in that waste work may exceed the gain obtained by dealing with larger quantities of water. The parallel case in a screw steamer is that wherein screws of too large diameter or too large surface may involve so much more waste work on frictional or edgewise resistances, that it is preferable to use smaller screws, which operate on smaller quantities of water, but secure a more economical expenditure of power for a given speed, or enable higher speeds to be attained with a given horse-power. In setting aside the commonly received view, and making trial of a system wherein the mean velocity of the outflowing jets is extremely great, while the quantity of water operated on is small, Dr. Fleischer has made an experiment of the greatest interest to all concerned with steam propulsion. If his figures are accepted it is obvious that his system involves much less waste work than the Ruthven system, between the power indicated in the cylinders and the power accounted for in the outflowing jets. On the other hand, as we have endeavoured to explain, this economy of the Fleischer system does not represent the comparative efficiency of the propelling apparatus: because the high and variable velocity of outflow must involve a considerable amount of waste work in the race. A complete comparison could only be made if in the same vessel, or in two vessels of identical form and with identical boiler-power, there were fitted, first, the Fleischer hydromotor; and secondly, the Ruthven arrangement. Then with the same steam-producing power a careful series of trials would settle the matter conclusively. The Swedes did something of this kind in order to compare the efficiencies of twin-screws and water-jets, with the result that the latter were shown to be greatly inferior. Of course it cannot be expected that Dr. Fleischer would undertake such trials unaided; on the other hand, if his system is put forward for adoption in preference to the Ruthven system, it must, at least, be shown to be more efficient, not only in certain intermediate stages in the operations of giving momentum to the jets, but as a whole. This result does not appear to have been attained as yet, so far as can be judged from the published results of trials. The information which is accessible is not complete, and some of the proposed standards of comparison are open to doubt. It is to be hoped, however, that the zeal and ability which have been displayed already by Dr. Fleischer will be still further illustrated in the continued investigation of the capabilities of his novel system of propulsion.

W. H. WHITE

A RAPID-VIEW INSTRUMENT FOR MOMENTARY ATTITUDES

THE wonderful photographs by Muybridge of the horse in motion and those by Maret of the bird on the wing induced me to attempt the construction of apparatus by which the otherwise unassisted eye could verify their results and catch other transient phases of rapid gesture. Its execution has proved unexpectedly easy, and the result is that even the rudest of the instruments I have used is sufficient for the former purpose; it will even show the wheel of a bicycle at full speed as a well-defined and apparently stationary object. This little apparatus may prove to be an important instrument of research in the hands of observers of beasts, birds and insects, and of physicists who investigate such subjects as the behaviour of fluids in motion.

My object was (1) to transmit a brief glimpse of a moving body, (2) to transmit two or more such glimpses separated by very short intervals, and to cause the successive images to appear as simultaneous pictures in separate compartments in the same field of view.

The power of the eye to be impressed by a glimpse of very brief duration has not, I think, been duly recognized. Its sensitivity is vastly superior to that of a so-called "instanteous" photographic plate when exposed in a camera, but it is of a different quality, because the impression induced at each instant of time upon the eye lasts barely for the tenth of a second, whereas that upon a photographic plate is accumulative. There is a continual and rapid leakage of the effect of light upon the eye that wastes the continual supply of stimulus, so that the brightness of the sensorial image at any moment is no more than the sum of a series of infinitesimally short impressions received during the past (say) tenth of a second, of which the most recent is the brightest, the earliest is the faintest, and the intermediate ones have intermediate degrees of strength according to some law, which an apparatus I shall describe gives us means of investigating. After the lapse of one-tenth of a second the capacity of the eye to receive a stronger impression has become saturated, and though the gaze may be indefinitely prolonged the image will become no brighter unless the illumination is increased.

This being premised, let us compare the sensitivity of the eye with that of the rapid plate in the photographic camera under conditions in which the eye is just capable of obtaining a clear view, let us say during an overcast day in a sitting room whose window does not occupy more than one-thirtieth of the total area of wall and ceiling, which is the light under which most of us habitually write and read. A glimpse under these circumstances of one-tenth of a second in duration, suffices, as we have just seen, to give a clear view, but the sensitive photographic plates sold in the shops as "instantaneous" will not give a portrait in that light under thirty seconds exposure. In other words, the sensitivity of the eye is fully 300 times as great as that of the plate. Of course I am aware that more sensitive plates than these have been made, and I have seen a rapidly revolving wheel photographed under the momentary illumination of an electric spark, but I have never heard of that being done when at the same time the revolving wheel was not perfectly distinct to the eye.

The range of ordinary illumination is very great. The photographer who requires thirty seconds in a dim window-light, would photograph clouds in some minute fraction of a second, showing that the illumination of the latter is fully one thousand-fold greater. If then the eye has been shaded and adapted to a dim light, an object in bright sunshine may require no more than the thousandth part of the tenth of a second to be visible, and in saying this, I am confident that I am underestimating what could be done. Consider what even this means: a cannon ball of ten inches diameter in its mid career travels with a velocity of little more than 1,000 feet in a second; in one ten thousandth of a second it would shift its place through only one tenth of its diameter, and would present to the eye, if it could be viewed under the above-mentioned conditions, the appearance of an almost circular disc elongated before and behind by only a slight blur.

It may be said, how is it possible to give such brief exposures as the above? I see no difficulty at all in the matter. Let us take two examples, (1) of quick movement, and (2) of very quick, but by no means the quickest possible, movement. As regards the former, I can flip with my forefinger, and with the greatest ease, a light weight (such as a very small stone) nine feet up in the air; now the maximum velocity of the tip of my forefinger is that of the initial velocity of the stone, which is calculated at once by the usual formula, $v = \sqrt{2fs}$, or taking $2f = 64$, which it is very nearly, $v = 8\sqrt{s}$, the units being in feet and seconds. The velocity in question is therefore 24 feet, or 288 inches per second. As regards a very rapid movement, we may take that of the wing of a bird, which can undoubtedly be rivalled mechanically. A pigeon is by no means the swiftest of birds, but it can fly easily at the rate of 35 miles an hour, and the part of the wing by which it is chiefly propelled and which cannot be its extreme tip, must move much more rapidly than this; let us say, very moderately, at 70 miles an hour, or 1,232 inches per second.

Now the duration of an exposure depends on three data, namely, the rapidity with which the screen moves past the eye, the width of the slit through which the momentary glimpse is obtained, and the diameter of the available portion of the pupil of the eye. I prefer not to limit the pupil by using a small eyehole which is a source of much trouble in actual work, but to have as large an eyehole as is in any way desirable. I find the width of the pupil of my eye in an indoor light as measured by holding a scale beside it and reading off in the looking-glass, to be about 0·1 inch, and I use a slit of the same diameter. The exposure begins when the advancing edge of the slit is in front of the near edge of the pupil, and it ceases when these conditions are reversed, in other words it lasts during the time that the screen is occupied in moving through one fifth of an inch. In the cases just taken of velocities of 288 and 1,232 inches per second, the duration of the exposure would be the 1,440th and the 6,160th part of a second, respectively. There is therefore no difficulty either theoretical or practical about shortness of exposure and sufficiency of illumination. The power exists, and can be utilized, of seeing bodies in motion by a rapid-view instrument, showing them in apparent stillness, and leaving a sharply-defined image on the eye, that can be drawn from visual memory, which in some persons is very accurate and tenacious.

I find on trial that great rapidity of exposure is in nowise essential for analysing the attitudes of a galloping horse or a flying crow. The instrument I commonly carry with me is a very rude one, but convenient for the pocket, and is shewn below. The duration of the exposure given by it under the action of its spring is the 360th part of a second, but the beginning and end of the exposure ought not to count, so little light passing through the edges of the pupil at those times that what is then seen is relatively faint and is disregarded. I estimate its practical duration at about one 500th of a second, and it is rather less when the finger acts with a sharp tap in opposition to the spring. The instrument is shewn in Fig. 1, without its sliding lid, which protects it from injury in the pocket. A is an arm which turns through a small angle round C, its motion being limited by two pins. Its free end carries a vertical screen, R R, which is a cylindrical (or better, a conical sheet described) round an axis passing through C perpendicular to the arm. As the arm travels to and fro, this screen passes closely in front of the end of the box, which is cut into a hollow cylinder (or cone) to correspond. There is a slit in the middle of the screen, and an eyehole in the centre of the end of the box. When the slit passes in front of the eyehole, and the instrument is held as in Fig. 2, a view is obtained. A stud, S, projects upwards from the arm, and an india-rubber band, B, passing round a fixed pin and a descending spoke of the arm acts as a spring in causing the stud S to rise through a hole in the side of the box, where the finger can press it like the stop of a *cornet à piston*. In using the instrument it is held in the hand as in Fig. 2, with the eyehole in front of the eye. Nothing is then visible, but on pressing or tapping the stud the slit passes rapidly in front of the eyehole, and the view is obtained.

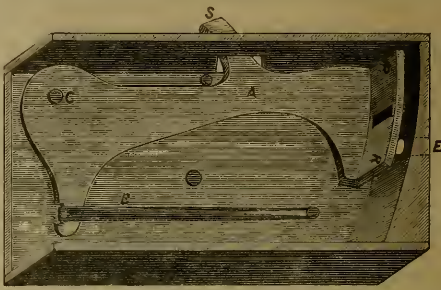

Fig. 1.

After this, the stud is released and the arm springs backwards, when a second view can be obtained, or the eye may be purposely closed for the moment.

I measured the velocity of the instrument by filing a nick on the stud and laying a light weight (a small bent nail) upon it, after having temporarily put in a peg that checked the arm in its recoil when the slit was opposite the eyehole. Then holding the instrument firmly against the wall with the projecting end of the stud as vertical as might be, I drew back the arm and released it, and noted the height to which the weight was tossed. It was three inches. This gave the velocity of the stud in the central portion of the arm, and from this datum the velocity of the more distant screen was easily calculated. I have made more elaborate instruments with multiple levers and with revolving discs (Messrs. Tisley, 172, Brompton Road, are now making one of these for me), but am not as yet prepared to recommend any one of them in particular. Different sorts would be probably be wanted by different persons. For instance it might in some cases be convenient that the trigger should be pulled at the right moment by a bystander, the eye of the observer being in the meantime kept closely shaded from the surrounding light. Again, there are periodic movements which would be best analysed by a slit in a rotating disc whose period of rota-

Fig. 2

tion was a little slower than that of the movement, so that each exposure should show a phase one step in advance of the previous ones; or, again, the rapidity of the periods or that of the motion may be such as to make it necessary to expose only at each second, third, or longer periodic interval. This would be effected by the use of two discs rotating at different velocities. Suppose, for example, one to revolve three times while the other revolved twice, then the two slits would be in accord in front of the eye-hole only once in three revolutions.

In order to present the images formed by two successive glimpses as simultaneous pictures seen side by side in the field of view, I took a prismatic eyeglass of the sort sold by spectacle-makers to correct want of parallelism in the optical axes. I cut it in two pieces, and placed these in opposite ways in front of two horizonal slits, lying one above the other in a shutter that fell vertically between slides. When the first slit came in front of the eye, the image it transmitted was deflected four degrees to the left; and when the second slit followed it, its image was deflected four degrees to the right, and two apparently simultaneous pictures were produced. Also, by crossing the prisms I found it would be easy to construct an apparatus with four successive slits shewing four images; 1, up to the left, 2, up to the right; 3, down to the left, and 4, down to the right. I doubt, however, whether this would be often found a useful development of the instrument, owing to the difficulty of watching more than a small area with attention.

I noticed an important optical effect, namely that the image first seen was always considerably fainter than the others, showing that its brightness had faded in the brief interval that elapsed before comparison began. It would appear that the law of the rate of fading could be investigated by this apparatus. I have not now the opportunity of doing so myself, but if I had, I should mount two prisms below radial slits in a disc that was revolving steadily at a known velocity, and I should watch a circular wafer through them. The width of the slits would be adjustable, and so would the angular distance of the prisms, and I should measure under various circumstances the width of the second slit that was necessary to tone down its image to an equal brightness with that seen through the first. Or the investigation might be made without prisms, by using two wafers and watching them with the same eye through slits at different radial distances, separated by various angular intervals, the adjustments being such that only the outside wafer should be seen through the outer slit, and the inside wafer through the inner one.

FRANCIS GALTON

THE CHEMISTRY OF THE PLANTÉ AND FAURE CELL

PART III.—*The Discharge of the Cell*

THE two plates of a Planté or Faure battery consist essentially of lead peroxide as the negative element, and metallic lead in a spongy condition as the positive. These are brought into communication with one another through the lead plates which support them, together with the connecting wire.

The lead peroxide reacts both with the lead plate that supports it, and with the lead on the opposite plate. At first sight, it might be expected that the reaction between it and the supporting plate would be the greater, as the space between them is so small, and the resistance of the intervening liquid in consequence almost inappreciable. The action is, indeed, probably greater at the first moment, but, as explained in our first paper, sulphate of lead is immediately produced, and that which lies at or near the points of junction, forms no doubt a serious obstacle to further local action, and admits of the lead on the opposite plate coming more fully into play.

If we consider *a priori* what is likely to be the reaction between lead peroxide and lead, with water as the connecting fluid, we should expect:—

$$PbO_2 \mid H_2O \mid H_2O \mid Pb = PbO \mid H_2O \mid PbH_2O_2.$$

On experiment this is found to be actually the case, yellow oxide appearing on the negative plate, and white hydrate on the positive.

If, however, the reaction takes place in presence of dilute sulphuric acid, the result will inevitably be sulphate on both sides, for even if oxide be first formed, it will be attacked by that acid. Of course this production of lead sulphate on each side might be expected gradually to produce a perfect electrical equilibrium. This, in fact, does take place under certain circumstances, but not under others. The reaction on the negative plate is always of this character, as far as our analyses have shown. We have invaribly found the deposit to consist of sulphate of lead mixed with unaltered peroxide. If, however, the cell be allowed to discharge itself rapidly, the lead on the positive plate is converted, not only into the sulphate, but, very partially, into lead peroxide. This is sometimes evident to the eye from the puce colour of the superficial layer, and we found also that this was confirmed by several chemical tests.

It is difficult to conceive how the reduction of the peroxide of lead on the one plate to oxide or sulphate, should be attended by a direct oxidation of lead on the other plate up to peroxide itself, as that would involve a reversal of the electromotive force. It is more easy to imagine that the peroxide results from the oxidation of sulphate of lead already formed, through the agency of electrolytic oxygen.

When this peroxide is formed on the positive plate, it is not difficult to foresee what must happen. A state of electrical equilibrium will be approached before the peroxide of lead on the negative plate is exhausted. But the two sides are in very different positions with regard to local action. On the negative plate, the peroxide being mixed with a great deal of lead sulphate, it will suffer decomposition only very slowly through the agency of the supporting plate, but the lead peroxide on the positive plate, being mixed not only with lead sulphate, but with spongy metallic lead, will be itself speedily reduced to sulphate. Hence, on breaking the circuit, when local action alone can take place, the peroxide formed on the positive plate during the discharges will be destroyed much more easily than the original peroxide on the other plate. The difference of potential between the plates will be restored, and on connection the cell will be again found in an active condition.

Now it has been frequently observed that partially discharged accumulators do give an increased current after repose, that is, after the circuit has been broken and re-established. It remained for us to ascertain whether the chemical change above described coincided in any way with the physical phenomena. For this purpose we prepared plates according to the method of Faure, and examined carefully the changes of electromotive force and strength of current, which took place during their discharge under known resistances, and the chemical changes that took place under the same circumstances.

We found that the initial electromotive force of freshly prepared cells was 2·25, 2·25, 2·21, and 2·31 volts, averaging 2·25, but that after standing for thirty minutes or so, or when allowed to discharge for a few minutes, it was reduced to about 2·0 volts. We take this to represent the normal electromotive force of the arrangement of lead, lead peroxide, and dilute sulphuric acid, and believe that the higher figure obtained at the first moment is due to the hydrogen and oxygen occluded on the respective plates, and which either diffuse out or are speedily destroyed.

We found, however, that in the discharge the electromotive force diminished under certain conditions. Thus, in an experiment in which the external resistance was 1 ohm, and the internal 0·58 ohm, the E.M.F. sank in forty-five minutes from 2·25 to 1·92, but after being disconnected for thirty minutes, it was found to have risen to 1·96, and after eighteen hours' repose it had actually risen to 1·98 volts. These observations were made many times in succession during the course of the experiment, which lasted six days.

With twenty times the external resistance, the diminution of electromotive force was much slower; but after discharging three days, the fall was more pronounced, and the rise on repose very apparent.

With 100 ohms resistance, the electromotive force varied very little for three days.

It is more difficult to obtain satisfactory chemical evidence of a quantitative character. It is clear that as chemical examination means the destruction of the substances, the same plate cannot be analysed in two consecutive stages. Nor can two plates be easily compared with one another, although they have been formed under the same circumstances. Even the same positive plate, during or after discharge, presents to the eye very different appearances in different parts. To a certain extent we obviated this difficulty by cutting the plate in two, longitudinally, analysing the one half at once, and allowing the other to repose for a given time before examining it for peroxide of lead.

As to the estimation of peroxide in the presence of metallic lead, we finally adopted as the best method that of reducing it by means of oxalic acid, although we were not certain that the whole amount is obtained in this way, even though the solution be kept hot for a considerable time.

By this method many chemical examinations were made of the positive plate. The results are as follows:—First of all, when the external resistance did not exceed 20 ohms, the peroxide of lead was generally visible in patches, and its presence was demonstrated and approximately measured by various chemical tests. On repose, the quantity of this peroxide visibly diminished, and in the majority of instances the chemical analyses also showed a smaller amount. In all cases sulphate of lead makes its appearance early in the action, and gradually increases in quantity, becoming finally the only product of the discharge.

The deposit on the negative plate shows the presence of nothing but sulphate of lead in addition to the unchanged peroxide. At the conclusion of the action, we have always found more or less of this substance unaltered. Thus, as one instance, after a discharge lasting five days, and approximately complete, we found that only 68 per cent. of the deposit was lead sulphate.

We conclude therefore that the chemical action of the discharge is essentially what is expressed by the following theoretical formula:—

$$PbO_2 \mid H_2SO_4 \mid H_2SO_4 \mid Pb = PbO \mid H_2O \mid H_2SO_4 \mid PbSO_4,$$

which becomes

$$PbSO_4 \mid H_2O \mid H_2O \mid PbSO_4.$$

This reaction is, however, sometimes complicated by the formation of a small amount of peroxide of lead on the positive plate. We believe this to be due to the oxidation of sulphate, an action which was explained in our last paper.

Another conclusion has reference to the resuscitation of power observed on repose. This is not due to any purely physical action but is a necessary consequence of the formation of PbO_2 on the positive plate. As sooner or later the result of the action becomes solely $PbSO_4$, this temporary formation of peroxide does not seriously affect the quantity of electrical force that may be regained from the accumulator, but it does affect the evenness of its flow. The flow is more regular if the discharge be made slowly, but in that case the loss on the negative plate from local action will probably be greater.

As to practical conclusions, we may note—1. Although, as stated in our paper of March 9, the most economical arrangement for the initial charging of the cell is to "make the red lead to be hydrogenated much smaller in amount than that to be oxidated," yet, as foreshadowed in the same paper, this arrangement is not desirable for the discharge of the cell. Nor is it for its subsequent charging, since, as will have been seen, the substances to be acted upon are now very different. On the negative plate there will be the sulphate of lead produced by the discharge, plus sulphate of lead produced by local action, together with more or less unaltered peroxide. On the positive plate there will be the sulphate of lead produced by the discharge, together with excess of lead, if any. Unless, therefore, the peroxide of lead unacted upon is allowed to be very considerable, the quantity of lead compound on the two sides ought to approach equality. 2. Care should be taken that sulphuric acid is in sufficient excess to allow of there still remaining some of it in solution after all the available lead has been converted into sulphate. If it is removed and only water is present, an oxide or hydrate will be produced with probably some serious consequences to the cell.

ON THE DEVELOPMENT OF THE CROCODILIAN SKULL

THE most striking thing in the development of the Crocodile is the structure of its visceral arches, and especially those that form the jaws and the hyoid or lingual arch.

(*a*) *Endoskeletal Parts of the Upper Jaw.*—Inside the massive outer bones of the upper face, or maxillaries and jugals, there are the more delicate palatines, transpalatines, and pterygoids. These are formed in a membranous tract of the palate, and but little cartilage, such as is seen in fishes, makes its appearance.

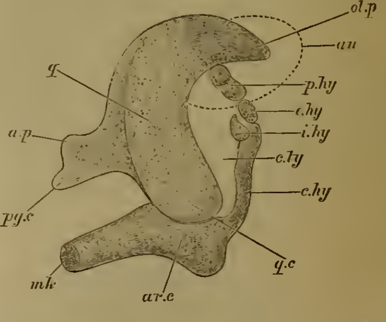

Fig. 1. × 13.

Fig. 1.—Upper part of mandibular and hyoid arches, outer view of second stage (*Alligator missisipensis*), 1½ inch long. *a u*, auditory capsule (in outline); *q*, quadrate cartilage; *ot.p*, its otic process; *a.p*, ascending process; *pg.c*, pterygoid cartilage; *q c*, condyle of quadrate; *mk*, Meckel's cartilage; *ar.c*, condyle of articular region of mandible; *p.hy*, pharyngo-hyal; *e.hy*, epi-hyal; *i.hy*, inter-hyal; *c.hy*, cerato-hyal.

The pterygoids assist the palatines and maxillaries in forming the "hard palate" or secondary floor to the nasal passages, just as in the Ant-bear, Tamandua, and some Cetacea amongst the Mammalia. This hard palate is not seen in Snakes, Lizards, and the smaller Tortoises, but is developed in some degree in the large Turtles. It is but little developed in Birds; for in them only a few such as the Hornbill and *Podargus* have the palatines meeting at the middle below.

The *quadrate* is very huge in the Crocodilia, and is *fixed* as in the Turtle and its congeners, and as in them it forms the greater part of the tympanic cavity; in Snakes, Lizards, and Birds the quadrate, or pier of the lower jaw, is movable.

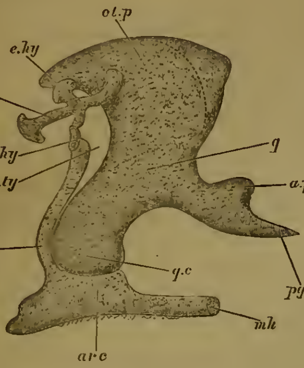

FIG. 2.

FIG. 2.—Upper part of mandibular and hyoid arches of third stage (*Crocodilus palustris*) outer view, 1⅝ inch long. Letters as in Fig. 2, except *co*, columella.

In Salamanders the quadrate cartilage grows up to the top of the skull, in front of the ear-capsule; this part is called the "ascending process; the other fork runs inwards under the fifth nerve, and is either articulated to or fuses with the basis cranii.

In all lizards except the Chameleons such an ascending process is found, but it is segmented off from the quadrate and becomes ossified as the "columella," which supports the roof (this is not the auditory columella, or stapes); I call the former the "epipterygoid." In the Crocodile there appears, very early, a forked process to the quadrate; here the upper fork is the rudiment of the ascending process or "columella," and the horizontal fork is a rudiment of the pterygoid cartilage, which is so large in Sharks and Skates, and forms their upper jaw.

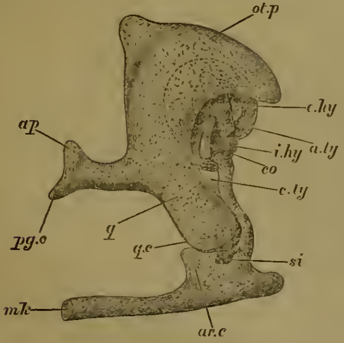

FIG. 3.

FIG. 3.—Same part of same species (fourth stage), 3½ inches long, as Fig. 2 (inner view); *a.ty*, cartilaginous annulus tympanicus.

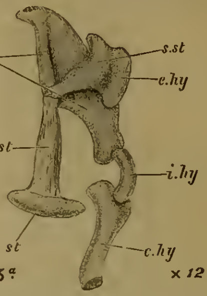

FIG. 3a.

FIG. 3*a*.—Part of same object as Fig. 3 (inner view). Letters same as last, with addition of *st*, stapedial plate; *m.st*, medio-stapedial; *e.st*, extra-stapedial; *s.st*, supra-stapedial.

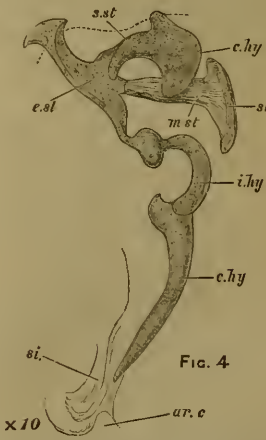

FIG. 4

FIG. 4.—Same species as last (fifth stage, 4½ inches long), outer view. Lettering the same, with addition of *si*, siphonium.

The lower jaw of the Crocodilia corresponds with that of the other Sauropsida—the other Reptiles and Birds, being composed of six splint bones, and an ossification of the articular end of the cartilage, "articulare internum," which unites with the nearest splint, "articulare externum," to form one bone, this, however, is pneumatic, the cartilage itself being hollowed out and communicating by a tube with the cavity of the ear-drum. That tube is called the "siphonium," and Prof. Huxley (see *Proc. Zool. Soc.*, May 27, 1869, p. 391) thought that Prof. Peters had mistaken this tube for a rod of cartilage, which the latter described ("Monatsber. König. Akad. der Wissenschaft. zu Berlin," November, 1868, p. 592) as running directly from the auditory columella into Meckel's cartilage. Such a continuity of the auditory columella (*stapes* and *incus* in one) with the hyoid arch and the endoskeletal lower jaw does, however, exist from an early period, up to the middle of incubation. Prof. Peters' observations were made upon small embryos, Prof. Huxley's upon ripe young; the former observed rightly, but his reasoning upon the facts seems to me to be quite at fault; Prof. Huxley had not the proper materials to work upon, but his reasoning was perfect, and the truth of his deductions, in spite of his mistake about the temporary continuity of the mandibular and hyoid arches, appears to me to be absolutely incontrovertible.

As far as I have seen, there is no other type in which the hyoid "cornu" is chondrified continuously with Meckel's cartilage, or the endoskeletal lower jaw.

This may be an acquired peculiarity, but I rather incline to the view that it is an old *hereditary* characteristic, derived from a very remote ancestry, in which the visceral arches formed a basketwork of cartilage, and not a series of properly segmented arches, such as we are familiar with in most fishes. In *some fishes*, the "marsipobranchii"—Hag and Lamprey—we still see this lower, non-differentiated state of things.

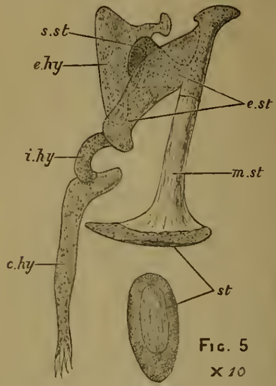

Fig. 5

Fig. 5.—Same species as last (same stage, more advanced, 5 inches long), outer view. Lettering the same; the internal face of the stapes, *st*, is shown.

There is a small distal part to the lingual or hyoid arch, but the lower part of the "cornu" (cerato-hyal) is aborted by the continuity of its upper half with the lower jaw.

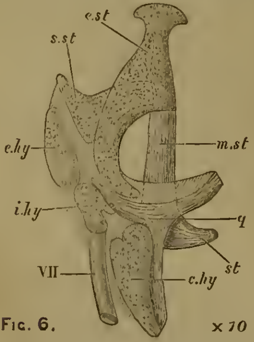

Fig. 6.

Fig. 6.—Same species as last (seventh stage, ripe embryo, 10 inches long), outer view. Lettering the same, with addition of *q*, quadrate bone; VII., facial nerve.

The rest of the arch resembles the branchial arch of a fish, and is like the proper hyoid arch of a Chimæra; the segments correspond very closely, but there is one piece too many, but this intercalary piece—the "inter-hyal"—is found in ganoid and osseous fishes—uniting their hyomandibular with their epihyal.

This fish-like hyoid soon becomes a continuous bar, as in the New Zealand Lizard (*Hatteria*), where the auditory columella and the hyoid arch are one continuous structure.

That condition, however, in the Crocodile, is only continued through the middle part of the term of incubation; towards the latter part of the time the parts that were fused all come to pieces again, and the ripe young has a free columella, with small, distinct nuclei of cartilage attached to the hinder margin of the ear-drum, these are *remnants* of the *epi-*, *inter-*, and *cerato-hyals*—the latter become free from the lower jaw during the middle of the incubating period.

The complex triple Eustachian tubes are formed after the middle of incubation, but before that time the basis cranii had become hollowed out, and so also had the quadrate and the articular end of the mandible.

By the time of hatching there are in the complex tympanic labyrinth or diverticula of the 1st *visceral* cleft, the following parts, namely:—

a. The drum-cavity hollowed out of the quadratum.

b. The middle, single, and the lateral, forked Eustachian tubes.

c. The extension of the tympanic cavity into the whole posterior sphenoid, base and wings, into the periotic bones, and into the whole circle of the occipital arch or ring.

d. Through the "siphonium," into the articular region of the lower jaw.

The investing bones are solid; only the ossifications of the primary chondrocranium are pneumatic; this hollowing out begins to take place before ossification sets in.

The pneumaticity of the Crocodile's endocranium is similar to what obtains in birds, the whole tympanic labyrinth in the two types is singularly like, and singularly unlike.

Note.—For descriptions of these parts in the bird-class I must refer the reader to my papers in the Royal, Linnean, and Zoological Societies. A full account of the development of the skull of the Crocodilia will soon appear in the *Transactions* of the latter society.

W. K. Parker

PROF. HAECKEL IN CEYLON AND INDIA

I.

PROF. ERNST HAECKEL of Jena, as most of the readers of NATURE are doubtless aware, has lately returned to his University after a six months' journey in India and Ceylon, undertaken in the interests of science with the object of providing additional data in support of the theory of evolution, of which he is the most able and best-known exponent in Germany. The veneration which he constantly expresses for Mr. Darwin, of whom he may be said to have been the first and perhaps the chief disciple on the Continent, would of itself suffice to give his opinions and observations weight in this country. No one, however, who has read the series of letters now being contributed by Prof. Haeckel to the *Deutsche Rundschau*, can fail to find them on their own merits both delightful and instructive. They are written in a popular form, but contain traces of profound scientific knowledge combined with great quickness and freshness of observation, and an almost boyish exuberance of delight in the presence of nature's wonders. Of the three letters or articles already published, the first contains an account of the voyage to India, the second, entitled "A Week in Bombay," describes with vivid enthusiasm the caves of Elephanta and the other marvels of that most interesting of tropical cities, and the third, contained in the June number of the *Rundschau*, of which we propose to give a short reproduction for the benefit of our English readers, brings the Professor to the "promised land" of his scientific yearnings—that island of Ceylon which exhibits in all its varied charms "the highest conceivable development of Indian nature."

It was on November 21, 1881, that the Austrian Lloyd steamer *Helios*, bearing Prof. Haeckel and his numerous chests, some containing scientific instruments, others empty for the reception of specimens, came to an anchor in the harbour of Colombo. He describes in a few graphic words the vision of beauty which met his eager gaze as the morning twilight cleared away, and the island, with its fringe of delicate palm forests, and more thickly wooded interior highlands, crowned in the centre by the mysterious summit of Adam's Peak, expanded before him in all the blaze of tropical sunshine. Directly in front lay the fort and harbour, to the right (or south) the beautiful suburb of Colpetty, in which the majority of the Europeans have their residence, and to the left (or north), the Pettah or "Black town," inhabited by the native races. Prof. Haeckel was warmly received on landing by his countryman, Herr Stipperger, the agent of the Austrian Lloyd, in whose bungalow, on the northern side of the town, at a considerable distance from the fort, and still farther from Colpetty, he passed the two first weeks of his stay in Colombo, which he describes as among the most delightful of his life. His first drive in Ceylon, from the Fort to Whist Bungalow, through the Pettah, opened out before him. as he himself says, a quick succession of scenes of Eastern beauty. The brown clay huts of the natives, each with its garden of cocoa-nut palms and plantains; the motley population of red-brown Singhalese, and darker Tamils, grouped round the doors, carrying on all their domestic concerns in the open air, combined with the bright red tint of the soil to produce bewildering contrasts of form and colour, together with a charming impression of primitive simplicity, and harmony with surrounding nature. It would be impossible to make even a passing mention of the Singhalese and their domestic life without digressing into a description of their most valued and often their only possession, the cocoa nut palm of whose substance every part is turned by them into account.

"The number of cocoa palms on the island," says Prof. Haeckel, "is calculated at 40,000,000, each palm yielding from 80 to 100 nuts (8-10 quarts of oil). It is not found in the northern half of the island, nor on a great part of the eastern coast. Its place is here supplied by the not less useful palmyra palm (*Borassus flabelliformis*). This is the same which covers the hot and dry districts of Hindostan, growing in great profusion near Bombay. Even from a distance the two palms vary greatly. The palmyra is a fan-palm, with a strong, very straight black stem, topped by a thick bunch of fan-shaped leaves. The cocoa, on the other hand, is a feather-palm, its slender white stem, 60 to 80 feet high, is gracefully curved, and adorned with a bushy crown of feathery leaves. The lovely Areca palm (*Areca catechu*) has similar, but stiffer and smaller leaves, and a tapering reed-like stem; it is an invariable feature of a Singhalese garden, carefully tended for the sake of the nut, which, being chewed together with the leaf of the betel pepper, colours the teeth and saliva red. Another palm, the Kitool (*Caryota urens*) is cultivated chiefly on account of its abundant sugar-sap, from which palm-sugar (*Djaggeri*) and palm wine (*Toddy*) are prepared. Its stiff strong stem supports a crown of double-feathered leaves resembling those of the maiden-hair fern (*Adiantum capillus Veneris*)."

"After the palms the most important trees in the little gardens of the Singhalese are the bread-fruit and the mango. Of the former there are two kinds, the ordinary bread-fruit (*Artocarpus incisa*), and the Jak tree (*Artocarpus integrifolia*), growing everywhere in great profusion. Another tree frequently cultivated by the natives is the curious cotton tree (*Bombax*). Mingled with these round the Singhalese huts is the beautiful banana or pisang tree, well deserving the name of "fig of Paradise" (*Musa sapientum*). Its beautiful yellow fruit, affording excellent nourishment either raw or cooked, is here seen in numerous varieties. Magnificent clusters of its gigantic light green leaves topping a slender stem from 20 to 30 feet high overhang the Singhalese huts, and form their loveliest adornment. Scarcely less effective are the arrowy leaves of the Aroideæ, especially of the Caladium, cultivated for its esculent roots, the same being the case with the Manihot, with its lovely clusters of hand-shaped leaves (belonging to the Euphorbiaceæ)."

Prof. Haeckel next proceeds to give a short statistical account of the population of Ceylon. In Columbo itself, as well as in the whole southern and western crests of the island (with the exception of the north-west) the large majority of the population consists of Singhalese proper, or descendants of the Indian Hindoos who overran Ceylon in the sixth century B.C., but in the northern half of the island, and on the east coast, as well as in large tracts of the central highlands, the Singhalese have been driven out by the Malabars or Tamils from the southern parts of the Indian peninsula, more especially from the Malabar coast. At present the Tamils comprise about a third of the whole population of Ceylon, and their number is yearly increasing; they are stronger and hardier than the Singhalese, and all the heavier labour falls to their share, the Singhalese only occupying themselves in the lighter kinds of agricultural work. Besides these, there are the Indo-Arabians of Ceylon (called Moormen or Moors), descendants of the Arabs who gained a footing in the island more than two centuries ago. The residue of the native population is composed of the wild aborigines (Veddahs and Rodiyahs) of immigrant tribes from various parts of Asia and Africa, and of Malays, Javanese, Parsees, Afghans, Negroes, and Kaffirs; in all about 25,000. Europeans number altogether only three to four thousand, principally, of course, English and Scotch. The whole of this motley population at the present time may be calculated at 2,500,000, divided as follows:—

Singhalese (chiefly Buddhists)	1,500,000
Tamils (or Malabars, chiefly Hindoos)	820,000
Indo-Arabians (Moors, chiefly Mohamedans) ...	150,000
Mixed descendants of various races	10,000
Asiatics and Africans (Malays, Chinese, Kaffirs, Negroes, &c.)	8,000
Burghers (Portuguese and Dutch half-bloods) ...	6,000
Europeans (chiefly English)	4,000
Veddahs (aborigines)	2,000
Total	2,500,000

A considerable number of all the native races have been converted to Christianity.

Whist Bungalow, where, as we have already mentioned, Prof. Haeckel spent the earlier part of his stay in Ceylon, received its somewhat curious name from the passionate addiction to card-playing of a former possessor. It is situated on one of the most picturesque spots in the neighbourhood of Colombo—that which lies to the north of the fort on the angle between it and the mouth of the river Kalany. Some portions of the description of the site of the bungalow and of his friend's garden must be given in Prof. Haeckel's own words:—

"The airy verandah commands a magnificent view of the sea, of the mouth of the Kalany, and of a lovely little island covered with vegetation, which lies in its delta. Further north, the eye follows a long strip of cocoa wood extending along the coast to Negombo. To the south lies the garden of the Bungalow, and beyond it a picturesque plot of land scattered over with fishing huts, nestling under the shade of slender palms; in their midst a little Buddhist temple, and further on a rocky swamp

---

[1] Sir J. Emerson Tennent ("Ceylon," I., p, 127), mentions, as curiously illustrative of the minute subdivision of property in Ceylon, a case which was decided in the district court of Galle, the subject in dispute being a claim to the 2520th *part of ten cocoa nut trees!*

covered with screw pine (*Pandanus*), &c. From this swamp springs a narrow sandy neck of land extending northward to the river's mouth, and so lying as to inclose a peaceful little lake in front of our garden. A few fishing huts are erected on this tongue of land, and from morning to night it presents a constant succession of animated and amusing pictures. Here in the early morning, before sunrise, the inhabitants of the huts assemble to take their morning bath in the river. Then the horses and oxen have their turn, and are brought down to water. Busy washers are at their work all day, beating the clothes with flat stones, and spreading them on the shore to dry. Fishing boats go up and down continually; and in the evening, when they have been drawn up to land, and the great square sails have been spread to dry, the lagoon, with its long row of motionless sails, looks wonderfully picturesque, especially when the evening breeze swells the sails, and the sun, sinking into the sea, floods the whole shore with a radiance of gold, orange, and purple. . . . . The garden of Whist Bungalow has been converted, by the care and taste of its proprietor, into a veritable earthly paradise, containing examples of almost every native plant of importance, and thus forming a valuable botanical collection, as well as a fragrant and delightful pleasure garden. On the very first morning of my stay, as I wandered in rapturous delight under the shade of palms and fig trees, bananas and acacias, I gained a very comprehensive idea of the flora of the plains. Here the noble palm, in all its variety of foliage and fruit, rears its stately columns; cocoa and talipat, areca and borassus, caryota and palmyra; here the banana spreads its great feathery leaves to the wind, and displays its clusters of precious golden fruit. As well as various kinds of the common banana (*Musa sapientum*), a fine example of the Traveller's tree of Madagascar may here be seen (*Urania speciosa*). It stands just at the division of the principal walk, from which the path to the right leads to the bungalow, and that to the left brings us to a magnificent specimen of the banyan or sacred fig tree (*Ficus bengalensis*), forming, with its hanging air-roots and numerous stems, a very striking object; beautiful Gothic arches open out among the roots which, pillar-wise, support the main structure of the tree. Other trees of various groups (terminalia, laurels, myrtles, ironwood trees, bread-fruit, &c.) are over-grown and intertwined with those lovely creeping and climbing plants which play so important a part in the flora of Ceylon. These belong to the most varied families, for in the dense forests of this magic island, and under the favourable influences of moisture and warmth, a countless multitude of climbing plants strive and cling, and grasp their way upward to the light and air.

"Among the charms of this most lovely garden must be included the large-leaved Calla plants or Aroideæ, and the graceful feathery ferns, two groups of plants, which, both by their individual mass and by the beauty and size of their development, occupy an important place in the lower flora of Ceylon. Scattered among them are many of the finest shrubs and flowering plants of the tropics, partly indigenous, partly introduced from other tropical regions, especially from South America, but all perfectly at home here. Among these rises the stately Hibiscus, with great yellow or red flowers, the flame tree or acacia, a mass of splendid flame-coloured clusters (*Cœsalpinia*); venerable tamarinds with their aromatic blossoms; while from every branch hang clinging convolvuli with gigantic bell-shaped flowers, and aristolochias, yellow and brown. Rubiaceous plants, such as lilies, orchids, &c., bear extraordinarily large and beautiful blossoms. . . . The animal life inhabiting this garden of Eden does not altogether correspond in variety and abundance with its vegetable world; this is especially the case with its larger and more striking forms. In this respect, as far as I have been able to ascertain, the island is inferior to the Indian mainland and to Sunda Island, and still more so to tropical Africa and Brazil. I must confess that my first impression was one of disappointment, which rather increased than diminished as I came to know the fauna more intimately, even in the wilder parts of the island. I had expected to find the trees and bushes thronged with apes and parrots, and the flowering plants with butterflies and winged insects of curious form and brilliant hue. But my expectations were doomed to remain unfulfilled, and my only consolation was that other zoologists visiting the island had been equally disappointed. Nevertheless, careful search reveals much that is curious and interesting, even to the zoologist, and in its main features the fauna of Ceylon, though not so rich and brilliant, is quite as singular and characteristic as its flora.

"The vertebrate animals which first claimed my attention in Whist Bungalow and the immediate neighbourhood of Colombo, were numerous reptiles of brilliant colours and curious forms, especially snakes and grasshoppers, and pretty little tree frogs (*Ixalus*), whose weird, bell-like note, resounded in the evenings. The birds chiefly visiting the gardens are starlings and crows, water-wagtails and bee-catchers, and above all the pretty little honey-sucker (*Nectarinia*), which here takes the place of the humming-bird; kingfishers and herons abound on the river banks. Among mammalia the most frequently occurring is the pretty little squirrel that leaps about among the trees and shrubs, and is very tame and confiding; its colour is a brown grey, with three white stripes lengthwise down its back (*Sciurus tristriatus*). Among the insects, dense swarms of which abound everywhere, the first to be named are ants (from the minutest to the most gigantic sizes) including the destructive termites or white ant; wasps and bees among the hymenoptera, and gnats and flies among the diptera are also very abundant. The larger and finer forms of insect life, such as chafers, butterflies, &c., do not exist in any proportion to the flora of the island. Orthoptera (grasshoppers, crickets, &c.), on the other hand, are very varied and curious in form. I will content myself at present with this cursory mention of a subject to which I hope later to return.

"Of articulate animals the spiders (*Arachnidæ*) form a very interesting and curious class, from the minutest mites and ticks upwards to the bird-spinners and scorpions. The closely-allied Millipeds or Myriapodæ are very numerous and of colossal size, sometimes as much as a foot long. I saw one famous specimen on my first morning in the garden of Whist Bungalow, but I was too lost in admiration of the glories of the vegetable kingdom round me to have time for a nearer examination of the animal world."

In this first intoxication of delight which accompanies the realisation of a life-long dream, we must for the present leave Prof. Haeckel, hoping in a future number to give some further account of his observations on the fauna and flora of Ceylon.

NOTES

WE hear that Princeton College, New Jersey, is going to despatch a second scientific expedition this summer to the "bad lands" of Dakotah and Nebraska in search of fossils. It will be under the charge of Mr. W. B. Scott, of the "E. M." Geological Museum of Princeton, who ii known to many readers of NATURE on this side of the Atlantic by his papers on the development of *Petromyzon*, &c. A former expedition of a similar kind, undertaken in 1877 under the same auspices, and composed of Messrs. Scott, H. F. Osborn, and F. Speir, jun., succeeded in making a valuable collection of vertebrate remains, which have been fully described in the "Palæontological Report of the Princeton Scientific Expedition of 1877" (Princeton, 1878), and now adorn the geological museum there.

AN interesting telephonic experiment was made on Tuesday at Malta, during the bombardment of the Forts at Alexandria. A telephone was attached at Malta to the Alexandria cable, and connection was made with the other end of the cable on board the *Chiltern*, off Alexandria. It was found that, owing either to the distance, or to the vibration caused by the firing, it was impracticable to send a verbal message, but the firing at Alexandria was distinctly heard, through the telephone, at Malta—a distance of more than a thousand miles.

A VISIT was paid on Tuesday to the School of Military Engineering and the Royal Engineer establishment at Chatham by the members of the Society of Telegraph Engineers and Electricians. Over 500 of the members, associates, and friends of the society accepted the invitation of the president, Col. Webber, R.E., and were entertained by him at luncheon at the Royal Engineers officers' mess. The guests were shown over the schools, following a programme arranged by the Acting Commandant, and conducted by the officers of the Royal Engineers, who were indefatigable in providing for the entertainment of all. A lecture on torpedo warfare was delivered in the theatre by Major Armstrong, R.E., and the guests visited amongst other sights in the Royal Engineer Institution the schools of electricity, photography, chemistry, architecture, and surveying. Outside, the Engineers' Field Park, the mechanical workshops, the construction of military bridges, use of brushwood for military purposes, siege batteries, earthworks, demolition of railways and stockades, also submarine mine explosions, afforded a most interesting programme, especially so at a moment when all these appliances may be at any moment brought into practical use.

THE Rector of a small parish in Warwickshire is endeavouring to protect and preserve a fine granite boulder, identified as having been floated from Mount Sorrel in Leicestershire, a distance of sixty miles, and now exposed to danger of destruction. To rail it in and record its history by a permanent inscription will cost about 12*l*. The parish is a poor one, and the Rector crippled by an unlet glebe; but 5*l*. has been promised in the village, and 1*l*. has been given by the Boulder Committee of the British Association through its Secretary, Rev. H. W. Crosskey, who has seen the boulder, and will vouch for its scientific interest and value. If any reader of NATURE is good enough to send a small contribution towards the 6*l*. still wanted, to the address of "Rector—care of Editor of NATURE," it will be acknowledged in these columns.

WE regret to announce the sudden death of M. Antoine Breguet, at the early age of thirty years. He was the son of M. Breguet, the member of the Institute, one of the directors of the International Exhibition of Electricity in Paris, and had had for two years the editorship of the *Revue Scientifique*, and the direction of the well-known Breguet optical and horological workshop.

THERE is now at Gresham College, in Basinghall Street, an interesting collection of objects which have been sent over from the Technical School at Iserlohn, in Westphalia. They comprise examples in wax, plaster, wood, and metal, the works executed by students in the special trade-school which was founded by the Prussian Government, and which is said to have rendered important service to the manufactures of the district. The collection has been sent over in response to the application of Mr. Philip Magnus, one of the Royal Commissioners on Technical Education, and inspection will be permitted on application to that gentleman during this week.

BY last advices from Manila (May 17), according to the *London and China Telegraph*, two German naturalists, Messrs. Schadenburg and Koch, had just arrived there from Mindanao, where they had recently successfully ascended a volcano called Apo, the highest mountain in the Philippines, a feat only once before achieved by Europeans, this being in October, 1880. After several vain attempts, Senor Rajal, in 1880, a few months after assuming the governorship of the district, determined to ascend the volcano, notwithstanding the opposition of the Bagobo savages, who assured him that a human sacrifice was essential for success. His influence over them was, however, so great that he prevailed on fifty of the savages to accompany him as guides and porters, and was thus enabled to set out on the expedition in October that year with several Spaniards and Dr. Montano, a French naturalist. The ascent proved so dangerous and difficult that only Dr. Montano and Senor Martinez reached the top on the north-east side of the volcano, its height being determined by them at 3130 metres above the sea. The safe return of this expedition after nine days' absence without the human sacrifice required by the savages resulted in lessening their superstitious dread of the Apo. The *Diario* states that Messrs. Koch and Schadenburg made two ascents of the Apo in February and March last, under the guidance of several savages, during which they ascertained the height of its south-west peak to be 3000 metres (10,824 Eng. feet) above sea level.

IN the July number of the *American Naturalist* is a paper of much value by Mr. Ivan Petroff on the Limit of the Innuit Tribes on the Alaska Coast, in which the writer combats some of the conclusions come to by Mr. Dall. Mr. Petroff has been familiar for years with these coasts, and his conjectures as to the origin and migration of the Innuits and other tribes will interest ethnologists. In this connection Mr. Petroff has some important observations on the rate of accumulation of shell-heaps. He says:—"The time required for the formation of a so-called layer of 'kitchen refuse' found under the sites of Aleutian or Innuit dwellings, I am inclined to think less than indicated by Mr. Dall's calculations. Anybody who has watched a healthy Innuit family in the process of making a meal on the luscious echinus or sea urchin, would naturally imagine that in the course of a month they might pile up a great quantity of spinous *débris*. Both hands are kept busy conveying the sea fruit to the capacious mouth; with a skilful combined action of teeth and tongue, the shell is cracked, the rich contents extracted, and the former falls rattling to the ground in a continuous shower of fragments until the meal is concluded. A family of three or four adults, and perhaps an equal number of children, will leave behind them a shell monument of their voracity a foot or eighteen inches in height after a single meal. In localities in Prince William Sound I had an opportunity to examine the camp-sites of sea-otter hunters on the coast contiguous to their hunting-grounds. Here they live almost exclusively upon echinus, clams, and mussels, which are consumed raw in order to avoid building fires and making smoke, and thereby driving the sensitive sea-otter from the vicinity. The heaps of refuse created under such circumstances during a single season were truly astonishing in size. They will surely mislead the ingenious calculator of the antiquities of shell heaps a thousand years hence."

IN the same article Mr. Petroff has also some interesting observations on the action of tides on the coast:—"As an instance of the rapidity with which the tides of this region will change outlines of coast and other land marks, I may cite an observation made by me during my stay on Nuchek island last summer. At a short distance from the settlement there was a cave in a rocky cliff situated about three or four feet above high water mark. I visited the place frequently, as it afforded a view over the approaches to the harbour. About the middle of June an eclipse of the moon occurred when it was full or nearly so, causing tidal commotion of unusual extent and violence. When I visited my cave on the day following the eclipse, I found it almost filled with shingles and *débris*. This cave was situated at about the same height above the water as the cave of Amaknak, from which Mr. Dall extracted such voluminous information as to the antiquity of strata of refuse found therein. I cite these instances only for the purpose of showing that it is not safe to ascribe great age to any and all accumulations of *débris* found on the coast of Alaska, and also as a support for my theory of a general Innuit migration along the coast at a comparatively recent period, subsequent to the invention of the kaiak or a similar structure."

FROM the Italian Census of December 31, 1881, it appears that in 23 out of 24 provincial chief towns the number of persons knowing how to read and write has greatly increased since 1871. In ten years the citizens of Udine had increased in such knowledge at the rate of 9 per cent.; in Como, 6·50 per cent. Brescia made a strange exception; in 1871 there were 2899 persons ignorant of reading and writing, and in 1881 this number was increased to 3120 persons; data are wanting to explain this fact. In the 24 capitals of provinces the average result is that a little more than 50 per cent. of the inhabitants know how to read and write.

MESSRS. TRÜBNER AND CO. have issued a second and much enlarged edition of their "Catalogue of the Principal Languages and Dialects of the World." The original catalogue contained about 1100 titles on 64 pages, while this edition enumerates nearly 3000 titles on 170 pages. The utility of such a catalogue to students of language is obvious.

WITH praiseworthy promptness Messrs. Blackie and Son have issued the third volume of the new edition of the Imperial Dictionary, edited by Mr. Charles Annandale. This volume extends from L to Screak, and in all respects is up to the two first volumes. The only omission of importance we detect is Photophone, which perhaps came too late to be put in its proper place.

A FRENCH engineer has originated a plan by means of which passing ships could send messages by submarine cables; he would float buoys with the necessary connecting wires and apparatus at intervals of a day's journey along the line of the cable, each numbered and properly lighted at night. The writer in the *Moniteur de la Flotte* considers that the plan presents but few difficulties, and would obviate much anxiety and many dangers.

DR. SCHLIEMANN is carrying on new excavations at Hissarlik, with the assistance of two eminent German architects. No fewer than 150 workmen are daily employed in laying bare the foundations of the ancient cities. Two perfectly distinct cities have lately been discovered in the burnt stratum, the lower one resting on the large walls which have hitherto by mistake been attributed to the second city. Hissarlik now turns out to have been the Acropolis of this lower burnt city, this being proved by the walls and the pottery, as well as by two vast brick buildings, one of them 43 feet broad by 100 feet long, the other 23 feet broad by less than 100 feet long. These buildings seem to have been temples, a separate gateway, flanked by enormous towers, leading up to them. There are, besides, three or four large buildings, apparently dwelling-houses, but no smaller buildings. The city walls now stand out very imposing. They rest on a substructure of large blocks, 33 feet high, afterwards superseded by great brick walls. All the treasures formerly found by Dr. Schliemann are now ascribed to the first burnt city. Dr. Schliemann has found in the temples copper nails of a very peculiar shape, weighing from 1000 to 1190 grammes. The second burnt city, being the third city from the rock, and hitherto identified with the Homeric Troy, turns out to have had but very small houses and no lower town at all. Dr. Schliemann will continue his excavations till the beginning of August.

SOME interesting objects which have, according to the *Daily News* correspondent, just been found in Neuchatel are considered by Swiss archæologists to throw a new light on the history of the lake-dwellers, and the discovery is consequently looked upon as one of importance. Amongst the objects are a carriage-wheel with iron rim, iron swords, and many human bones.

THE *Field Naturalist* is the name of a new natural history journal, published by A. Heywood of Manchester; it is stated to be "a medium of intercommunication," and for this purpose it will doubtless be of service to the many cultivators of science throughout the country.

THE *Proceedings* of the Liverpool Naturalists' Field Club for 1881-82, gives the usual account of the numerous excursions of this Society; they seem to have been successful. We have also received an interesting brief Report of the work done by the York School Natural History Society during the past year; this Society has founded a special section, exclusively devoted to scientific workers.

THE additions to the Zoological Society's Gardens during the past week include a Red-legged Partridge (*Caccabis rufa*), European, presented by Dr. A. O. Grosvenor; a Ring Ouzel (*Turdus torquatus*), British, presented by Mr. H. A. Macpherson; a Red-sided Eclectus (*Eclectus polychlorus*) from New Guinea, presented by Mr. A. Lubbock; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Master Charles Ed. Napier; a Dwarf Chameleon (*Chamæleo pumilus*), eighteen Rough-scaled Lizards (*Zonurus cordylus*), a Banded Skink (*Euprepes vittatus*), a South African Skink (*Scelotes bipes*), four Beetles (*Scarites rugosus*), four Beetles (*Psorodes*, sp. inc.) from Robben Island, South Africa, presented by the Rev. G. H. R. Fiske, C.M.Z.S.; a Goshawk (*Astur palumbarius*), European, deposited; two Black Leopards (*Felis pardus*), an African Elephant (*Elephas africanus* ♂) from Africa, a Hardwick's Hemigale (*Hemigale hardwicki*) from Borneo, a Cuvier's Lagotis (*Lagotis cuvieri*) from Patagonia, a Pronghorn Antelope (*Antilocapra americana*) from North America, a Malayan Tapir (*Tapirus indicus*), two —— Hornbills (*Buceros*, sp. inc.) from Malacca, purchased; a One-Wattled Cassowary (*Casuarius uniappendiculatus*) from New Guinea, received in exchange; three Chiloe Wigeons (*Mareca chiloensis*), bred in the Gardens.—The following insects have emerged during the week:—Silk Moths: *Actias selene*, *Telea polyphemus*; Butterflies: *Parnassius apollo*, *Vanessa polychlorus*, *Thecla spini*, *Melanagria galathea*; Moths: *Deilephila euphorbiæ*, *Sciapteron tabaniformis*, *Bembecia hylæiformis*, *Zygæna filipendulæ*, *Plusia concha*.

PROF. MENDELEEF ON THE HEAT OF COMBUSTION OF HYDROCARBONS[1]

"IN considering the numerical data as to the heat of combustion," Prof. Mendeleeff says, "it will be perceived that until now sufficient attention has not been given to the distinction between purely calorimetrical data and those physical and mechanical changes which accompany chemical reactions, while it was recognised long ago that it is essential to separate, as far as possible, the heat of the reaction from the heat disengaged by physico-mechanical processes. The drawback arising from this is especially noticeable with regard to the heat of combustion of compounds of carbon, as this heat is used for measuring the heat of formation of compounds of carbon from simple bodies, which last is, as is known, but a small fraction of all the heat of combustion." Thus, for example, when the products of combustion of CO_2 and of H_2O act on incandescent charcoal, both reactions are very similar, if we do not give attention to the physical process which accompanies the second reaction. The

---

[1] "Notice on the Heat of Combustion of Hydrocarbons," in the *Journal of the Russian Chemical and Physical Society*, vol xiv. pp. 230-238.

reaction $CO_2 + C = CO + CO$ shows that out of two volumes of CO_2 we receive four volumes of CO, and it is accompanied with absorption of heat, which is determined by the fact that the combustion of one atomic weight of carbon develops 97 K (*i.e.* 97 great calorics, or 97,000 common ones), while the combustion of CO develops 68·4 K; the reaction is thus accompanied by the following thermal result: $97·0 \text{ K} - 2 \times 68·4 \text{ K} = -39·8 \text{ K}$. The result $(97·0 - 68·4 - 68·4 = -39·8 \text{ K})$ is the same for the following reaction: $H_2O + C = CO + H_2$; and, if the combustion of hydrogen in the calorimeter were not accompanied by a formation of liquid water, it might be admitted that the combustion of CO and of H_2 develops the same amount of heat, which, however, is not the case.

After having shown how the conclusions on the heat of formation of hydrocarbons from hydrogen and coal, or diamond, are vitiated by not taking into account the heat developed, or absorbed, by physical and mechanical processes, and how M. Thomsen (*Berliner Berichte*, 1880, p. 1321) was brought to erroneous conclusions as to the structure of the molecule of coal and diamond, as well as to the structure of hydrocarbons; M. Mendeleef says:—"In using calorimetrical data of chemical reactions to judge of the variation of chemical energy in a reaction, it is necessary to free them from the influence of physical and mechanical processes which accompany the reaction. Of course, the relative influence of these secondary processes is not very great, as the chemical process is the most important one, especially in such energetic reactions as the combustion of hydrocarbons; but it is important, for strictly maintaining the principle itself of thermo-chemistry, always to apply this correction, as we always apply the correction for loss of weight in the air, especially when weighing gases." "Only in the gaseous state can we consider the thermal relations of bodies free from the influence of the modified internal work, as was well pointed out by Berthelot in the first chapters of his work: 'Essai de Mécanique chimique'; therefore, all comparisons must be made in the gaseous state, as well for the bodies entering into reaction, as for those which we receive. When the determination of the heat of combustion is made for solid or liquid bodies, we obviously must add the latent heat of evaporation (and liquefaction) of the body, and deduct the latent heat of evaporation of water. This last is well known, and for a molecular weight in grammes (18 grammes) of water, it is equal to about 10·7 K at the temperature of 15° to 20° Cels. As to the heat of evaporation of hydrocarbons, it is still not sufficiently known. But we know that the heat necessary for the evaporation of *molecular quantities* of different bodies comparatively volatile, varies from 4 K (as for NH_3 and N_2O) to 15 K (as for quicksilver and ethyl), and usually is between 6 K to 10 K." This correction not being very great, and the determinations of heat of combustion not being yet very accurate, Prof. Mendeleef takes, for those bodies whose heat of evaporation is not yet determined, an approximate correction. Another correction is that which results from changes of volume of combining bodies. The mechanical work which results from this increase or decrease of volume is not very great (0·57 K in most of the determinations of Thomsen), but always must be taken into account.

By applying these corrections, Prof. Mendeleef gives a new corrected table of heats of combustion of twenty different hydrocarbons, as well as the heats of formation of these bodies from CH_4, CO, and CO_2. The corrections are not insignificant, as, for instance, for hydrogen, CH^4, C^2H^6, C^3H^5, and C^7H^{16}, whose heats of combustion, as determined by Thomsen, Berthelot, and Loughinin, are respectively—68·4, 213·5, 373·5, 533·5, and 1137·4; the corrected figures, as given by M. Mendeleef, are—57·4, 192, 342, 492, and 1062.

THE WEDGE PHOTOMETER[1]

MUCH attention has recently been directed to the use of a wedge of shade glass as a means of measuring the light of the stars. While it has been maintained by various writers that this device is not a new one, the credit for its introduction as a practical method of stellar photometry seems clearly to belong to Prof. Pritchard, director of the University Observatory, Oxford. Various theoretical objections have been offered to this photometer, and numerous sources of error suggested. Prof. Pritchard has made the best possible reply to these criticisms by measuring a number of stars, and showing that his results agreed very closely with those obtained elsewhere by wholly different methods. His instrument consists of a wedge of shade glass of a neutral tint inserted in the field of the telescope, and movable so that a star may be viewed through the thicker or thinner portions at will. The exact position is indicated by means of a scale. The light of different stars is measured by bringing them in turn to the centre of the field, and moving the wedge from the thin towards the thick end until the star disappears. The exact point of disappearance is then read by the scale. The stars must always be kept in the same part of the field, or the readings will not be comparable. By a long wedge the error from this source will be reduced. A second wedge in the reversed position will render the absorption uniform throughout the field. Instead of keeping the star in the same place by means of clockwork, the edges of the wedge may be placed parallel to the path of the star, when the effect of its motion will be insensible. To obtain the best results, the work should be made purely differential, that is, frequent measures should be made of stars in the vicinity assumed as standards. Otherwise large errors may be committed, due to the varying sensitiveness of the eye, to the effect of moonlight, twilight, &c., and to various other causes.

A still further simplification of this photometer may be effected by substituting the diurnal motion of the earth for the scale as a measure of the position of the star as regards the wedge. It is only necessary to insert in the field a bar parallel to the edge of the wedge, and place it at right angles to the diurnal motion, so that a star in its transit across the field will pass behind the bar, and then undergo a continually increasing absorption as it passes towards the thicker portion of the wedge. It will thus grow fainter and fainter, until it finally disappears. It is now only necessary to measure the interval of time from the passage behind the bar until the star ceases to be visible, to determine the light. Moreover, all stars, whether bright or faint, will pass through the same phases, appearing in turn of the 10, 11, 12, &c., magnitude, until they finally become invisible. For stars of the same declination, the variation in the times will be proportioned to the variations in the thickness of the glass. But since the logarithm of the light transmitted varies as the thickness of the glass, and the stellar magnitude varies as the logarithm of the light, it follows that the time will vary as the magnitude. For stars of different declinations, the times of traversing a given distance will be proportional to the secant of the declination. If δ, δ' are the declinations of two stars having magnitudes m and m', and t, t' are the times between their transits over the bar and their disappearances, it follows that $m' - m = \text{A} (t \sec \delta - t' \sec \delta')$. For stars in the same declination calling $\text{A} \sec \delta = \text{A}'$ we have $m' - m = \text{A}' (t - t')$. Accordingly the distance of the bar from the edge of the wedge is unimportant, and, as in Prof. Pritchard's form of the instrument, it is only necessary to determine the value of a single constant, A. Various methods may be employed to determine this quantity. Prof. Pritchard has recommended reducing the aperture of the telescope. This method is open to the objection that the images are enlarged by diffraction when the aperture is diminished; constant errors may thus be introduced. Changing the aperture of a large telescope requires some time, and in the interval the sensibility of the eye may alter. These difficulties are avoided by the following method, which may be employed at any time. Cover the wedge with a diaphragm in which are two rectangular apertures, and place a uniformly illuminated surface behind it. Bring the two rectangles into contact by a double image prism, and measure their relative light by a Nicol. From the interval between the rectangles and the focal length of the telescope, the light in magnitudes corresponding to one second, or A may be deduced. Perhaps the best method with a small telescope is to measure a large number of stars whose light has already been determined photometrically, and deduce A from them.

The great advantage claimed for this form of wedge photometer is the simplicity of its construction, of the method of observing, and of the computations required to reduce the results. It may be easily transported and inserted in the field of any telescope like a ring micrometer. The time, if the observer is alone, may be taken by a chronograph or stop-watch. Great accuracy is not needed, since if ten seconds correspond to one magnitude, it will only be necessary to observe the time to single seconds. The best method is to employ an assistant to record and take the time from a chronometer or clock. If the stars are observed in zones, the transits over the bar serve to identify or

---

[1] By Prof. Edward C. Pickering. Presented May 10, 1882, at the American Academy of Arts and Sciences.

locate them, as well as to determine their light. A wedge inserted in the field of a transit instrument will permit the determination of the light of each star observed without interfering with the other portion of the observation. If the stars are all bright, time may be saved by dispensing with the thin portion of the wedge. In equatorial observations of asteroids the light may be measured photometrically with little additional expenditure of time. Perhaps the most useful application would be in the observation of zones. When the stars are somewhat scattered it would often happen that their light might be measured without any loss of time. By this instrument another field of usefulness is opened for the form of horizontal telescope advocated at a former meeting of this Academy (*Proc. Amer. Acad.* XVI. 364). Very perfect definition would not be required, since it would affect all the stars equally. To an amateur who would regard the complexity of an instrument as a serious objection to it, a means is now afforded of easily reducing his estimates of magnitude to an absolute system, and thus rendering them of real value.

ELECTRICITY ON PIKE'S PEAK

THE following extracts relative to electricity, from Pike's Peak Monthly Abstract Journals, have been very kindly forwarded to us by General Hazen, the chief of the U.S. Signal Service, in accordance with a request made by us; we believe their publication will prove useful:—

November 23, 1873.—Atmospheric electricity manifested itself when line was broken by a crackling sound when binding screws were touched, and bright sparks drawn when storepipe was touched by my fingers.

December 7, 1873.—While line was broken I heard relay working; thinking line had been repaired, I hastened to adjust; received a severe shock, which convinced me that something stronger than our battery had charged the wire. Instrument cut out and lightning arrester screwed closer; in a few minutes a continuous stream of electricity passed between the two plates of the arrester with a loud noise, resembling that produced by a child's rattle; the fluid passed not in sparks, but in five or six continuous streams of light, as thick as a pencil lead, for two or three minutes at a time, with short intervals between; this continued for over an hour.

December 11, 1873.—On retiring I accidentally touched my drawers with two fingers of my hand, and drew two sparks from them. This is a common phenomenon after a snow-storm.

January 12, 1874.—Electric shocks.

January 24, 1874.—Received electric shock when opening stove door; as usual, it was not repeated.

February 25, 1874.—Same as January 24.

May 11, 1874.—During the entire day severe shocks were felt by any one touching the wire, and, the line being open, I could make plain signals with the key for about ten minutes.

May 20, 1874.— p.m., report could not be sent on account of atmospheric electricity (a thunder-storm).

May 21, 1874.—A flash of fire about two feet long leaped from arrester into the office, illuminating the rooms.

May 24, 1874.—A heavy thunder-storm passed slowly and directly over the peak; large sparks passed constantly through the arrester, while a strange crackling of the snow could be heard at times. While making the 2 p.m. observation, I heard the snow crackle as above mentioned, and felt at the same time on both temples, directly below the brass buttons of my cap, a pain as if from a slight burn. Putting up my hands, there was a sharp crack, and all pain had disappeared.

May 29, 1874.—At 6.20 a terrific storm commenced; blinding flashes of fire came into bath-rooms from the lightning-arrester and stoves; loud reports followed in rapid succession.

July 1, 1874.—A party of visitors were caught in a thunderstorm not far from the summit, and all state that they experienced peculiar burning sensations on face and hands, and heard a hissing sound proceeding from hair and whiskers.

July 9, 1874.—Heavy thunder-storm; large sparks passed through the arrester during its continuance. Mr. Copley telegraphed me this forenoon that he twice got knocked down, while repairing the line, by electric shocks.

July 14, 1874.—Thunder storm; lightning in beginning very severe. I received a very painful shock while working over the line by my fingers accidentally touching the metal of the key.

July 15, 1874.—Thunder heard in the distance throughout the evening, while strong ground currents passed through the arrester.

July 16, 1874.—Severe thunder-storm; sharp flashes and retorts came through the arrester to the terror of several lady visitors. Outside the building the electric effects were still more startling. The strange crackling of the hail mentioned before was again heard, and at the same time my whiskers became strongly electrified and repellant, and gave quite audible hissing sounds. In spite of the cap I wore my scalp appeared to be pricked with hundreds of red hot needles, and a burning sensation was felt on hands and face; several of the visitors who were outside had the same experience. A large dog who had followed his master out-doors became terrified, and made for the door with a pitiful howl. Lightning was seen in all directions in the evening, and ground currents passed incessantly through the arrester.

July 19, 1874.—A severe thunderstorm passed close over the Peak between 1.30 and 2.30 p.m.; lightning struck wire between 2nd and 3rd poles from the house; for a moment the wire resembled a rope of fire and vibrated violently for some minutes after the discharge—no damage done. Frequent loud discharges took place along the ground-wire between it and the rocks on which it rests. Hair and whiskers of anyone outdoors were electrified by each discharge.

July 21, 1874.—Heaviest thunderstorm of the season to-day; lightning terrific; constant crackling of fallen hail and peculiar clattering of the rocks as if shaken by subterranean convulsions, indicated the highly electrified state of the summit.

August 2, 1874.—I was obliged to keep the telegraph instruments cut out during the greater part of the day.

August 3, 1874.—The lightning rendered the line almost useless the entire afternoon; I got severely shocked when sending my report.

August 13, 1874.—Seventeen visitors to day; some of them made the ascent during a severe thunderstorm, and were much alarmed by the effects of the electricity upon their hair, one of them declared that his hair stood up so stiffly as to lift off his hat!

October 5, 1874.—Severe thunderstorm below summit in afternoon, observers severely shocked whilst calling Fenton at lower station.

May 22, 1875.—During storms to-day (hail and snow) electricity quite strong.

May 23, 1875.—Electricity strong at intervals during day and night.

May 24, 1875.—Hail from 3.55 p.m. till midnight, accompanied by very strong electricity, decreasing and increasing in intensity, a notable fact in all hail-storms.

May 25, 1875.—Electricity has shown itself nearly all day with variable force (hail frequent during the day).

May 29, 1875.—Hail about midday accompanied by electricity. In all our hailstorms the fall of hail entirely ceases for about a half a minute, following a heavy electric discharge, and the hailfall is considerably heavier for some little time following the discharge than before.

July 5, 1875.—Terrible electric storm in afternoon, at first its effects were felt only by the line, but about 2 p.m. its presence was evident everywhere on the summit; a constant stream of flame from the arrester; a constant crackling noise heard out of doors as though made by small pistols.

May 11, 1876.—During hailstorm at 7.30 I was compelled to cut out the wires owing to intensity, this I attempted with ungloved hand, and learned a lesson that was an impressive one; luckily I escaped with a slightly bruised head and a fearful scare.

May 25, 1874.—During a thunderstorm the wire outside, at two or three places, kept up a peculiar singing noise, resembling the singing cricket. I have previously noticed that the singing noise is never heard except when the atmosphere is very damp, and rain, hail, or snow is falling.

June 16, 1876.—At 5.20 p.m., as I was sitting on a rock near the monument, on the eastern edge of the summit, a blinding flash of lightning darted from a cloud seemingly not more than 500 feet north-east of me, and was accompanied by a sharp, quick, deafening report, and at the same time I felt the electricity dart through my entire person, jerking my extremities together as though by a most violent convulsion, and leaving tingling sensations in them for a quarter of an hour afterwards. Straine, who was sowing wood in the shed at the time received a similarly violent shock, and says that a ball of lightning appeared to pass through the store-room and wood-shed in which he was working, leaving behind a strong sulphurous smell.

July 13, 1876.—Singing on the wire. It also seemed to come from the instrument shelter and the house, as well as from the wire. Thunder loud and continuous during the afternoon.

July 23, 1876.—The anemometer stopped working on account of the electric storm. Privates Straine and O'Keefe were shocked while trying to fix it, so that they had to give it up until the storm had subsided somewhat.

August 18, 1876.—A beautiful phenomenon was observed by myself, Private Greenwell, and four visitors. The peculiar singing noise (or sizzing noise) was heard again, always before in day, but this time at night, but the line for an eighth of a mile was distinctly outlined in brilliant light which was thrown out from the wire in beautiful scintillations. Near us we could observe these little jets of flame very plainly. They were invariably in the shape of a quadrant, and the rays concentrated at the surface of the line in a small mass about the size of a currant, which had a bluish tinge. These little quadrants of light were constantly jumping from one point of the line to another, now pointing in one direction then in another. There was no heat to this light, and when I touched the wire I could only feel the slightest tingling sensation. Not only was the wire outlined in this manner, but every exposed metallic point and surface was similarly tipped or covered. The cups of the anemometer appeared as four balls of fire revolving slowly round a common centre. The wind vane was outlined with the same phosphorescent light, and one of the visitors was very much alarmed by sparks, which were plainly visible in his hair, though none appeared in ours. At the time of this phenomena snow was falling.

March 27, 1877.—Singing noise heard upon the wire today.

May 12, 1877.—Hailstorm, accompanied by intense electricity.

May 24, 1877.—Sergeant Hobbs and Private Greenwell received severe shocks during the day.

August 6, 1877.—Intense electricity; all metal objects were tipped with sparks.

November 25, 1877.—Snow-storm all day attended by intense electricity, which could be heard crackling in a person's hair continuously, although no reports of thunder were heard.

December 26, 1877.—The atmospheric electricity was very intense during the day, and at times would crackle on various objects in the room.

January 25, 1878.—Several thunderstorms occurred in the surrounding parks and gulches. The electricity on the summit was very intense, causing a continuous snapping of the lightning arrester.

May 12, 1878.—A snow-storm commenced during the night, and at 1 p.m. was drifting furiously by a rising gale. The electricity varied with wind-gusts, and was so intense at times as to render our position exceedingly dangerous. The telegraph wires were cut out, but violent sparks would still jump six inches between the disconnected *windows*. One violent discharge seemed to have occurred in the chimney, for a terrible commotion was caused in the soot and ashes.

May 24, 1878.—At 8 p.m. snow commenced, attended with severe electricity, lasting for an hour. The wires had to be cut out and parted, and a vivid glaring was continuous in the windows. A lamp set in the north window would, with its flame, cast a shadow on the opposite wall for several seconds.

July 1, 1878.—During afternoon sleet fell, accompanied by intense electricity. At 3.20 a violent explosion occurred in the room, near the stove, scattering the wood and knocking down the stove-pipe.

April 10, 1879.—The telegraph wire heavily charged with a ground current of electricity this evening, and it was with difficulty that signal was transmitted. The current at times was entirely reversed.

June 16, 1879.—Light sleet, accompanied by thunder. Only a few peals were heard, when it gave way to a strong steady current over the wire, and for twenty minutes one of those electric storms peculiar and common to Pike's Peak prevailed. A queer hissing sound from the telegraph line, the wind-vane post, and other posts standing in a deep snow-drift near by. I stepped out to view the phenomenon, but was not standing in the snow-drift long, when the same buzz started from the top of my head, my hair became restless, and feeling a strange creeping sensation all over my body, I made quick steps for the station; once inside upon the dry floor, the effects soon left me. After getting inside I opened the telegraph key, and found a continuous bright spark passing between the key and the anvil, even when they were separated one-eighth of an inch; and by putting two thicknesses of writing-paper in this space, it was scorched, and perforated by numerous burnt holes. By accident I completed the circuit with both hands, when I received a shock that sent me back on the floor.

June 29, 1879.—Thunder-storm (very severe), 11.10 to 11.30 a.m., during which time a bolt passed through the arrester with a report exceeding that of a rifle, and threw sparks all over the office. The suddenness and violence of the shock stunned me, so that it was a little while before I could realise what had happened.

August 11, 1879.—During passage of a thunder-storm over the Peak a great amount of atmospheric electricity was manifested.

August 12, 1879.—Heavy snow and sleet began falling at 5.30 p.m.; at 5.40 p.m. a ball of lightning went through the arrester with the report of a rifle, throwing a ball of fire across the room against the stove and tin sheathing; the wood-packers, Messrs. Wade and McDonald, had taken refuge in the station for a few minutes, but concluded immediately that this was rather an uncomfortable place during a storm, and left immediately; their dog however was far in advance in seeking shelter outside. Mr. Wade declared that the lightning struck him in his feet and legs. At 6 p.m. the lightning struck the wire and building at the north end, where the wires come through the window and arrester with a crash equal to any 40-pounder. It burned every one of the four wires coming in at the window into small pieces, throwing them with great force in every direction, and filled the room with smoke from the burned gutta-percha insulation; the window-sash was splintered on the outside, one pane of glass broken, and another coated with melted copper. The anemometer wires were also burned up and the dial of the anemometer burned and blown to pieces. Private Sweeny was about deaf for some time afterwards. One piece of the wire was thrown with such force that when it struck the barometer three feet distant it was wound around it, without, however, doing any damage to the barometer.

July 2, 1880.—Line worked poorly on account of storm, each flash of lightning causing the instrument to be thrown out of adjustment; the signals at midnight were got off with great difficulty.

July 19, 1880.—Atmospheric electricity quite prevalent during the evening.

July 21, 1880.—Hail in afternoon and night, accompanied by heavy flashes of lightning which played around the arrester, and exploded with great force.

July 23, 1880.—Hail, rain and snow during the day; ended at 5.40 p.m. Intense ground currents during prevalence of storm.

June 23, 1881.—A light fall of hail, accompanied by terrific flashes of lightning, which snapped on the lightning arrester, and exploded with great violence.

July 4, 1881.—During the progress of the rain-storm it was accompanied by the heaviest discharges of lightning and thunder that I ever witnessed in all my experience at this station. The lightning snapped on the arrester and exploded with great violence in the office. Several times during the evening I was certain that the station building would be struck and demolished, as the lightning was almost continuous.

August 21, 1881.—Heavy hail began falling at 12.30 p.m., continued at intervals until 4.15 p.m., when it ceased. The hail was accompanied with the heaviest discharges of lightning that I ever witnessed in all my experience at this station. It was impossible to remain in the office during the progress of the hailstorm, as the lightning was almost continuous, and snapped and exploded in all directions, so that I was compelled to retreat to the kitchen for safety. The south-west portion of the station-building was struck by lightning, but no damage of any consequence was done, nor was the station-building impaired by the shock. The lightning arrester and ground wires were badly damaged, but the worst feature of the storms was the fact that both the station and extra barometers were also struck, and the cisterns of both cracked.

During the storm a shepherd was killed by lightning, and when found was stripped of his clothing and boots; he had taken refuge under a tree.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

EDINBURGH.—Five Fellowships in connection with this University (the gift of an anonymous donor) of the value of 100*l*. each, for one year, but renewable for one or two further years at the pleasure of the Senatus Academicus, will be open to applicants in October next. There will be no examinations for election to these Fellowships, but Fellows will be elected by the Senatus Academicus after consideration of the qualifications and circumstances of the applicants. The Fellowships are open to any graduate of a Scottish University, not being more than thirty years of age at the date of application, and provided that he be not an assistant to any Professor, or an examiner in any department. They are intended for persons having attained some proficiency in, and who are desirous to prosecute, unprofessional study and research in one of the following subjects:—Mathematics (pure and applied), or experimental physics, chemistry, biology, mental philosophy, history, or the history of literature. Persons desiring to hold one of these Fellowships should address an application to the secretary of the Senatus, with statement as to previous course of study, and general purposes with respect to future work. Each Fellow will be expected to reside in Edinburgh during the winter and summer sessions of the University (1882-83) to prosecute his particular branch of study under the advice of the Professor to whose department the subject belongs; and within a year after his election to give evidence of his progress by the preparation of a thesis, the completion of a research, the delivery of a lecture, or in some other way approved by the Senatus Academicus. No other fellowship, scholarship, or bursary, in this or any other University, will be tenable together with one of the elective Fellowships.
