From formula (3), $w = \frac{1000\text{ H.P.}}{v} = \frac{16.67\text{ H.P.}}{V} = \frac{3820\text{ H.P.}}{d \times \text{r.p.m.}} = \frac{500\text{ H.P.}}{L \times \text{r.p.m.}}$.

From formula (4), $w = \frac{733\text{ H.P.}}{v} = \frac{12.22\text{ H.P.}}{V} = \frac{2800\text{ H.P.}}{d \times \text{r.p.m.}} = \frac{360\text{ H.P.}}{L \times \text{r.p.m.}}$.

From formula (5),* $w = \frac{513\text{ H.P.}}{v} = \frac{8.56\text{ H.P.}}{V} = \frac{1960\text{ H.P.}}{d \times \text{r.p.m.}} = \frac{257\text{ H.P.}}{L \times \text{r.p.m.}}$.

Many authorities use formula (1) for double belts and formula (2) or (3) for single belts.

To obtain the width by Nagle's formula, $w = \frac{550\text{ H.P.}}{CVt(S - 0.012\ V^2)}$, or divide the given horse-power by the figure in the table corresponding to the given thickness of belt and velocity in feet per second.

The formula to be used in any particular case is largely a matter of judgment. A single belt proportioned according to formula (1), if tightly stretched, and if the surface is in good condition, will transmit the horse-power calculated by the formula, but one so proportioned is objectionable, first, because it requires so great an initial tension that it is apt to stretch, slip, and require frequent restretching and relacing; and second, because this tension will cause an undue pressure on the pulley-shaft, and therefore an undue loss of power by friction. To avoid these difficulties, formula (2), (3), or (4), or Mr. Nagle's table, should be used; the latter especially in cases in which the velocity exceeds 4000 ft. per min.

The following are from the notes of the late Samuel Webber. (*Am. Mach.* May 11, 1909.)

Good oak-tanned leather from the back of the hide weighs almost exactly one avoirdupois ounce for each one-hundredth of an inch in thickness, in a piece of leather one foot square, so that

	Lbs. per Sq. Ft.	Approx. Thickness.	Actual Thickness.	Vel. per Inch for 1 H.P.	Safe Strain per Inch Width.
Single belt	16 oz.	1/6 in.	0.16 in.	625 ft.	52.8 lbs.
Light double	24 "	1/4 "	0.24 "	417 "	78.1 "
Medium	28 "	5/16 "	0.28 "	357 "	92.5 "
Standard	33 "	1/3 "	0.33 "	303 "	109 "
3-ply	45 "	9/16 "	0.45 "	222 "	148 "

The rule for velocity per inch width for 1 H.P. is:

Multiply the denominator of the fraction expressing the thickness of the belt in inches by 100, and divide it by the numerator;

Good, well-calendered rubber belting made with 30-ounce duck and new (i. e., not reclaimed vulcanized) rubber will be as follows:

Nomenclature.	Approximate Thickness.	Safe Working Strain for 1 Inch Width.	Velocity per Inch for for 1 H.P.
3-ply	0.18 in.	45 pounds	735 ft. per min.
4 "	0.24 "	65 "	508 " " "
5 "	0.30 "	85 "	388 " " "
6 "	0.35 "	105 "	314 " " "
7 "	0.40 "	125 "	264 " " "
8 "	0.45 "	145 "	218 " " "

The thickness of rubber belt does not necessarily govern the strength, but the weight of duck does, and with 30-ounce duck, the safe working strains are as above.

Belt Factors. W. W. Bird (*Jour. Worcester Polyt. Inst.*, Jan. 1910.) — The factors given in the table below, for use in the formula H.P. = $vw \div F$, in which F is an empirical factor, are based on the following assumptions: A belt of single thickness will stand a stress on the tight

* For double belts.

side, T_1, of 60 lbs. per inch of width, a double belt 105 lbs., and a triple belt 150 lbs., and have a fairly long life, requiring only occasional taking up; the ratio of tensions T_1/T_2 should not exceed 2 on small, 2.5 on medium and 3 on large pulleys; the creep (travel of the belt relative to the surface of the pulley due to the elasticity of the belt and not to slip) should not exceed 1%—this requires that the difference in tensions $T_1 - T_2$ should not be greater than 40 lbs. per inch of width for single, 70 for double and 100 for triple belts.

Pulley diam,	Under 8 in.	8 to 36 in.	Over 3 ft.	Under 14 in.	14 to 60 in.	Over 5 ft.	Under 21 in.	21 to 84 in.	Over 7 ft.
Belt thickness.	Single.	S'gle.	S'gle.	Dbl.	Dbl.	Dbl.	Triple.	Triple.	Triple.

Taylor's Rules for Belting. — F. W. Taylor (*Trans. A. S. M. E.*, xv, 204) describes a nine years' experiment on belting in a machine shop, giving results of tests of 42 belts running night and day. Some of these belts were run on cone pulleys and others on shifting, or fast-and-loose, pulleys. The average net working load on the shifting belts was only 0.4 of that of the cone belts.

The shifting belts varied in dimensions from 39 ft. 7 in. long, 3.5 in. wide, 0.25 in. thick, to 51 ft. 5 in. long, 6.5 in. wide, 0.37 in. thick. The cone belts varied in dimensions from 24 ft. 7 in. long, 2 in. wide, 0.25 in. thick, to 31 ft. 10 in. long, 4 in. wide, 0.37 in. thick.

Belt-clamps were used having spring-balances between the two pairs of clamps, so that the exact tension to which the belt was subjected was accurately weighed when the belt was first put on, and each time it was tightened. The tension under which each belt was spliced was carefully figured so as to place it under an initial strain—while the belt was at rest immediately after tightening—of 71 lbs. per inch of width of double belts. This is equivalent, in the case of

Oak tanned and fulled belts, to 192 lbs. per sq. in. section;
Oak tanned, not fulled belts, to 229 " " " " "
Semi-raw-hide belts, to 253 " " " " "
Raw-hide belts to 284 " " " " "

From the nine years experiment Mr. Taylor draws a number of conclusions, some of which are given in an abridged form below.

In using belting so as to obtain the greatest economy and the most satisfactory results, the following rules should be observed:

	Oak Tanned and Fulled Leather Belts.	Other Types of Leather Belts and 6- to 7-ply Rubber Belts.
A double belt, having an arc of contact of 180°, will give an effective pull on the face of a pulley per inch of width of belt of.....	35 lbs.	30 lbs.
Or, a different form of same rule: The number of sq. ft. of double belt passing around a pulley per minute required to transmit one horse-power is...............	80 sq. ft.	90 sq. ft.
Or: The number of lineal feet of double belting 1 in. wide passing around a pulley per minute required to transmit one horse-power is..................................	950 ft.	1100 ft.
Or: A double belt 6 in. wide, running 4000 to 5000 ft. per min., will transmit.............	30 H.P.	25 H.P.

The terms "initial tension," "effective pull," etc., are thus explained by Mr. Taylor: When pulleys upon which belts are tightened are at rest both strands of the belt (the upper and lower) are under the same stress per in. of width. By "tension," "initial tension," or "tension while at rest," we mean the stress per in. of width, or sq. in. of section, to which one of the strands of the belt is tightened, when at rest. After the belts are in motion and transmitting power, the stress on the slack side, or strand, of the belt becomes less, while that on the tight side — or the side which does the pulling — becomes greater than when the belt was at rest. By the term "total load" we mean the total stress per in. of width, or sq. in. of section, on the tight side of belt while in motion.

The difference between the stress on the tight side of the belt and its slack side, while in motion, represents the effective force or pull which is transmitted from one pulley to another. By the terms "working load," "net working load," or "effective pull," we mean the difference in the tension of the tight and slack sides of the belt per in. of width, or sq. in. section, while in motion, or the net effective force that is transmitted from one pulley to another per in. of width or sq. in. of section.

The discovery of Messrs. Lewis and Bancroft (*Trans. A. S. M. E.*, vii, 549) that the "sum of the tension on both sides of the belt does not remain constant," upsets all previous theoretical belting formulæ.

The belt speed for maximum economy should be from 4000 to 4500 ft. per minute.

The best distance from center to center of shafts is from 20 to 25 ft.

Idler pulleys work most satisfactorily when located on the slack side of the belt about one-quarter way from the driving-pulley.

Belts are more durable and work more satisfactorily made narrow and thick, rather than wide and thin.

It is safe and advisable to use: a double belt on a pulley 12 in. diameter or larger; a triple belt on a pulley 20 in. diameter or larger; a quadruple belt on a pulley 30 in. diameter or larger.

As belts increase in width they should also be made thicker.

The ends of the belt should be fastened together by splicing and cementing, instead of lacing, wiring, or using hooks or clamps of any kind.

A V-splice should be used on triple and quadruple belts and when idlers are used. Stepped splice, coated with rubber and vulcanized in place, is best for rubber belts.

For double belting the rule works well of making the splice for all belts up to 10 in. wide, 10 in. long; from 10 in. to 18 in. wide the splice should be the same width as the belt, 18 in. being the greatest length of splice required for double belting.

Belts should be cleaned and greased every five to six months.

Double leather belts will last well when repeatedly tightened under a strain (when at rest) of 71 lbs. per in. of width, or 240 lbs. per sq. in. section, but they will not maintain this tension for any length of time.

Belt-clamps having spring-balances between the pairs of clamps should be used for weighing the tension of the belt each time it is tightened.

The stretch, durability, cost of maintenance, etc., of belts proportioned (A) according to the ordinary rules of a total load of 111 lbs. per inch of width, corresponding to an effective pull of 65 lbs. per inch of width, and (B) according to a more economical rule of a total load of 54 lbs., corresponding to an effective pull of 26 lbs. per inch of width, are found to be as follows:

When it is impracticable to accurately weigh the tension of a belt in tightening it, it is safe to shorten a double belt one-half inch for every 10 ft. of length for (A) and one inch for every 10 ft. for (B), if it requires tightening.

Double leather belts, when treated with great care and run night and day at moderate speed, should last for 7 years (A); 18 years (B).

The cost of all labor and materials used in the maintenance and repairs of double belts, added to the cost of renewals as they give out, through a term of years, will amount on an average per year to 37% of the original cost of the belts (A); 14% or less (B).

In figuring the total expense of belting, and the manufacturing cost chargeable to this account, by far the largest item is the time lost on the machines while belts are being relaced and repaired.

The total stretch of leather belting exceeds 6% of the original length.

The stretch during the first six months of the life of belts is 36% of their entire stretch (A); 15% (B).

A double belt will stretch 0.47% of its length before requiring to be tightened (A); 0.81% (B).

The most important consideration in making up tables and rules for the use and care of belting is how to secure the minimum of interruptions to manufacture from this source.

The average double belt (A), when running night and day in a machine-shop, will cause at least 26 interruptions to manufacture during its life, or 5 interruptions per year, but with (B) interruptions to manufacture will not average oftener for each belt than one in sixteen months.

The oak-tanned and fulled belts showed themselves to be superior in all respects except the coefficient of friction to either the oak-tanned not fulled, the semi-raw-hide, or raw-hide with tanned face.

Belts of any width can be successfully shifted backward and forward on tight and loose pulleys. Belts running between 5000 and 6000 ft. per min. and driving 300 H.P. are now being daily shifted on tight and loose pulleys, to throw lines of shafting in and out of use.

The best form of belt-shifter for wide belts is a pair of rollers twice the width of belt, either of which can be pressed onto the flat surface of the belt on its slack side close to the driven pulley, the axis of the roller making an angle of 75° with the center line of the belt.

Remarks on Mr. Taylor's Rules. (W. Kent, *Trans. A. S. M. E.*, xv, 242.)—The most notable feature in Mr. Taylor's paper is the great difference between his rules for proper proportioning of belts and those given by earlier writers. A very commonly used rule is, one horse-power may be transmitted by a single belt 1 in. wide running x ft. per min., substituting for x various values, according to the ideas of different engineers, ranging usually from 550 to 1100.

The practical mechanic of the old school is apt to swear by the figure 600 as being thoroughly reliable, while the modern engineer is more apt to use the figure 1000. Mr. Taylor, however, instead of using a figure from 550 to 1100 for a single belt, uses 950 to 1100 for double belts. If we assume that a double belt is twice as strong, or will carry twice as much power, as a single belt, then he uses a figure at least twice as large as that used in modern practice, and would make the cost of belting for a given shop twice as large as if the belting were proportioned according to the most liberal of the customary rules.

This great difference is to some extent explained by the fact that the problem which Mr. Taylor undertakes to solve is quite a different one from that which is solved by the ordinary rules with their variations. The problem of the latter generally is, "How wide a belt must be used, or how narrow a belt may be used, to transmit a given horse-power?" Mr. Taylor's problem is: "How wide a belt must be used so that a given horse-power may be transmitted with the minimum cost for belt repairs, the longest life to the belt, and the smallest loss and inconvenience from stopping the machine while the belt is being tightened or repaired?"

The difference between the old practical mechanic's rule of a 1-in.-wide single belt, 600 ft. per min., transmits one horse-power, and the rule commonly used by engineers, in which 1000 is substituted for 600, is due to the belief of the engineers, not that a horse-power could not be transmitted by the belt proportioned by the older rule, but that such a proportion involved undue strain from overtightening to prevent slipping, which strain entailed too much journal friction, necessitated frequent tightening, and decreased the length of the life of the belt.

Mr. Taylor's rule substituting 1100 ft. per min. and doubling the belt, is a further step, and a long one, in the same direction. Whether it will be taken in any case by engineers will depend upon whether they appreciate the extent of the losses due to slippage of belts slackened by use under overstrain, and the loss of time in tightening and repairing belts, to such a degree as to induce them to allow the first cost of the belts to be doubled in order to avoid these losses.

It should be noted that Mr. Taylor's experiments were made on rather narrow belts, used for transmitting power from shafting to machinery, and his conclusions may not be applicable to heavy and wide belts, such as engine fly-wheel belts.

Barth's Studies on Belting. (*Trans. A. S. M. E.*, 1909.)—Mr. Carl G. Barth has made an extensive study of the work of earlier writers on the subject of belting, and has derived several new formulæ and diagrams showing the relation of the several variables that enter into the belt problem. He has also devised a slide rule by which calculations of belts may easily be made. He finds that the coefficient of friction depends on the velocity of the belt, and may be expressed by the formula $f = 0.54 - \frac{140}{500 + V}$, in which V is the velocity in feet per minute.

Taking Mr. Taylor's data as a starting point, Mr Barth has adopted the rule, as a basis for use of belts on belt-driven machines, that for the driving belt of a machine the *minimum initial tension* must be such that when the belt is doing the maximum amount of work intended, the *sum of the tension in the tight side of the belt and one-half the tension in the slack side will equal* 240 *lbs. per square inch of cross-section for all belt speeds;* and that for a belt driving a countershaft, or any other belt inconvenient to get at for retightening or more readily made of liberal dimensions, this sum will equal 160 lbs. Further, the maximum initial tension, that is, the initial tension under which a belt is to be put up in the first place, and to which it is to be retightened as often as it drops to the minimum, must be such that the sum defined above is 320 lbs. for a machine belt, and 240 lbs. for a counter-shaft belt or a belt similarly circumstanced.

From a set of curves plotted by Mr. Barth from his formula the following tables are derived. The figures are based upon the conditions named in the above rule, and on an arc of contact = 180°.

Belts on Machines. Tension in tight side + 1/2 tension in slack side = 240 lbs.

Velocity, ft. per min...	500	1000	2000	3000	4000	5000	6000
Initial tension, t_0.....	124	120	121	128	136	144	152
Centrifugal tension t_c .	0 +	3	13	31	56	86	124
Difference, $t_0 - t_c$.....	123	117	108	97	80	58	28
Tension on tight side, t_1	210	212	211	207	198	187	173
Tension on slack side, t_2	60	54	57	68	84	107	134
Effective pull, $t_1 - t_2$..	150	158	154	139	114	80	39
Sum of tensions $t_1 + t_2$	270	268	269	274	282	294	307
H.P. per sq. in. of section...............	2.27	4.79	9.33	12.64	13.82	12.12	7.09
H.P. per in. width, 5/16 in. thick...........	0.71	1.50	2.82	3.95	4.32	3.71	2.22

Belts driving countershafts, $t_1 + 1/2\, t_2 = 160$ lbs.

Velocity of belt, ft. per min.....	500	1000	2000	3000	4000	5000
Initial tension, t_0..............	82	81	83	89	96	102
Tension on tight side, t_1........	140	141	140	134	125	114
Tension on slack side, t_2........	40	38	41	53	69	92
Effective pull, $t_1 - t_2$...........	100	103	99	81	56	22
Sum of tensions...............	180	179	181	187	194	206
H.P. per sq. in. of section.......	1.51	3.12	6.04	7.36	6.79	3.33
H.P. per in. width, 5/16 in. thick	0.47	0.97	1.87	2.30	2.12	1.04

MISCELLANEOUS NOTES ON BELTING.

Formulæ are useful for proportioning belts and pulleys, but they furnish no means of estimating how much power a particular belt may be transmitting at any given time, any more than the size of the engine is a measure of the load it is actually drawing, or the known strength of a horse is a measure of the load on the wagon. The only reliable means of determining the power actually transmitted is some form of dynamometer. (See *Trans. A. S. M. E.*, vol. xii, p. 707.)

If we increase the thickness, the power transmitted ought to increase in proportion; and for double belts we should have half the width required for a single belt under the same conditions. With large pulleys and moderate velocities of belt it is probable that this holds good. With small pulleys, however, when a double belt is used, there is not such perfect contact between the pulley-face and the belt, due to the rigidity of the latter, and more work is necessary to bend the belt-fibers than when a thinner and more pliable belt is used. The centrifugal force tending to throw the belt from the pulley also increases with the thickness, and for these reasons the width of a double belt required to transmit a given horse-power when used with small pulleys is generally assumed not less than seven-tenths the width of a single belt to transmit the same power. (Flather on "Dynamometers and Measurement of Power.")

F. W. Taylor, however, finds that great pliability is objectionable, and favors thick belts even for small pulleys. The power consumed in bending the belt around the pulley he considers inappreciable. According to Rankine's formula for centrifugal tension, this tension is proportional to the sectional area of the belt, and hence it does not increase with increase of thickness when the width is decreased in the same proportion, the sectional area remaining constant.

Scott A. Smith (*Trans. A. S. M. E.*, x, 765) says: The best belts are made from all oak-tanned leather, and curried with the use of cod oil and tallow, all to be of superior quality. Such belts have continued in use thirty to forty years when used as simple driving-belts, driving a proper amount of power, and having had suitable care. The flesh side should not be run to the pulley-face, for the reason that the wear from contact with the pulley should come on the grain side, as that surface of the belt is much weaker in its tensile strength than the flesh side; also as the grain is hard it is more enduring for the wear of attrition; further, if the grain is actually worn off, then the belt may not suffer in its integrity from a ready tendency of the hard grain side to crack.

The most intimate contact of a belt with a pulley comes, first, in the smoothness of a pulley-face, including freedom from ridges and hollows left by turning-tools; second, in the smoothness of the surface and evenness in the texture or body of a belt; third, in having the crown of the driving and receiving pulleys exactly alike, — as nearly so as is practicable in a commercial sense; fourth, in having the crown of pulleys not over 1/8 in. for a 24-in. face, that is to say, that the pulley is not to be over 1/4 in. larger in diameter in its center; fifth, in having the crown other than two planes meeting at the center; sixth, the use of any material on or in a belt, in addition to those necessarily used in the currying process, to keep them pliable or increase their tractive quality, should wholly depend upon the exigencies arising in the use of belts; non-use is safer than over-use; seventh, with reference to the lacing of belts, it seems to be a good practice to cut the ends to a convex shape by using a former, so that there may be a nearly uniform stress on the lacing through the center as compared with the edges. For a belt 10 ins. wide, the center of each end should recede 1/10 in.

Lacing of Belts. — In punching a belt for lacing, use an oval punch, the longer diameter of the punch being parallel with the sides of the belt. Punch two rows of holes in each end, placed zigzag. In a 3-in. belt there should be four holes in each end — two in each row. In a 6-in. belt, seven holes — four in the row nearest the end. A 10-in. belt should have nine holes. The edge of the holes should not come nearer than 3/4 in. from the sides, nor 7/8 in. from the ends of the belt. The second row should be at least 1 3/4 ins. from the end. On wide belts these distances should be even a little greater.

Begin to lace in the center of the belt and take care to keep the ends exactly in line, and to lace both sides with equal tightness. The lacing should not be crossed on the side of the belt that runs next the pulley. In taking up belts, observe the same rules as in putting on new ones.

Setting a Belt on Quarter-twist. — A belt must run squarely on to the pulley. To connect with a belt two horizontal shafts at right angles with each other, say an engine-shaft near the floor with a line attached to the ceiling, will require a quarter-turn. First, ascertain the central point on the face of each pulley at the extremity of the horizontal diameter where the belt will leave the pulley, and then set that point on the driven pulley plumb over the corresponding point on the driver. This will cause the belt to run squarely on to each pulley, and it will leave at an angle greater or less, according to the size of the pulleys and their distance from each other.

In quarter-twist belts, in order that the belt may remain on the pulleys, the central plane on each pulley must pass through the point of delivery of the other pulley. This arrangement does not admit of reversed motion.

To find the Length of Belt required for two given Pulleys. — When the length cannot be measured directly by a tape-line, the following approximate rule may be used: Add the diameter of the two pulleys together, divide the sum by 2, and multiply the quotient by 3 1/4, and add the product to twice the distance between the centers of the shafts. (See accurate formula below.)

To find the Angle of the Arc of Contact of a Belt. — Divide the difference between the radii of the two pulleys in inches by the distance between their centers, also in inches, and in a table of natural sines find the angle most nearly corresponding with the quotient. Multiply this angle by 2, and add the product to 180° for the angle of contact with the larger pulley, or subtract it from 180° for the smaller pulley.

Or, let R = radius of larger pulley, r = radius of smaller;
L = distance between centers of the pulleys;
a = angle whose sine is $(R - r) \div L$.
Arc of contact with smaller pulley = $180° - 2a$;
Arc of contact with larger pulley = $180° + 2a$.

To find the Length of Belt in Contact with the Pulley. — For the larger pulley, multiply the angle a, found as above, by 0.0349, to the product add 3.1416, and multiply the sum by the radius of the pulley. Or length of belt in contact with the pulley

$$= \text{radius} \times (\pi + 0.0349\,a) = \text{radius} \times \pi(1 + a/90).$$

For the smaller pulley, length = radius $\times$ $(\pi - 0.0349\,a)$

$$= \text{radius} \times \pi(1 - a) \div 90.$$

The above rules refer to **Open Belts.** The accurate formula for length of an open belt is,

$$\text{Length} = \pi R(1 + a/90) + \pi r(1 - a/90) + 2\,L\cos a.$$
$$= R\,(\pi + 0.0349\,a) + r\,(\pi - 0.0349\,a) + 2\,L\cos a,$$

in which R = radius of larger pulley, r = radius of smaller pulley, L = distance between centers of pulleys, and a = angle whose sine is

$$(R - r) \div L;\ \cos a = \sqrt{L^2 - (R - r)^2} \div L.$$

An approximate formula is

Length $= 2\,L + \pi\,(R + r) + (R - r)^2/L$

For $L = 4$, $R = 2$, $r = 1$, this formula gives length = 17.6748, the accurate formula giving 17.6761

For Crossed Belts the formula is

$$\text{Length of belt} = \pi\,R(1 + \beta/90) + \pi r(1 + \beta/90) + 2\,L\cos\beta$$
$$= (R + r) \times (\pi + 0.0349\,\beta) + 2\,L\cos\beta,$$

in which β = angle whose sine is $(R + r) \div L$; $\cos\beta = \sqrt{L^2 - (R + r)^2} \div L$.

To find the Length of Belt when Closely Rolled. — The sum of the diameter of the roll, and of the eye in inches, $\times$ the number of turns made by the belt and by 0.1309, = length of the belt in feet.

To find the Approximate Weight of Belts. — Multiply the length of belt, in feet, by the width in inches, and divide the product by 13 for single and 8 for double belt.

Good oak-tanned leather from the back of the hide weighs almost exactly 1 oz. per sq. ft. per 0.01 in. thickness. The thickness of single belts is 0.16 in.; of light double belts, 0.24 in.; of medium weight double belt, 0.28 in.; of standard double belt, 0.33 in.; of 3-ply belts, 0.45 in. (W. O. Webber, in *Trans. Natl. Assoc. Cotton Mfrs.*, 1908, p. 345.)

Relations of the Size and Speeds of Driving and Driven Pulleys. —The driving pulley is called the driver, D, and the driven pulley the driven, d. If the number of teeth in gears is used instead of diameter, in these calculations, number of teeth must be substituted wherever diameter occurs. R = revs. per min. of driver, r = revs. per min. of driven.

$$D = dr \div R;$$

Diam. of driver = diam. of driven × revs. of driven ÷ revs. of driver.
$$d = DR \div r;$$
Diam. of driven = diam. of driver × revs. of driver ÷ revs. of driven.
$$R = dr \div D;$$
Revs. of driver = revs. of driven × diam. of driven ÷ diam. of driver.
$$r = DR \div d;$$
Revs. of driven = revs. of driver × diam. of driver ÷ diam. of driven.

Evils of Tight Belts. (Jones and Laughlins.) — Clamps with powerful screws are often used to put on belts with extreme tightness, and with most injurious strain upon the leather. They should be very judiciously used for horizontal belts, which should be allowed sufficient slackness to move with a loose undulating vibration on the returning side, as a test that they have no more strain imposed than is necessary simply to transmit the power.

On this subject a New England cotton-mill engineer of large experience says: I believe that three-quarters of the trouble experienced in broken pulleys, hot boxes, etc., can be traced to the fault of tight belts. The enormous and useless pressure thus put upon pulleys must in time break them, if they are made in any reasonable proportions, besides wearing out the whole outfit, and causing heating and consequent destruction of the bearings. Below are figures showing the power taken, in average modern mills with first-class shafting, to drive the shafting alone:

Mill No.	Whole Load, H.P.	Shafting Alone.		Mill No.	Whole Load, H.P.	Shafting Alone.	
		Horse-power.	Per cent of whole.			Horse-power.	Per cent of whole.
1	199	51	25.6	5	759	172.6	22.7
2	472	111.5	23.6	6	235	84.8	36.1
3	486	134	27.5	7	670	262.9	39.2
4	677	190	28.1	8	677	182	26.8

These may be taken as a fair showing of the power that is required in many of our best mills to drive shafting. It is unreasonable to think that all that power is consumed by a legitimate amount of friction of bearings and belts. I know of no cause for such a loss of power but tight belts. These, when there are hundreds or thousands in a mill, easily multiply the friction on the bearings, and would account for the figures.

Sag of Belts. Distance between Pulleys.— In the location of shafts that are to be connected with each other by belts, care should be taken to secure a proper distance one from the other. This distance should be such as to allow of a gentle sag to the belt when in motion.

A general rule may be stated thus: Where narrow belts are to be run over small pulleys 15 feet is a good average, the belt having a sag of 1 1/2 to 2 inches.

For larger belts, working on larger pulleys, a distance of 20 to 25 feet does well, with a sag of 2 1/2 to 4 inches.

For main belts working on very large pulleys, the distance should be 25 to 30 feet, the belts working well with a sag of 4 to 5 inches.

If too great a distance is attempted, the belt will have an unsteady, flapping motion, which will destroy both the belt and machinery.

Arrangement of Belts and Pulleys. — If possible to avoid it, connected shafts should never be placed one directly over the other, as in such case the belt must be kept very tight to do the work. For this purpose belts should be carefully selected of well-stretched leather.

It is desirable that the angle of the belt with the floor should not exceed 45°. It is also desirable to locate the shafting and machinery so that belts should run off from each shaft in opposite directions, as this arrangement will relieve the bearings from the friction that would result when the belts all pull one way on the shaft.

In arranging the belts leading from the main line of shafting to the counters, those pulling in an opposite direction should be placed as near each other as practicable, while those pulling in the same direction should be separated. This can often be accomplished by changing the relative positions of the pulleys on the counters. By this procedure much of the friction on the journals may be avoided.

If possible, machinery should be so placed that the direction of the belt motion shall be from the top of the driving to the top of the driven pulley, when the sag will increase the arc of contact.

The pulley should be a little wider than the belt required for the work.

The motion of driving should run with the laps of the belts.

Tightening or guide pulleys should be applied to the slack side of belts and near the smaller pulley.

Jones and Laughlins, in their Useful Information, say: The diameter of the pulleys should be as large as can be admitted, provided they will not produce a speed of more than 4750 feet of belt motion per minute.

They also say: It is better to gear a mill with small pulleys and run them at a high velocity, than with large pulleys and to run them slower. A mill thus geared costs less and has a much neater appearance than with large heavy pulleys.

M. Arthur Achard (*Proc. Inst. M. E.*, Jan., 1881, p. 62) says: When the belt is wide a partial vacuum is formed between the belt and the pulley at a high velocity. The pressure is then greater than that computed from the tensions in the belt, and the resistance to slipping is greater. This has the advantage of permitting a greater power to be transmitted by a given belt, and of diminishing the strain on the shafting.

On the other hand, some writers claim that the belt entraps air between itself and the pulley, which tends to diminish the friction, and reduce the tractive force. On this theory some manufacturers perforate the belt with numerous holes to let the air escape.

Care of Belts. — Leather belts should be well protected against water, loose steam, and all other moisture, with which they should not come in contact. But where such conditions prevail fairly good results are obtained by using a special dressing prepared for the purpose of water-proofing leather, though a positive water-proofing material has not yet been discovered.

Belts made of coarse, loose-fibered leather will do better service in dry and warm places, but if damp or moist conditions exist then the very finest and firmest leather should be used. (Fayerweather & Ladew.)

Do not allow oil to drip upon the belts. It destroys the life of the leather.

Leather belting cannot safely stand above 130° of heat.

"Duxbak" waterproof belt is advertised to withstand any amount of moisture, and temperatures up to 200 degrees.

Strength of Belting.—The ultimate tensile strength of belting does not generally enter as a factor in calculations of power transmission.

The strength of the solid leather in belts is from 2000 to 5000 lbs. per square inch; at the lacings, even if well put together, only about 1000 to 1500. If riveted, the joint should have half the strength of the solid belt. The working strain on the driving side is generally taken at not over one-third of the strength of the lacing, or from one-eighth to one-sixteenth of the strength of the solid belt. Dr. Hartig found that the tension in practice varied from 30 to 532 lbs. per sq. in., averaging 273 lbs.

Effect of Humidity Upon a Leather Belt. (W. W. Bird and F. W. Roys, *Trans. A. S. M. E.*, 1915.)—Tests with a 4-in. oak-tanned single belt, with constant horse-power transmitted, and with the center distance and humidity varying, showed increase of the sum of the tensions as the humidity decreased, figures taken from curves of the results being as follows:

Center distance:	9 ft. 6 in.,	9 ft. 6½ in.,	9 ft. 7 in.,	9 ft. 7½ in.
Relative Humidity.	Sum of the Tensions, pounds.			
90	95	210	325	445
55	125	260	400	550
20	150	310	465	620

Increase of temperature as well as increase of humidity tends to lengthen the belt and decrease the tension. The most important conclusions are:

1. If a belt be set up at a medium relative humidity, the tensions will not be excessive at lower relative humidities, nor will there be any great danger of slipping at high relative humidities unless there are excessive temperature changes.

2. If a belt be set up at any relative humidity with a spring or gravity tightener, a load 50 per cent greater than the standard can be transmitted at either high or low humidity without danger of stretching the belt, slipping, or excessive pressure on the bearings.

Adhesion Independent of Diameter. (Schultz Belting Co.) — 1. The adhesion of the belt to the pulley is the same — the arc or number of degrees of contact, aggregate tension or weight being the same — without reference to width of belt or diameter of pulley.

2. A belt will slip just as readily on a pulley four feet in diameter as it will on a pulley two feet in diameter, provided the conditions of the faces of the pulleys, the arc of contact, the tension, and the number of feet the belt travels per minute are the same in both cases.

3. To obtain a greater amount of power from belts the pulleys may be covered with leather; this will allow the belts to run very slack and give 25% more durability.

Endless Belts. — If the belts are to be endless, they should be put on and drawn together by "belt clamps" made for the purpose. If the belt is made endless at the belt factory, it should never be run on to the pulleys, lest the irregular strain spring the belt. Lift out one shaft, place the belt on the pulleys, and force the shaft back into place.

Belt Data. — A fly-wheel at the Amoskeag Mfg. Co., Manchester, N.H., 30 feet diameter, 110 inches face, running 61 revs. per min., carried two heavy double-leather belts 40 inches wide each, and one 24 inches wide. The engine indicated 1950 H.P., of which probably 1850 H.P. was transmitted by the belts. The belts were heavily loaded, but not overtaxed, the speed being 323 ft. per min. for 1 H.P. per inch of width.

Samuel Webber (*Am. Mach.*, Feb. 22, 1894) reports a case of a belt 30 ins. wide, 3/8 in. thick, running for six years at a velocity of 3900 ft. per min., on to a pulley 5 ft. diameter, and transmitting 556 H.P. This gives a velocity of 210 ft. per min. for 1 H.P. per in. of width. By Mr. Nagle's table of riveted belts this belt would be designed for 332 H.P. By Mr. Taylor's rule it would be used to transmit only 123 H.P.

The above may be taken as examples of what a belt may be made to do, but they should not be used as precedents in designing. It is not stated how much power was lost by the journal friction due to overtightening of these belts.

The United States Navy Department Specifications for Leather Belting.—Belting to be cut from No. 1 native packer steer hides or their equal. All hides to be tanned with white or chestnut oak by slow process (six to eight months) and chemical processes must not be used. The leather is to be thoroughly cured by hand and must not be stuffed or loaded for artificial weight. Leather must not crack open on grain side when doubled strongly by hand with grain side out. Belting is to be cut from central part of the hide no further than 15 in. from backbone or more than 48 in. from tail toward shoulder.

Belts 8 in. and over must be cut to include backbone. All leather is to be stretched 6 in. in lengthwise direction of the butt and is not to exceed 54 in. after stretching. Centers and sides are to be stretched 6 in. separately. That is, all side leathers from which widths under 8 in. are to be cut, must be stretched after the belting is removed from the backbone center section. Center sections are to be stretched in exactly the same size for which they are to be used.

For single belts up to 6 in., laps must not exceed 6 in. nor be less than 3 1/2 in. long. For single belts over 6 in. laps must not be more than 1 in. wider than belt.

For double belts, laps must not exceed 5 1/2 in. nor to be less than 3 1/2 in. No filling straps will be permitted. All laps must be held securely at every part with the best quality of belt cement, and when pulled apart shall show no resinous, vitreous, oily or watered condition. Belting is to be stretched again after manufacture.

Belting is to weigh for all sizes of single belts 16 oz. per sq. ft. and for double belts per sq. ft. as follows: 1 to 2 in., 26 oz.; 2 1/2 to 4 in., 28 oz.; 4 1/2 to 5 in., 30 oz.; 6 in. and over, 32 oz.

Only hand cut, green slaughter hides of the best quality are to be used for lacing. Raw hide laces to be cut 1/4, 5/16, 3/8, 7/16, 1/2, 5/8, and 3/4-in. sizes. They must be cut lengthwise from the hide and have an ultimate tensile strength of not less than

Width, in............	1/4	5/16	3/8	7/16	1/2	5/8	3/4
Tensile strength, lb....	95	125	155	165	180	205	230

Belt Dressings.—We advise that no belt dressing should be used except when the belt becomes dry and husky, and in such instances we recommend the use of a dressing. Where this is not used beef tallow at blood-warm temperature should be applied and then dried in, either by artificial heat or the sun. The addition of beeswax to the tallow will be of some service if the belts are used in wet or damp places. Resin should never be used on leather belting. (Fayerweather & Ladew.)

Belts should not be soaked in water before oiling, and penetrating oils should only be used when a belt gets very dry and husky from neglect. It may then be moistened a little, and neatsfoot oil applied. Frequent applications of such oils to a new belt render the leather soft and flabby, thus causing it to stretch, and making it liable to run out of line. A composition of tallow and oil, with a little resin or beeswax, is better to use. Prepared castor-oil dressing is good, and may be applied with a brush or rag while the belt is running. (Alexander Bros.)

Some forms of belt dressing, the compositions of which have not been published, appear to have the property of increasing the coefficient of friction between the belt and the pulley, enabling a given power to be transmitted with a lower belt tension than with undressed belts. C. W. Evans (*Power*, Dec., 1905), gives a diagram, plotted from tests, which shows that three of these compositions gave increased transmission for a given tension, ranging from about 10% for 90 lbs. tension per inch of width to 100% increase with 20 lbs. tension.

Cement for Cloth or Leather. (Molesworth.) — 16 parts gutta-percha, 4 india-rubber, 2 pitch, 1 shellac, 2 linseed-oil, cut small, melted together and well mixed.

Rubber Belting. — The advantages claimed for rubber belting are perfect uniformity in width and thickness; it will endure a great degree of heat and cold without injury; it is also specially adapted for use in damp or wet places, or where exposed to the action of steam; it is very durable, and has great tensile strength, and when adjusted for service it has the most perfect hold on the pulleys, hence is less liable to slip than leather.

Never use animal oil or grease on rubber belts, as it will soon destroy them.

Rubber belts will be improved, and their durability increased, by putting on with a painter's brush, and letting it dry, a composition made of equal parts of red lead, black lead, French yellow, and litharge, mixed with boiled linseed-oil and japan enough to make it dry quickly. The effect of this will be to produce a finely polished surface. If, from dust or other cause, the belt should slip, it should be lightly moistened on the pulley side with boiled linseed-oil. (From manufacturers' circulars.)

The best conditions are large pulleys and high speeds, low tension and reduced width of belt. 4000 ft. per min. is not an excessive speed on proper sized pulleys.

H.P. of a 4-ply rubber belt = (length of arc of contact on smaller pulley in ft. × width of belt in ins. × revs. per min.) ÷ 325. For a 5-ply belt multiply by $1\frac{1}{3}$, for a 6-ply by $1\frac{2}{3}$, for a 7-ply by 2, for an 8-ply by $2\frac{1}{3}$. When the proper weight of duck is used a 3- or 4-ply rubber belt is equal to a single leather belt and a 5- or 6-ply rubber to a double leather belt. When the arc of contact is 180°, H.P. of a 4-ply belt = width in ins. × velocity in ft. per min. ÷ 650. (Boston Belting Co.)

Steel Belts.—The Eloesser-Kraftband-Gesellschaft, of Berlin, has introduced a steel belt for heavy power transmission at high speeds (*Am. Mach.*, Dec. 24, 1908). It is a thin flat band of tempered steel. The ends are soldered and then clamped by a special device consisting of two steel plates, tapered to thin edges, which are curved to the radius of the smallest pulley to be used, and joined together by small screws which pass through holes in the ends of the belt. It is stated that the slip of these belts is less than 0.1%; they are about one-fifth the width of a leather belt for the same power, and they are run at a speed of 10,000 ft. per minute or upwards. The following figures give a comparison of a rope drive with six ropes 1.9 ins. diam., a leather belt 9.6 ins. wide and a steel belt 4 ins. wide, for transmitting 100 H.P. on pulleys 3 ft. diam. 30 ft. apart at 200 r.p.m.

	Rope Drive.	Leather Belt.	Steel Belt.
Weight of pulley, lbs.	2200	1120	460
Weight of rope or belt, lbs.	530	240	30
Total cost of drive	$335	$425	$250
Power lost, per cent of 100 H.P.	13	6	0.5

ROLLER CHAIN AND SPROCKET DRIVES.

The following is abstracted from an article by A. E. Michel, in *Mach'y*, Feb., 1905. (Revised, March, 1915.)

Steel chain of accurate pitch, high tensile strength, and good wearing qualities, possesses, when used within proper limitations, advantages enjoyed by no other form of transmission. It is compact, affords a positive speed ratio, and at slow speeds is capable of transmitting heavy strains. On short transmissions it is more efficient than belting and will operate more satisfactorily in damp or oily places. There is no loss of power from stretch, and as it allows of a low tension, journal friction is minimized.

Roller chain has been known to stand up at a speed of 4,000 ft. per min., and transmit 25 H.P. at 1,250 ft. per min.; but speeds of 1,000 ft. per min. and under give better satisfaction. Block chain is adapted to slower speeds, say 700 ft. per min. and under, and is extensively used on bicycles, small motor cars and machine tools. Where speed and pull are not fixed quantities, it is advisable to keep the speed high, and chain pull low, yet it should be borne in mind that high speeds are more destructive to chains of large than to those of small pitch.

The following table of tensile strengths, based on tests of "Diamond" chains taken from stock, may be considered a fair standard:

ROLLER CHAIN.

Pitch, in.	1/2	5/8	3/4	1	1 1/4	1 1/2	1 3/4	2
Tens. strength, lbs.	2,500	3,900	5,600	10,000	15,600	18,500	30,500	40,000

Block chain... 1 inch, 1,200 to 2,500; 1 1/2 inch, 5,000.

The safe working load of a chain is dependent on the amount of rivet bearing surface, and varies from 1/6 to 1/30 of the tensile strength, according to the speed, size of sprockets, and other conditions peculiar to each case. The tendency now is to use the widest possible chain in order to secure maximum rivet bearing surface, thus insuring minimum wear from friction. Manufacturers are making heavier chains than heretofore for the same duty. As short pitch is always desirable, special double and even triple width chains are now made to conform to the requirements when a heavy single width chain of greater pitch is not practical. A double chain has a little more than twice the rivet bearing surface and half again as much tensile strength as the corresponding single one.

The length of chain for a given drive may be found by the following formula:

All dimensions in inches. D = Distance between centers of shafts. A = Distance between limiting points of contact. R = Pitch radius of large sprocket. r = Pitch radius of small sprocket. N = Number of teeth of large sprocket. n = Number of teeth of small sprocket. P = Pitch of chain and sprockets. $(180° + 2\alpha)$ = angle of contact on large sprocket. $(180° - 2\alpha)$ = angle of contact on small sprocket. α = angle whose sine is $(R - r)/D$. $A = D \cos \alpha$.

Length of chain required:

$$L = \frac{180 + 2\alpha}{360} NP + \frac{180 - 2\alpha}{360} nP + 2D \cos \alpha.$$

For block chain, the total length specified in ordering should be in multiples of the pitch. For *roller* chain, the length should be in multiples of twice the pitch, as a union of the ends can be effected only with an outside and an inside link.

Wherever possible, the distance between centers of shafts should permit of adjustment in order to regulate the sag of the chain. A chain should be adjusted, in proportion to its length, to show slack when running, care being taken to have it neither too tight nor too loose, as either condition is destructive. If a fixed center distance must be used, and results in too much sag, the looseness should be taken up by an idler, and when there is any considerable tension on the slack side, this idler must be a sprocket. Where an idler is not practical, another combination of sprockets giving approximately the same speed ratio may be tried, and in this manner a combination giving the proper sag may always be obtained. The Diamond Chain and Mfg. Co. says that the center line distance between sprockets should not be less than $1\frac{1}{2}$ times the diameter of the larger sprocket nor more than 10 or 12 ft.

In automobile drives, too much sag or too great a distance between shafts causes the chain to whip up and down—a condition detrimental to smooth running and very destructive to the chain. In this class of work a center distance of over 4 ft. has been used, but greater efficiency and longer life are secured from the chain on shorter lengths, say 3 ft. and under.

Sprocket Wheels. Properly proportioned and machined sprockets are essential to successful chain gearing. The important dimensions of a sprocket are the pitch diameter and the bottom and outside diameters. For block chain these are obtained as follows:

N = No. of teeth. b = Diameter of round part of chain block. B = Center to center of holes in chain block. A = Center to center of holes in side links. $\alpha = 180°/N$. $\tan \beta = \sin \alpha \div (B/A + \cos \alpha)$.

$$\text{Pitch diameter} = A/\sin \beta.$$

Bottom diam. = pitch diam. $- b$. Outside diam. = pitch diam. $+ b$.

For roller chain: N = Number of teeth. P = Pitch of chain. D = Diameter of roller. $\alpha = 180°/N$. Pitch diameter $= P/\sin \alpha$.

Bottom diam. = pitch diam. $- D$.

For sprockets of 17 teeth and over, outside diam. = pitch diam. $+ D$.

The outside diameters of small sprockets are cut down so that the teeth will clear the roller perfectly at high speeds.

$$\text{Outside diam.} = \text{pitch diam.} + D - E.$$

Pitch.	Values of E. 8 to 12 Teeth.	Values of E. 13 to 16 Teeth.
$\frac{1}{2}$ in. to $\frac{3}{4}$ in.	0.062 in.	0.031 in.
1 in. to 2 in.	0.125 in.	0.062 in.

Sprocket diameters should be very accurate, particularly the base diameter, which should not vary more than 0.002 in. from the calculated values. Sprockets should be gauged to discover thick teeth and inaccurate diameters. A poor chain may operate on a good sprocket, but a bad sprocket will ruin a good chain. Sprockets of 12 to 60 teeth give best results. Fewer may be used, but cause undue elongation in the chain, wear the sprockets and consume too much power. Eight-tooth sprockets ruin almost every roller chain applied to them, and ten and eleven teeth are fitted only for medium and slow speeds with other conditions unusually favorable.

Sprocket teeth seldom break from insufficient strength, but the tooth must be properly shaped. A chain will not run well unless the sprockets have sidewise clearance and teeth narrowed at the ends by curves beginning at the pitch line.

Calling W the width of the chain between the links,

$A = \frac{1}{2} W$ = width of tooth at top. B = uniform width below pitch line.
$B = W - \frac{1}{64}$ in. when $W = \frac{1}{4}$ in. or less.
$= W - \frac{1}{32}$ in. when $W = \frac{5}{16}$ to $\frac{5}{8}$ in. inclusive.
$= W - \frac{1}{16}$ in. when $W = \frac{3}{4}$ in. or over.

If the sprocket is flanged the chain must seat itself properly without the side bars coming into contact with the flange.

The principal cause of trouble within the chain is elongation. It is the result of stretch of material or natural wear of rivets and their bearings. To guard against the former, chain makers use special materials of high tensile strength, but a chain subjected to jars and jolts beyond the limit of elasticity of the material may be put in worse condition in an instant than in months of natural wear. If for any reason a link elongates unduly it should be replaced at once, as one elongated link will eventually ruin the entire chain. Such elongation frequently results from all the load being thrown on at once.

To minimize natural wear, chains should be well greased inside and out protected from mud and heavy grit, cleaned often and replaced to run in the same direction and same side up. A new chain should never be applied to a much-worn sprocket.

Importance of pitch line clearances: In a sprocket with no clearances a new chain fits perfectly, but after natural wear the pitch of chain and sprocket become unlike. The chain is then elongated and climbs the teeth, which act as wedges, producing enormous strain, and it quickly wrecks itself. With the same chain on a driven sprocket, cut with clearances, all rollers seat against their teeth. After long and useful life, the working roller shifts to the top, and the other rollers still seat with the same ease as when new. Theoretically, all the rollers share the load. This never occurs in practice, for infinitesimal wear within the chain causes one, and only one, roller to bear perfectly seated against the working face of the sprocket tooth at any one time. Clearance alone on the driver will not provide for elongation. To operate properly the pitch of the driver must be lengthened, which is done by increasing the pitch diameter by an amount dependent upon the clearance allowed. For theoretical reasoning on this subject see "Roller Chain Gear," a treatise on English practice, by Hans Renold.

When the load reverses, each sprocket becomes alternately driver and driven. This happens in a motor car during positive and negative acceleration, or in ascending or descending a hill. In this event, the above construction is not applicable, for a driven sprocket of longer pitch than the chain will stretch it. No perfect method of equalizing the pitch of a roller chain and its sprockets under reversible load and at all periods of chain elongation has been found. This fault is eliminated in the "silent" type of chain; hence it runs smooth at a very much greater speed than roller chain will stand.

In practice there are comparatively few roller chain drives with chain pull always in the same direction, so manufacturers generally cut the driver sprockets for these with normal pitch diameter, same as the driven. Recent experiments have proven that the difficulties are greatly lessened by cutting both driver and driven with liberal pitch line clearance. Accordingly, chain makers now advise the following pitch line clearance for standard rollers:

Pitch, in.,	1/2	3/4	1	1 1/4	1 1/2	1 3/4	2
Clearance, in.,	1/32	1/16	3/32	3/16	7/32	1/8	5/32

Cutters may be obtained from Brown & Sharpe Mfg. Co. with this clearance.

Belting versus Chain Drives.—Chains are suitable for positive transmissions of very heavy powers at slow speed. They are properly used for conveying ashes, sand, chemicals and liquids which would corrode or destroy belting. Chains of this kind are generally made of malleable iron. For conveyers for clean substances, flour, wheat and other grains, belts are preferable, and in the best installations leather is preferred to cotton or rubber, being more durable. Transmission chains have to be carefully made. If the chain is to run smoothly, noiselessly, and without considerable friction, both the links and the sprockets must be mathematically correct. This perfection of design is found only in the highest and best makes of steel chain.

Deterioration of chains starts in with the beginning of service. Even in such light and flexible duty as bicycle transmission, a chain is subjected to sudden severe strains, which either stretch the chain or distort the bearing surfaces. Either mishap is fatal to smooth, frictionless running. If the transmission is positive, as from motor or shaft to a machine tool, sudden variations in strain become sledge-hammer blows, and the chain must either break or the parts yield. To avoid the evils arising from the stretching of the chain, self-adjusting forms of teeth have been invented, and the Renold and the Morse silent-chain gears are examples.

Chain drives are recommended for use under the following conditions: (1) Where room is lacking for the proper size pulleys for belts. (2) Where the centers between shafts are too short for belts. (3) Where a positive speed ratio is desired. (4) Where there is moisture, heat or dust that would prevent a belt working properly. (5) Where a maximum power per inch of width is desired.

The Renold and the Morse chain gears use springs in the sprocket wheel to absorb the shock when a reversal of strain takes place, which is infrequent in ordinary power transmission, but is found in reciprocating air-compressors and pumps, in gas-engine drives where an insufficient balance wheel is supplied, and where a heavy shock load occurs and it is desirable to cushion the effect by mounting the wheel on springs.

Nickel steel is generally used for the chains. The joint pins are made from 3 1/2% nickel chrome steel, heat-treated. The ends of the joint pins are softened by an electric arc to facilitate riveting to the chain links.

Data Used in the Preliminary Design of Morse Silent Chain Drives

Pitch, in.	1/2	5/8	3/4	9/10	1 2/10	1 1/2	2	3

APPROXIMATE WEIGHTS FOR SOLID AND ARMED SPROCKETS.

T = Number of teeth. F = Face in inches.
C = Constant in lb. per in. in face per tooth as per table.
Weight of armed sprocket = $T \times F \times C$.
Add 25% for split and 50% for spring and split sprockets.
Weight of solid pinion = $T^2 \times (F + 1) \times C$.

NOTES.

1.—Number of teeth = T.
Exact outside diameter = D.
For T less than 20 teeth, D = pitch diameter.
For T more than 20 teeth, D = pitch diameter + addendum.
2.—Use sprockets having an odd number of teeth whenever possible.
3.—When specially authorized, a larger number of teeth than shown may be cut in large sprocket.
4.—Thickness of sprocket rim, including teeth, should be at least 1.2 times the chain pitch.
5.—The number of grooves in the sprocket, their width and distance apart, varies according to pitch and width of chain. Leave the designing and turning of grooves to the manufacturer.
6.—The width of the sprocket should be 1/8 to 1/4 in. greater on small drives, and 1/4 to 1/2 in. greater on large drives than the nominal width of the chain.

7.—An even number of links in the chain and an odd number of teeth in the wheels are desirable.
8.—Horizontal drives preferred; tight chain on top necessary for short drives without center adjustment, and desirable for long drives with or without center adjustment.
9.—Adjustable wheel centers desirable for horizontal drives and necessary for vertical drives.
10.—Avoid vertical drives.
11.—Allow a side clearance for chain (parallel to axis of sprockets and measured from nominal width of chain) equal to the pitch.
12.—Maximum linear velocity for commercial service, 1200 to 1600 ft. per min.

Comparison of Rope and Chain Drives.—Horse-power, 1200; 240 to 80 r.p.m.

	Rope.	Chain.
Distance between centers.............	42 ft.	8 ft. 4 in.
Diameter driving sheave or sprocket.......	6 ft. 4 1/2 in.	30.21 in.
Diameter driven sheave or sprocket........	20 ft.	89.42 in.

The rope drive has 30 ropes, each 1 3/4 in. diameter. The chain drive has a Morse silent chain, length, 33.5 ft.; width, 27 in.; pitch, 3 in.

Data of Some Chain Drives that Have Given Good Service

Pitch, In.	Width, In.	Speed, Ft. per Min.	Sprockets, No of Teeth.	Center Distance, In.	Rev. per Min.	H.P. Transmitted.

A chain transmission gear of 5000 H.P. has been built, with the total width of chain 168 in. The efficiency of the best chain drives when in good condition is claimed to be from 98 to 99%.

GEARING.

TOOTHED-WHEEL GEARING.

Pitch, Pitch-circle, etc. — If two cylinders with parallel axes are pressed together and one of them is rotated on its axis, it will drive the other by means of the friction between the surfaces. The cylinders may be considered as a pair of spur-wheels with an infinite number of very small teeth. If actual teeth are formed upon the cylinders, making alternate elevations and depressions in the cylindrical surfaces, the distance between the axes remaining the same, we have a pair of gear-wheels which will drive one another by pressure upon the faces of the teeth, if the teeth are properly shaped. In making the teeth the cylindrical surface may entirely disappear, but the position it occupied may still be considered as a cylindrical surface, which is called the "pitch-surface," and its trace on the end of the wheel, or on a plane cutting the wheel at right angles to its axis, is called the "pitch-circle" or "pitch-line." The diameter of this circle is called the pitch-diameter, and the distance from the face of one tooth to the corresponding face of the next tooth on the same wheel, measured on an arc of the pitch-circle, is called the "pitch of the tooth," or the circular pitch.

If two wheels having teeth of the same pitch are geared together so that their pitch-circles touch, it is a property of the pitch-circles that their diameters are proportional to the number of teeth in the wheels, and vice versa; thus, if one wheel is twice the diameter (measured on the pitch-circle) of the other, it has twice as many teeth. If the teeth are properly shaped the linear velocities of the two wheels are equal, and the angular velocities, or speeds of rotation, are inversely proportional to the number of teeth and to the diameter. Thus the wheel that has twice as many teeth as the other will revolve just half as many times in a minute.

The "pitch," or distance measured on an arc of the pitch-circle from the face of one tooth to the face of the next, consists of two parts — the "thickness" of the tooth and the "space" between it and the next tooth. The space is larger than the thickness by a small amount called the "backlash," which is allowed for imperfections of workmanship. In finely cut gears the backlash may be almost nothing.

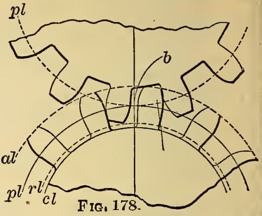

Fig. 178.

The length of a tooth in the direction of the radius of the wheel is called the "depth," and this is divided into two parts: First, the "addendum," the height of the tooth above the pitch line; second, the "dedendum," the depth below the pitch-line, which is an amount equal to the addendum of the mating gear. The depth of the space is usually given a little "clearance" to allow for inaccuracies of workmanship, especially in cast gears.

Referring to Fig. 178, *pl*, *pl* are the pitch-lines, *al* the addendum-line, *rl* the root-line or dedendum-line, *cl* the clearance-line, and *b* the backlash. The addendum and dedendum are usually made equal to each other. (Some writers make the dedendum include the clearance.)

$$\textit{Diametral pitch} = \frac{\text{No of teeth}}{\text{diam. of pitch-circle in inches}} = \frac{3.1416}{\text{circular pitch}};$$

$$\text{Circular pitch} = \frac{\text{diam.} \times 3.1416}{\text{No. of teeth}} = \frac{3.1416}{\text{diametral pitch}}.$$

Some writers use the term diametral pitch to mean $\frac{\text{diam.}}{\text{No. of teeth}} = \frac{\text{circular pitch}}{3.1416}$, but the first definition is the more common and the more convenient. A wheel of 12 in. diam. at the pitch-circle, with 48 teeth, is $48/12 = 4$ diametral pitch, or simply 4 pitch. The circular pitch of the same wheel is $12 \times 3.1416 \div 48 = 0.7854$, or $3.1416 \div 4 = 0.7854$ in.

Relation of Diametral to Circular Pitch.

Diametral Pitch.	Circular Pitch.	Diametral Pitch.	Circular Pitch.	Circular Pitch.	Diametral Pitch.	Circular Pitch.	Diametral Pitch.

$$\text{Since circ. pitch} = \frac{\text{diam.} \times 3.1416}{\text{No. of teeth}}, \text{ diam.} = \frac{\text{circ. pitch} \times \text{No. of teeth}}{3.1416},$$

which always brings out the diameter as a number with an inconvenient fraction if the pitch is in even inches or simple fractions of an inch. By the diametral-pitch system this inconvenience is avoided. The diameter may be in even inches or convenient fractions, and the number of teeth is usually an even multiple of the number of inches in the diameter.

For diameter of wheels of any other pitch than 1 in., multiply the figures in the table by the pitch. Given the diameter and the pitch, to find the number of teeth. Divide the diameter by the pitch, look in the table under diameter for the figure nearest to the quotient, and the number of teeth will be found opposite.

AUTHORITIES. — 1. Sir Wm. Fairbairn. 2, 3. Clark, R. T. D.; "used by engineers in good practice." 4. Molesworth. 5, 6. Coleman Sellers: 5 for cast, 6 for cut wheels. 7, 8. Unwin. 9, 10. Leading American manufacturers of cut gears.

The Chordal Pitch (erroneously called "true pitch" by some authors) is the length of a straight line or chord drawn from center to center of two adjacent teeth. The term is now but little used, except in connection with chain and sprocket gearing.

Chordal pitch = diam. of pitch-circle × sine of $\frac{180°}{\text{No. of teeth}}$. Chordal pitch of a wheel of 10 in. pitch diameter and 10 teeth, $10 \times \sin 18° =$ 3.0902 in. Circular pitch of same wheel = 3.1416. Chordal pitch is used with chain or sprocket wheels, to conform to the pitch of the chain.

Gears with Short Teeth. — There is a tendency in recent years to depart widely from the proportions of teeth given in the above and to use much shorter teeth, especially for heavy machinery. C. W. Hunt gives addendum and dedendum each = 0.25, and the clearance 0.05 of the circular pitch, making the total depth of tooth 0.55 of the circular pitch. The face of the tooth is involute in form, and the angle of action is $14\frac{1}{2}°$, C. H. Logue uses a 20° involute with the following proportions: Addendum $0.25P' = 0.7854 \div P$; dedendum $0.30\,P' = 0.9424 \div P$; clearance, $0.05P' = 0.157P$: whole depth $0.55P' = 1.7278 \div P$. $P' =$ circular pitch, P = diametral pitch. See papers by R. E. Flanders and Norman Litchfield in *Trans. A. S. M. E.*, 1908.

John Walker (*Am. Mach.*, Mar. 11, 1897) says: For special purposes of slow-running gearing with great tooth stress I should prefer a length of tooth of 0.4 of the pitch, but for general work a length of 0.6 of the pitch. In 1895 Mr. Walker made two pairs of cut steel gears for the Chicago cable railway with 6-in. circular pitch, length = 0.4 pitch. The pinions had 42 teeth and the gears 62, each 20-in. face. The two pairs were set side by side on their shafts, so as to stagger the teeth, making the total face 40 ins. The gears transmitted 1500 H.P. at 60 r.p.m. replacing cast-iron gears of $7\frac{1}{2}$ in. pitch which had broken in service.

Formulæ for Determining the Dimensions of Small Gears.

(Brown & Sharpe Mfg. Co.)

P = diametral pitch or the number of teeth to one inch of diameter of pitch-circle;

D' = diameter of pitch-circle D = whole diameter N = number of teeth V = velocity	Larger Wheel.	These wheels run together.
d' = diameter of pitch-circle d = whole diameter n = number of teeth v = velocity	Smaller Wheel.	

a = distance between the centers of the two wheels;
b = number of teeth in both wheels;
t = thickness of tooth or cutter on pitch-circle;
s = addendum;
D'' = working depth of tooth;
f = amount added to depth of tooth for rounding the corners and for clearance;
$D'' + f$ = whole depth of tooth;
π = 3.1416.
P' = circular pitch, or the distance from the center of one tooth to the center of the next measured on the pitch-circle.

Formulæ for a single wheel:

$$P = \frac{N+2}{D};\quad D' = \frac{D \times N}{N+2};\quad D'' = \frac{2}{P} = 2s;\quad s = \frac{1}{P} = \frac{P'}{\pi} = 0.3183\,P';$$

$$P = \frac{N}{D'};\quad D' = \frac{N}{P};\quad N = PD - 2;\ N = PD';\quad s = \frac{D'}{N} = \frac{D}{N+2};$$

$$P' = \frac{\pi}{P};\quad D = \frac{N+2}{P};\quad f = \frac{t}{10};\quad s + f = \frac{1}{P}\left(1 + \frac{\pi}{20}\right) = 0.3685\,P.$$

$$P = \frac{\pi}{P'};\quad D = D' + \frac{2}{P};\quad t = \frac{1.57}{P} = \tfrac{1}{2}P'.$$

Formulæ for a pair of wheels:

$$b = 2\,aP;\quad n = \frac{PD'V}{v};\quad D = \frac{2a\,(N+2)}{b};$$

$$N = \frac{nv}{V};\quad v = \frac{PD'V}{n};\quad d = \frac{2\,a\,(n+2)}{b};$$

$$n = \frac{NV}{v}; \qquad v = \frac{NV}{n}; \qquad a = \frac{b}{2P};$$

$$N = \frac{bv}{v+V}; \qquad V = \frac{nv}{N}; \qquad a = \frac{D' + d'}{2};$$

$$n = \frac{bV}{v+V}; \qquad D' = \frac{2av}{v+V}; \qquad d' = \frac{2aV}{v+V}.$$

Width of Teeth. — The width of the faces of teeth is generally made from 2 to 3 times the circular pitch, that is from 6.28 to 9.42 divided by the diametral pitch. There is no standard rule for width.

The following sizes are given in a stock list of cut gears in "Grant's Gears:"

Diametral pitch..	3	4	6	8	12	16
Face, inches.....	3 and 4	2 1/2	1 3/4 and 2	1 1/4 and 1 1/2	3/4 and 1	1/2 and 5/8

The Walker Company gives:

Circular pitch, in..	1/2	5/8	3/4	7/8	1	1 1/2	2	2 1/2	3	4	5	6
Face, in..........	1 1/4	1 1/2	1 3/4	2	2 1/2	4 1/2	6	7 1/2	9	12	16	20

The following proportions of gear-wheels are recommended by Prof. Coleman Sellers. (*Stevens Indicator*, April, 1892.)

Proportions of Gear-wheels.

Diametral Pitch.	Circular Pitch. P	Outside of Pitch-line. $P \times 0.3$.	Inside of Pitch-line. For Cast or Cut Bevels or for Cast Spurs. $P \times 0.4$.	Inside of Pitch-line. For Cut Spurs. $P \times 0.35$.	Width of Space. For Cast Spurs or Bevels. $P \times 0.525$.	Width of Space. For Cut Bevels or Spurs. $P \times 0.51$.

Thickness of rim below root = depth of tooth.

Rules for Calculating the Speed of Gears and Pulleys. — The relations of the size and speed of driving and driven gear-wheels are the same as those of belt pulleys. In calculating for gears, multiply or divide by the diameter of the pitch-circle or by the number of teeth, as may be required. In calculating for pulleys, multiply or divide by their diameter in inches.

If D = diam. of driving wheel, d = diam. of driven, R = revolutions per minute of driver, r = revs. per min. of driven, $RD = rd$;

$$R = rd \div D; r = RD \div d; D = dr \div R; d = DR \div r.$$

If N = No. of teeth of driver and n = No. of teeth of driven, $NR = nr$;

$$N = nr \div R; \quad n = NR \div r; \quad R = rn \div N; \quad r = RN \div n.$$

To find the number of revolutions of the last wheel at the end of a train of spur-wheels, all of which are in a line and mesh into one another, when the revolutions of the first wheel and the number of teeth or the diameter of the first and last are given: Multiply the revolutions of the first wheel by its number of teeth or its diameter, and divide the product by the number of teeth or the diameter of the last wheel.

To find the number of teeth in each wheel for a train of spur-wheels, each to have a given velocity: Multiply the number of revolutions of the driving-wheel by its number of teeth, and divide the product by the number of revolutions each wheel is to make.

To find the number of revolutions of the last wheel in a train of wheels and pinions, when the revolutions of the first or driver, and the diameter, the teeth, or the circumference of all the drivers and pinions are given; Multiply the diameter, the circumference, or the number of teeth of all the driving-wheels together, and this continued product by the number of revolutions of the first wheel, and divide this product by the continued product of the diameter, the circumference, or the number of teeth of all the driven wheels, and the quotient will be the number of revolutions of the last wheel.

EXAMPLE. — 1. A train of wheels consists of four wheels each 12 in. diameter of pitch-circle, and three pinions 4, 4, and 3 in. diameter. The large wheels are the drivers, and the first makes 36 revs. per min. Required the speed of the last wheel.

$$\frac{36 \times 12 \times 12 \times 12}{4 \times 4 \times 3} = 1296 \text{ r.p.m.}$$

2. What is the speed of the first large wheel if the pinions are the drivers, the 3-in. pinion being the first driver and making 36 revs. per min.?

$$\frac{36 \times 3 \times 4 \times 4}{12 \times 12 \times 12} = 1 \text{ r.p.m.} \quad Ans.$$

Milling Cutters for Interchangeable Gears.—The Pratt & Whitney Co. makes a series of cutters for cutting epicycloidal teeth. The number of cutters to cut from a pinion of 12 teeth to a rack is 24 for each pitch coarser than 10. The Brown & Sharpe Mfg. Co. makes a similar series, and also a series for involute teeth, in which eight cutters are made for each pitch, as follows:

No.	1	2	3	4	5	6	7	8
Will cut from	135	55	35	26	21	17	14	12
to	Rack	134	54	34	25	20	16	13

FORMS OF THE TEETH.

In order that the teeth of wheels and pinions may run together smoothly and with a constant relative velocity, it is necessary that their working faces shall be formed of certain curves called odontoids. The essential property of these curves is that when two teeth are in contact the common normal to the tooth curves at their point of contact must pass through the pitch-point, or point of contact of the two pitch-circles. Two such curves are in common use — the cycloid and the involute.

The Cycloidal Tooth. — In Fig. 179 let PL and pl be the pitch-circles of two gear-wheels; GC and gc are two equal generating-circles, whose radii should be taken as not greater than one-half of the radius of the smaller pitch-circle. If the circle gc be rolled to the left on the larger pitch-circle PL, the point 0 will describe an epicycloid, 0 *efgh*. If the other generating-circle GC be rolled to the right on PL, the point 0 will describe a hypocycloid 0 *abcd*. These two curves, which are tangent at 0, form the two parts of a tooth curve for a gear whose pitch-circle is PL. The upper part $0h$ is called the face and the lower part $0d$ is called the flank. If the same circles be rolled on the other pitch-circle pl, they will describe the curve for a tooth of the gear pl, which will work properly with the tooth on PL.

The cycloidal curves may be drawn without actually rolling the generating-circle, as follows: On the line PL, from 0, step off and mark equal distances, as 1, 2, 3, 4, etc. From 1, 2, 3, etc., draw radial lines toward the center of PL, and from 6, 7, 8, etc., draw radial lines from the same center, but beyond PL. With the radius of the generating-circle, and with centers successively placed on these radial lines, draw arcs of circles tangent to PL at 1, 2, 3, 6, 7, 8, etc. With the dividers set to one of the equal divisions, as 01, step off on the generating circle gc the points a', b', c', d', then take successively the chordal distances $0a'$, $0b'$, $0c'$, $0d'$, and lay them off on the several arcs $6e$, $7f$, $8g$, $9h$, and $1a$, $2b$, $3c$, $4d$; through the points $efgh$ and $abcd$ draw the tooth curves.

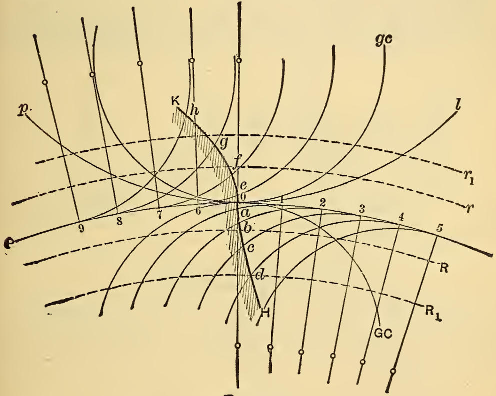

FIG. 179.

The curves for the mating tooth on the other wheel may be found in like manner by drawing arcs of the generating-circle tangent at equidistant points on the pitch-circle pl.

The tooth curve of the face $0h$ is limited by the addendum-line r or r_1, and that of the flank $0H$ by the root curve R or R_1. R and r represent the root and addendum curves for a large number of small teeth, and R_1r the like curves for a small number of large teeth. The form or appearance of the tooth therefore varies according to the number of teeth, while the pitch-circle and the generating-circle may remain the same.

In the cycloidal system, in order that a set of wheels of different diameters but equal pitches shall all correctly work together, it is necessary that the generating-circle used for the teeth of all the wheels shall be the same, and it should have a diameter not greater than half the diameter of the pitch-line of the smallest wheel of the set. The customary standard size of the generating-circle of the cycloidal system is one having a diameter equal to the radius of the pitch-circle of a wheel having 12 teeth. (Some gear-makers adopt 15 teeth.) This circle gives a radial flank to the teeth of a wheel having 12 teeth. A pinion of 10 or even a smaller number of teeth can be made, but in that case the flanks will be undercut, and the tooth will not be as strong as a tooth with radial flanks. If in any case the describing circle be half the size of the pitch-circle, the flanks will be radial; if it be less, they will spread out toward the root of the tooth, giving a stronger form; but if greater, the flanks will curve in toward each other, whereby the teeth become weaker and difficult to make.

In some cases cycloidal teeth for a pair of gears are made with the generating-circle of each gear having a radius equal to half the radius of its pitch-circle. In this case each of the gears will have radial flanks. This method makes a smooth working gear, but a disadvantage is that the wheels are not interchangeable with other wheels of the same pitch but different numbers of teeth.

The rack in the cycloidal system is equivalent to a wheel with an infinite number of teeth. The pitch is equal to the circular pitch of the mating gear. Both faces and flanks are cycloids formed by rolling the generating-circle of the mating gear-wheel on each side of the straight pitch-line of the rack.

Another method of drawing the cycloidal curves is shown in Fig. 180. It is known as the method of tangent arcs. The generating-circles, as before, are drawn with equal radii, the length of the radius being less than half the radius of *pl*, the smaller pitch-circle. Equal divisions 1, 2,

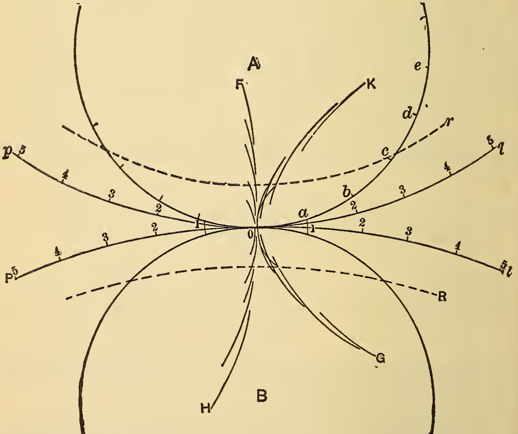

Fig. 180.

3, 4, etc., are marked off on the pitch-circles and divisions of the same length stepped off on one of the generating-circles, as 0, *a*, *b*, *c*. From the points 1, 2, 3, 4, 5 on the line *p* 0, with radii successively equal to the chord distances 0*a*, 0*b*, 0*c*, 0*d*, 0*e*, draw the five small arcs *F*. A line drawn through the outer edges of these small arcs, tangent to them all, will be the hypocycloidal curve for the flank of a tooth below the pitch-line *pl*. From the points 1, 2, 3, etc., on the line 0*l*, with radii as before, draw the small arcs *G*. A line tangent to these arcs will be the epicycloid for the face of the same tooth for which the flank curve has already been drawn. In the same way, from centers on the line *P*0, and 0*L*, with the same radii, the tangent arcs *H* and *K* may be drawn, which will give the tooth for the gear whose pitch-circle is *PL*.

If the generating-circle had a radius just one-half of the radius of *pl*, the hypocycloid *F* would be a straight line, and the flank of the tooth would have been radial.

The Involute Tooth. — In drawing the involute-tooth curve, Fig. 181, the angle of obliquity, or the angle which a common tangent to the teeth, when they are in contact at the pitch-point, makes with a line joining the centers of the wheels, is first arbitrarily determined. It is customary to take it at 15°. The pitch-lines *pl* and *PL* being drawn in contact at *O*, the line of obliquity *AB* is drawn through *O* normal to a common tangent to the tooth curves, or at the given angle of obliquity to a common tangent to the pitch-circles. In the cut the angle is 20°. From the centers of the pitch-circles draw circles *c* and *d* tangent to the line *AB*. These circles are called base-lines or base-circles, from which the involutes *F* and *K* are drawn. By laying off convenient distances, 0, 1, 2, 3, which should each be less than 1/10 of the diameter of the base-circle, small arcs can be drawn with successively increasing radii, which will form the involute. The involute extends from the points *F* and *K* down to their

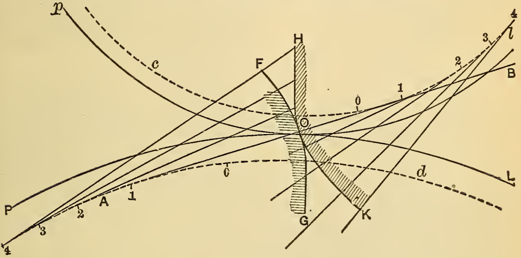

FIG. 181.

respective base-circles, where a tangent to the involute becomes a radius of the circle, and the remainders of the tooth curves, as *G* and *H*, are radial straight lines.

To draw the teeth of a rack which is to gear with an involute wheel (Fig. 182). — Let *AB* be the pitch-line of the rack and $AI = II'$ = the pitch. Through the pitch-point *I* draw *EF* at the given angle of obliquity.

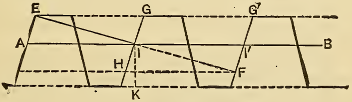

FIG. 182.

Draw *AE* and *I'F* perpendicular to *EF*. Through *E* and *F* draw lines *EGG'* and *FH* parallel to the pitch-line. *EGG'* will be the addendum-line and *HF* the flank-line. From *I* draw *IK* perpendicular to *AB* equal to the greatest addendum in the set of wheels of the given pitch and obliquity plus an allowance for clearance equal to 1/8 of the addendum. Through *K*, parallel to *AB*, draw the clearance-line. The fronts of the teeth are planes perpendicular to *EF*, and the backs are planes inclined at the same angle to *AB* in the contrary direction. The outer half of the working face *AE* may be slightly curved. Mr. Grant makes it a circular arc drawn from a center on the pitch-line with a radius = 2.1 inches divided by the diametral pitch, or 0.67 in. × circular pitch.

In the involute system the customary standard form of tooth is one having an angle of obliquity of 15° (Brown and Sharpe use 14 1/2°), an addendum of about one-third the circular pitch, and a clearance of about one-eighth of the addendum. In this system the smallest gear of a set has 12 teeth, this being the smallest number of teeth that will gear together when made with this angle of obliquity. In gears with less than 30 teeth the points of the teeth must be slightly rounded over to avoid interference (see Grant's Teeth of Gears). All involute teeth of the same pitch and with the same angle of obliquity work smoothly together. The rack to gear with an involute-toothed wheel has straight faces on its teeth, which make an angle with the middle line of the tooth equal to the angle of obliquity, or in the standard form the faces are inclined at an angle of 30° with each other.

To Draw an Angle of 15° without using a Protractor. — From *C*, on the line *AC*, with radius *AC*, draw an arc *AB*, and from *A*, with the same radius, cut the arc at *B*. Bisect the arc *BA* by drawing small arcs at *D* from *A* and *B* as centers, with the same radius, which must be greater than one-half of *AB*. Join *DC*, cutting *BA* at *E*. The angle *ECA* is 30°. Bisect the arc *AE* in like manner, and the angle *FCA* will be 15°.

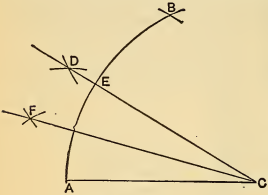

FIG. 183.

A property of involute-toothed wheels is that the distance between the axes of a pair of gears may be altered to a considerable extent without interfering with their action. The backlash is therefore variable at will, and may be adjusted by moving the wheels farther from or nearer to each other, and may thus be adjusted so as to be no greater than is necessary to prevent jamming of the teeth.

The relative merits of cycloidal and involute-shaped teeth are a subject of dispute, but there is an increasing tendency to adopt the involute tooth for all purposes.

Clark (R. T. D., p. 734) says: Involute teeth have the disadvantage of being too much inclined to the radial line, by which an undue pressure is exerted on the bearings.

Unwin (Elements of Machine Design, 8th ed., p. 265) says: The obliquity of action is ordinarily alleged as a serious objection to involute wheels. Its importance has perhaps been overrated.

George B. Grant (*Am. Mach.*, Dec. 26, 1885) says:

1. The work done by the friction of an involute tooth is always less than the same work for any possible epicycloidal tooth.
2. With respect to work done by friction, a change of the base from a gear of 12 teeth to one of 15 teeth makes an improvement for the epicycloid of less than one-half of one per cent.
3. For the 12-tooth system the involute has an advantage of 1 1/5 per cent, and for the 15-tooth system an advantage of 3/4 per cent.
4. That a maximum improvement of about one per cent can be accomplished by the adoption of any possible non-interchangeable radial flank tooth in preference to the 12-tooth interchangeable system.
5. That for gears of very few teeth the involute has a decided advantage.
6. That the common opinion among millwrights and the mechanical public in general in favor of the epicycloid is a prejudice that is founded on long-continued custom, and not on an intimate knowledge of the properties of that curve.

Wilfred Lewis (*Proc. Engrs. Club of Phila.*, vol. x, 1893) says a strong reaction in favor of the involute system is in progress, and he believes that an involute tooth of 22 1/2° obliquity will finally supplant all other forms.

Approximation by Circular Arcs. — Having found the form of the actual tooth-curve on the drawing-board, circular arcs may be found by trial which will give approximations to the true curves, and these may be used in completing the drawing and the pattern of the gear-wheels. The root of the curve is connected to the clearance by a fillet, which should be as large as possible to give increased strength to the tooth, provided it is not large enough to cause interference.

Molesworth gives a method of construction by circular arcs as follows: From the radial line at the edge of the tooth on the pitch-line, lay off the line HK at an angle of 75° with the radial line; on this line will be the centers of the root AB and the point EF. The lines struck from these centers are shown in thick lines. Circles drawn through centers thus found will give the lines in which the remaining centers will be. The radius DA for striking the root AB is the pitch + the thickness of the tooth. The radius CE for striking the point of the tooth EF = the pitch.

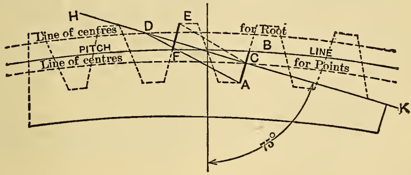

FIG. 184.

George B. Grant says: It is sometimes attempted to construct the curve by some handy method or empirical rule, but such methods are generally worthless.

Stub Gear Teeth.—The stub gear tooth developed by the Fellows Gear Shaper Co. has been largely adopted for automobile drives. The stub gear tooth has a shorter addendum and dedendum than the ordinary involute tooth. The pressure angle is 20° and the teeth are based on two diametral pitches, one of which is used to obtain the dimensions of the addendum and dedendum, while the other is used for the dimensions of the tooth thickness, the number of teeth and pitch diameter. Stub tooth gears are designated by a fraction as $^4/_5$ pitch, $^{10}/_{12}$ pitch, etc. The numerator designates the pitch determining the thickness of the tooth and number of teeth. The denominator designates the pitch determining depth of the tooth. The clearance is (0.25 ÷ diametral pitch). The advantages of this form of tooth compared to the ordinary involute gear tooth are: greater strength; same arc of rolling contact as in $14\,^1/_2$° involute tooth; avoidance of extreme sliding contact; more even wearing contact. Dimensions of the Fellows system of stub gear teeth are given in the table below:

Fellows Stub Gear Tooth System (Dimensions in Inches).

Diametral Pitch.	Thickness of Tooth.	Addendum.	Working Depth.	Depth of Space Below Pitch Line.	Clearance.	Whole Depth of Tooth.
$^4/_5$	0.3927	0.2000	0.4000	0.2500	0.0500	0.4500
$^5/_7$	.3142	.1429	.2858	.1786	.0357	.3214
$^6/_8$	.2618	.1250	.2500	.1562	.0312	.2812
$^7/_9$	.2244	.1111	.2222	.1389	.0278	.2500
$^8/_{10}$	.1963	.1000	.2000	.1250	.0250	.2250
$^9/_{11}$	.1745	.0909	.1818	.1136	.0227	.2045
$^{10}/_{12}$	.1571	.0833	.1667	.1041	.0208	.1875
$^{12}/_{14}$	.1309	.0714	.1429	.0993	.0179	.1607

Another system of stub gear teeth is also in use, in which the tooth dimensions are based upon circular pitch. The addendum is 0.250 × circular pitch, and the dedendum is 0.300 × circular pitch. The former system is the one in more general use.

Stepped Gears. — Two gears of the same pitch and diameter mounted side by side on the same shaft will act as a single gear. If one gear is keyed on the shaft so that the teeth of the two wheels are not in line, but the teeth of one wheel slightly in advance of the other, the two gears form a stepped gear. If mated with a similar stepped gear on a parallel shaft the number of teeth in contact will be twice as great as in an ordinary gear, which will increase the strength of the gear and its smoothness of action.

Twisted Teeth. — If a great number of very thin gears were placed together, one slightly in advance of the other, they would still act as a stepped gear. Continuing the subdivision until the thickness of each separate gear is infinitesimal, the faces of the teeth instead of being in steps take the form of a spiral or twisted surface, and we have a twisted gear. The twist may take any shape, and if it is in one direction for half the width of the gear and in the opposite direction for the other half, we have what is known as the herring-bone or double helical tooth. The obliquity of the twisted tooth if twisted in one direction causes an end thrust on the shaft, but if the herring-bone twist is used, the opposite obliquities neutralize each other. This form of tooth is much used in heavy rolling-mill practice, where great strength and resistance to shocks are necessary. They are frequently made of steel castings (Fig. 185). The angle of the tooth with a line parallel to the axis of the gear is usually 30°.

FIG. 185.

Spiral or Helical Gears. — If a twisted gear has a uniform twist it becomes what is commonly called a spiral gear (properly a helical gear). The line in which the pitch-surface intersects the face of the tooth is part of a helix drawn on the pitch-surface. A spiral wheel may be made with only one helical tooth wrapped around the cylinder several times, in which it becomes a screw or worm. If it has two or three teeth so wrapped, it is a double- or triple-threaded screw or worm. A spiral-gear meshing into a rack is used to drive the table of some forms of planing-machine. For methods of laying out and producing spiral gears see Brown and Sharpe's treatise on Gearing and Halsey's Worm and Spiral Gearing, also *Machy.*, May 1906 and *Machy's* Reference Series No. 20.

Worm-gearing. — When the axes of two spiral gears are at right angles, and a wheel of one, two, or three threads works with a larger wheel of many threads, it becomes a worm-gear, or endless screw, the smaller wheel or driver being called the worm, and the larger, or driven wheel, the worm-wheel. With this arrangement a high velocity ratio may be obtained with a single pair of wheels. For a one-threaded wheel the velocity ratio is the number of teeth in the worm-wheel. The worm and wheel are commonly so constructed that the worm will drive the wheel, but the wheel will not drive the worm.

To find the diameter of a worm-wheel at the throat, number of teeth and pitch of the worm being given: Add 2 to the number of teeth, multiply the sum by 0.3183, and by the pitch of the worm in inches.

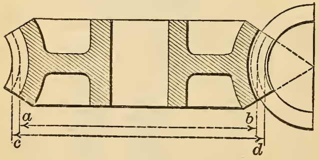

FIG. 186.

To find the number of teeth, diameter at throat and pitch of worm being given: Divide 3.1416 times the diameter by the pitch, and subtract 2 from the quotient.

In Fig. 186 *ab* is the diam. of the pitch-circle, *cd* is the diam. at the throat.

EXAMPLE. — Pitch of worm 1/4 in., number of teeth 70; required the diam. at the throat. $(70 + 2) \times 0.3183 \times 0.25 = 5.73$ in.

For design of worm gearing see Kimball and Barr's Machine Design. For efficiency of worm-gears see page 1171.

The Hindley Worm. — In the Hindley worm-gear the worm, instead of being cylindrical in outline, is of an hour-glass shape, the pitch line of the worm being a curved line corresponding to the pitch line of the gear. It is claimed that there is surface contact between the faces of the teeth of the worm and gear, instead of only line contact as in the case of the ordinary worm gear, but this is denied by some writers. For discussion of the Hindley worm see *Am. Mach.*, April 1, 1897 and *Machy.*, Dec. 1908. The Hindley gear is made by the Albro-Clem Elevator Co., Philadelphia.

Teeth of Bevel-wheels. (Rankine's Machinery and Millwork.) — The teeth of a bevel-wheel have acting surfaces of the conical kind, generated by the motion of a line traversing the apex of the conical pitch-surface, while a point in it is carried round the traces of the teeth upon a spherical surface described about that apex.

The operations of drawing the traces of the teeth of bevel-wheels exactly, whether by involutes or by rolling curves, are in every respect analogous to those for drawing the traces of the teeth of spur-wheels; except that in the case of bevel-wheels all those operations are to be performed on the surface of a sphere described about the apex, instead of on a plane, substituting poles for centers and great circles for straight lines.

In consideration of the practical difficulty, especially in the case of large wheels, of obtaining an accurate spherical surface, and of drawing upon it when obtained, the following approximate method, proposed originally by Tredgold, is generally used:

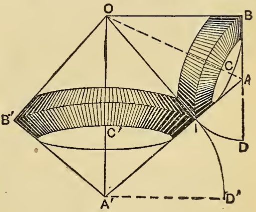

FIG. 187.

Let O, Fig. 187, be the common apex of the pitch-cones, OBI, $OB'I$, of a pair of bevel-wheels; OC, OC', the axes of those cones; OI their line of contact. Perpendicular to OI draw AIA', cutting the axes in A, A'; make the outer rims of the patterns and of the wheels portions of the cones ABI, $A'B'I$, of which the narrow zones occupied by the teeth will be sufficiently near for practical purposes to a spherical surface described about O. As the cones ABI, $A'B'I$ cut the pitch-cones at right angles in the outer pitch-circles IB, IB', they may be called the normal cones. To find the traces of the teeth upon the normal cones, draw on a flat surface circular arcs, ID, ID', with the radii AI, $A'I$; those arcs will be the developments of arcs of the pitch-circles IB, IB' when the conical surfaces ABI, $A'B'I$ are spread out flat. Describe the traces of teeth for the developed arcs as for a pair of spur-wheels, then wrap the developed arcs on the normal cones, so as to make them coincide with the pitch-circles, and trace the teeth on the conical surfaces.

For formulæ and instructions for designing bevel-gears, and for much other valuable information on the subject of gearing, see "Practical Treatise on Gearing," and "Formulas in Gearing," published by Brown & Sharpe Mfg. Co.; and "Teeth of Gears," by George B. Grant, Lexington, Mass. The student may also consult Rankine's Machinery and Millwork, Reuleaux's Constructor, and Unwin's Elements of Machine Design. See also article on Gearing, by C. W. MacCord in App. Cyc. Mech., vol. ii.

Annular and Differential Gearing. (S. W. Balch, *Am. Mach.*, Aug. 24, 1893.) — In internal gears the sum of the diameters of the describing circles for faces and flanks should not exceed the difference in the pitch diameters of the pinion and its internal gear. The sum may be equal to this difference or it may be less; if it is equal, the faces of the teeth of each wheel will drive the faces as well as the flanks of the teeth of the other wheel. The teeth will therefore make contact with each other at two points at the same time.

Cycloidal tooth-curves for interchangeable gears are formed with describing circles of about 5/8 the pitch diameter of the smallest gear of the series. To admit two such circles between the pitch-circles of the pinion and internal gear the number of teeth in the internal gear should exceed the number in the pinion by 12 or more, if the teeth are of the customary proportions and curvature used in interchangeable gearing.

Very often a less difference is desirable, and the teeth may be modified in several ways to make this possible.

First. The tooth curves resulting from smaller describing circles may be employed. These will give teeth which are more rounding and narrower at their tops, and therefore not as desirable as the regular forms.

Second. The tips of the teeth may be rounded until they clear. This is a cut-and-try method which aims at modifying the teeth to such outlines as smaller describing circles would give.

Third. One of the describing circles may be omitted and one only used, which may be equal to the difference between the pitch-circles. This will permit the meshing of gears differing by six teeth. It will usually prove inexpedient to put wheels in inside gears that differ by much less than 12 teeth.

If a regular diametral pitch and standard tooth forms are determined on, the diameter to which the internal gear-blank is to be bored is calculated by subtracting 2 from the number of teeth, and dividing the remainder by the diametral pitch.

The tooth outlines are the match of a spur-gear of the same number of teeth and diametral pitch, so that the spur-gear will fit the internal gear as a punch fits its die, except that the teeth of each should fail to bottom in the tooth spaces of the other by the customary clearance of one-tenth the thickness of the tooth.

Internal gearing is particularly valuable when employed in differential action. This is a mechanical movement in which one of the wheels is mounted on a crank so that its center can move in a circle about the center of the other wheel. Means are added which restrain the wheel on the crank from turning over and confine it to the revolution of the crank.

The ratio of the number of teeth in the revolving wheel compared with the difference between the two will represent the ratio between the revolving wheel and the crank-shaft by which the other is carried. The advantage in accomplishing the change of speed with such an arrangement, as compared with ordinary spur-gearing, lies in the almost entire absence of friction and consequent wear of the teeth.

But for the limitation that the difference between the wheels must not be too small, the possible ratio of speed might be increased almost indefinitely, and one pair of differential gears made to do the service of a whole train of wheels. If the problem is properly worked out with bevel-gears this limitation may be completely set aside, and external and internal bevel-gears, differing by but a single tooth if need be, made to mesh perfectly with each other.

EFFICIENCY OF GEARING.

An extensive series of experiments on the efficiency of gearing, chiefly worm and spiral gearing, is described by Wilfred Lewis in *Trans. A. S. M. E.*, vii, 273. The average results are shown in a diagram, from which the following approximate average figures are taken:

EFFICIENCY OF SPUR, SPIRAL, AND WORM-GEARING.

Gearing.	Pitch.	Velocity at pitch-line in feet per min.				
		3	10	40	100	200
Spur pinion...............	....	0.90	0.935	0.97	0.98	0.985
Spiral pinion.............	45°	.81	.87	.93	.955	.965
" "	30	.75	.815	.89	.93	.945
" "	20	.67	.75	.845	.90	.92
" "	15	.61	.70	.805	.87	.90
Spiral pinion or worm.....	10	.51	.615	.74	.82	.86
" " "	7	.43	.53	.72	.765	.815
" " "	5	.34	.43	.60	.70	.765

The experiments showed the advantage of spur-gearing over all other kinds in both durability and efficiency. The variation from the mean results rarely exceeded 5% in either direction, so long as no cutting occurred, but the variation became much greater and very irregular as soon as cutting began. The loss of power varies with the speed, the pressure, the temperature, and the condition of the surfaces. The high friction of worm- and spiral-gearing is largely due to end thrust on the collars of the shaft, and may be considerably reduced by roller-bearings for the collars.

When two worms with opposite spirals run in two spiral worm-gears that also work with each other, and the pressure on one gear is opposite that on the other, there is no thrust on the shaft. Even with light loads a worm will begin to heat and cut if run at too high a speed, the limit for safe working being a velocity of the rubbing surfaces of 200 to 300 ft. per minute, the former being preferable where the gearing has to work continuously. The wheel teeth will keep cool, as they form part of a casting having a large radiating surface; but the worm itself is so small that its heat is dissipated slowly. Whenever the heat generated increases faster than it can be conducted and radiated away, the cutting of the worm may be expected to begin. A low efficiency for a worm-gear means more than the loss of power, since the power which is lost reappears as heat and may cause the rapid destruction of the worm.

Unwin (Elements of Machine Design, p. 294) says: The efficiency is greater the less the radius of the worm. Generally the radius of the worm = 1.5 to 3 times the pitch of the thread of the worm or the circular pitch of the worm-wheel. For a one-threaded worm the efficiency is only 2/5 to 1/4: for a two-threaded worm, 4/7 to 2/5; for a three-threaded worm, 2/3 to 1/2. As so much work is wasted in friction it is natural that the wear is excessive. The table below gives the calculated efficiencies of worm-wheels of 1, 2, 3, and 4 threads and ratios of radius of worm to pitch of teeth of from 1 to 6, with a coefficient of friction of 0.15.

No. of Threads.	Radius of Worm ÷ Pitch.								
	1	1 1/4	1 1/2	1 3/4	2	2 1/2	3	4	6
1	0.50	0.44	0.40	0.36	0.33	0.28	0.25	0.20	0.14
2	.67	.62	.57	.53	.50	.44	.40	.33	.25
3	.75	.70	.67	.63	.60	.55	.50	.43	.33
4	.80	.76	.73	.70	.67	.62	.57	.50	.40

Efficiency of Worm Gearing. — Worm gearing as a means of transmitting power has generally been looked upon with suspicion, its efficiency being considered necessarily low and its life short. When properly proportioned, however, it is both durable and reasonably efficient. Mr. F. A. Halsey discusses the subject in *Am. Machinist*, Jan. 13 and 20, 1898. He quotes two formulas for the efficiency of worm gearing:

$$E = \frac{\tan\alpha\,(1 - f\tan\alpha)}{\tan\alpha + f}, \ldots (1) \qquad E = \frac{\tan\alpha\,(1 - f\tan\alpha)}{\tan\alpha + 2f} \text{ approx.,} \ldots (2)$$

in which E = efficiency; α = angle of thread, being angle between thread and a line perpendicular to the axis of the worm; f = coefficient of friction.

Eq. (1) applies to the worm thread only, while (2) applies to the worm and step combined, on the assumption that the mean friction radius of the two is equal. Eq. (1) gives a maximum for E when $\tan\alpha = \sqrt{1 + f^2} - f$ . . . (3) and eq. (2) a maximum when $\tan\alpha = \sqrt{2 + 4f^2} - 2f$ . . . . (4) Using 0.05 for f gives α in (3) = 43° 34′ and in (4) = 52° 49′.

On plotting equations (1) and (2) the curves show the striking influence of the pitch-angle upon the efficiency, and since the lost work is expended in friction and wear, it is plain why worms of low angle should be short-lived and those of high angle long-lived. The following table is taken from Mr. Halsey's plotted curves:

RELATION OF THREAD-ANGLE, SPEED AND EFFICIENCY OF WORM-GEARS.

Velocity of Pitch-line, Feet per Minute.	Angle of Thread.					
	5	10	20	30	40	45
	Efficiency.					
3	35	52	66	73	76	77
5	40	56	69	76	79	80
10	47	62	74	79	82	82
20	52	67	78	83	85	86
40	60	74	83	87	88	88
100	70	82	88	91	91	91
200	76	85	91	92	92	92

The experiments of Mr. Wilfred Lewis on worms show a very satisfactory correspondence with the theory. Mr. Halsey gives a collection of data comprising 16 worms doing heavy duty and having pitch-angles ranging between 4° 30′ and 45°, which show that every worm having an angle above 12° 30′ was successful in regard to durability, and every worm below 9° was unsuccessful, the overlapping region being occupied by worms some of which were successful and some unsuccessful. In several cases worms of one pitch-angle had been replaced by worms of a different angle, an increase in the angle leading in every case to better results and a decrease to poorer results. He concludes with the following table from experiments by Mr. James Christie, of the Pencoyd Iron Works, and gives data connecting the load upon the teeth with the pitch-line velocity of the worm.

LIMITING SPEEDS AND PRESSURES OF WORM GEARING.

	Single-thread Worm 1″ Pitch, $2\frac{7}{8}$ Pitch Diam.				Double-thread Worm 2″ Pitch, $2\frac{7}{8}$ Pitch Diam.			Double-thread Worm $2\frac{1}{2}$″ Pitch, $4\frac{1}{2}$ Pitch Diam.

Efficiency of Automobile Gears. (G. E. Quick, *Horseless Age*, Feb.12, 1908.)—A set of slide gears was tested by an electric-driven absorption dynamometer. The following approximate results are taken from a series of plotted curves:

Horse-power input............		2	4	6	8	10	14	18
	r.p.m.	Efficiency, per cent.						
Direct driven, third speed......	800	89	95	97	97.5	97.5	97.5	96
Direct driven, third speed......	1,500	80	89	93	95	96.5	97	97
Second speed, ratio 1.76 to 1 ...	800	87	92.5	94	95	94	93	.....
Second speed, ratio 1.76 to 1 ...	1,500	79	88	92.5	94	95	95	94
First speed, ratio 3.36 to 1.....	800	75	87.5	93	94	94	93.5	92.5
First speed, ratio 3.36 to 1......	1,500	70	84	89	92	93	92	.....
Reverse speed, ratio 4.32 to 1...	800	75	84	87	87	86	82.5	.....
Reverse speed, ratio 4.32 to 1...	1,500	.....	70	79	83	86	87	85
Worm-gear axle, ratio 6.83 to 1..	400	85	87	86.5	85.5	84	80	75
Worm-gear axle, ratio 6.83 to 1..	800	83	87	88.5	89	89	88	87
Worm-gear axle, ratio 6.83 to 1..	1,500	80	85	87.5	88.5	89	89	89

Two bevel-wheel axles were tested, one a floating type, ratio 15 to 32, $14\frac{1}{2}$° involute; the other a solid wheel and axle type, ratio 13 to 54, 20° involute. Both gave efficiencies of 95 to 96 % at 800 to 1500 r.p.m., and 10 to 26 H.P., with lower efficiencies at lower power and at lower speed. The friction losses include those of the journals and thrust ball bearings.

The worm was 6-threaded, lead, 4.69 in.; pitch diam., 2.08 in.; the gear had 41 teeth; pitch diam., 10.2 in. The worm was of hardened steel and the gear of phosphor-bronze. A test of a steel gear and steel worm gave somewhat lower efficiencies. In both tests the heating was excessive both in the gears and in the thrust bearings, the balls in which were $\frac{7}{16}$ in. diam.

STRENGTH OF GEAR-TEETH.

The strength of gear-teeth and the horse-power that may be transmitted by them depend upon so many variable and uncertain factors that it is not surprising that the formulas and rules given by different writers show a wide variation. In 1879 John H. Cooper (*Jour. Frank. Inst.*, July, 1879) found that there were then in existence about 48 well-established rules for horse-power and working strength, differing from each other in extreme cases about 500%. In 1886 Prof. Wm. Harkness (*Proc. A. A. A. S.*, 1886), from an examination of the bibliography of the subject, beginning in 1796, found that according to the constants and formulæ used by various authors there were differences of 15 to 1 in the power which could be transmitted by a given pair of geared wheels. The various elements which enter into the constitution of a formula to represent the working strength of a toothed wheel are the following: 1. The strength of the metal, usually cast iron, which is an extremely variable quantity. 2. The shape of the tooth, and especially the relation of its thickness at the root or point of least strength to the pitch and to the length. 3. The point at which the load is taken to be applied, assumed by some authors to be at the pitch-line, by others at the extreme end, along the whole face, and by still others at a single outer corner. 4. The consideration of whether the total load is at any time received by a single tooth or whether it is divided between two teeth. 5. The influence of velocity in causing a tendency to break the teeth by shock. 6. The factor of safety assumed to cover all the uncertainties of the other elements of the problem.

Prof. Harkness, as a result of his investigation, found that all the formulæ on the subject might be expressed in one of three forms, viz.:

$$\text{Horse-power} = CVpf, \quad \text{or} \quad CVp^2, \quad \text{or} \quad CVp^2f;$$

in which C is a coefficient, V = velocity of pitch-line in feet per second, p = pitch in inches, and f = face of tooth in inches.

From an examination of precedents he proposed the following formula for cast-iron wheels:

$$\text{H.P.} = \frac{0.910\ Vpf}{\sqrt{1 + 0.65\ V}}.$$

He found that the teeth of chronometer and watch movements were subject to stresses four times as great as those which any engineer would dare to use in like proportion upon cast-iron wheels of large size.

It appears that all of the earlier rules for the strength of teeth neglected the consideration of the variations in their form; the breaking strength, as said by Mr. Cooper, being based upon the thickness of the teeth at the pitch-line or circle, as if the thickness at the root of the tooth were the same in all cases as it is at the pitch-line.

Wilfred Lewis (*Proc. Eng'rs Club, Phila.*, Jan., 1893; *Am. Mach.*, June 22, 1893) seems to have been the first to use the form of the tooth in the construction of a working formula and table. He assumes that in well-constructed machinery the load can be more properly taken as well distributed across the tooth than as concentrated in one corner, but that it cannot be safely taken as concentrated at a maximum distance from the root less than the extreme end of the tooth. He assumes that the whole load is taken upon one tooth, and considers the tooth as a beam loaded at one end, and from a series of drawings of teeth of the involute, cycloidal, and radial flank systems, determines the point of weakest cross-section of each, and the ratio of the thickness at that section to the pitch. He thereby obtains the general formula,

$$W = spfy;$$

in which W is the load transmitted by the teeth, in pounds; s is the safe working stress of the material, taken at 8000 lbs. for cast iron, when the working speed is 100 ft. or less per minute; p = pitch; f = face, in inches; y = a factor depending on the form of the tooth, whose value for different cases is given in the table on page 1174.

The values of s in the above table are given by Mr. Lewis tentatively, in the absence of sufficient data upon which to base more definite values, but they have been found to give satisfactory results in practice.

Example. Required to find the working strength of a 12-toothed pinion, 1-inch pitch, 2½-inch face, driving a wheel of 60 teeth at 100 feet or less per minute, and let the teeth be of the 20-degree involute form. In the formula $W = spfy$ we have for a cast-iron pinion $s = 8000$, $pf = 2.5$, and $y = 0.078$; and multiplying these values together, we have $W = 1560$ pounds. For the wheel we have $y = 0.134$ and $W = 2680$ pounds.

The cast-iron pinion is, therefore, the measure of strength; but if a steel pinion be substituted we have $s = 20{,}000$ and $W = 3900$ pounds, in which combination the wheel is the weaker, and it therefore becomes the measure of strength.

For bevel-wheels Mr. Lewis gives the following, referring to Fig. 188:

D = large diameter of bevel; d = small diameter of bevel; p = pitch at large diameter; n = actual number of teeth; f = face of bevel; N = formative number of teeth = $n \times$ secant a, or the number corresponding to radius R; y = factor depending upon shape of teeth and formative number N; W = working load on teeth, assumed to be applied at the large end of the bevel gear on the pitch line.

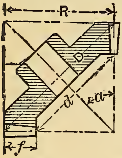

FIG. 188.

$$W = spfy\ \frac{D^3-d^3}{3D^2(D-d)}\text{; or, more simply, } W = spfy\ \frac{d}{D};$$

which gives almost identical results when d is not less than $^2/_3\ D$, as is the case in good practice.

In *Am. Mach.*, June 22, 1893, Mr. Lewis gives the following formulæ for the working strength of the three systems of gearing, which agree very closely with those obtained by use of the table:

For involute, 20° obliquity, $W = spf\left(0.154 - \frac{0.912}{n}\right)$;

For involute 15°, and cycloidal, $W = spf\left(0.124 - \frac{0.684}{n}\right)$;

For radial flank system, $W = spf\left(0.075 - \frac{0.276}{n}\right)$;

in which the factor within the parenthesis corresponds to y in the general formula. For the horse-power transmitted, Mr. Lewis's general formula $W = spfy = \frac{33{,}000 \text{ H.P.}}{v}$, may take the form $\text{H.P.} = \frac{spfyv}{33{,}000}$, in which v = velocity in feet per minute; or since $v = d\pi \times$ r.p.m. $\div 12 =$ v .2618 $d \times$ r.p.m., in which d = diameter in inches,

$$\text{H.P.} = \frac{Wv}{33{,}000} = \frac{spfy \times d \times \text{r.p.m.}}{126{,}050} = 0.000007933\ dspfy \times \text{r.p.m.}$$

It must be borne in mind, however, that in the case of machines which consume power intermittently, such as punching and shearing machines, the gearing should be designed with reference to the maximum load W, which can be brought upon the teeth at any time, and not upon the average horse-power transmitted.

SAFE WORKING STRESS, s, FOR DIFFERENT SPEEDS.

Speed of Teeth in Ft. per Minute.	100 or less.	200	300	600	900	1200	1800	2400
Cast iron	8000	6000	4800	4000	3000	2400	2000	1700
Steel	20000	15000	12000	10000	7500	6000	5000	4300

Comparison of the Harkness and Lewis Formulæ. — Take an average case in which the safe working strength of the material, $s = 6000$,

$v = 200$ ft. per min., and $y = 0.100$, the value in Mr. Lewis's table for an involute tooth of 15° obliquity, or a cycloidal tooth, the number of teeth in the wheel being 27.

$$\text{H.P.} = \frac{spfyv}{33{,}000} = \frac{6000\ pfv \times 0.100}{33{,}000} = \frac{pfv}{55} = 1.091\ pfV,$$

if V is taken in feet per second.

Prof. Harkness gives $\text{H.P.} = \dfrac{0.910\ Vpf}{\sqrt{1 + 0.65\ V}}$. If the V in the denominator be taken at $200 \div 60 = 3\frac{1}{3}$ ft. per sec., H.P. $= 0.571\ pfV$, or about 52% of the result given by Mr. Lewis's formula. This is probably as close an agreement as can be expected, since Prof. Harkness derived his formula from an investigation of ancient precedents and rule-of-thumb practice, largely with common cast gears, while Mr. Lewis's formula was derived from considerations of modern practice with machine-molded and cut gears.

Mr. Lewis takes into consideration the reduction in working strength of a tooth due to increase in velocity by the figures in his table of the values of the safe working stress s for different speeds. Prof. Harkness gives expression to the same reduction by means of the denominator of his formula, $\sqrt{1 + 0.65\ V}$. The decrease in strength as computed by this formula is somewhat less than that given in Mr. Lewis's table, and as the figures given in the table are not based on accurate data, a mean between the values given by the formula and the table is probably as near to the true value as may be obtained from our present knowledge. The following table gives the values for different speeds according to Mr. Lewis's table and Prof. Harkness's formula, taking for a basis a working stress s, for cast-iron 8000, and for steel 20,000 lbs. at speeds of 100 ft. per minute and less:

v = speed of teeth, ft. per min.	100	200	300	600	900	1200	1800	2400
V = speed of teeth, ft. per sec.	$1\frac{2}{3}$	$3\frac{1}{3}$	5	10	15	20	30	40
Safe stress s, cast iron, Lewis	8000	6000	4800	4000	3000	2400	2000	1700
Relative do., $s \div 8000$	1	0.75	0.6	0.5	0.375	0.3	0.25	0.2125
$1 \div \sqrt{1 + 0.65\ V}$	.6930	.5621	.4850	.3650	.3050	.2672	.2208	.1924
Relative val. $c \div 0.693$	1	0.811	0.700	0.526	0.439	0.385	0.318	0.277
$s_1 = 8000 \times (c \div 0.693)$	8000	6488	5600	4208	3512	3080	2544	2216
Mean of s and s_1, cast-iron = s_2	8000	6200	5200	4100	3300	2700	2300	2000
Mean of s and s_1, for steel = s_3	20000	15500	13000	10300	8100	6800	5700	4900
Safe stress for steel, Lewis	20000	15000	12000	10000	7500	6000	5000	4300

In *Am. Mach.*, Jan. 30, 1902, Mr. Lewis says that 8,000 lbs. was given as safe for cast-iron teeth, either cut or cast, and that 20,000 lbs. was intended for any steel suitable for gearing whether cast or forged. These were the unit stresses for static loads.

The iron should be of good quality capable of sustaining about a ton on a test bar 1 in. square between supports 12 in. apart, and the steel should be solid and of good quality. The value given for steel was intended to include the lower grades, but when the quality is known to be high, correspondingly higher values may be assigned.

Comparing the two formulæ for the case of $s = 8000$, corresponding to a speed of 100 ft. per min., we have

$$\text{Harkness: H.P.} = 1 \div \sqrt{1 + 0.65\ V} \times 0.910 Vpf = 1.053\ pf,$$

$$\text{Lewis: H.P.} = \frac{spfyv}{33{,}000} = \frac{spfy\ V}{550} = \frac{8000 \times 1\frac{2}{3}\ pfy}{550} = 24.24\ pfy$$

in which y varies according to the shape and number of the teeth.

For radial-flank gear with 12 teeth $y = 0.052$; $24.24\ pfy = 1.260 pf$;
For 20° inv., 19 teeth, or 15° inv., 27 teeth $y = 0.100$; $24.24\ pfy = 2.424 pf$;
For 20° involute, 300 teeth $y = 0.150$; $24.24\ pfy = 3.636 pf$.

Thus the weakest-shaped tooth, according to Mr. Lewis, will transmit 20 per cent more horse-power than is given by Prof. Harkness's formula, in which the shape of the tooth is not considered, and the average-shaped tooth, according to Mr. Lewis, will transmit more than double the horse-power given by Prof. Harkness's formula.

Comparison of Other Formulæ.—Mr. Cooper, in summing up his examination, selected an old English rule, which Mr. Lewis considers as a passably correct expression of good general averages, viz.: $X = 2000\ pf$, X = breaking load of tooth in pounds, p = pitch, f = face. If a factor of safety of 10 be taken, this would give for safe working load $W = 200\ pf$.

George B. Grant, in his Teeth of Gears, page 33, takes the breaking load at 3500 pf, and, with a factor of safety of 10, gives $W = 350\ pf$.

Nystrom's Pocket-Book, 20th ed., 1891, says: "The strength and durability of cast-iron teeth require that they shall transmit a force of 80 lbs. per inch of pitch and per inch breadth of face." This is equivalent to $W = 80\ pf$, or only 40% of that given by the English rule.

F. A. Halsey (Clark's Pocket-Book) gives a table calculated from the formula $\text{H.P.} = pfd \times \text{r.p.m.} \div 850$.

Jones & Laughlins give $\text{H.P.} = pfd \times \text{r.p.m.} \div 550$.

These formulæ transformed give $W = 128\ pf$ and $W = 218\ pf$, respectively.

Unwin, on the assumption that the load acts on the corners of the teeth, derives a formula $p = K\sqrt{W}$, in which K is a coefficient derived from existing wheels, its values being: for slowly moving gearing not subject to much vibration or shock $K = 0.04$; in ordinary mill-gearing, running at greater speed and subject to considerable vibration, $K = 0.05$; and in wheels subjected to excessive vibration and shock, and in mortise gearing, $K = 0.06$. Reduced to the form $W = Cpf$, assuming that $f = 2\,p$, these values of K give $W = 262\ pf$, $200\ pf$. and $139\ pf$, respectively.

Unwin also give the following, based on the assumption that the pressure is distributed along the edge of the tooth: $p = K_1\sqrt{p/f}\sqrt{W}$, where K_1 = about 0.0707 for iron wheels and 0.0848 for mortise wheels when the breadth of face is not less than twice the pitch. For the case of $f = 2\,p$ and the given values of K_1 this reduces to $W = 200\ pf$ and $W = 139\ pf$, respectively.

Box, in his Treatise on Mill Gearing, gives $\text{H.P.} = 12\,p^2f\sqrt{dn} \div 1000$, in which n = number of revolutions per minute. This formula differs from the more modern formulæ in making the H.P. vary as p^2f, instead of as pf, and in this respect it is no doubt incorrect.

Making the H.P. vary as $\sqrt{dn}$ or as $\sqrt{v}$, instead of directly as v, makes the velocity a factor of the working strength as in the Harkness and Lewis formulæ, the relative strength varying as $1/\sqrt{v}$, which for different velocities is as follows:

Speed of teeth in ft. per min., v =	100	200	300	600	900	1200	1800	2400
Relative strength =	1	0.707	0.574	0.408	0.333	0.289	0.236	0.20

showing a somewhat more rapid reduction than is given by Mr. Lewis.

For the purpose of comparing different formulæ they may in general be reduced to either of the following forms:

$$\text{H.P.} = Cpfv, \qquad \text{H.P.} = C_1pfd \times \text{r.p.m.}, \qquad W = cpf,$$

in which p = pitch, f = face, d = diameter, all in inches; v = velocity in feet per minute, r.p.m. revolutions per minute, and C, C_1 and c coefficients. The formulæ for transformation are as follows:

$$\text{H.P.} = Wv \div 33{,}000 = W \times d \times \text{r.p.m.} \div 126{,}050;$$

$$W = \frac{33{,}000\ \text{H.P.}}{v} = \frac{126{,}050\ \text{H.P.}}{d \times \text{r.p.m.}} = 33{,}000\ Cpf;\ pf = \frac{\text{H.P.}}{Cv} = \frac{\text{H.P.}}{C_1 d \times \text{r.p.m.}} = \frac{W}{c}$$

$$C_1 = 0.2618\ C;\ c = 33{,}000\ C;\ C = 3.82\ C_1, = \frac{c}{33{,}000};\ c = 126{,}050\ C_1.$$

In the Lewis formula C varies with the form of the tooth and with the speed, and is equal to $sy \div 33{,}000$, in which y and s are the values taken from the table, and $c = sy$.

In the Harkness formula C varies with the speed and is equal to

$\frac{910}{\sqrt{1 + 0.65\ V}}$ (V being in feet per second), $= 0.01517 \div \sqrt{1 + 0.011\ v}$.

In the Box formula C varies with the pitch and also with the velocity; and equals $\frac{12\ p\ \sqrt{d} \times \text{r.p.m.}}{1000\ v} = 0.02345 \frac{p}{\sqrt{v}}$, $c = 33{,}000\ C = 774 \frac{p}{\sqrt{v}}$.

For $v = 100$ ft. per min. $C = 77.4\ p$; for $v = 600$ ft. per min., $c = 31.6\ p$. In the other formulæ considered C, C_1, and c are constants. Reducing the several formulæ to the form $W = cpf$, we have the following:

COMPARISION OF DIFFERENT FORMULÆ FOR STRENGTH OF GEAR-TEETH.

Safe working pressure per inch pitch and per inch of face, or value of c in formula $W = cpf$:

	v = ft. per min. 100	600
Lewis: Weak form of tooth, radial flank, 12 teeth c =	416	208
Medium tooth, inv. 15°, or cycloid, 27 teeth . c =	800	400
Strong form of tooth, inv. 20°, 300 teeth. . c =	1200	600
Harkness: Average tooth.................... c =	347	184
Box: Tooth of 1 inch pitch.................. c =	77.4	31.6
Box: Tooth of 3 inches pitch................ c =	232	95

The Gleason Works gives for ft. per min.	500	1000	1500	2000	2500
working stress in pounds = p.f. ×	480	400	340	290	240

These are for cut gears, 18 teeth or more, rigidly supported, for average steady loads. Hammering loads, as in rolling mills and saw mills, require heavier gears.

C. W. Hunt, *Trans.* A.S.M.E., 1908, gives a table of working loads of cut cast gears with a strong short form of tooth, which is practically equivalent to $W = 700$ pf.

Various, in which c is independent of form and speed: Old English rule, $c = 200$; Grant, $c = 350$; Nystrom, $c = 80$; Halsey, $c = 128$; Jones & Laughlins, $c = 218$; Unwin, $c = 262$, 200, or 139, according to speed, shock, and vibration.

The value given by Nystrom and those given by Box for teeth of small pitch are so much smaller than those given by the other authorities that they may be rejected as having an entirely unnecessary surplus of strength. The values given by Mr. Lewis seem to rest on the most logical basis, the form of the teeth as well as the velocity being considered; and since they are said to have proven satisfactory in an extended machine practice, they may be considered reliable for gears that are so well made that the pressure bears along the face of the teeth instead of upon the corners. For rough ordinary work the old English rule $W = 200\ pf$ is probably as good as any, except that the figure 200 may be too high for weak forms of tooth and for high speeds.

The formula $W = 200\ pf$ is equivalent to H.P. $= pfd \times$ r.p.m. $\div 630 = pfv \div 165$ or, H.P. $= 0.0015873\ pfd \times$ r.p.m. $= 0.006063\ pfv$.

Raw-hide Pinions. — Pinions of raw-hide are in common use for gearing shafts driven by electric motors to other shafts which carry machine-cut cast-iron or steel gears, in order to reduce vibration, noise and wear. A formula for the maximum horse-power to be transmitted by such gears, given by the New Process Raw-Hide Co., Syracuse, N. Y., is H.P. = pitch diam. × circ. pitch × face × r.p.m. ÷ 850, or $pfd \times$ r.p.m. ÷ 850. This is about 3/4 of the H.P. for cast-iron teeth by the old English rule. The formula is to be used only when the circular pitch does not exceed 1.65 ins.

Composite gears also are made, consisting of alternate sheets of raw-hide or fibre and steel or bronze, so that a high degree of strength is combined with the smooth-running quality of the fibre.

Maximum Speed of Gearing. — A. Towler, *Eng'g*, April 19, 1889, p. 388, gives the maximum speeds at which it was possible under favorable conditions to run toothed gearing safely as follows, in ft. per min.: Ordinary cast-iron wheels, 1800; Helical, 2400; Mortise, 2400; Ordinary cast-steel wheels, 2600; Helical, 3000; special cast-iron machine-cut wheels, 3000.

Prof. Coleman Sellers (*Stevens Indicator*, April, 1892) recommends that gearing be not run over 1200 ft. per minute, to avoid great noise. The

Walker Company, Cleveland, Ohio, say that 2200 ft. per min. for iron gears and 3000 ft. for wood and iron (mortise gears) are excessive, and should be avoided if possible. The Corliss engine at the Philadelphia Exhibition (1876) had a fly-wheel 30 ft. in diameter running 35 r.p.m. geared into a pinion 12 ft. diam. The speed of the pitch-line was 3300 ft. per min.

A Heavy Machine-cut Spur-gear was made in 1891 by the Walker Company, Cleveland, Ohio, for a diamond mine in South Africa, with dimensions as follows: Number of teeth, 192; pitch diameter, 30 ft. 6.66 ins.; face, 30 ins.; pitch, 6 ins.; bore, 27 ins.; diameter of hub, 9 ft. 2 ins.; weight of hub, 15 tons; and total weight of gear, 66 3/4 tons. The rim was made in 12 segments, the joints of the segments being fastened with two bolts each. The spokes were bolted to the middle of the segments and to the hub with four bolts in each end.

Frictional Gearing. — In frictional gearing the wheels are toothless, and one wheel drives the other by means of the friction between the two surfaces which are pressed together. They may be used where the power to be transmitted is not very great; when the speed is so high that toothed wheels would be noisy; when the shafts require to be frequently put into and out of gear or to have their relative direction of motion reversed; or when it is desired to change the velocity-ratio while the machinery is in motion, as in the case of disk friction-wheels for changing the feed in machine tools.

Let P = the normal pressure in pounds at the line of contact by which two wheels are pressed together, T = tangential resistance of the driven wheel at the line of contact, f = the coefficient of friction, V the velocity of the pitch-surface in feet per second, and H.P. = horse-power; then T may be equal to or less than fP; H.P. $= TV \div 550$. The value of f for metal on metal may be taken at 0.15 to 0.20; for wood on metal, 0.25 to 0.30; and for wood on compressed paper, 0.20. The tangential driving force T may be as high as 80 lbs. per inch width of face of the driving surface, but this is accompanied by great pressure and friction on the journal-bearings.

In frictional grooved gearing circumferential wedge-shaped grooves are cut in the faces of two wheels in contact. If P = the force pressing the wheels together, and N = the normal pressure on all the grooves, $P = N(\sin a + f \cos a)$, in which $2a$ = the inclination of the sides of the grooves, and the maximum tangential available force $T = fN$. The inclination of the sides of the grooves to a plane at right angles to the axis is usually 30°.

Frictional Grooved Gearing. — A set of friction-gears for transmitting 150 H.P. is on a steam-dredge described in *Proc. Inst. M. E.*, July, 1888. Two grooved pinions of 54 in. diam., with 9 grooves of 1 3/4 in. pitch and angle of 40° cut on their face, are geared into two wheels of 127 1/2 in. diam. similarly grooved. The wheels can be thrown in and out of gear by levers operating eccentric bushes on the large wheel-shaft. The circumferential speed of the wheels is about 500 ft. per min. Allowing for engine friction, if half the power is transmitted through each set of gears the tangential force at the rims is about 3960 lbs., requiring, if the angle is 40° and the coefficient of friction 0.18, a pressure of 7524 lbs. between the wheels and pinion to prevent slipping.

The wear of the wheels proving excessive, the gears were replaced by spur-gear wheels and brake-wheels with steel brake-bands, which arrangement has proven more durable than the grooved wheels. Mr. Daniel Adamson states that if the frictional wheels had been run at a higher speed the results would have been better, and says they should run at least 30 ft. per second.

Power Transmitted by Friction Drives. (W. F. M. Goss, *Trans. A. S. M. E.*, 1907.)—A friction drive consists of a fibrous or somewhat yielding driving wheel working in rolling contact with a metallic driven wheel. Such a drive may consist of a pair of plain cylinder wheels mounted upon parallel shafts, or a pair of beveled wheels, or of any other arrangement which will serve in the transmission of motion by rolling contact.

Driving wheels of each of the materials named in the table below were tested in peripheral contact with driving wheels of iron, aluminum and type metal. All the wheels were 16 in. diam.; the face of the driving wheels was $1^3/_4$ in., and that of the driven wheels $^1/_2$ in. Records were made of the pressure of contact, of the coefficient of friction developed, and of the percentage of slip resulting from the development of the said coefficient of friction. Curves were plotted showing the relation of the coefficient and the slip for pressures of 150 and 400 lbs. per inch width of face in contact. Another series of tests was made in which the slip was maintained constant at 2% and the pressures were varied. In most of the combinations it was found that with constant slip the coefficient of friction diminished very slightly as the pressure of contact was increased, so that it may be considered practically constant for all pressures between 150 and 400 lbs. per sq. in.

The crushing strength of each material under the conditions of the test was determined by running each combination with increasing loads until a load was found under which the wheel failed before 15,000 revolutions had been made. The results showed the failure of the several fiber wheels under loads per inch of width as follows: Straw fiber 750 lbs.; leather fiber, 1,200 lbs.; tarred fiber, 1,200 lbs.; leather, 750 lbs.; sulphite fiber, 700 lbs. One-fifth of these pressures is taken as a safe working load. The coefficient of friction approaches its maximum value when the slip between driver and driven wheel is 2%. The safe working horse-power of the drive is calculated on the basis of 60% the coefficient developed at a pressure of 150 lbs. per inch of width, a reduction of 40% being made to cover possible decrease of the coefficient in actual service and to cover also loss due to friction of the journals. From these data the following table is constructed showing the H.P. that may be transmitted by driving wheels of the several materials named when in frictional contact with iron, aluminum and type metal.

The formula for horse-power is $\text{H.P.} = \frac{\pi d}{12} \times \frac{WPN \times 0.6f}{33000} = KdWN$, in which d = diam. in inches, W = width of face in inches, P = safe working pressure in lbs. per in. of width, N = revs. per min., f = coefficient of friction, 0.6 a factor for the decrease of the coefficient in service and for the loss in journal friction, K a coefficient including P, f and the numerical constants.

COEFFICIENTS OF FRICTION AND HORSE-POWER OF FRICTION DRIVES.

Horse-power $= K \times dWN$.

Friction Clutches. — Much valuable information on different forms of friction clutches is given in a paper by Henry Souther in *Trans. A. S. M. E.*, 1908, and in the discussion on the paper. All friction clutches contain two surfaces that rub on each other when the clutch is thrown into gear, and until the friction between them is increased, by the pressure with which they are forced together, to such an extent that the surfaces bind and enable one surface to drive the other. The surfaces may be metal on metal, metal on wood, cork, leather or other substance, leather on leather or other substance, etc. The surfaces may be disks, at right angles to the shaft, blocks sliding on the outer or inner surface, or both, of a pulley rim, or two cones, internal and external, one fitting in the other, or a band or ribbon around a pulley. The driving force which is just sufficient to cause one part of the clutch to drive the other is the product of the total pressure, exerted at right angles to the direction of sliding, and the coefficient of friction. The latter is an exceedingly variable quantity, depending on the nature and condition of the sliding surfaces and on their lubrication. The surfaces must have sufficient area so that the pressure per square inch on that area will not be sufficient to cause undue heating and wear. The total pressure on the parts of the mechanism that forces the surfaces together also must not cause undue wear of these parts.

For cone clutches, Reuleaux states that the angle of the cone should not be less than 10°, in order that the parts may not become wedged together. He gives the coefficient of cast iron on cast iron, for such clutches, at 0.15.

For clutches with maple blocks on cast iron Mr. Souther gives a coefficient of 0.37, and for a speed of 100 r.p.m. he gives the following table of capacity of such clutches, made by the Dodge Mfg. Co.

Horse-power.	Block Area, Ins.	Diam. at Block, Ins.	Circumferential Pull at Block Center, Lbs.	Total Pressure.	Total Pressure per Sq. In.
25	120	16	1,960	5,300	44
32	141	18	2,240	6,000	44.5
50	208	21.5	2,900	7,800	37.5
98	280	27.5	4,500	12,000	43.5

Prof. I. N. Hollis has found the coefficient of cork on cast iron to be from 0.33 to 0.37, or about double that of cast iron on cast iron or on bronze. A set of cork blocks outlasted a set of maple blocks in the ratio of five to one. Prof. C. M. Allen has found the torque for cork inserts to be nearly double that of a leather-faced clutch for a given dimension.

Disk clutches for automobiles are made with frictional surfaces of leather, bronze, or copper against iron or steel. The Cadillac Motor Car Co. give the following: Mean radius of leather frictional surface $4\frac{5}{16}$ ins; area of do., $36\frac{1}{2}$ sq. ins.; axial pressure, 1000 to 1200 lbs.; H.P. capacity at 400 r.p.m., $5\frac{1}{2}$ H.P.; at 1400 r.p.m., 10 H.P.

C. H. Schlesinger (*Horseless Age*, Oct. 2, 1907) gives the following formula for the ordinary cone clutch:

$$\text{H.P.} = PfrR \div 63{,}000 \sin. \theta,$$

in which P = assumed pressure of engaging spring in lbs., f = coeff. of friction, which in ordinary practice is about 0.25; r = mean radius of the cone, ins.; R=r.p.m. of the motor; θ = angle of the cone with the axis. Mr. Souther says the value of f = 0.25 is probably near enough for a properly lubricated leather-iron clutch.

The Hele-Shaw clutch, with V-shaped rings struck up in the surfaces of disks, is described in *Proc. Inst. M. E.*, 1903. A clutch of this form 18 ins. diam. between the V's transmitted 1000 H.P. at 700 or 800 r.p.m.

Coil Friction Clutches. (H. L. Nachman, *Am. Mach.*, April 1, 1909.) — Friction clutches are now in use which will transmit 1000, and even more, horse-power. A type of clutch which is satisfactory for the transmission of large powers is the coil friction clutch. It consists of a steel coil wound on a chilled cast-iron drum. At each end of the coil a head is formed. The head at one end is attached to the pulley or shaft that is to be set in motion, while that at the other end of the coil serves as a point of application of a force which pulls on the coil to wind it on the drum, thus gripping it firmly.

The friction of the coil on the drum is the same as that of a rope or belt on a pulley. That is, the relation of the tensions at the two ends of the coil may be found from the equation $P/Q = e^{\mu\alpha}$ where P = pull at fixed end of coil; Q = pull at free end of coil; e = base of natural logarithms = 2.718; μ = coefficient of friction between coils and drum; and α = Angle subtended by coil in radian measure, = 6.283 for each turn of coil.

Values of P/Q for different numbers of turns are as follows, assuming N = 0.05 for steel on cast iron, lubricated:

No. of turns	1	2	3	4	5	6	7	8
P/Q =	1.37	1.87	2.57	3.51	4.81	6.58	8.60	12.33

If D = diam. of drum in ins., N = revs., per min., then H.P. $= \pi DNP \div (12 \times 33{,}000) = 0.00000793\ DNP$.

HOISTING AND CONVEYING.

Strength of Ropes and Chains.—For the weight and strength of rope for hoisting see notes and tables on pages 410 to 416. For strength of chains see page 264.

Chain Blocks. — Referring to the table on the next page, the speed of a chain block is governed by the pull required on the hand chain and the distance the hand chain must travel to lift the load the required distance. The speeds are given for short lifts with men accustomed to the work; for continuous easy lifting two-thirds of these speeds are attainable. The triplex block lifts rapidly, and the speed increases for light loads because the length of hand chain to be overhauled is small. This fact also enables the operator to lower the load very quickly with the triplex block. The 12- to 20-ton triplex blocks are provided with two separate hand wheels, thus permitting two men to hoist simultaneously, thereby securing double speed. In the triplex block the power is transmitted to the hoisting-chain wheel by means of a train of spur gearing operated by the hand chain. In the duplex block the power is transmitted through a worm wheel and screw. In the differential block the power is applied by pulling on the slack part of the load chain and the force is multiplied by means of a differential sheave. (See page 539.) The relative efficiency and durability of the three types are as follows:

	Differential.	Duplex.	Triplex.

Proportions of Hooks.—The following formulæ are given by Henry R. Towne, in his Treatise on Cranes, as a result of an extensive experimental and mathematical investigation. They apply to hooks of capacities from 250 lb. to 20,000 lb. Each size of hook is made from some commercial size of round iron. The basis in each case is, therefore, the size of iron of which the hook is to be made, indicated by A in the diagram. The dimension D is arbitrarily assumed. The other dimensions, as given by the formulæ, are those which, while preserving a proper bearing-face on the interior of the hook for the ropes or chains which may be passed through it, give the greatest resistance to spreading and to ultimate rupture, which the amount of material in the original bar admits of. The symbol Δ is used to indicate the nominal capacity of the hook in tons of 2000 lb. The formulæ which determine the lines of the other parts of the hooks of the several sizes are as follows, the measurements being all expressed in inches:

$D = 0.5\,\Delta + 1.25;$
$E = 0.64\,\Delta + 1.60;$
$F = 0.33\,\Delta + 0.85;$
$G = 0.75\,D;$
$H = 1.08\,A;$
$I = 1.33\,A;$
$J = 1.20\,A;$
$K = 1.13\,A;$
$L = 1.05\,A;$
$M = 0.50\,A;$
$N = 0.85\,B - 0.16;$
$O = 0.363\,\Delta + 0.66;$
$Q = 0.64\,\Delta + 1.60;$
$U = 0.866\,A.$

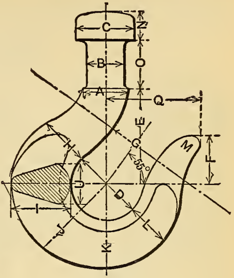

FIG. 189.

The dimensions A are necessarily based upon the ordinary merchant sizes of round iron. The sizes which it has been found best to select are the following:

Capacity of hook:											
1/8	1/4	1/2	1	1 1/2	2	3	4	5	6	8	10 tons
Dimension A:											
5/8	11/16	3/4	1 1/16	1 1/4	1 3/8	1 3/4	2	2 1/4	2 1/2	2 7/8	3 1/4 in.

Experiment has shown that hooks made according to the above formulæ will give way first by opening of the jaw, which, however, will not occur except with a load much in excess of the nominal capacity of the hook. This yielding of the hook when overloaded becomes a source of safety, as it constitutes a signal of danger which cannot easily be overlooked, and which must proceed to a considerable length before rupture will occur and the load be dropped.

Heavy Crane Hooks.—A. E. Holcomb, vice-pres. of the Earth Moving Machinery Co., contributes the following (1908). Seven years ago, while engaged in the design of a 100-ton crane, I made a study of the variations in strength with the different sectional forms for hooks in most common use. As a result certain values which gave the best results were substituted in "Gordon's" formula and a formula was thereby obtained which was good for hooks of any size desired, provided the proper allowable fiber stress per square inch was made use of when designing. From this formula the enclosed table was made up and was published in the *American Machinist* of Oct. 31, 1901. Since that time hundreds of hooks of cast or hammered steel have been designed and made according to my formula, and not one of them, so far as I know, has ever failed.

The Industrial Works, Bay City, Michigan, manufacturers of heavy cranes, in December, 1904, made the following test under actual working conditions:

A hook was made of hammered steel having an elastic limit or yield point at approximately 36,000 lbs. per sq. in. fiber stress and having the following important dimensions: $d = 7\,5/8$ in.; $r = 4\,1/2$ in.; $D = 20\,7/16$ in.

When the applied load reached 150,000 lbs. the hook straightened out until the opening at the mouth of the hook was $2\,1/2$ in. larger than formerly, and the distance from center of action line of load to center of gravity of section was found to have decreased $1/2$ in., at which point the hook held the load. Upon increasing the load still further, the hook opened still more. From the dimensions of the hook as originally formed, we find from the formula or table that the fiber stress with a load of 150,000 lbs. was 37,900 lbs. per sq. in., or in excess of the yield point, whereas making use of the dimensions obtained from the hook when it held we find that the fiber stress per square inch was reduced to 35,940 lbs., or under the yield point.

The designer must use his own judgment as to the selection of a proper allowable fiber stress, being governed therein by the nature of the material to be used and the probability of the hook being overloaded at some time. Under average conditions I have made use of the following values for (f):

	Values of (f) in pounds for a load of —					
	1,000 to 5000 lbs.	5,000 to 15,000 lbs.	15,000 to 30,000 lbs.	30,000 to 60,000 lbs.	60,000 to 100,000 lbs.	100,000 lbs. and up.
Cast iron	2,000	2,500	....	....	....	....
Steel casting	6,000	8,000	10,000	11,250	12,500	....
Hammered steel	12,000	16,000	20,000	22,500	25,000	27,500

Mr. Holcomb's formula is given below, and his table in condensed form is given on page 1185.

DIRECTIONS. — P and f being known, assume r to suit the requirements for which the hook is to be designed. Divide P by f and find the quotient in the column headed by the required r. At the side of the Table, in the same row, will be found the necessary depth of section, d.

Notation. — P = load. S = area of section. R^2 = square of the radius of gyration. f = allowable fiber stress in lbs. per sq. in., 20,000 lbs. for hammered steel. For other letters see Fig. 190.

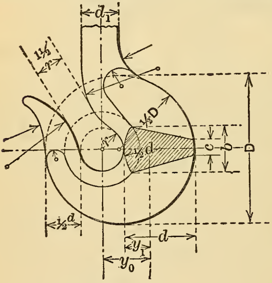

FIG. 190.

$$\frac{P}{f} = \frac{S}{1 + \frac{y_0 y_1}{R^2}}. \quad \text{General formula.}$$

$$S = \frac{b + c}{2} \times d. \quad \dots\dots \quad (1)$$

$$R^2 = \frac{d^2(b^2 + 4\,bc + c^2)}{18(b^2 + 2\,bc + c^2)}. \quad \dots \quad (2)$$

$$y_1 = \frac{b + 2\,c}{b + c} \times \frac{d}{3}. \quad \dots\dots \quad (3)$$

$$y_0 = \left(\frac{b + 2\,c}{b + c} \times \frac{d}{3}\right) + r. \quad \dots \quad (4)$$

Assuming $b = 0.66\,d$; $c = 0.22\,d$, we have:

$$\frac{P}{f} = \frac{d^3}{7.44\,d + 12.393\,r} = K. \quad (5)$$

$$d_1 = 0.5\,d.$$

$$D = 2r + 1.5\,d.$$

For values of K and r intermediate to those given in the table approximate values of d may be found by interpolation. Thus, for $K = 3.700$, $r = 2.75$.

Tabular values,	$r = 2.5$	3.0	Int. for 2.75
$d = 6.50$	$K = 3.462$	3.213	3.338
$d = 7.00$	$K = 4.128$	3.842	3.985

Whence: $$d = 6.5 + \left\{\frac{(3.700 - 3.338)}{(3.985 - 3.338)}\right\} \times (7.0 - 6.5) = 6.78.$$

In like manner, if d and r are given the value of K and the corresponding safe load may be found.

Strength of Hooks and Shackles. (Boston and Lockport Block Co., 1908.)—Tests made at the Watertown arsenal on the strength of hooks and shackles showed that they failed at the loads given in the table on page 1185. In service they should be subjected to only 50% of the figures in the table. Ordinarily the hook of a block gives way first, and where heavy weights are to be handled shackles are superior to hooks and should be used wherever possible.

Horse-power Required to Raise a Load at a Given Speed. — H.P. = $\frac{\text{Gross weight in lb.}}{33{,}000} \times$ speed in ft. per min. To this add 25% to 50% for friction, contingencies, etc. The gross weight includes the weight of

* All the hooks failed by straightening the hook.

cage, rope, etc. In a shaft with two cages balancing each other use the net load + weight of one rope, instead of the gross weight.

To find the load which a given pair of engines will start. — Let A = area of cylinder in square inches, or total area of both cylinders, if there are two; P = mean effective pressure in cylinder in lb. per sq. in.; S = stroke of cylinder, inches; C = circumference of hoisting-drum, inches; L = load lifted by hoisting-rope, lb.; F = friction, expressed as a diminution of the load. Then $L = \frac{A \times P \times 2S}{C} - F$.

An example in *Coll'y Engr.*, July, 1891, is a pair of hoisting-engines 24″ × 40″, drum 12 ft. diam., average steam-pressure in cylinder = 59.5 lb.; A = 904.8; P = 59.5; S = 40; C = 452.4. Theoretical load, not allowing for friction, $A \times P \times 2S \div C$ = 9589 lb. The actual load that could just be lifted on trial was 7988 lb., making friction loss F = 1601 lb., or 20 + per cent of the actual load lifted, or 16⅔% of the theoretical load.

The above rule takes no account of the resistance due to inertia of the load, but for all ordinary cases in which the acceleration of speed of the cage is moderate, it is covered by the allowance for friction, etc. The resistance due to inertia is equal to the force required to give the load the velocity acquired in a given time, or, as shown in Mechanics, equal to the product of the mass by the acceleration, or $R = \frac{WV}{gT}$, in which R = resistance in lb. due to inertia; W = weight of load in lb.; V = maximum velocity in ft. per second; T = time in seconds taken to acquire the velocity V; g = 32.16.

Safe Loads for Ropes and Chains.—The table on p. 1187 was prepared by the National Founder's Association and published in *Indust. Eng.*, Sept., 1914. It shows the safe loads that can be carried by wire rope, crane chain and manila rope of the sizes given when used in the positions and combinations shown. The loads in the table are lower than those usually specified, in order to insure absolute safety. When handling molten metal, the ropes and chains should be 25 per cent stronger than the figures in the table.

Effect of Slack Rope upon Strain in Hoisting. — A series of tests with a dynamometer are published by the Trenton Iron Co., which show that a dangerous extra strain may be caused by a few inches of slack rope. In one case the cage and full tubs weighed 11,300 lb.; the strain when the load was lifted gently was 11,525 lb.; with 3 in. of slack chain it was 19,025 lb.; with 6 in. slack 25,750 lb., and with 9 in. slack 27,950 lb.

Limit of Depth for Hoisting. — Taking the weight of a cast-steel hoisting-rope of 1⅛ in. diameter at 2 lb. per running foot, and its breaking strength at 84,000 lb., it should, theoretically, sustain itself until 42,000 feet long before breaking from its own weight. But taking the usual factor of safety of 7, then the safe working length of such a rope would be only 6000 ft. If a weight of 3 tons is now hung to the rope, which is equivalent to that of a cage of moderate capacity with its loaded cars, the maximum length at which such a rope could be used, with the factor of safety of 7, is 3000 ft., or

$$2x + 6000 = 84{,}000 \div 7; \therefore x = 3000 \text{ feet.}$$

This limit may be greatly increased by using special steel rope of higher strength, by using a smaller factor of safety, and by using taper ropes. (See paper by H. A. Wheeler, *Trans. A. I. M. E.*, xix. 107.)

Large Hoisting Records. — At a colliery in North Derbyshire during the first week in June, 1890, 6309 tons were raised from a depth of 509 yards, the time of winding being from 7 a.m. to 3.30 p.m.

At two other Derbyshire pits, 170 and 140 yards in depth, the speed of winding and changing has been brought to such perfection that tubs are drawn and changed three times in one minute. (*Proc. Inst. M. E.*, 1890.)

At the Nottingham Colliery near Wilkesbarre, Pa., in Oct., 1891, 70,152 tons were shipped in 24.15 days, the average hoist per day being 1318 mine cars. The depth of hoist was 470 ft., and all coal came from one opening. The engines were first motion, 22 ×48 in., conical drums 4 ft. 1 in. long, 7 ft. diameter at small end and 9 ft. at large end. (*Eng'g News*, Nov. 1891.)

Large Engines.—Two 34 × 60 in. four-cylinder engines built by Nordberg Mfg. Co. for the Tamarack copper mine at Calumet. Mich., are

designed to lift a load from a depth of 6,000 ft. at an average hoisting speed of 5,000 ft. per min. The load is made up of ore, 12,000 lbs.; cage and cars, 8,500 lbs.; 6,500 ft. of 1½-in. rope, 21,200 lbs.; total, 41,700 lbs. The center lines of the cylinders are placed 90° apart and the cranks 135° apart. By this arrangement three of the four cylinders are always available for starting the hoist.

Pneumatic Hoisting. (H. A. Wheeler, *Trans. A. I. M. E.* xix, 107.)—A pneumatic hoist was installed in 1876 at Epinac, France, consisting of two continuous air-tight iron cylinders extending from the bottom to the top of the shaft. Within the cylinder moved a piston from which was hung the cage. It was operated by exhausting the air from above the piston, the lower side being open to the atmosphere. Its use was discontinued on account of the failure of the mine. Mr. Wheeler gives a description of the system, but criticizes it as not being equal on the whole to hoisting by steel ropes.

Pneumatic hoisting-cylinders using compressed air have been used at blast-furnaces, the weighted piston counterbalancing the weight of the cage, and the two being connected by a wire rope passing over a pulley-sheave above the top of the cylinder. In the more modern furnaces steam-engine or electric hoists are generally used.

Electric Mine-Hoists.—An important paper on this subject, by D. B. Rushmore and K. A. Pauly, will be found in *Trans. A. I. M. E.*, 1910. See also Electrical Hoisting, page 1464.

Counterbalancing of Winding-engines. (H. W. Hughes, *Columbia Coll. Qly.*) — Engines running unbalanced are subject to enormous variations in the load; for let W = weight of cage and empty tubs, say 6270 lb.; c = weight of coal, say 4480 lb.; r = weight of hoisting rope, say 6000 lb.; r' = weight of counterbalance rope hanging down pit, say 6000 lb. The weight to be lifted will be:

If weight of rope is unbalanced.	If weight of rope is balanced.	
At beginning of lift:		
$W + c + r - W$ or 10,480 lb.	$W + c + r - (W + r')$,	or 4480 lb.
At middle of lift:		
$W + c + \frac{r}{2} - \left(W + \frac{r}{2}\right)$ or 4480 lb.	$W + c + \frac{r}{2} + \frac{r'}{2} - \left(W + \frac{r}{2} + \frac{r'}{2}\right)$,	
At end of lift:		
$W + c - (W + r)$ or *minus* 1520 lb.	$W + c + r' - (W + r)$,	

That counterbalancing materially affects the size of winding-engines is shown by a formula given by Mr. Robert Wilson, which is based on the fact that the greatest work a winding-engine has to do is to get a given mass into a certain velocity uniformly accelerated from rest, and to raise a load the distance passed over during the time this velocity is being obtained.

Let W = the weight to be set in motion: one cage, coal, number of empty tubs on cage, one winding rope from pit head-gear to bottom, and one rope from banking level to bottom.
- v = greatest velocity attained, uniformly accelerated from rest;
- g = gravity = 32.2;
- t = time in seconds during which v is obtained;
- L = unbalanced load on engine;
- R = ratio of diameter of drum and crank circles;
- P = average pressure of steam in cylinders;
- N = number of cylinders;
- S = space passed over by crank-pin during time t;
- C = 2/3, constant to reduce angular space passed through by crank to the distance passed through by the piston during the time t;
- A = area of one cylinder, without margin for friction. To this an addition for friction, etc., of engine is to be made, varying from 10 to 30% of A.

1st. Where load is balanced.

$$A = \frac{\left\{\left(\frac{Wv^2}{2g}\right) + \left(L\,\frac{vt}{2}\right)\right\}R}{PNSC}.$$

2d. Where load is unbalanced:

The formula is the same, with the addition of another term to allow for the variation in the lengths of the ascending and descending ropes. In this case
- h_1 = reduced length of rope in t attached to ascending cage;
- h_2 = increased length of rope in t attached to descending cage;
- w = weight of rope per foot in pounds. Then

$$A = \frac{\left[\left(\frac{Wv^2}{2g}\right) + \left\{\left(L\,\frac{vt}{2}\right) - \frac{h_1 w + h_2 w}{2}\right\}\right]R}{PNSC}.$$

Applying the above formula when designing new engines, Mr. Wilson found that 30 in. diameter of cylinders would produce equal results, when balanced, to those of the 36-in. cylinder in use, the latter being unbalanced.

Counterbalancing may be employed in the following methods:

(*a*) *Tapering Rope.* — At the initial stage the tapering rope enables us to wind from greater depths than is possible with ropes of uniform section.

The thickness of such a rope at any point should only be such as to safely bear the load on it at that point.

With tapering ropes we obtain a smaller difference between the initial and final load, but the difference is still considerable, and for perfect equalization of the load we must rely on some other resource. The theory of taper ropes is to obtain a rope of uniform strength, thinner at the cage end where the weight is least, and thicker at the drum end where it is greatest.

(b) *The Counterpoise System* consists of a heavy chain working up and down a staple pit, the motion being obtained by means of a special small drum placed on the same axis as the winding drum. It is so arranged that the chain hangs in full length down the staple pit at the commencement of the winding; in the center of the run the whole of the chain rests on the bottom of the pit, and, finally, at the end of the winding the counterpoise has been rewound upon the small drum, and is in the same condition as it was at the commencement.

(c) *Loaded-wagon System.* — A plan, formerly much employed, was to have a loaded wagon running on a short incline in place of this heavy chain; the rope actuating this wagon being connected in the same manner as the above to a subsidiary drum. The incline was constructed steep at the commencement, the inclination gradually decreasing to nothing. At the beginning of a wind the wagon was at the top of the incline, and during a portion of the run gradually passed down it till, at the meet of cages, no pull was exerted on the engine — the wagon by this time being at the bottom. In the latter part of the wind the resistance was all against the engine, owing to its having to pull the wagon up the incline, and this resistance increased from nothing at the meet of cages to its greatest quantity at the conclusion of the lift.

(d) *The Endless-rope System* is preferable to all others, if there is sufficient sump room and the shaft is free from tubes, cross timbers, and other impediments. It consists in placing beneath the cages a tail rope, similar in diameter to the winding rope, and, after conveying this down the pit, it is attached beneath the other cage.

(e) *Flat Ropes Coiling on Reels.* — This means of winding allows of a certain equalization, for the radius of the coil of ascending rope continues to increase, while that of the descending one continues to diminish. Consequently, as the resistance decreases in the ascending load the leverage increases, and as the power increases in the other, the leverage diminishes. The variation in the leverage is a constant quantity, and is equal to the thickness of the rope where it is wound on the drum.

By the above means a remarkable uniformity in the load may be obtained, the only objection being the use of flat ropes, which weigh heavier and only last about two-thirds the time of round ones.

(f) *Conical Drums.* — Results analogous to the preceding may be obtained by using round ropes coiling on conical drums, which may either be smooth, with the successive coils lying side by side, or they may be provided with a spiral groove. The objection to these forms is, that perfect equalization is not obtained with the conical drums unless the sides are very steep, and consequently there is great risk of the rope slipping; to obviate this, scroll drums were proposed. They are, however, expensive, and the lateral displacement of the winding rope from the center line of pulley becomes very great, owing to their necessary large width.

(g) *The Koepe System of Winding.*—An iron pulley with a single circular groove takes the place of the ordinary drum. The winding rope passes from one cage, over its head-gear pulley, round the drum, and, after passing over the other head-gear pulley, is connected with the second cage. The winding rope thus encircles about half the periphery of the drum in the same manner as a driving-belt on an ordinary pulley. There is a balance rope beneath the cages, passing round a pulley in the sump; the arrangement is like an endless rope, with the cages as points of attachment.

CRANES.

Classification of Cranes. (Henry R. Towne, *Trans. A. S. M. E.* iv., 288. Revised in *Hoisting*, published by The Yale & Towne Mfg. Co.)

A Hoist is a machine for raising and lowering weights. A Crane is a hoist with the added capacity of moving the load in a horizontal or lateral direction.

Cranes are divided into two classes, as to their motions, viz. *Rotary* and *Rectilinear*, and into four groups, as to their source of motive power, viz.:

Hand. — When operated by manual power.

Power. — When driven by power derived from line shafting.

Steam, Electric, Hydraulic, or *Pneumatic.* — When driven by an engine or motor attached to the crane, and operated by steam, electricity, water, or air transmitted to the crane from a fixed source of supply.

Locomotive. — When the crane is provided with its own boiler or other generator of power, and is self-propelling; usually being capable of both rotary and rectilinear motions.

Rotary and Rectilinear Cranes are thus subdivided.

ROTARY CRANES.

(1) *Swing-cranes.* — Having rotation, but no trolley motion.

(2) *Jib-cranes.* — Having rotation, and a trolley traveling on the jib.

(3) *Column-cranes.* — Identical with the jib-cranes, but rotating around a fixed column (which usually supports a floor above).

(4) *Pillar-cranes.* — Having rotation only; the pillar or column being supported entirely from the foundation.

(5) *Pillar Jib-cranes.* — Identical with the last, except in having a jib and trolley motion.

(6) *Derrick-cranes.* — Identical with jib-cranes, except that the head of the mast is held in position by guy-rods, instead of by attachment to a roof or ceiling.

(7) *Walking-cranes.*—Consisting of a pillar or jib-crane mounted on wheels and arranged to travel longitudinally upon one or more rails.

(8) *Locomotive-cranes.*—Consisting of a pillar-crane mounted on a truck, and provided with a steam-engine capable of propelling and rotating the crane, and of hoisting and lowering the load.

RECTILINEAR CRANES.

(9) *Bridge-cranes.* — Having a fixed bridge spanning an opening, and a trolley moving across the bridge.

(10) *Tram-cranes.* — Consisting of a truck, or short bridge, traveling longitudinally on overhead rails, and without trolley motion.

(11) *Traveling-cranes.* — Consisting of a bridge moving longitudinally on overhead tracks, and a trolley moving transversely on the bridge.

(12) *Gantries.* — Consisting of an overhead bridge, carried at each end by a trestle traveling on longitudinal tracks on the ground, and having a trolley moving transversely on the bridge.

(13) *Rotary Bridge-cranes.* — Combining rotary and rectilinear movements and consisting of a bridge pivoted at one end to a central pier or post, and supported at the other end on a circular track; provided with a trolley moving transversely on the bridge.

For descriptions of these several forms of cranes see Towne's "Treatise on Cranes."

Stresses in Cranes. — See Stresses in Framed Structures, p. 541, *ante.*

Position of the Inclined Brace in a Jib-crane. — The most economical arrangement is that in which the inclined brace intersects the jib at a distance from the mast equal to four-fifths the effective radius of the crane. (*Hoisting.*)

Electric Overhead Traveling Cranes. (From data supplied by Alliance Machine Co., Alliance, O., and Pawling & Harnischfeger, Milwaukee.) — Electric overhead traveling cranes usually have 3 motors, for hoisting, traversing the hoist trolley on the bridge and for moving the bridge, respectively. The usual range of motor sizes is as follows: Hoist, 15–50 H.P.; trolley, 3–15 H.P.; bridge, 15–50 H.P. The speeds at which the various motions are made range as follows, the figures being feet per minute: Hoist, 8–60; trolley traverse, 75–200; bridge travel, 200–600. These speeds are varied in the same capacity of crane to suit each particular installation. In general, the speed of the bridge in feet per minute should not exceed (length of runway + 100). If the runway is long and covered by more than one crane, the speed may be made equal to the average distance between cranes + 100. Usually 300 ft. per min. is a good speed. For small cranes in special cases, the speeds may be increased, but for cranes of over 50 tons capacity the speed should be below 300 ft. per min. unless the building is made especially strong to stand the strains incident to starting and stopping heavy cranes geared for high speeds.

Cranes of over 15 tons capacity usually have an auxiliary hoist of 1/5 the capacity of the main hoist, and usually operated by a separate motor. Wire rope is now almost exclusively used for hoisting with cranes. The diameter of the drums and sheaves should be not less than 30 times the diameter of the hoisting rope, and should have a factor of safety of 5. Cranes are equipped with automatic load brakes to sustain the load when lifted and to regulate the speed when lowering, it being necessary for the hoist to drive the load down.

The voltage now standard for crane service is 220 volts at the crane motor, although 110 volts for small cranes is not objectionable. Voltages of 500–600 are inadvisable, especially in foundries and steel works, where dust and metallic oxides cover many parts of the crane and necessitate frequent cleaning to avoid grounds. On account of the danger from the higher voltages, the operators are apt to neglect this part of their work.

Power Required to Drive Cranes. (Morgan Engineering Co., Alliance, O., 1909.) — The power required to drive the different parts of cranes is determined by allowing a certain friction percentage over the power required to move the dead load. On hoist motions 33 1/3% is allowed for friction of the moving parts, thus giving a motor of 1/3 greater capacity than if friction were neglected. For bridge and trolley motions, a journal friction of the track wheel axles of 10% of the total weight of the crane and load is allowed. There is then added an allowance of 33 1/3% of the horse-power required to drive the crane and load plus the track wheel axle friction, to cover friction of the gearing. In selecting motors, the most important consideration is the maximum starting torque which the motor can exert. With alternating-current motors, this is less than with direct-current motors, requiring a larger motor, particularly on the bridge and trolley motions which require the greatest starting torque.

Walter G. Stephan says (*Iron Trade Rev.*, Jan. 7, 1909) that the bridge girders should be made of two plates latticed, or box girders, their depth varying from 1/10 to 1/20 of the span. The important feature of crane girder design is ample strength and stiffness, both vertically and laterally. Especial attention should be given to the transverse strain on the bridge due to sudden stopping or starting of heavy loads. The wheel base on the end trucks should have a ratio to the crane span of 1 to 6, although for long spans this ratio must necessarily be reduced to 1 to 8. Quick-traveling cranes should have as long a wheel base as possible, since the tendency to twist increases with the speed. Where several wheels are necessary at each end to support the crane, equalizing means should be used.

A recent development in cranes is the four- or six-girder crane for handling ladles of molten metal in steel works. The main trolley runs on the outer girders, with the hoist ropes depending between the outer and inner girders. The auxiliary trolley runs on the inner girders, thus being able to pass between the main ropes, and tilt the ladle in either direction.

Dimensions and Wheel Loads of Electric Traveling Cranes.

A 150-ton Pillar-crane was erected in 1893 on Finnieston Quay, Glasgow. The jib is formed of two steel tubes, each 39 in. diam. and 90 ft. long. The radius of sweep for heavy lifts is 65 ft. The jib and its load are counterbalanced by a balance-box weighted with 100 tons of iron and steel punchings. In a test a 130-ton load was lifted at the rate of 4 ft. per minute, and a complete revolution made with this load in 5 minutes. *Eng'g News*, July 20, 1893.

Compressed-air Traveling-cranes.— Compressed-air overhead traveling-cranes have been built by the Lane & Bodley Co., of Cincinnati. They are of 20 tons nominal capacity, each about 50 ft. span and 400 ft. length of travel, and are of the triple-motor type, a pair of simple reversing-engines being used for each of the necessary operations, the pair of engines for the bridge and the pair for the trolley travel being each 5-inch bore by 7-inch stroke, while the pair for hoisting is 7-inch bore by 9-inch stroke.

The air-pressure when required is somewhat over 100 pounds. The air-compressor is allowed to run continuously without a governor, the speed being regulated by the resistance of the air in a receiver. An auxiliary receiver is placed on each traveler, whose object is to provide a supply of air near the engines for immediate demands and independent of the hose connection. Some of the advantages said to be possessed by this type of crane are: simplicity; absence of all moving parts, excepting those required for a particular motion when that motion is in use; no danger from fire, leakage, electric shocks, or freezing; ease of repair; variable speeds and reversal without gearing; almost entire absence of noise; and moderate cost.

Quay-cranes. — An illustrated description of several varieties of stationary and traveling cranes, with results of experiments, is given in a paper on Quay-cranes in the Port of Hamburg by Chas. Nehls, *Trans. A. S. C. E.*, 1893.

Hydraulic Cranes, Accumulators, etc. — See Hydraulic Pressure Transmission, page 812, *ante*.

Electric versus Hydraulic Cranes for Docks. — A paper by V. L. Raven, in *Trans. A. S. M. E.*, 1904, describes some tests of capacity and efficiency of electric and hydraulic power plants for dock purposes at Middlesbrough, Eng. In loading two cargoes of rails, weighing respectively 1210 and 1225 tons, the first was done with a hydraulic crane, in 7 hours, with 3584 lbs. of coal burned in the power station, and the second with an electric crane in $5^1/_4$ hours, with 2912 lbs. of coal. The total cost including labor, per 100 tons, was 327 pence with the hydraulic and 245 pence for the electric crane, a saving by the latter of 25 %.

Loading and Unloading and Storage Machinery for coal, ore, etc., is described by G. E. Titcomb in *Trans. A. S. M. E.*, 1908. The paper illustrates automatic ore unloaders for unloading ore from the hold of a vessel and loading it onto cars, and car-dumping machinery, by which a 50-ton car of coal is lifted, turned over and its contents discharged through a chute into a vessel. Methods of storage of coal and of reloading it on cars are also described.

Power Required for Traveling-Cranes and Hoists. — Ulrich Peters, in *Machy*, Nov. 1907, develops a series of formulæ for the power required to hoist and to move trolleys on cranes. The following is a brief abstract. Resistance to be overcome in moving a trolley or crane-bridge. P_1 = rolling friction of trolley wheels, P_2 = journal friction of wheels or axles, P_3 = inertia of trolley and load. P = sum of these resistances $= P_1 + P_2 + P_3 = (T+L)\left(\frac{f_1 + f_2 d}{D} + \frac{v}{1932 t}\right)$ in which T = weight of trolley, L = load, f_1 = coeff. of rolling friction, about 0.002, (0.001 to 0.003 for cast iron on steel); f_2 = coeff. of journal friction, = 0.1 for starting and 0.01 for running, assuming a load on brasses of 1000 to 3000 lb. per sq. in.; [f_2 is more apt to be 0.05 unless the lubrication is perfect. See Friction and Lubrication, W. K.] d = diam. of journal; D = diam. of wheels; v = trolley speed in ft. per min.; t = time in seconds in which the trolley under full load is required to come to the maximum speed. Horse-power = sum of the resistances × speed, ft. per min. ÷ 33,000.

Force required for hoisting and lowering: F_h = actual hoisting force, F_0 = theoretical force or pull, L = load, v = speed in ft. per min. of the rope or chain, c = hoisting speed of the load L, c/v = transmission ratio of the hoist, e = efficiency = F_0/F_h. The actual work to raise the load per minute $= F_h v = Lc = F_0 v \div e$. The efficiency e is the product of the efficiencies of all the several parts of the hoisting mechanism, such as sheaves, windlass, gearing, etc. Methods of calculating these efficiencies, with examples, are given at length in the original paper by Mr. Peters.

Lifting Magnets. — (From data furnished by the Electric Controller and Mfg. Co., Cleveland, and the Cutler-Hammer Clutch Co., Milwaukee). Lifting magnets first came into use about 1898. They have had wide application for handling pig iron, scrap, castings, etc. A lifting magnet comprises essentially a magnet winding, a pole-piece, a shoe and a protecting case, which is ribbed to afford ample radiating surface to dissipate the heat generated in operation. The winding usually consists of coils, each wound with copper ribbon and insulated with asbestos. The insulation must be designed to withstand a higher voltage than the line voltage, due to the inductive kick when the circuit is opened. The wearing plate, which takes the shocks incident to picking up the load, is usually made of manganese steel. The shape of the pole piece or lifting surface of the magnet must be varied, as the same shape is not usually applicable to all classes of materials. For handling pig iron, scrap, etc., a concave pole surface is usually superior to a flat one, which is adapted to handling plates or flat material of similar character, and which bear equally on the piece to be lifted at both the edge and center. A test of a lifting magnet made at the works of the Youngstown Sheet and Tube Co., in 1907, showed the following results:

Total pig iron unloaded, 109,350 pounds; weight of average lift, 785 pounds; time required, 2 hours, 15 minutes; current on magnet, 1 hour 15 minutes; current required, 30 amperes.

The No. 3 and No. 4 magnets are particularly fitted for use on steam-driven locomotive cranes, and when so used are usually supplied with current from a small steam-driven generator set mounted on the crane, steam being drawn from the boiler of the crane. Nos. 5 and 6 are adapted for use with overhead electric traveling cranes in cases where large lifts and high speed of handling are essential.

SIZES AND CAPACITIES OF THE ELECTRIC CONTROLLER & MFG. CO.'S TYPE S–A LIFTING MAGNETS (1909).

Size.	Diam.	Weight.	Average Current at 220 Volts.	Lifts in Machine Cast Pig Iron.	
				Maximum Lift.	Average Lift.

5	52	4,800	35	3,087	1,800
6	61	6,600	45	4,589	2,600

SIZES AND CAPACITIES OF LIFTING MAGNETS (CUTLER-HAMMER), 1908.

Size, In.	Weight Lb.	Maximum* Lifting Capacity, Lb.	Average Lifting Capacity, Lb.	Current Required at 220 Volts, Amperes.	Head-room Required, Ft.
10	75	800	100–300	1	....
35	1,650	5,000	500–1,000	15–18	4
50	5,000	20,000	1,000–2,000	30–35	6

* This capacity can be obtained only under the most favorable conditions, with complete magnetic contact between the magnet and the piece to be lifted.

The capacity of a lifting magnet in service depends on many other factors than the design of the magnet. Most important is the character of the material handled. Much more can be handled at a single lift with material like billets, ingots, etc., than with scrap, wire, pig iron, etc. The speed of the crane, from which the magnet is suspended, and the distance it must transport the material are also important factors to be considered in calculating the capacity of a given magnet under given conditions. The following results have been selected from a great number of tests of the Electric Controller and Mfg. Co.'s No. 2 Type S magnets in commercial service, and represent what is probably average practice. It should be borne in mind that the average lift is determined from a large number of lifts, including lifts made from a full car of, say, pig iron, where the magnetic conditions are very favorable, and also the "lean" lifts where the car is nearly empty, and magnetic conditions unfavorable; the magnet can reach only a few pigs at one time on the lean lifts, with a consequent heavy decrease in the size of the load. The average lift is therefore less than the maximum lift in handling a given lot of material.

When operated from an ordinary electric overhead traveling crane a magnet of the type used in these trials will handle from 20 to 30 tons per hour of the scrap used by open-hearth furnaces. If operated from a special fast crane, the amount may be somewhat increased. Average lifts in pounds for various materials are as follows:

Skull cracker balls up to 20,000; ingot (or if ground man places magnet, two), each, 6,000; billet slabs, 900–6,000.

The above weights depend on dimensions and whether in pile or stacked evenly.

Machine cast pig iron, 1,250; sand cast pig iron, 1,150.

These are values obtained in unloading railway cars, including lean lifts in cleaning up.

Machine cast pig iron, 1,350; sand cast pig iron, 1,200.

The above are average lifts from stockpile.

Heavy melting stock (billets, crop ends of billets, rails or structural shapes, 1,250; boiler plate scrap, 1,100; farmers' scrap (harvesting machinery parts, plow points, etc.), 900; small risers from steel castings, 1,600; fine wire scrap, scrap tubing not over 3 ft. long, loose even or lamination scrap, 500; bundled scrap, 1,200; miscellaneous junk dealers' scrap, 400–800.

Commercial Results with a 52-inch, 5,000 pound Magnet.

* 1. Machine cast pig handled from stock pile to charging boxes. 2. Bull heads, ditto. 3. Sand cast pig unloaded from car to stock pile. 4. Baled tin and wire unloaded from car to stock pile. 5. Boiler plate scrap handled from stock pile to charging boxes. 6. Farmers' scrap, comprising knotters and butters from threshing and binding machines, sections of cutter bars from mowers, broken steel teeth from hay rakes, plow points, etc., from stock pile to charging boxes. 7. Small risers from steel castings, handled from stock pile to charging boxes. 8. Laminated plates from armatures and transformers, mixed sizes, from stock pile to charging boxes. 9. Cast iron sewer pipe, 3 feet diameter, weighing 2,000 pounds each, lifted from cars to flat boat. Each pipe had to be blocked and lashed to prevent washing overboard. 10. Pennsylvania Railroad East-River tunnel section castings, convex on one side, concave on other, weighing 4,000 pounds each. Handled from local float to barge for shipment. 11. Steel plate 1/2-inch × 10 inches × 6 feet 0 inches handled from car to float. 12. Steel rails, 40 pounds per yard, 25 feet long. Handled from car to lighter, about 8 rails per lift.

The above results of tests relate to the Electric Controller & Mfg. Co.'s No. 2 Type " S " magnet, 52 in. diameter and weighing 5200 lbs. and are the average of a large number of tests made at various plants between the years 1905 and 1908. This type of magnet is being superseded by the No. 4 Type S-A magnet which is 43 in. diameter, weighs 3200 lbs. and gives substantially the same average lift.

TELPHERAGE.

Telpherage is a name given to a system of transporting materials in which the load is suspended from a trolley or small truck running on a cable or overhead rail, and in which the propelling force is obtained from an electric motor carried on the trolley. The trolley, with its motor, is called a "telpher." A historical and illustrated description of the system is given in a paper by C. M. Clark, in *Trans. A. I. E. E.*, 1902. A series of circulars of the Link Belt Co., Philadelphia, show numerous illustrations of the system in operation for handling different classes of materials. Telpherage is especially applicable for moving packages in warehouses, on wharfs, etc. The moving machinery consists of the telpher or the conveying power, with accompanying trailers; the portable electric hoist or the vertical elevating power, and the carriers containing the load. Among the accessories are brakes, switches and controlling devices of many kinds.

An automatic line is controlled by terminal and intermediate switches which are operated by the men who do the loading and unloading, no additional labor being required. A non-automatic line necessitates a boy to accompany the telpher. The advisability of using the non-automatic rather than the automatic line is usually determined by the distance between stations.

COAL-HANDLING MACHINERY.

The following notes and tables are supplied by the Link-Belt Co.

In large boiler-houses coal is usually delivered from hopper-cars into a track-hopper, about 10 feet wide and 12 to 16 feet long. A feeder set under the track-hopper feeds the coal at a regular rate to a crusher, which reduces it to a size suitable for stokers.

After crushing, the coal is elevated or conveyed to overhead storage-bins. Overhead storage is preferred for several reasons:

1. To avoid expensive wheeling of coal in case of a breakdown of the coal-handling machinery.
2. To avoid running the coal-handling machinery continuously.
3. Coal kept under cover indoors will not freeze in winter and clog the supply-spouts to the boilers.
4. It is often cheaper to store overhead than to use valuable ground-space adjacent to the boiler-house.
5. As distinguished from vault or outside hopper storage, it is cheaper to build steel bins and supports than masonry pits.

Weight of Overhead Bins. — Steel bins of approximately rectangular cross-section, say 10 × 10 feet, will weigh, exclusive of supports, about one-sixth as much as the contained coal. Larger bins, with sloping bottoms, may weigh one-eighth as much as the contained coal. Bag bottom bins of the Berquist type will weigh about one-twelfth as much as the contained coal, not including posts, and about one-ninth as much, including posts.

Supply-pipes from Bins. — The supply-pipes from overhead bins to the boiler-room floor, or to the stoker-hoppers, should not be less than 12 inches in diameter. They should be fitted at the top with a flanged casting and a cut-off gate, to permit removal of the pipe when the boilers are to be cleaned or repaired.

Types of Coal Elevators. — Coal elevators consist of buckets of various shapes attached to one or more strands of link-belting or chain, or to rubber belting. The buckets may either be attached continuously or at intervals. The various types are as follows:

Continuous bucket elevators consist usually of one strand of chain and two sprocket-wheels with buckets attached continuously to the chain. Each bucket after passing the head wheel acts as a chute to direct the flow from the next bucket. This type of elevator will handle the larger sizes of coal. It runs at slow speeds, usually from 90 to 175 feet per minute, and has a maximum capacity of about 120 tons per hour.

Centrifugal discharge elevators consist usually of a single strand of chain, with the buckets attached thereto at intervals. They are used to handle the smaller sizes of coal in small quantities. They run at high speeds, usually 34 to 40 revolutions of the head wheel per minute, and have a capacity up to 40 tons per hour.

Perfect discharge elevators consist of two strands of chain, with buckets at intervals between them. A pair of idlers set under the head wheels cause the buckets to be completely inverted, and to make a clean delivery into the chutes at the elevator head. This type of elevator is useful in handling material which tends to cling to the buckets. It runs at slow speeds, usually less than 150 feet per minute. The capacity depends on the size of the buckets.

Combined Elevators and Conveyors are of the following types:

Gravity discharge elevators, consisting of two strands of chain, with spaced V-shaped buckets fastened between them. After passing the head wheels the buckets act as conveyor-flights and convey the coal in a trough to any desired point. This is the cheapest type of combined elevator and conveyor, and is economical of power. A machine carrying 100 tons of coal per hour, in buckets 20 inches wide, 10 inches deep, and 24 inches long, spaced 3 feet apart, requires 5 H.P. when loaded and 1 1/2 H.P. when empty for each 100 feet of horizontal run, and 1/9 H.P. for each foot of vertical lift.

Rigid bucket-carriers consist of two strands of chain with a special bucket rigidly fastened between them. The buckets overlap and are so shaped that they will carry coal around three sides of a rectangle. The coal is carried to any desired point and is discharged by completely inverting the bucket over a turn-wheel.

Pivoted bucket-carriers consist of two strands of long pitch steel chain to which are attached, in a pivotal manner, large malleable iron or steel buckets so arranged that their adjacent lips are close together or overlap. Overlapping buckets require special devices for changing the lap at the corner turns. Carriers in which the buckets do not overlap should be fitted with auxiliary pans or buckets, arranged in such a manner as to catch the spill which falls between the lips at the loading point, and so shaped as to return the spill to the buckets at the corner turns. Pivoted bucket-carriers will carry coal around four sides of a rectangle, the buckets being dumped on the horizontal run by striking a cam suitably placed. Buckets for these carriers are usually of 2 ft. pitch, and range in width from 18 in. to 48 in. They run at low speeds, usually not over 50 ft. per minute, 40 ft. per minute being most usual. At the latter speed, the capacities when handling coal vary from 40 tons per hour for the 18 in. width to 120 tons for the 48 in. width. On account of the superior construction of these carriers and the slow speed at which they run, they are economical of power and durable. The rollers mounted on the chain joints are usually 6 in. diameter, but for severe duty 8-in. rollers are often used. It is usual to make these hollow to carry a quantity of oil for internal lubrication.

Coal Conveyors. — Coal conveyors are of four general types, viz., scraper or flight, bucket, screw, and belt conveyors.

The flight conveyor consists of a trough of any desired cross-section and a single or double strand of chain carrying scrapers or flights of approximately the same shape as the trough. The flights push the coal ahead of them in the trough to any desired point, where it is discharged through openings in the bottom of the trough.

For short, low-capacity conveyors, malleable link hook-joint chains are used. For heavier service, malleable pin-joint chains, steel link chains, or monobar, are required. For the heaviest service, two strands of steel link chain, usually with rollers, are used.

Flight conveyors are of three types: plain scraper, suspended flight, and roller flight.

In the plain scraper conveyor, the flight is suspended from the chain and drags along the bottom of the trough. It is of low first cost and is useful where noise of operation is not objectionable. It has a maximum capacity of about 30 tons per hour, and requires more power than either of the other two types of flight conveyors.

Suspended flight conveyors use one or two strands of chain. The flights are attached to cross-bars having wearing-shoes at each end. These wearing-shoes slide on angle-iron tracks on each side of the conveyor trough. The flights do not touch the trough at any point. This type of conveyor is used where quietness of operation is a consideration. It is of higher first cost than the plain scraper conveyor, but requires one-fourth less power for operation. It is economical up to a capacity of about 80 tons per hour.

The roller flight conveyor is similar to the suspended flight, except that the wearing-shoes are replaced by rollers. It is highest in first cost of all the flight conveyors, but has the advantages of low power consumption (one-half that of the scraper), low stress in chain, long life of chain, trough, and flights, and noiseless operation. It has an economical maximum capacity of about 120 tons per hour.

The following formula gives approximately the horse-power at the head wheel required to operate flight conveyors:

$$\text{H.P.} = (ATL + BWS) \div 1000.$$

T = tons of coal per hour; L = length of conveyor in feet, center to center; W = weight of chain, flights, and shoes (both runs) in pounds; S = speed in feet per minute; A and B constants depending on angle of incline from horizontal. See example below.

EXAMPLE.—Required the H.P. for a monobar conveyor 200 ft. center to center carrying 100 tons of coal per hour, up a 10° incline at a speed of 100 feet per minute. Conveyor has No. 818 chain and 8 × 19 suspended flights, spaced 18 inches apart.

$$\text{H.P.} = \frac{0.5 \times 100 \times 200 + 0.008\ (400 \times 5.7 + 267 \times 15.55) \times 100}{1000} = 15.15.$$

The following table shows the conveying capacities of various sizes of flights at 100 feet per minute in tons, of 2000 lb., per hour. The values are true for continuous feed only.

Size of Flight.	Horizontal Conveyors, Tons.				Inclined Conveyors, Tons.		
	Flight Every 16″.	Flight Every 18″.	Flight Every 24″.	Pounds Coal per Flight.	10° Flights Every 24″.	20° Flights Every 24″.	30° Flights Every 24″.
6 × 14	69.75	62	46.5	31	40.5	31.5	22.5
8 × 19	....	130	97.5	65	78	62	52
10 × 24	....	....	172.5	115	150	120	90
10 × 30	....	....	220	147	184	146	116
10 × 36	....	....	268	179	225	177	142
10 × 42	....	....	315	210	264	210	167

Bucket Conveyors. — Rigid bucket-carriers are used to convey large quantities of coal over a considerable distance when there is no intermediate point of discharge. These conveyors are made with two strands of steel roller chain. They are built to carry as much as 10 tons of coal per minute.

Screw Conveyors. — Screw conveyors consist of a helical steel flight, either in one piece or in sections, mounted on a pipe or shaft, and running in a steel or wooden trough. These conveyors are made from 4 to 18 inches in diameter, and in sections 8 to 12 feet long. The speed ranges from 20 to 60 revolutions per minute and the capacity from 10 to 30 tons of coal per hour. It is not advisable to use this type of conveyor for coal, as it will only handle the smaller sizes and the flights are very easily damaged by any foreign substance of unusual size or shape.

Belt Conveyors. — Rubber and cotton belt conveyors are used for handling coal, ore, sand, gravel etc., in all sizes. They combine a high carrying capacity with low power consumption.

In some cases the belt is flat, the material being fed to the belt at its center in a narrow stream. In the majority of cases, however, the belt is troughed by means of idler pulleys set at an angle from the horizontal and placed at intervals along the length of the belt. Rubber belts are often made more flexible for deep troughing by removing some of the layers of cotton from the belt and substituting therefor an extra thickness of rubber.

Belt conveyors may be used for elevating materials up to about 23° incline. On greater inclines the material slides back on the belt and spills. With many substances it is important to feed the belt steadily if the conveyor stands at or near the limiting angle. If the flow is interrupted the material may slide back on the belt.

Belt conveyors are run at any speed from 200 to 800 feet per minute, and are made in widths varying from 12 inches to 60 inches.

Values of A and B.

Angle, Deg.	*A*	*B*	Angle, Deg.	*A*	*B*	Angle, Deg.	*A*	*B*
0	0.343	0.01	10	0.50	0.01	30	0.79	0.009
2	0.378	0.01	14	0.57	0.01	34	0.84	0.008
4	0.40	0.01	18	0.63	0.009	38	0.88	0.008
6	0.44	0.01	22	0.69	0.009	42	0.92	0.007
8	0.47	0.01	26	0.74	0.009	46	0.95	0.007

For suspended flight conveyors take B as 0.8 and for roller flights as 0.6, of the values given in the table.

8×18	10.1	12.7		
8×20	11.0	13.4		
8×24	12.6	14.4		
10×24	15.2	17.4		

Capacity of Belt Conveyors in Tons of Coal per Hour.

Width of Belt, Ins.	Velocity, Feet per Minute. 300	350	400
12	34		
14	47		
16	62	72	82
18	78	91	104

Width of Belt, Ins.	Velocity, Feet per Minute. 300	350	400	450	500
20	96	112	128		
24	139	162	186	210	
30	218	254	290	326	
36	315	368	420	472	520

For materials other than coal, the figures in the above table should be multiplied by the coefficients given in the table below:

Material.	Coefficient.	Material.	Coefficient.
Ashes (damp)	0.86	Earth	1.4
Cement	1.76	Sand	1.8
Clay	1.26	Stone (crushed)	2.0
Coke	0.60		

Belt Conveyor Construction. (C. K. Baldwin, *Trans. A. S. M. E.*, 1908.)—The troughing idlers should be spaced as follows, depending on the weight of the material carried:

Belt width	12–16 in.	18–22 in.	24–30 in.	32–36 in.
Spacing, ft.	4½–5	4–4½	3½–4	3–3½

The stress in the belt should not exceed 18 to 20 lb. per inch of width per ply with rubber belts. This may be increased about 20% with belts in which 28 oz. duck is used. Where the power required is small the stiffness of the belt fixes the number of plies. The minimum number of plies is as follows:

Belt width, in.	12–14	16–20	22–28	30–36
Minimum plies	3	4	5	6

Pulleys of small diameter should be avoided on heavy belts, or the constant bending of the belt under heavy stress will cause the friction to lose its hold and destroy the belt. In many cases it is advisable to cover the driving pulley with a rubber lagging to increase the tractive power, particularly in dusty places. The minimum size of driving pulleys to be used is shown in the table below.

Smallest Diameter of Driving Pulleys for Belt Conveyors.

Width of Belt.	Diameter of Pulley.	Width of Belt.	Diameter of Pulley.	Width of Belt.	Diameter of Pulley.
In.	In.	In.	In.	In.	In.
12	16–18	22	20–30	32	30–36
14	16–18	24	24–30	34	30–42
16	20–24	26	24–30	36	30–48
18	20–24	28	24–30	....	....
20	20–24	30	30–36	....	....

Horse-power to Drive Belt Conveyors. (C. K. Baldwin, *Trans. A. S. M. E.*, 1908.) — The power required to drive a belt conveyor depends on a great variety of conditions, as the spacing of idlers, type of drive, thickness of belt, etc. In figuring the power required, the belt should run no faster than is necessary to carry the desired load. If it should be necessary to increase the speed, the load should be increased in proportion and the power figured accordingly.

For level conveyors H.P. $= C \times T \times L \div 1000$.

For inclined conveyors

$$\text{H.P.} = (C \times T \times L \div 1000) + (T \times H \div 1000).$$

C = power constant from table below; T = load, tons per hour; L = length of conveyor, center to center, ft.; H = vertical height material is lifted, ft.; S = belt speed, ft. per minute; B = width of belt, in.

For each movable or fixed tripper add horse-power in column 3 of table. Add 20% to horse-power for each conveyor under 50 ft. long. Add 10% to horse-power for each conveyor between 50 ft. and 100 ft. long. The formulæ above do not include gear friction, should the conveyor be gear-driven.

When horse-power and speed are known the stress in the belt in pounds per inch of width is

$$\text{Stress} = \frac{\text{H.P.} \times 33{,}000}{\text{S} \times \text{B}}.$$

From this the number of plies can be found, using 20 lb. per ply per inch of width as a maximum for rubber belts.

Relative Wearing Power of Conveyor Belts. (T. A. Bennett, *Trans. A. S. M. E.*, 1908.)—Different materials used in the construction

Constants for Formulæ for Belt Conveyors.

	1	2	3	4	5
Width of Belt, In.	*C* for Material Weighing from 25 Lb. to 75 Lb. per Cu. Ft.	*C* for Material Weighing from 75 Lb. to 125 Lb. per Cu. Ft.	H.P. Required for Each Movable or Fixed Tripper.	Minimum Plies of Belt.	Maximum Plies of Belt.
12	0.234	0.147	1/2	3	4
14	0.226	0.143	1/2	3	4

36	0.157	0.112	3 1/4	6	10

of conveyors were subjected to the uniform action of a sand blast for 45 minutes, and the relative abrasive resisting qualities were found to be as follows, taking the volume of rubber belt worn away as 1.0:

Rubber belt	1.0	Woven cotton belt, high grade	6.5
Rolled steel bar	1.5	Stitched duck, high grade	8.0
Cast iron	3.5	Woven cotton belt, low grade,	9.0 to 15.0
Balata belt, including gum cover	5.0		

A Symposium on Hoisting and Conveying was presented at the Detroit meeting of the A. S. M. E, 1908 (*Trans.*, vol. xxx.), in papers by G. E. Titcomb, S. B. Peck, C. K. Baldwin, C. J. Tomlinson and E. J. Haddock. Among the subjects discussed are the loading and unloading of cargo steamers; car unloaders; storing of ore and coal; continuous conveying of merchandise; conveying in a Portland cement plant, and suspension cableways.

PNEUMATIC CONVEYING

Pneumatic Conveying.—A pneumatic conveying system consists of a pipe line, a feeding hopper, a blower or exhauster, and a receiver. It is used for conveying grain, slack coal, sawdust, shavings, and other light material. Grain has been carried over 2,000 ft. horizontally and raised to any desired height. The pressure system is simpler and requires less pipe than the vacuum system, but the latter is more common and is adapted to a greater variety of conditions. The principal advantages of the pneumatic system, as against all types of mechanical conveyors, are simplicity, adaptability to peculiar conditions, the little attention required, few repairs, and shut-downs. (For details of apparatus, etc., see bulletins of the Connersville Blower Co.)

Pneumatic Postal Transmission.—A paper by A. Falkenau (Eng'rs Club of Philadelphia, April, 1894), entitled the "First United States Pneumatic Postal System," gives a description of the system used in London and Paris, and that recently introduced in Philadelphia between the main post-office and a substation. In London the tubes are 2¼ and 3-inch lead pipes laid in cast-iron pipes for protection. The carriers used in 2¼-inch tubes are but 1¼ inches diameter, the remaining space being taken up by packing. Carriers are despatched singly. First, vacuum alone was used; later, vacuum and compressed air. The tubes used in the Continental cities in Europe are wrought iron, the Paris tubes being 2½ inches diameter. There the carriers are despatched in trains of six to ten, propelled by a piston. In Philadelphia the size of tube adopted is 6⅛ inches, the tubes being of cast iron bored to size. The lengths of the outgoing and return tubes are 2928 feet each. The pressure at the main station is 7 lb., at the substation 4 lb., and at the end of the return pipe atmospheric pressure. The compressor has two air-cylinders 18 × 24 in. Each carrier holds about 200 letters, but 100 to 150 are taken as an average. Eight carriers may be despatched in a minute, giving a delivery of 48,000 to 72,000 letters per hour.* The time required in transmission is about 57 seconds.

Pneumatic postal transmission tubes were laid in 1898 by the Batcheller Pneumatic Tube Co. between the general post-offices in New York and Brooklyn, crossing the East River on the Brooklyn bridge. The tubes are cast iron, 12-ft. lengths, bored to $8\frac{1}{8}$ in. diameter. The joints are bells, calked with lead and yarn. There are two tubes, one operating in each direction. Both lines are operated by air-pressure above the atmospheric pressure. One tube is operated by an air-compressor in the New York office and the other by one located in the Brooklyn office.

The carriers are 24 in. long, in the form of a cylinder 7 in. diameter, and are made of steel, with fibrous bearing-rings which fit the tube. Each carrier will contain about 600 ordinary letters, and they are despatched at intervals of 10 seconds in each direction, the time of transit between the two offices being $3\frac{1}{2}$ minutes, the carriers travelling at a speed of from 30 to 35 miles per hour.

One of the air-compressors is of the duplex type and has two steam-cylinders 10 × 20 in. and two air-cylinders 24 × 20 in., delivering 1570 cu. ft. of free air per minute, at 75 r.p.m. The power is about 50 H.P.

Two other duplex air-compressors have steam-cylinders 14 × 18 in. and air-cylinders $26\frac{1}{4} \times 18$ in. They are designed for 80 to 90 r.p.m. and to compress to 20 lb. per sq. in.

Another double line of pneumatic tubes has been laid between the main office and Postal Station H, Lexington Ave. and 44th St., in New York City. This line is about $3\frac{1}{2}$ miles in length. There are three intermediate stations. The carriers can be so adjusted when they are put into the tube that they will traverse the line and be discharged automatically from the tube at the station for which they are intended. The tubes are of the same size as those of the Brooklyn line and are operated in a similar manner. The initial air-pressure is about 12 to 15 lb. On the Brooklyn line it is about 7 lb.

There is also a tube system between the New York Post-office and the Produce Exchange. For a very complete description of the system and its machinery see "The Pneumatic Despatch Tube System," by B. C. Batcheller, J. B. Lippincott Co., Philadelphia, 1897.

WIRE-ROPE HAULAGE.

Methods for transporting coal and other products by means of wire rope, though varying from each other in detail, may be grouped in five classes:

I. The Self-acting or Gravity Inclined Plane.
II. The Simple Engine-plane.
III. The Tail-rope System.
IV. The Endless-rope System.
V. The Cable Tramway.

The following brief description of these systems is abridged from a pamphlet on Wire-rope Haulage, by Wm. Hildenbrand, C.E., published by John A. Roebling's Sons Co., Trenton, N. J.

I. The Self-acting Inclined Plane. — The motive power for the self-acting inclined plane is gravity; consequently this mode of transporting coal finds application only in places where the coal is conveyed from a higher to a lower point and where the plane has sufficient grade for the loaded descending cars to raise the empty cars to an upper level.

At the head of the plane there is a drum, which is generally constructed of wood, having a diameter of seven to ten feet. It is placed high enough to allow men and cars to pass under it. Loaded cars coming from the pit are either singly or in sets of two or three switched on the track of the plane, and their speed in descending is regulated by a brake on the drum.

Supporting rollers, to prevent the rope dragging on the ground, are

* A report of a U. S. Postal Commission states that up to the present time (1910), the sending and receiving apparatus does not permit the successful operation of carrier service with an interval of less than 13 to 15 seconds between carriers, for 6- and 8-in. tubes.

generally of wood, 5 to 6 in. in diameter and 18 to 24 in. long, with 3/4 to 7/8 in. iron axles. The distance between the rollers varies from 15 to 30 ft., steeper planes requiring less rollers than those with easy grades. Considering only the reduction of friction and what is best for the preservation of rope, a general rule may be given to use rollers of the greatest possible diameter, and to place them as close as economy will permit

The smallest angle of inclination at which a plane can be made self-acting will be when the motive and resisting forces balance each other. The motive forces are the weights of the loaded car and of the descending rope. The resisting forces consist of the weight of the empty car and ascending rope, of the rolling and axle friction of the cars, and of the axle friction of the supporting rollers. The friction of the drum, stiffness of rope, and resistance of air may be neglected. A general rule cannot be given, because a change in the length of the plane or in the weight of the cars changes the proportion of the forces; also, because the coefficient of friction, depending on the condition of the road, construction of the cars, etc., is a very uncertain factor.

For working a plane with a 5/8-in. steel rope and lowering from one to four pit cars weighing empty 1400 lb. and loaded 4000 lb., the rise in 100 ft. necessary to make the plane self-acting will be from about 5 to 10 ft., decreasing as the number of cars increase, and increasing as the length of plane increases.

A gravity inclined plane should be slightly concave, steeper at the top than at the bottom. The maximum deflection of the curve should be at an inclination of 45 degrees, and diminish for smaller as well as for steeper inclinations.

II. The Simple Engine-plane. — The name "Engine-plane" is given to a plane on which a load is raised or lowered by means of a single wire rope and stationary steam-engine. It is a cheap and simple method of conveying coal underground, and therefore is applied wherever circumstances permit it. Under ordinary conditions such as prevail in the Pennsylvania mine region, a train of twenty-five to thirty loaded cars will descend, with reasonable velocity, a straight plane 5000 ft. long on a grade of 1 3/4 ft. in 100, while it would appear that 2 1/4 ft. in 100 is necessary for the same number of empty cars. For roads longer than 5000 ft. or containing sharp curves, the grade should be correspondingly larger.

III. The Tail-rope System. — Of all methods for conveying coal underground by wire rope, the tail-rope system has found the most application. It can be applied under almost any condition. The road may be straight or curved, level or undulating, in one continuous line or with side branches. In general principle a tail-rope plane is the same as an engine-plane worked in both directions with two ropes. One rope, called the "main rope," serves for drawing the set of full cars outward; the other, called the "tail-rope," is necessary to take back the empty set, which on a level or undulating road cannot return by gravity. The two drums may be located at the opposite ends of the road, and driven by separate engines, but more frequently they are on the same shaft at one end of the plane. In the first case each rope would require the length of the plane, but in the second case the tail rope must be twice as long, being led from the drum around a sheave at the other end of the plane and back again to its starting-point. When the main rope draws a set of full cars out, the tail-rope drum runs loose on the shaft, and the rope, being attached to the rear car, unwinds itself steadily. Going in, the reverse takes place. Each drum is provided with a brake to check the speed of the train on a down grade and prevent its overrunning the forward rope. As a rule, the tail rope is strained less than the main rope, but in cases of heavy grades dipping outward it is possible that the strain in the former may become as large, or even larger, than in the latter, and in the selection of the sizes reference should be had to this circumstance.

IV. The Endless-rope System. — The principal features of this system are as follows:

1. The rope, as the name indicates, is endless. 2. Motion is given to the rope by a single wheel or drum, and friction is obtained either by a grip-wheel or by passing the rope several times around the wheel. 3. The rope must be kept constantly tight, the tension to be produced by artificial means. It is done in placing either the return-wheel or an extra tension wheel on a carriage and connecting it with a weight hanging over a pulley, or attaching it to a fixed post by a screw which occasionally can be

shortened. 4. The cars are attached to the rope by a grip or clutch, which can take hold at any place and let go again, starting and stopping the train at will, without stopping the engine or the motion of the rope. 5. On a single-track road the rope works forward and backward, but on a double track it is possible to run it always in the same direction, the full cars going on one track and the empty cars on the other.

This method of conveying coal, as a rule, has not found as general an introduction as the tail-rope system, probably because its efficacy is not so apparent and the opposing difficulties require greater mechanical skill and more complicated appliances. Its advantages are, first, that it requires one-third less rope than the tail-rope system. This advantage, however, is partially counterbalanced by the circumstance that the extra tension in the rope requires a heavier size to move the same load than when a main and tail rope are used. The second and principal advantage is that it is possible to start and stop trains at will without signaling to the engineer. On the other hand, it is more difficult to work curves with the endless system, and still more so to work different branches, and the constant stretch of the rope under tension or its elongation under changes of temperature frequently causes the rope to slip on the wheel, in spite of every attention, causing delay in the transportation and injury to the rope.

Stress in Hoisting-ropes on Inclined Planes.

(Trenton Iron Co., 1906.)

Rise per 100 Ft Horizontal.	Angle of Inclination.	Stress in Lb. per Ton of 2000 Lb.	Rise per 100 Ft. Horizontal.	Angle of Inclination.	Stress in Lb. per Ton of 2000 Lb.	Rise per 100 Ft Horizontal.	Angle of Inclination.	Stress in Lb. per Ton of 2000 Lb.
Ft.			Ft.			Ft.		
5	2° 52′	140	55	28° 49′	1003	110	47° 44′	1516
10	5° 43′	240	60	30° 58′	1067	120	50° 12′	1573
15	8° 32′	336	65	33° 02′	1128	130	52° 26′	1620
20	11° 18′	432	70	35° 00′	1185	140	54° 28′	1663
25	14° 03′	527	75	36° 53′	1238	150	56° 19′	1699
30	16° 42′	613	80	38° 40′	1287	160	58° 00′	1730
35	19° 18′	700	85	40° 22′	1332	170	59° 33′	1758
40	21° 49′	782	90	42° 00′	1375	180	60° 57′	1782
45	24° 14′	860	95	43° 32′	1415	190	62° 15′	1804
50	26° 34′	933	100	45° 00′	1454	200	63° 27′	1822

The above table is based on an allowance of 40 lb. per ton for rolling friction, but an additional allowance must be made for stress due to the weight of the rope proportional to the length of the plane. A factor of safety of 5 to 7 should be taken.

In hoisting the slack-rope should be taken up gently before beginning the lift, otherwise a severe extra strain will be brought on the rope.

V. Wire-rope Tramways. — The methods of conveying products on a suspended rope tramway find especial application in places where a mine is located on one side of a river or deep ravine and the loading station on the other. A wire rope suspended between the two stations forms the track on which material in properly constructed "carriages" or "buggies" is transported. It saves the construction of a bridge or trestlework and is practical for a distance of 2000 feet without an intermediate support.

There are two distinct classes of rope tramways:

1. The rope is stationary, forming the track on which a bucket holding the material moves forward and backward, pulled by a smaller endless wire rope. 2. The rope is movable, forming itself an endless line, which serves at the same time as supporting track and as pulling rope.

Of these two the first method has found more general application, and is especially adapted for long spans, steep inclinations, and heavy loads.

The second method is used for long distances, divided into short spans, and is only applicable for light loads delivered at regular intervals.

For detailed descriptions of the several systems of wire-rope transportation, see circulars of John A. Roebling's Sons Co., The Trenton Iron Co., A. Leschen & Sons Rope Co. See also paper on Two-rope Haulage Systems, by R. Van A. Norris, *Trans. A. S. M. E.*, xii. 626.

In the Bleichert System of wire-rope tramways, in which the track rope is stationary, loads up to 2000 lb. are carried at a speed of 3 to 4 miles per hour. While the average spans on a level are from 150 to 200 ft., in crossing rivers, ravines, etc., spans up to 1500 ft. are frequently adopted. In a tramway on this system at Bingham, Utah, the total length of the line is 12,700 ft. with a fall of 1120 ft. The line operates by gravity and carries 35 tons per hour. The cost of conveying on this carrier is 7 3/4 cents per ton of 2000 lb. for labor and repairs, without any apparent deterioration in the condition of track cables and traction rope.

The Aerial Wire-rope Tramway of A. Leschen & Sons Co. is of the double-rope type, in which the buckets travel upon stationary track cables and are propelled by an endless traction rope. The buckets are attached to the traction rope by means of clips — spaced according to the desired tonnage. The hold on the rope is positive, but the clip is easily removable. The bucket is held in its normal position in the frame by two malleable iron latches — one on each side. A tripping bar engages these latches at the unloading terminal when the bucket discharges its material. This operation is automatic and takes place while the carriers are moving. At the loading terminal, the bucket is automatically returned to its normal position and latched. Special carriers are provided for the accommodation of any class of material. At each of the terminal stations is a 10-ft. sheave wheel around which the traction rope passes, these wheels being provided with steel grids for the control of the traction rope. When the loaded carriers travel down grade and the difference in elevation is sufficient, this tramway will operate by the force due to gravity, otherwise the power is applied to the sheaves through bevel gearing. Numerous modifications of the system are in use to suit different conditions.

An Aerial Tramway 21.5 miles long, with an elevation of the loading end above the discharging end of 11,500 ft., built by A. Bleichert & Co. for the government of the Argentine Republic, connecting the mines of La Mejicana with the town of Chilecito, is described by Wm. Hewitt in *Indust. Eng.*, Aug. 15, 1909. Some of the inclinations are as much as 45 deg., there are some spans nearly 3000 ft. long, and there is a tunnel nearly 500 ft. long. The line is divided into eight sections, each with an independent traction rope. The gravity of the descending loaded carriers is sufficient to make the line self-operating when it is once set in motion, but in order to ensure full control, and to provide for carrying four tons upward while the descending carriers are empty, four steam engines are installed, one for each two sections. The carriers hold 10 cu. ft., or about 1100 lbs. of ore. The speed is 500 ft. per minute, and the interval between carriers 45 seconds. The stress in the traction rope is as high as 11,000 lbs. in some sections.

Suspension Cableways or Cable Hoist-conveyors.

(Trenton Iron Co.)

In quarrying, rock-cutting, stripping, piling, dam-building, and many other operations where it is necessary to hoist and convey large individual loads economically, it frequently happens that the application of a system of derricks is impracticable, by reason of the limited area of their efficiency and the room which they occupy. To meet such conditions cable hoist-conveyors are adopted, as they can be operated in clear spans up to 1500 ft., and in lifting individual loads up to 15 tons. Two types are made — one in which the hoisting and conveying are done by separate running ropes, and the other applicable only to inclines in which the carriage descends by gravity, and but one running rope is required. The moving of the carriage in the former is effected by means of an endless rope, and these are commonly known as "endless-rope" hoist-conveyors to distinguish them from the latter, which are termed "inclined" hoist-conveyors.

The general arrangement of the endless-rope hoist-conveyors consists of a main cable passing over towers, A-frames or masts, as may be most convenient, and anchored firmly to the ground at each end, the requisite tension in the cable being maintained by a turnbuckle at one anchorage.

Upon this cable travels the carriage, which is moved back and forth over the line by means of the endless rope. The hoisting is done by a separate rope, both ropes being operated by an engine specially designed for the purpose, which may be located at either end of the line, and is constructed in such a way that the hoisting-rope is coiled up or paid out automatically as the carriage is moved in and out. Loads may be picked up or discharged at any point along the line. Where sufficient inclination can be obtained in the main cable for the carriage to descend by gravity, and the loading and unloading are done at fixed points, the endless rope can be dispensed with. The carriage, which is similar in construction to the carriage used in the endless-rope cableways, is arrested in its descent by a stop-block, which may be clamped to the main cable at any desired point, the speed of the descending carriage being under control of a brake on the engine-drum.

A Double-suspension Cableway, carrying loads of 15 tons, erected near Williamsport, Pa., by the Trenton Iron Co., is described by E. G. Spilsbury in *Trans. A. I. M. E.*, xx. 766. The span is 733 ft., crossing the Susquehanna River. Two steel cables, each 2 in. diam., are used. On these cables runs a carriage supported on four wheels and moved by an endless cable 1 inch in diam. The load consists of a cage carrying a railroad-car loaded with lumber, the latter weighing about 12 tons. The power is furnished by a 50-H.P. engine, and the trip across the river is made in about three minutes.

A hoisting cableway on the endless-rope system, erected by the Lidgerwood Mfg. Co., at the Austin Dam, Texas, had a single span 1350 ft. in length, with main cable 2 1/2 in. diam., and hoisting-rope 1 3/4 in. diam. Loads of 7 to 8 tons were handled at a speed of 600 to 800 ft. per minute.

Another, of still longer span, 1650 ft., was erected by the same company at Holyoke, Mass., for use in the construction of a dam. The main cable is the Elliott or locked-wire cable, having a smooth exterior. In the construction of the Chicago Drainage Canal twenty cableways, of 700 ft. span and 8 tons capacity, were used, the towers traveling on rails,

Tension required to Prevent Slipping of Rope on Drum. (Trenton Iron Co., 1906.) — The amount of artificial tension to be applied in an endless rope to prevent slipping on the driving-drum depends on the character of the drum, the condition of the rope and number of laps which it makes. If T and S represent respectively the tensions in the taut and slack lines of the rope; W, the necessary weight to be applied to the tail-sheave; R, the resistance of the cars and rope, allowing for friction; n, the number of half-laps of the rope on the driving-drum; and f, the coefficient of friction, the following relations must exist to prevent slipping:

$$T = Se^{fn\pi},\ W = T + S, \quad \text{and } R = T - S;$$

$$\text{from which we obtain} \quad W = \frac{e^{fn\pi} + 1}{e^{fn\pi} - 1} R,$$

in which $e = 2.71828$, the base of the Naperian system of logarithms.

The following are some of the values of f:

	Dry.	Wet.	Greasy.
Wire-rope on a grooved iron drum....	0.120	0.085	0.070
Wire-rope on wood-filled sheaves.....	0.235	0.170	0.140
Wire-rope on rubber and leather filling	0.495	0.400	0.205

The importance of keeping the rope dry is evident from these figures.

The values of the coefficient $\frac{e^{fn\pi} + 1}{e^{fn\pi} - 1}$, corresponding to the above values of f, for one up to six half-laps of the rope on the driving-drum or sheaves. are given in the table at the top of p. 1207.

When the rope is at rest the tension is distributed equally on the two lines of the rope, but when running there will be a difference in the tensions of the taut and slack lines equal to the resistance, and the values of T and S may be readily computed from the foregoing formulæ.

VALUES OF COEFFICIENT $(e^{fn\pi}+1) \div (e^{fn\pi}-1)$

f	n = Number of Half-laps on Driving-wheel.					
	1	2	3	4	5	6
0.070	9.130	4.623	3.141	2.418	1.999	1.729
0.085	7.536	3.833	2.629	2.047	1.714	1.505
0.120	5.345	2.777	1.953	1.570	1.358	1.232
0.140	4.623	2.418	1.729	1.416	1.249	1.154
0.170	3.833	2.047	1.505	1.268	1.149	1.085
0.205	3.212	1.762	1.338	1.165	1.083	1.043
0.235	2.831	1.592	1.245	1.110	1.051	1.024
0.400	1.795	1.176	1.047	1.013	1.004	1.001
0.495	1.538	1.093	1.019	1.004	1.001	....

The increase in tension in the endless rope, compared with the main rope of the tail-rope system, where the stress in the rope is equal to the resistance, is about as follows:

n =	1	2	3	4	5	6
Increase in tension in endless rope, compared with direct stress %....	40	9	2 1/3	2/3	1/5	1/10

These figures are useful in determining the size of rope. For instance, if the rope makes two half-laps on the driving drum, the strength of the rope should be 9% greater than a main rope in the tail-rope system.

General Formulæ for Estimating the Deflection of a Wire Cable Corresponding to a Given Tension.

(Trenton Iron Co., 1906.)

Let s = distance between supports or span AB; m and n = arms into which the span is divided by a vertical through the required point of deflection x, m representing the arm corresponding to the loaded side; y = horizontal distance from load to point of support corresponding with m; w = wt. of rope per ft.; g = load; t = tension; h = required deflection at any point x; all measures being in feet and pounds.

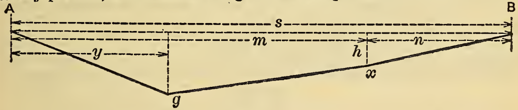

FIG. 191.

For deflection due to rope alone,

$$h = \frac{mnw}{2t} \text{ at } x, \text{ or } \frac{ws^2}{8t} \text{ at center of span.}$$

For deflection due to load alone,

$$h = \frac{gny}{ts} \text{ at } x, \text{ or } \frac{gy}{2t} \text{ at center of span.}$$

$$\text{If } y = 1/2\, s,\ h = \frac{gn}{2t} \text{ at } x, \text{ or } \frac{gs}{4t} \text{ at center of span.}$$

$$\text{If } y = m,\ h = \frac{gmn}{ts} \text{ at } x, \text{ or } \frac{gs}{4t} \text{ at center of span.}$$

For total deflection,

$$h = \frac{wmns + 2\,gny}{2\,ts} \text{ at } x, \text{ or } \frac{ws^2 + 4\,gy}{8\,t} \text{ at center of span.}$$

$$\text{If } y = 1/2\, s,\ h = \frac{wmn + gn}{2t} \text{ at } x, \text{ or } \frac{ws^2 + 2\,gs}{8\,t} \text{ at center of span.}$$

$$\text{If } y = m,\ h = \frac{wmns + 2\,gmn}{2\,ts} \text{ at } x, \text{ or } \frac{ws^2 + 2\,gs}{8\,t} \text{ at center of span.}$$

If the tension is required for a given deflection, transpose t and h in above formulæ.

Taper Ropes of Uniform Tensile Strength. — The true form of rope is not a regular taper but follows a logarithmic curve, the girth rapidly increasing toward the upper end. Mr. Chas. D. West gives the following formula, based on a breaking strain of 80,000 lb. per sq. in. of the rope, core included, and a factor of safety of 10: $\log G = F \div 3680 + \log g$, in which F = length in fathoms, and G and g the girth in inches at any two sections F fathoms apart. The girth g is first calculated for a safe strain of 8000 lb. per sq. in., and then G is obtained by the formula. **For a mathematical investigation see** *The Engineer*, **April, 1880, p. 267.**

TRANSMISSION OF POWER BY WIRE ROPE.

The following notes have been furnished to the author by Mr. Wm. Hewitt, Vice-President of the Trenton Iron Co. (See also circulars of the Trenton Iron Co. and of the John A. Roebling's Sons Co., Trenton, N. J.; "Transmission of Power by Wire Ropes," by A. W. Stahl, Van Nostrand's Science Series, No. 28; and Reuleaux's Constructor.)

The load stress or working tension should not exceed the difference between the safe stress and the bending stress as determined by the table on page 1209.

The approximate strength of iron-wire rope composed of wires having a tensile strength of 75,000 to 90,000 lbs. per sq. in. is half that of cast-steel rope composed of wires of a tensile strength of 150,000 to 190,000 lbs. per sq. in. Extra strong steel wires have a tensile strength of 190,000 to 225,000 and plow-steel wires 225,000 to 275,000 lbs. per sq. in.

The 19-wire rope is more flexible than the 7-wire, and for the same load stress may be run around smaller sheaves, but it is not as well adapted to withstand abrasion or surface wear.

The working tension may be greater, therefore, as the bending stress is less; but since the tension in the slack portion of the rope cannot be less than a certain proportion of the tension in the taut portion, to avoid slipping, a ratio exists between the diameter of sheave and the wires composing the rope corresponding to a maximum safe working tension. This ratio depends upon the number of laps that the rope makes about the sheaves, and the kind of filling in the rims or the character of the material upon which the rope tracks.

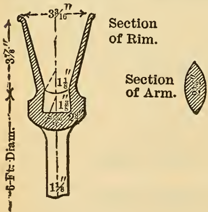

FIG. 192.

For ordinary purposes the maximum safe stress should be about one-third the ultimate, and for shafts and elevators about one-fourth the ultimate. In estimating the stress due to the load for shafts and elevators, allowance should be made for the additional stress due to acceleration in starting. For short inclined planes not used for passengers a factor of safety as low as 2½ is sometimes used, and for derricks, in which large sheaves cannot be used, and long life of the rope is not expected, the factor of safety may be as low as 2.

The Seale wire rope is made of six strands of 19 wires, laid 9 around 9 around 1, the intermediate layer being smaller than the others. It is intermediate in flexibility between the 7-wire and the ordinary 19-wire rope. (In the Seale cable d = diam. of larger wires.) All ropes 6 strands each. Extra flexible rope has 8 strands.

The sheaves (Fig. 192), are usually of cast iron, and are made as light as possible consistent with the requisite strength. Various materials have been used for filling the bottom of the groove, such as tarred oakum, jute yarn, hard wood, India-rubber, and leather. The filling which gives the best satisfaction, however, in ordinary transmissions consists of

segments of leather and blocks of India-rubber soaked in tar and packed alternately in the groove. Where the working tension is very great, however, the wood filling is to be preferred, as in the case of long-distance transmissions where the rope makes several laps about the sheaves, and is run at a comparatively slow speed.

The Bending Stress is determined by the formula

$$k = \frac{Ea}{2.06\ (R \div d) + C}$$

k = bending stress in lbs.; E = modulus of elasticity = 28,500,000; a = aggregate area of wires, sq. ins.; R = radius of bend; d = diam. of wires, ins.

For 7-wire rope $d = 1/9$ diam. of rope; $C = 9.27$.
" 19-wire " $d = 1/15$ " " " $C = 15.45$.
" the Seale cable $d = 1/12$ " " " $C = 12.36$.

From this formula the tables below and on p. 1210 have been calculated.

Horse-Power Transmitted. — The general formula for the amount of power capable of being transmitted is as follows:

$$H.P. = [cd^2 - 0.000006\,(w + g_1 + g_2)]v;$$

in which d = diameter of the rope in inches, v = velocity of the rope in feet per second, w = weight of the rope, g_1 = weight of the terminal sheaves and shafts, g_2 = weight of the intermediate sheaves and shafts (all in lbs.), and c = a constant depending on the material of the rope, the filling in the grooves of the sheaves, and the number of laps about the sheaves or drums, a single lap meaning a half-lap at each end. The values of c for one up to six laps for steel rope are given in the following table:

c = for steel rope on	Number of laps about sheaves or drums					
	1	2	3	4	5	6
Iron.....................	5.61	8.81	10.62	11.65	12.16	12.56
Wood....................	6.70	9.93	11.51	12.26	12.66	12.83
Rubber and leather.......	9.29	11.95	12.70	12.91	12.97	13.00

The values of c for iron rope are one half the above.

When more than three laps are made, the character of the surface in contact is immaterial as far as slippage is concerned.

From the above formula we have the general rule, that *the actual horse-power capable of being transmitted by any wire rope approximately equals c times the square of the diameter of the rope in inches, less six millionths the entire weight of all the moving parts, multiplied by the speed of the rope, in feet per second.*

Instead of grooved drums or a number of sheaves, about which the rope makes two or more laps, it is sometimes found more desirable, especially where space is limited, to use grip-pulleys. The rim is fitted with a continuous series of steel jaws, which bite the rope in contact by reason of the pressure of the same against them, but as soon as relieved of this pressure they open readily, offering no resistance to the egress of the rope.

In the ordinary or "flying" transmission of power, where the rope makes a single lap about sheaves lined with rubber and leather or wood, the ratio between the diameter of the sheaves and the wires of the rope, corresponding to a maximum safe working tension, is: For 7-wire rope, steel, 79.6; iron, 160.5. For 12-wire rope, steel, 59.3; iron, 120. For 19-wire rope, steel, 47.2; iron, 95.8.

Diameters of Minimum Sheaves in Inches, Corresponding to a Maximum Safe Working Tension.

Diameter of Rope, In.	Steel.			Iron.		
	7-Wire.	12-Wire.	19-Wire.	7-Wire.	12-Wire.	19-Wire.
1/4	20	15	12	40	30	24
5/16	25	19	15	50	38	30
3/8	30	22	18	60	45	36
7/16	35	26	21	70	53	42
1/2	40	30	24	80	60	48
9/16	45	33	27	90	68	54
5/8	50	37	30	100	75	60
11/16	55	41	32	110	83	66
3/4	60	44	35	120	90	72
7/8	70	52	41	140	105	84
1	80	59	47	160	120	96

Assuming the sheaves to be of equal diameter, and of the sizes in the above table, the *horse-power that may be transmitted by a steel rope making a single lap on wood-filled sheaves* is given in the table below.

The transmission of greater horse-powers than 250 is impracticable with filled sheaves, as the tension would be so great that the filling would quickly cut out, and the adhesion on a metallic surface would be insufficient where the rope makes but a single lap. In this case it becomes necessary to use the Reuleaux method, in which the rope is given more than one lap, as referred to below, under the caption "Long-distance Transmissions."

Horse-power Transmitted by a Steel Rope on Wood-filled Sheaves.

7/8	52	104	156	206	......	......	......	......	......	......
1	68	135	202	......	......	......	......	......	......	......

The horse-power that may be transmitted by iron ropes is one-half of the above.

This table gives the amount of horse-power transmitted by wire ropes under maximum safe working tensions. In using wood-lined sheaves, therefore, it is well to make some allowance for the stretching of the rope, and to advocate somewhat heavier equipments than the above table would give; that is, if it is desired to transmit 20 horse-power, for instance, to put in a plant that would transmit 25 to 30 horse-power, avoiding the necessity of having to take up a comparatively small amount of stretch. On rubber and leather filling, however, the amount of power capable of being transmitted is 40 per cent greater than for wood, so that this filling is generally used, and in this case no allowance need be made for stretch, as such sheaves will likely transmit the power given by the table, under all possible deflections of the rope.

Under ordinary conditions, ropes of seven wires to the strand, laid about a hemp core, are best adapted to the transmission of power, but conditions often occur where 12- or 19-wire rope is to be preferred, as stated below, under "Limits of Span."

Deflections of the Rope. — The tension of the rope is measured by the amount of sag or deflection at the center at the span, and the deflection corresponding to the maximum safe working tension is determined by the following formulæ, in which S represents the span in feet:

		Steel Rope.	Iron Rope.
Def. of still rope at center, in feet . .	h	$= .00004\,S^2$	$h = .00008\,S^2$
" driving " " " . . .	h_1	$= .000025\,S^2$	$h_1 = .00005\,S^2$
" slack " " " . . .	h_2	$= .0000875\,S^2$	$h_2 = .00017\,5S^2$

Limits of Span. — On spans of less than sixty feet, it is impossible to splice the rope to such a degree of nicety as to give exactly the required deflection, and as the rope is further subject to a certain amount of stretch, it becomes necessary in such cases to apply mechanical means for producing the proper tension in order to avoid frequent splicing, which is very objectionable; but care should always be exercised in using such tightening devices that they do not become the means, in unskilled hands, of overstraining the rope. The rope also is more sensitive to every irregularity in the sheaves and the fluctuations in the amount of power transmitted, and is apt to sway to such an extent beyond the narrow limits of the required deflections as to cause a jerking motion, which is very injurious. For this reason on very short spans it is found desirable to use a considerably heavier rope than that actually required to transmit the power; or in other words, instead of a 7-wire rope corresponding to the conditions of maximum tension, it is better to use a 19-wire rope of the same size wires, and to run this under a tension considerably below the maximum. In this way are obtained the advantages of increased weight and less stretch, without having to use larger sheaves, while the wear will be greater in proportion to the increased surface.

In determining the maximum limit of span, the contour of the ground and the available height of the terminal sheaves must be taken into consideration. It is customary to transmit the power through the lower portion of the rope, as in this case the greatest deflection in this portion occurs when the rope is at rest. When running, the lower portion rises and the upper portion sinks, thus enabling obstructions to be avoided which otherwise would have to be removed, or make it necessary to erect very high towers. The maximum limit of span in this case is determined by the maximum deflection that may be given to the upper portion of the rope when running, which for sheaves of 10 ft. diameter is about 600 feet.

Much greater spans than this, however, are practicable where the contour of the ground is such that the upper portion of the rope may be the driver, and there is nothing to interfere with the proper deflection of the under portion. Some very long transmissions of power have been effected in this way without an intervening support, one at Lockport, N.Y., having a clear span of 1700 feet.

Long-distance Transmissions. — When the distance exceeds the limit for a clear span, intermediate supporting sheaves are used, with plain grooves (not filled), the spacing and size of which will be governed by the contour of the ground and the special conditions involved. The size of these sheaves will depend on the angle of the bend, gauged by the tangents to the curves of the rope at the points of inflection. If the curvature due to this angle and the working tension, regardless of the size of the sheaves, as determined by the table on the next page, is less than that of the minimum sheave (see table p. 1211), the intermediate sheaves should not be smaller than such minimum sheave, but if the curvature is greater, smaller intermediate sheaves may be used.

In very long transmissions of power, requiring numerous intermediate supports, it is found impracticable to run the rope at the high speeds maintained in "flying transmissions." The rope therefore is run under a higher working tension, made practicable by wrapping it several times about grooved terminal drums, with a lap about a sheave on a take-up or counter-weighted carriage, which preserves a constant tension in the slack portion.

Inclined Transmissions. — When the terminal sheaves are not on the same elevation, the tension at the upper sheave will be greater than that at the lower, but this difference is so slight, in most cases, that it may be ignored. The span to be considered is the horizontal distance between the sheaves, and the principles governing the limits of span will hold good in this case, so that for every steep inclinations it becomes necessary to resort to tightening devices for maintaining the requisite tension in the rope. The limiting case of inclined transmissions occurs when one wheel is directly above the other. The rope in this case produces no tension whatever on the lower wheel, while the upper is subject only to the weight of the rope, which is usually so insignificant that it may be neglected altogether, and on vertical transmissions, therefore, mechanical tension is an absolute necessity.

Bending Curvature of Wire Ropes. — The curvature due to any bend in a wire rope is dependent on the tension, and is not always the same as the sheave in contact, but may be greater, which explains how it is that large ropes are frequently run around comparatively small sheaves without detriment, since it is possible to place these so close that the bending angle on each will be such that the resulting curvature will not overstrain the wires. This curvature may be ascertained from the formula and table below, which give the theoretical radii of curvature in inches for various sizes of ropes and different angles for one pound tension in the rope. Dividing these figures by the square root of the actual tension in pounds, gives the radius of curvature of the rope when this exceeds the curvature of the sheave. The rigidity of the rope or internal friction of the wires and core has not been taken into account in these figures, but the effect of this is insignificant, and it is on the safe side to ignore it. By the "angle of bend" is meant the angle between the tangents to the curves of the rope at the points of inflection. When the rope is straight the angle is 180°. For angles less than 160° the radius of curvature in most cases will be less than that corresponding to the safe working tension, and the proper size of sheave to use in such cases will be governed by the table headed "Diameters of Minimum Sheaves Corresponding to a Maximum Safe Working Tension" on p. 1211.

Radius of Curvature of Wire Ropes in Inches for 1-lb. Tension. Formula: $R^2 = Ed^4n \div 20t\ (1 - \sin \frac{1}{2}\theta)$; in which R = radius of curvature; E = modulus of elasticity = 28,500,000; d = diameter of wires; n = no. of wires in the rope; θ = angle of bend; t = working stress (lbs. and ins.). Divide by square root of stress in pounds to obtain radius in inches

The 7-wire rope has 6 strands of 7 wires each, the 19-wire rope has 6 strands of 19 wires each.

ROPE-DRIVING.

The transmission of power by cotton or manila ropes is a competitor with gearing and leather belting when the amount of power is large, or the distance between the power and the work is comparatively great. The following is condensed from a paper by C. W. Hunt, *Trans. A. S. M. E.*, xii, 230:

But few accurate data are available, on account of the long period required in each experiment, a rope lasting from three to six years. Installations which have been successful, as well as those in which the wear of the rope was destructive, indicate that 200 lbs. on a rope one inch in diameter is a safe and economical working strain. When the strain is materially increased, the wear is rapid.

In the following equations

C = circumference of rope, inches; g = gravity;
D = sag of the rope in feet; H = horse-power;
F = centrifugal force in pounds; L = distance between pulleys, ft.;
P = pounds per foot of rope; w = working strain in pounds;
R = force in pounds doing useful work;
S = strain in pounds on the rope at the pulley;
T = tension in pounds of driving side of the rope;
t = tension in pounds on slack side of the rope;
v = velocity of the rope in feet per second;
W = ultimate breaking strain in pounds.

$$W = 720\,C^2; \quad P = 0.032\,C^2; \quad w = 20\,C^2.$$

This makes the normal working strain equal to 1/36 of the breaking strength, and about 1/25 of the strength at the splice. The actual strains are ordinarily much greater, owing to the vibrations in running, as well as from imperfectly adjusted tension mechanism.

For this investigation we assume that the strain on the driving side of a rope is equal to 200 lbs. on a rope one inch in diameter, and an equivalent strain for other sizes, and that the rope is in motion at various velocities of from 10 to 140 ft. per second.

The centrifugal force of the rope in running over the pulley will reduce the amount of force available for the transmission of power. The centrifugal force $F = Pv^2 \div g$.

At a speed of about 80 ft. per second, the centrifugal force increases faster than the power from increased velocity of the rope, and at about 140 ft. per second equals the assumed allowable tension of the rope. Computing this force at various speeds and then subtracting it from the assumed maximum tension, we have the force available for the transmission of power. The whole of this force cannot be used, because a certain amount of tension on the slack side of the rope is needed to give adhesion to the pulley. What tension should be given to the rope for this purpose is uncertain, as there are no experiments which give accurate data. It is known from considerable experience that when the rope runs in a groove whose sides are inclined toward each other at an angle of 45° there is sufficient adhesion when the ratio of the tensions $T \div t = 2$.

For the present purpose T can be divided into three parts: 1. Tension doing useful work; 2. Tension from centrifugal force; 3. Tension to balance the strain for adhesion.

The tension t can be divided into two parts: 1. Tension for adhesion; 2. Tension from centrifugal force.

It is evident, however, that the tension required to do a given work should not be materially exceeded during the life of the rope.

There are two methods of putting ropes on the pulleys; one in which the ropes are single and spliced on, being made very taut at first, and less so as the rope lengthens, stretching until it slips, when it is re-spliced. The other method is to wind a single rope over the pulleys as many turns as needed to obtain the necessary horse-power and put a tension pulley to give the necessary adhesion and also take up the wear. The tension t on one of the ropes required to transmit the normal horse-power for the ordinary speeds and sizes of rope is computed by formula (1), below. The total tension T on the driving side of the rope is assumed to be the same at all speeds. The centrifugal force, as well as an amount equal to the tension for adhesion on the slack side of the rope, must be taken from the total tension T to ascertain the amount of force available for the transmission of power.

It is assumed that the tension on the slack side necessary for giving adhesion is equal to one half the force doing useful work on the driving

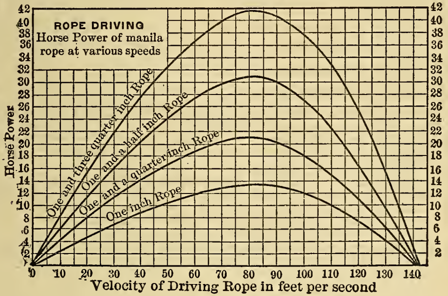

FIG. 193.

side of the rope; hence the force for useful work is $R = {}^2/_3\,(T - F)$; and the tension on the slack side to give the required adhesion is ${}^1/_3\,(T - F)$. Hence

$$t = (T - F)/3 + F \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The sum of the tensions T and t is not the same at different speeds, as the equation (1) indicates. As F varies as the square of the velocity, there is, with an increasing speed of the rope, a decreasing useful force, and an increasing total tension, t, on the slack side.

With these assumptions of allowable strains the horse-power will be

$$H = 2v\,(T - F) \div (3 \times 550) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Transmission ropes are usually from 1 to 2 inches in diameter. A computation of the horse-power for four sizes at various speeds and under ordinary conditions, based on a maximum strain equivalent to 200 lbs. for a rope one inch in diameter, is given in Fig. 193. The horse-power of other sizes is readily obtained from these. The maximum power is transmitted, under the assumed conditions, at a speed of about 80 feet per second.

The wear of the rope is both internal and external; the internal is caused by the movement of the fibers on each other, under pressure in bending over the sheaves, and the external is caused by the slipping and the wedging in the grooves of the pulley. Both of these causes of wear

Horse-power of Transmission Rope at Various Speeds.

Computed from formula (2) given above.

Diam. of Ropes.	Speed of the Rope in feet per minute.											Smallest Diam. of Pulleys in inches.
	1500	2000	2500	3000	3500	4000	4500	5000	6000	7000	8000	
1/2	1.45	1.9	2.3	2.7	3	3.2	3.4	3.4	3.1	2.2	0	20
5/8	2.3	3.2	3.6	4.2	4.6	5.0	5.3	5.3	4.9	3.4	0	24
3/4	3.3	4.3	5.2	5.8	6.7	7.2	7.7	7.7	7.1	4.9	0	30
7/8	4.5	5.9	7.0	8.2	9.1	9.8	10.8	10.8	9.3	6.9	0	36
1	5.8	7.7	9.2	10.7	11.9	12.8	13.6	13.7	12.5	8.8	0	42
1 1/4	9.2	12.1	14.3	16.8	18.6	20.0	21.2	21.4	19.5	13.8	0	54
1 1/2	13.1	17.4	20.7	23.1	26.8	28.8	30.6	30.8	28.2	19.8	0	60
1 3/4	18	23.7	28.2	32.8	36.4	39.2	41.5	41.8	37.4	27.6	0	72
2	23.2	30.8	36.8	42.8	47.6	51.2	54.4	54.8	50	35.2	0	84

are, within the limits of ordinary practice, assumed to be directly proportional to the speed.

The rope is supposed to have the strain T constant at all speeds on the driving side, and in direct proportion to the area of the cross-section; hence the catenary of the driving side is not affected by the speed or by the diameter of the rope.

The deflection of the rope between the pulleys on the slack side varies with each change of the load or change of the speed, as the tension equation (1) indicates.

The deflection of the rope is computed for the assumed value of T and t by the parabolic formula $S = \frac{PL^2}{8D} + PD$, S being the assumed strain T on the driving side, and t, calculated by equation (1), on the slack side. The tension t varies with the speed.

The following notes are from the circular of the C. W. Hunt Co.:

For a temporary installation, it might be advisable to increase the work to double that given in the table.

For convenience in estimating the necessary clearance on the driving and on the slack sides, we insert a table showing the sag of the rope at different speeds when transmitting the horse-power given in the preceding table. When at rest the sag is not the same as when running, being greater on the driving and less on the slack sides of the rope. The sag of the driving side when transmitting the normal horse-power is the same no matter what size of rope is used or what the speed driven at, because the assumption is that the strain on the rope shall be the same at all speeds when transmitting the assumed horse-power, but on the slack side the strains, and consequently the sag, vary with the speed of the rope and also with the horse-power. The table gives the sag for three speeds. If the actual sag is less than given in the table, the rope is strained more than the work requires.

This table is only approximate, and is exact only when the rope is running at its normal speed, transmitting its full load and strained to the assumed amount. All of these conditions are varying in actual work.

SAG OF THE ROPE BETWEEN PULLEYS.

Distance between Pulleys in feet.	Driving Side.	Slack Side of Rope.		
	All Speeds.	80 ft. per sec.	60 ft. per sec.	40 ft. per sec.
40	0 feet 4 inches	0 feet 7 inches	0 feet 9 inches	0 feet 11 inches
60	0 " 10 "	1 " 5 "	1 " 8 "	1 " 11 "
80	1 " 5 "	2 " 4 "	2 " 10 "	3 " 3 "
100	2 " 0 "	3 " 8 "	4 " 5 "	5 " 2 "
120	2 " 11 "	5 " 3 "	6 " 3 "	7 " 4 "
140	3 " 10 "	7 " 2 "	8 " 9 "	9 " 9 "
160	5 " 1 "	9 " 3 "	11 " 3 "	14 " 0 "

The size of the pulleys has an important effect on the wear of the rope — the larger the sheaves, the less the fibers of the rope slide on each other, and consequently there is less internal wear of the rope. The pulleys should not be less than forty times the diameter of the rope for economical wear, and as much larger as it is possible to make them. This rule applies also to the idle and tension pulleys as well as to the main driving-pulley.

TENSION ON THE SLACK PART OF THE ROPE.

Speed of Rope, in feet per second.	Diameter of the Rope and Pounds Tension on the Slack Rope								
	1/2	5/8	3/4	7/8	1	1 1/4	1 1/2	1 3/4	2
20	10	27	40	54	71	110	162	216	283
30	14	29	42	56	74	115	170	226	296
40	15	31	45	60	79	123	181	240	315
50	16	33	49	65	85	132	195	259	339
60	18	36	53	71	93	145	214	285	373
70	19	39	59	78	101	158	236	310	406
80	21	43	64	85	111	173	255	340	445
90	24	48	70	93	122	190	279	372	487

The angle of the sides of the grooves in which the rope runs varies, with different engineers, from 45° to 60°. It is very important that the sides of these grooves should be carefully polished, as the fibers of the rope rubbing on the metal as it comes from the lathe tools will gradually break fiber by fiber, and so give the rope a short life. It is also necessary to carefully avoid all sand or blow holes, as they will cut the rope out with surprising rapidity.

Much depends also upon the arrangement of the rope on the pulleys, especially where a tension weight is used. Experience shows that the increased wear on the rope from bending the rope first in one direction and then in the other is similar to that of wire rope. At mines where two cages are used, one being hoisted and one lowered by the same engine doing the same work, the wire ropes, cut from the same coil, are usually arranged so that one rope is bent continuously in one direction and the other rope is bent first in one direction and then in the other, in winding on the drum of the engine. The rope having the opposite bends wears much more rapidly than the other, lasting about three quarters as long as its mate. This difference in wear shows in manila rope, both in transmission of power and in coal-hoisting. The pulleys should be arranged, as far as possible, to bend the rope in one direction.

DIAMETER OF PULLEYS AND WEIGHT OF ROPE.

Diameter of Rope, in inches.	Smallest Diameter of Pulleys, in inches.	Length of Rope to allow for Splicing, in feet.	Approximate Weight, in lbs. per foot of rope.
1/2	20	6	0.12
5/8	24	6	0.18
3/4	30	7	0.24
7/8	36	8	0.32
1	42	9	0.49
1 1/4	54	10	0.60
1 1/2	60	12	0.83
1 3/4	72	13	1.10
2	84	14	1.40

For large amounts of power it is common to use a number of ropes lying side by side in grooves, each spliced separately. For lighter drives some engineers use one rope wrapped as many times around the pulleys as is necessary to get the horse-power required, with a tension pulley to take up the slack as the rope wears when first put in use. The weight put upon this tension pulley should be carefully adjusted, as the over-straining of the rope from this cause is one of the most common errors in rope-driving. We therefore give a table showing the proper strain on the rope for the various sizes, from which the tension weight to transmit the horse-power in the tables is easily deduced. This strain can be still further reduced if the horse-power transmitted is usually less than the nominal work which the rope was proportioned to do, or if the angle of groove in the pulleys is acute.

With a given velocity of the driving-rope, the weight of rope required for transmitting a given horse-power is the same, no matter what size rope is adopted. The smaller rope will require more parts, but the weight will be the same.

Miscellaneous Notes on Rope-Driving. — Reuleaux gives formulæ for calculating sources of loss in hemp-rope transmission due to (1) journal friction, (2) stiffness of ropes, and (3) creep of ropes. The constants in these formluæ are, however, uncertain from lack of experimental data. He calculates an average case giving loss of power due to journal friction = 4%, to stiffness 7.8%, and to creep 5%, or 16.8% in all, and says this is not to be considered higher than the actual loss.

Spencer Miller, in a paper entitled "A Problem in Continuous Rope-driving" (*Trans. A. S. C. E.*, 1897), reviews the difficulties which occur in rope-driving, with a continuous rope from a large to a small pulley. He adopts the angle of 45° as a minimum angle to use on the smaller pulley, and recommends that the larger pulley be grooved with a wider angle to a degree such that the resistance to slipping is equal in both wheels.

Mr. Miller refers to a 250-H.P. drive which has been running ten years, the large pulley being grooved 60° and the smaller 45°. This drive was designed to use a 1 1/4-in. manila rope, but the grooves were made deep

Data of Manila Transmission Rope.
From the "Blue Book" of The American Mfg. Co., New York.

Diam. of Rope.	Square of Diam.	Approximate Weight per Ft.	Breaking Strength, Lbs.	Maximum Allowable Tension.	Length of Splice, Ft. 3 Strands.	4 Strands.	6 Strands.	Smallest Diam. of Sheaves, Ins.	Maximum R.P.M.

2 1/2	6.25	2.13	43,700	1,250	10	16	22	90	230

Weight of transmission rope = 0.34 × diam.^{2}
Breaking strength = 7,000 × diam.^{2}
Maximum allowable tension = 200 × diam.^{2}
Diam. smallest practicable sheave, = 36 × diam.
Velocity of rope (assumed) = 5,400 ft. per min.

enough so that a 7/8-in. rope would not bottom. In order to determine the value of the drive a common 7/8-in. rope was put in at first, and lasted six years, working under a factor of safety of only 14. He recommends, however, for continuous rope-driving a factor of safety of not less than 20.

A heavy rope-drive on the separate, or English, rope system is described and illustrated in *Power*, April, 1892. It is in use at the India Mill at Darwen, England, and is driven by a 2000-H.P. engine at 54 revs. per min. The fly-wheel is 30 ft. diameter, weighs 65 tons, and is arranged with 30 grooves for 1 3/4-in. ropes. These ropes lead off to receiving-pulleys upon the several floors, so that each floor receives its power direct from the fly-wheel. The speed of the ropes is 5089 ft. per min., and five 7-ft. receivers are used. Lambeth cotton ropes are used. (For much other information on this subject see "Rope-Driving," by J. J. Flather, John Wiley & Sons.)

Cotton Ropes are advantageously used as bands or cords on the smaller machine appliances; the fiber, being softer and more flexible than manila hemp, gives good results for small sheaves; but for large drives, where power transmitted is in considerable amounts, cotton rope, as compared with manila, is hardly to be considered, on account of the following disadvantages: It is less durable; it is injuriously affected by the weather, so that for exposed drives, paper-mill work, or use in water-wheel pits, it is absolutely unsatisfactory; it is difficult, if not impossible, to splice uniformly; even the best quality cotton rope is much inferior to manila in strength, the breaking strain of the highest grade being but 4000 × diam.^{2} as against 7000 × diam.^{2} for manila; while, for the transmission of equal powers, the cost of a cotton rope varies from one-third to one-half more than manila. — ("Blue Book" of the Amer. Mfg. Co.)

A different opinion is found in a paper by E. Kenyon in *Proc. Inst. Engrs. and Shipbuilders of Scotland*, 1904. He says: Evidences of the progress of cotton in the manufacture of driving-ropes are so far-reaching that its superiority may be considered as much an accepted principle in rope transmission as the law of gravitation is in science. As to the longevity of cotton ropes, 24 cotton ropes 1 3/4-in. diam. are transmitting 820 H.P. at a peripheral speed of 4396 ft. per min., from a driving pulley 28 ft. diam. All the card-room ropes in this drive have been running since 1878, a period of 26 years, without any attention whatever.

FRICTION AND LUBRICATION.

Friction is defined by Rankine as that force which acts between two bodies at their surface of contact so as to resist their sliding on each other, and which depends on the force with which the bodies are pressed together.

Coefficient of Friction.—The ratio of the force required to slide a body along a horizontal plane surface to the weight of the body is called the coefficient of friction. It is equivalent to the tangent of the *angle of repose*, which is the angle of inclination to the horizontal of an inclined plane on which the body will just overcome its tendency to slide. The angle is usually denoted by θ, and the coefficient by f. $f = \tan \theta$.

Friction of Rest and of Motion. — The force required to start a body sliding is called the friction of rest, and the force required to continue its sliding after having started is called the friction of motion.

Rolling Friction is the force required to roll a cylindrical or spherical body on a plane or on a curved surface. It depends on the nature of the surfaces and on the force with which they are pressed together, but is essentially different from ordinary, or sliding, friction.

Friction of Solids.—Rennie's experiments (1829) on friction of solids, usually unlubricated and dry, led to the following conclusions:

1. The laws of sliding friction differ with the character of the bodies rubbing together.
2. The friction of fibrous material is increased by increased extent of surface and by time of contact, and is diminished by pressure and speed.
3. With wood, metal, and stones, within the limit of abrasion, friction varies only with the pressure, and is independent of the extent of surface, time of contact, and velocity.
4. The limit of abrasion is determined by the hardness of the softer of the two rubbing parts.
5. Friction is greatest with soft and least with hard materials.
6. The friction of lubricated surfaces is determined by the nature of the lubricant rather than by that of the solids themselves.

Friction of Rest. (Rennie.)

Pressure, Lbs. per Square Inch.	Values of f.			
	Wrought Iron on Wrought Iron.	Wrought on Cast Iron.	Steel on Cast Iron.	Brass on Cast Iron.
187	0.25	0.28	0.30	0.23
224	.27	.29	.33	.22
336	.31	.33	.35	.21
448	.38	.37	.35	.21
560	.41	.37	.36	.23
672	Abraded	.38	.40	.23
784	"	Abraded	Abraded	.23

Law of Unlubricated Friction. — A. M. Wellington, *Eng'g News*, April 7, 1888, states that the most important and the best determined of all the laws of unlubricated friction may be thus expressed:

The coefficient of unlubricated friction decreases materially with velocity, is very much greater at minute velocities of 0 +, falls very rapidly with minute increases of such velocities, and continues to fall much less rapidly with higher velocities up to a certain varying point, following closely the laws which obtain with lubricated friction.

Friction of Steel Tires Sliding on Steel Rails. (Westinghouse & Galton.)

Speed, miles per hour......	10	15	25	38	45	50
Coefficient of friction......	0.110	.087	.080	.051	.047	.040
Adhesion, lbs. per gross ton	246	195	179	128	114	90

Rolling Friction is a consequence of the irregularities of form and the roughness of surface of bodies rolling one over the other. Its laws are not yet definitely established in consequence of the uncertainty which exists in experiment as to how much of the resistance is due to roughness of surface, how much to original and permanent irregularity of form, and how much to distortion under the load. (Thurston.)

Coefficients of Rolling Friction.—If R = resistance applied at the circumference of the wheel, W = total weight, r = radius of the wheel, and f = a coefficient, $R = fW \div r$. f is very variable. Coulomb gives 0.06 for wood, 0.005 for metal, where W is in pounds and r in feet. Tredgold made the value of f for iron on iron 0.002. For wagons on soft soil Morin found f = 0.065, and on hard smooth roads 0.002.

A Committee of the Society of Arts (Clark, R. T. D.) reported a loaded omnibus to exhibit a resistance on various loads as below:

Pavement.	Speed per hour.	Coefficient.	Resistance.
Granite	2.87 miles.	0.007	17.41 per ton.
Asphalt	3.56 "	0.0121	27.14 "
Wood	3.34 "	0.0185	41.60 "
Macadam, graveled	3.45 "	0.0199	44.48 "
Macadam, granite, new	3.51 "	0.0451	101.09 "

Thurston gives the value of f for ordinary railroads, 0.003; well-laid railroad track, 0.002; best possible railroad track, 0.001.

The few experiments that have been made upon the coefficients of rolling friction, apart from axle friction, are too incomplete to serve as a basis for practical rules. (Trautwine.)

Laws of Fluid Friction. — For all fluids, whether liquid or gaseous, the resistance is (1) independent of the pressure between the masses in contact: (2) directly proportional to the area of rubbing-surface; (3) proportional to the square of the relative velocity at moderate and high speeds, and to the velocity nearly at low speeds; (4) independent of the nature of the surfaces of the solid against which the stream may flow, but dependent to some extent upon their degree of roughness; (5) proportional to the density of the fluid, and related in some way to its viscosity. (Thurston.)

The Friction of Lubricated Surfaces approximates that of solid friction as the journal is run dry, and that of fluid friction as it is flooded with oil.

Angles of Repose and Coefficients of Friction of Building Materials.
(From Rankine's Applied Mechanics.)

	θ.	$f = \tan\ \theta$.	$1 \div \tan\theta$
Dry masonry and brickwork	31° to 35°	0.6 to 0.7	1.67 to 1.4
Masonry and brickwork with damp mortar	36½°	0.74	1.35
Timber on stone	22°	about 0.4	2.5
Iron on stone	35° to 16⅔°	0.7 to 0.3	1.43 to 3.3

Iron on lignum vitæ	Oil, lard.	0.11	
	Unctuous.	0.19	
Bronze on bronze	Olive oil.	0.10	
	Lard.	0.09	

Prof. Thurston says concerning the foregoing figures that much better results are probably obtained in good practice with ordinary machinery. Those here given are so modified by variations of speed, pressure, and temperature, that they cannot be taken as correct for general purposes.

Friction of Motion.—The following is a table of the angle of repose θ, the coefficient of friction $f = \tan \theta$, and its reciprocal, $1 \div f$, for the materials of mechanism—condensed from the tables of General Morin (1831) and other sources, as given by Rankine:

No.	Surfaces.	θ.	f.	$1 \div f$.
1	Wood on wood, dry	14° to 26 1/2°	0.25 to 0.5	4 to 2
2	" " soaped	11 1/2° to 2°	0.2 to 0.04	5 to 25
3	Metals on oak, dry	26 1/2° to 31°	0.5 to 0.6	2 to 1.67
4	" " " wet	13 1/2° to 14°	0.24 to 0.26	4.17 to 3.85
5	" " " soapy	11 1/2°	0.2	5

Average Coefficients of Friction.—Journal of cast iron in bronze bearing; velocity 720 feet per minute; temperature 70° F.; intermittent feed through an oil-hole. (Thurston on Friction and Lost Work.)

Oils.	Pressures, Pounds per Square Inch.			
	8	16	32	48
Sperm, lard, neatsfoot, etc.	.159 to .250	.138 to .192	.086 to .141	.077 to .144
Olive, cotton-seed, rape, etc.	.160 to .283	.107 to .245	.101 to .168	.079 to .131
Cod and menhaden	.248 to .278	.124 to .167	.097 to .102	.081 to .122
Mineral lubricating-oils	.154 to .261	.145 to .233	.086 to .178	.094 to .222

With fine steel journals running in bronze bearings and continuous lubrication, coefficients far below those above given are obtained. Thus with sperm-oil the coefficient with 50 lbs. per square inch pressure was 0.0034; with 200 lbs., 0.0051; with 300 lbs., 0.0057.

For very low pressures, as in spindles, the coefficients are much higher. Thus Mr. Woodbury found, at a temperature of 100° and a velocity of 600 feet per minute,

Pressures, lbs. per sq. in.	1	2	3	4	5
Coefficient	0.38	0.27	0.22	0.18	0.17

These high coefficients, however, and the great decrease in the coefficient at increased pressures are limited as a practical matter only to the smaller pressures which exist especially in spinning machinery, where the pressure is so light and the film of oil so thick that the viscosity of the oil is an important part of the total frictional resistance.

Experiments on Friction of a Journal Lubricated by an Oil-bath (reported by the Committee on Friction, *Proc. Inst. M. E.*, Nov., 1883) show that the absolute friction, that is, the absolute tangential force per square inch of bearing, required to resist the tendency of the brass to go round with the journal, is nearly a constant under all loads, within ordinary working limits. Most certainly it does not increase in direct proportion to the load, as it should do according to the ordinary theory of solid friction. The results of these experiments seem to show that the friction of a perfectly lubricated journal follows the laws of liquid friction much more closely than those of solid friction. They show that under these circumstances the friction is nearly independent of the pressure per square inch, and that it increases with the velocity, though at a rate not nearly so rapid as the square of the velocity.

The experiments on friction at different temperatures indicate a great diminution in the friction as the temperature rises. Thus in the case of lard-oil, taking a speed of 450 r.p.m., the coefficient of friction at a temperature of 120° is only one-third of what it was at a temperature of 60°.

The journal was of steel, 4 ins. diameter and 6 ins. long, and a gun-metal brass, embracing somewhat less than half the circumference of the journal, rested on its upper side, on which the load was applied. When the bottom of the journal was immersed in oil, and the oil therefore carried under the brass by rotation of the journal, the greatest load carried with rape-oil was 573 lbs. per sq. in., and with mineral oil 625 lbs.

In experiments with ordinary lubrication, the oil being fed in at the center of the top of the brass, and a distributing groove being cut in the brass parallel to the axis of the journal, the bearing would not run cool with only 100 lbs. per sq. in., the oil being pressed out from the bearing-surface and through the oil-hole, instead of being carried in by it. On introducing the oil at the sides through two parallel grooves, the lubrication appeared to be satisfactory, but the bearing seized with 380 lbs per sq. in.

When the oil was introduced through two oil-holes, one near each end of the brass, and each connected with a curved groove, the brass refused to take its oil or run cool, and seized with a load of only 200 lbs. per sq. in.

With an oil-pad under the journal feeding rape-oil, the bearing fairly carried 551 lbs. Mr. Tower's conclusion from these experiments is that the friction depends on the quantity and uniformity of distribution of the oil, and may be anything between the oil-bath results and seizing, according to the perfection or imperfection of the lubrication. The lubrication may be very small, giving a coefficient of 1/100; but it appeared as though it could not be diminished and the friction increased much beyond this point without imminent risk of heating and seizing. The oil-bath probably represents the most perfect lubrication possible, and the limit beyond which friction cannot be reduced by lubrication; and the experiments show that with speeds of from 100 to 200 feet per minute, by properly proportioning the bearing-surface to the load, it is possible to reduce the coefficient of friction to as low as 1/1000. A coefficient of 1/150 is easily attainable, and probably is frequently attained, in ordinary engine-bearings in which the direction of the force is rapidly alternating and the oil given an opportunity to get between the surfaces, while the duration of the force in one direction is not sufficient to allow time for the oil film to be squeezed out.

Observations on the behavior of the apparatus gave reason to believe that with perfect lubrication the speed of minimum friction was from 100 to 150 feet per minute, and that this speed of minimum friction tends to be higher with an increase of load, and also with less perfect lubrication. By the speed of minimum friction is meant that speed in approaching which from rest the friction diminishes, and above which the friction increases.

Coefficients of Friction of Motion and of Rest of a Journal. — A cast-iron journal in steel boxes, tested by Prof. Thurston at a speed of rubbing of 150 feet per minute, with lard and with sperm oil, gave the following:

Press. per sq. in., lbs.	50	100	250	500	750	1000
Coeff., with sperm...	0.013	0.008	0.005	0.004	0.0043	0.009
Coeff., with lard.....	0.02	0.0137	0.0085	0.0053	0.0066	0.125

The coefficients at starting were:

With sperm.....	0.07	0.135	0.14	0.15	0.185	0.18
With lard.......	0.07	0.11	0.11	0.10	0.12	0.12

The coefficient at a speed of 150 feet per minute decreases with increase of pressure until 500 lbs. per sq. in. is reached; above this it increases. The coefficient at rest or at starting increases with the pressure throughout the range of the tests.

Coefficients of Friction of Journal with Oil-bath. — Abstract of results of Tower's experiments on friction (*Proc. Inst. M. E.*, Nov., 1883). Journal, 4 in. diam., 6 in. long; temperature, 90° F.

Lubricant in Bath.	Nominal Load, in Lbs. per Sq. In.

Comparative friction of different lubricants under same circumstances, temperature 90°, oil-bath: sperm-oil, 100; rape-oil, 106; mineral oil, 129; lard, 135; olive oil, 135; mineral grease, 217.

Value of Anti-friction Metals. (Denton.) — The various white metals available for lining brasses do not afford coefficients of friction lower than can be obtained with bare brass, but they are less liable to "overheating," because of the superiority of such material over bronze in ability to permit of abrasion or crushing, without excessive increase of friction.

Thurston (Friction and Lost Work) says that gun-bronze, Babbitt, and other soft white alloys have substantially the same friction; in other words, the friction is determined by the nature of the unguent and not by that of the rubbing-surfaces, when the latter are in good order. The soft metals run at higher temperatures than the bronze. This, however, does not necessarily indicate a serious defect, but simply deficient conductivity. The value of the white alloys for bearings lies mainly in their ready reduction to a smooth surface after any local or general injury by alteration of either surface or form.

Cast Iron for Bearings. (Joshua Rose.) — Cast iron appears to be an exception to the general rule, that the harder the metal the greater the resistance to wear, because cast iron is softer in its texture and easier to cut with steel tools than steel or wrought iron, but in some situations it is far more durable than hardened steel; thus when surrounded by steam it will wear better than will any other metal. Thus, for instance, experience has demonstrated that piston-rings of cast iron will wear smoother, better, and equally as long as those of steel, and longer than those of either wrought iron or brass, whether the cylinder in which it works be composed of brass, steel, wrought iron, or cast iron; the latter being the more noteworthy, since two surfaces of the same metal do not, as a rule, wear or work well together. So also slide-valves of brass are not found to wear so long or so smoothly as those of cast iron, let the metal of which the seating is composed be whatever it may; while, on the other hand, a cast-iron slide-valve will wear longer of itself and cause less wear to its seat, if the latter is of cast iron, than if of steel, wrought iron, or brass.

Friction of Metals under Steam-pressure. — The friction of brass upon iron under steam-pressure is double that of iron upon iron. (G. H. Babcock, *Trans. A. S. M. E.*, i, 151.)

Morin's "Laws of Friction." — 1. The friction between two bodies is directly proportioned to the pressure; i.e., the coefficient is constant for all pressures.

2. The coefficient and amount of friction, pressure being the same, are independent of the areas in contact.

3. The coefficient of friction is independent of velocity, although static friction (friction of rest) is greater than the friction of motion.

Eng'g News, April 7, 1888, comments on these "laws" as follows: From 1831 till about 1876 there was no attempt worth speaking of to enlarge our knowledge of the laws of friction, which during all that period was assumed to be complete, although it was really worse than nothing, since it was for the most part wholly false. In the year first mentioned Morin began a series of experiments which extended over two or three years, and which resulted in the enunciation of these three "fundamental laws of friction," no one of which is even approximately true.

For fifty years these laws were accepted as axiomatic, and were quoted as such without question in every scientific work published during that whole period. Now that they are so thoroughly discredited it has been attempted to explain away their defects on the ground that they cover only a very limited range of pressures, areas, velocities, etc., and that Morin himself only announced them as true within the range of his conditions. It is now clearly established that there are no limits or conditions within which any one of them even approximates to exactitude, and that there are many conditions under which they lead to the wildest kind of error, while many of the constants were as inaccurate as the laws. For example, in Morin's "Table of Coefficients of Moving Friction of Smooth Plane Surfaces, perfectly lubricated," which may be found in hundreds of text-books now in use, the coefficient of wrought iron on brass is given as 0.075 to 0.103, which would make the rolling friction of railway trains 15 to 20 lbs. per ton instead of the 3 to 6 lbs. which it actually is.

General Morin, in a letter to the Secretary of the Institution of Mechanical Engineers, dated March 15, 1879, writes as follows concerning his experiments on friction made more than forty years before: "The results furnished by my experiments as to the relations between pressure, surface, and speed on the one hand, and sliding friction on the other, have always been regarded by myself, not as mathematical laws, but as close approximations to the truth, within the limits of the data of the experiments themselves. The same holds, in my opinion, for many other laws of practical mechanics, such as those of rolling resistance, fluid resistance, etc."

Prof. J. E. Denton (*Stevens Indicator*, July, 1890) says: It has been generally assumed that friction between lubricated surfaces follows the simple law that the amount of the friction is some fixed fraction of the pressure between the surfaces, such fraction being independent of the intensity of the pressure per square inch and the velocity of rubbing, between certain limits of practice, and that the fixed fraction referred to is represented by the coefficients of friction given by the experiments of Morin or obtained from experimental data which represent conditions of practical lubrication, such as those given in Webber's Manual of Power.

By the experiments of Thurston, Woodbury, Tower, etc., however, it appears that the friction between lubricated metallic surfaces, such as machine bearings, is not directly proportional to the pressure, is not independent of the speed, and that the coefficients of Morin and Webber are about tenfold too great for modern journals.

Prof. Denton offers an explanation of this apparent contradiction of authorities by showing, with laboratory testing-machine data, that Morin's laws hold for bearings lubricated by a restricted feed of lubricant, such as is afforded by the oil-cups common to machinery; whereas the modern experiments have been made with a surplus feed or superabundance of lubricant, such as is provided only in railroad-car journals, and a few special cases of practice.

That the low coefficients of friction obtained under the latter conditions are realized in the case of car-journals, is proved by the fact that the temperature of car-boxes remains at 100° at high velocities; and experiment shows that this temperature is consistent only with a coefficient of friction of a fraction of one per cent. Deductions from experiments on train resistance also indicate the same low degree of friction. But these low coefficients do not account for the internal friction of steam-engines as well as do the coefficients of Morin and Webber.

In *American Machinist*, Oct. 23, 1890, Prof. Denton says: Morin's measurements of friction of lubricated journals did not extend to light pressures. They apply only to the conditions of general shafting and engine work.

He clearly understood that there was a frictional resistance, due solely to the viscosity of the oil, and that therefore, for very light pressures, the laws which he enunciated did not prevail.

He applied his dynamometers to ordinary shaft-journals without special preparation of the rubbing-surfaces, and without resorting to artificial methods of supplying the oil.

Later experimenters have with few exceptions devoted themselves exclusively to the measurement of resistance practically due to viscosity alone. They have eliminated the resistance to which Morin confined his measurements, namely, the friction due to such contacts of the rubbing-surfaces as prevail with a very thin film of lubricant between comparatively rough surfaces.

Prof. Denton also says (*Trans. A. S. M. E.*, x, 518): "I do not believe there is a particle of proof in any investigation of friction ever made, that Morin's laws do not hold for ordinary practical oil-cups or restricted rates of feed."

Laws of Friction of Well-lubricated Journals. — John Goodman (*Trans. Inst. C. E.*, 1886, *Eng'g News*, April 7 and 14, 1888), reviewing the results obtained from the testing-machines of Thurston, Tower, and Stroudley, arrives at the following laws:

Laws of Friction: Well-lubricated Surfaces.
(Oil-bath.)

1. The coefficient of friction with the surfaces efficiently lubricated is from 1/6 to 1/10 that for dry or scantily lubricated surfaces.

2. The coefficient of friction for moderate pressures and speeds varies approximately inversely as the normal pressure; the frictional resistance varies as the area in contact, the normal pressure remaining constant.

3. At very low journal speeds the coefficient of friction is abnormally high; but as the speed of sliding increases from about 10 to 100 ft. per min., the friction diminishes, and again rises when that speed is exceeded, varying approximately as the square root of the speed.

4. The coefficient of friction varies approximately inversely as the temperature, within certain limits, namely, just before abrasion takes place.

The evidence upon which these laws are based is taken from various modern experiments. That relating to Law 1 is derived from the "First Report on Friction Experiments," by Mr. Beauchamp Tower.

Method of Lubrication.	Coefficient of Friction.	Comparative Friction.
Oil-bath	0.00139	1.00
Siphon lubricator	0.0098	7.06
Pad under journal	0.0090	6.48

With a load of 293 lbs. per sq. in. and a journal speed of 314 ft. per min. Mr. Tower found the coefficient of friction to be 0.0016 with an oil-bath, and 0.0097, or six times as much, with a pad. The very low coefficients obtained by Mr. Tower will be accounted for by Law 2, as he found that the frictional resistance per square inch under varying loads is nearly constant, as below:

Load in lbs. per sq. in.	529	468	415	363	310	258	205	153	100
Frictional resist. per sq. in.	0.416	0.514	0.498	0.472	0.464	0.438	0.43	0.458	0.45

The frictional resistance per square inch is the product of the coefficient of friction into the load per square inch on horizontal sections of the brass. Hence, if this product be a constant, the one factor must vary inversely as the other, or a high load will give a low coefficient, and *vice versa*.

For ordinary lubrication, the coefficient is more constant under varying loads: the frictional resistance then varies directly as the load, as shown by Mr. Tower in Table VIII of his report (*Proc. Inst. M. E.*, 1883).

With respect to Law 3, A. M. Wellington (*Trans. A. S. C. E.*, 1884), in experiments on journals revolving at very low velocities, found that the friction was then very great, and nearly constant under varying conditions of the lubrication, load, and temperature. But as the speed increased the friction fell slowly and regularly, and again returned to the original amount when the velocity was reduced to the same rate. This is shown in the following table:

Speed, feet per minute:

0 + 2.16 3.33 4.86 8.82 21.42 35.37 53.01 89.28 106.02

Coefficient of friction:

0.118 0.094 0.070 0.069 0.055 0.047 0.040 0.035 0.030 0.026

It was also found by Prof. Kimball that when the journal velocity was increased from 6 to 110 ft. per min., the friction was reduced 70%; in another case the friction was reduced 67% when the velocity was increased from 1 to 100 ft. per min.; but after that point was reached the coefficient varied approximately with the square root of the velocity.

The following results were obtained by Mr. Tower:

Feet per minute	209	262	314	366	419	471	Nominal Load per Sq. In.
Coeff. of friction.....	0.0010	0.0012	0.0013	0.0014	0.0015	0.0017	520 lbs.
" "	.0013	.0014	.0015	.0017	.0018	.002	468 lbs.
" "	.0014	.0015	.0017	.0019	.0021	.0024	415 lbs.

The variation of friction with temperature is approximately in the inverse ratio, Law 4. Take, for example, Mr. Tower's results, at 262 ft. per minute:

Temp. F.	110°	100°	90°	80°	70°	60°
Observed................	0.0044	0.0051	0.006	0.0073	0.0092	0.0119
Calculated...............	0.00451	0.00518	0.00608	0.00733	0.00964	0.01252

This law does not hold good for pad or siphon lubrication, as then the coefficient of friction diminishes more rapidly for given increments of temperature, but on a gradually decreasing scale, until the normal temperature has been reached; this normal temperature increases directly as the load per sq. in. This is shown in the following table taken from Mr. Stroudley's experiments with a pad of rape-oil:

Temp. F.........	105°	110°	115°	120°	125°	130°	135°	140°	145°
Coefficient.......	0.022	0.0180	0.0160	0.0140	0.0125	0.0115	0.0110	0.0106	0.0102
Decrease of coeff..	.....	0.0040	0.0020	0.0020	0.0015	0.0010	0.0005	0.0004	0.0002

In the Galton-Westinghouse experiments it was found that with velocities below 100 ft. per min., and with low pressures, the frictional resistance varied directly as the normal pressure; but when a velocity of 100 ft. per min. was exceeded, the coefficient of friction greatly diminished; from the same experiments Prof. Kennedy found that the coefficient of friction for high pressures was sensibly less than for low.

Allowable Pressures on Bearing-surfaces. (*Proc. Inst. M. E.*, May, 1888.) — The Committee on Friction experimented with a steel ring of rectangular section, pressed between two cast-iron disks, the annular bearing-surfaces of which were covered with gun-metal, and were 12 in. inside diameter and 14 in. outside. The two disks were rotated together, and the steel ring was prevented from rotating by means of a lever, the holding force of which was measured. When oiled through grooves cut in each face of the ring and tested at from 50 to 130 revs. per min., it was found that a pressure of 75 lbs. per sq. in. of bearing-surface was as much as it would bear safely at the highest speed without seizing, although it carried 90 lbs. per sq. in. at the lowest speed. The coefficient of friction is also much higher than for a cylindrical bearing, and the friction follows the law of the friction of solids much more nearly than that of liquids. This is doubtless due to the much less perfect lubrication applicable to this form of bearing compared with a cylindrical one. The coefficient of friction appears to be about the same with the same load at all speeds, or, in other words, to be independent of the speed; but it seems to diminish somewhat as the load is increased, and may be stated approximately as 1/20 at 15 lbs. per sq. in., diminishing to 1/30 at 75 lbs. per sq. in.

The high coefficients of friction are explained by the difficulty of lubricating a collar-bearing. It is similar to the slide-block of an engine;

which can carry only about one-tenth the load per sq. in. that can be carried by the crank-pins.

In experiments on cylindrical journals it has been shown that when a cylindrical journal was lubricated from the side on which the pressure bore, 100 lbs. per sq. in. was the limit of pressure that it would carry; but when it came to be lubricated on the lower side and was allowed to drag the oil in with it, 600 lbs. per sq. in. was reached with impunity; and if the 600 lbs. per sq. in., which was reckoned upon the full diameter of the bearing, came to be reckoned on the sixth part of the circle that was taking the greater proportion of the load, it followed that the pressure upon that part of the circle amounted to about 1200 lbs. per sq. in.

In connection with these experiments Mr. Wicksteed states that in drilling-machines the pressure on the collars is frequently as high as 336 lbs. per sq. in., but the speed of rubbing in this case is lower than it was in any of the experiments of the Research Committee. In machines working very slowly and intermittently, as in testing-machines, very much higher pressures are admissible. Prof. Thurston (Friction and Lost Work, p. 240) says 7000 to 9000 lbs. pressure per square inch is reached on the slow working and rarely moved pivots of swing bridges.

Mr. Adamson mentions the case of a heavy upright shaft carried upon a small footstep-bearing, where a weight of at least 20 tons was carried on a shaft of 5 in. diameter, or, say, 20 sq. in. area, giving a pressure of 1 ton per sq. in. The speed was 190 to 200 revs. per min. It was necessary to force the oil under the bearing by means of a pump. For heavy horizontal shafts, such as a fly-wheel shaft, carrying 100 tons on two journals, his practice for getting oil into the bearings was to flatten the journal along one side throughout its whole length to the extent of about an eighth of an inch in width for each inch in diameter up to 8 in. diameter; above that size rather less flat in proportion to the diameter. At first sight it appeared alarming to get a continuous flat place coming round in every revolution of a heavily loaded shaft; yet it carried the oil effectually into the bearing, which ran much better in consequence than a truly cylindrical journal without a flat side.

In thrust-bearings on torpedo-boats Mr. Thornycroft allows a pressure of never more than 50 lbs. per sq. in.

Mr. Tower says (*Proc. Inst. M. E.*, Jan., 1884): In eccentric-pins of punching and shearing machines very high pressures are sometimes used without seizing. In addition to the alternation in the direction, the pressure is applied for only a very short space of time in these machines, so that the oil has no time to be squeezed out.

In the discussion on Mr. Tower's paper (*Proc. Inst. M. E.*, 1885) it was stated that it is well known from practical experience that with a constant load on an ordinary journal it is difficult and almost impossible to have more than 200 lbs. per square inch, otherwise the bearing would get hot and the oil go out of it; but when the motion was reciprocating, so that the load was alternately relieved from the journal, as with crank-pins and similar journals, much higher loads might be applied than even 700 or 800 lbs. per square inch.

Mr. Goodman (*Proc. Inst. C. E.*, 1886) found that the total frictional resistance is materially reduced by diminishing the width of the brass.

The lubrication is most efficient in reducing the friction when the brass subtends an angle of from 120° to 60°. The film is probably at its best between the angles 80° and 110°.

In the case of a brass of a railway axle-bearing where an oil-groove is cut along its crown and an oil-hole is drilled through the top of the brass into it, the wear is invariably on the off side, which is probably due to the oil escaping as soon as it reaches the crown of the brass, and so leaving the off side almost dry, where the wear consequently ensues.

In railway axles the brass wears always on the forward side. The same observation has been made in marine-engine journals, which always wear in exactly the reverse way to what might be expected. Mr. Stroudley thinks this peculiarity is due to a film of lubricant being drawn in from the under side of the journal to the aft part of the brass, which effectually lubricates and prevents wear on that side; and that when the lubricant reaches the forward side of the brass it is so attenuated down to a wedge shape that there is insufficient lubrication, and greater wear consequently follows.

C. J. Field (*Power*, Feb., 1893) says: One of the most vital points of an engine for electrical service is that of main bearings. They should have a surface velocity of not exceeding 350 feet per minute, with a mean bearing-pressure per square inch of projected area of journal of not more than 80 lbs. This is considerably within the safe limit of cool performance and easy operation. If the bearings are designed in this way, it would admit the use of grease on all the main wearing-surface, which in a large type of engines for this class of work we think advisable.

Oil-pressure in a Bearing. — Mr. Beauchamp Tower (*Proc. Inst. M. E.*, Jan., 1885) made experiments with a brass bearing 4 ins. diameter by 6 ins. long, to determine the pressure of the oil between the brass and the journal. The bearing was half immersed in oil, and had a total load of 8008 lbs. upon it. The journal rotated 150 r.p.m. The pressure of the oil was determined by drilling small holes in the bearing at different points and connecting them by tubes to a Bourdon gauge. It was found that the pressure varied from 310 to 625 lbs. per sq. in., the greatest pressure being a little to the "off" side of the center line of the top of the bearing, in the direction of motion of the journal. The sum of the upward force exerted by these pressures for the whole lubricated area was nearly equal to the total pressure on the bearing. The speed was reduced from 150 to 20 r.p.m., but the oil-pressure remained the same showing that the brass was as completely oil-borne at the lower speed as at the higher. The following was the observed friction at the lower speed:

Nominal load, lbs. per sq. in....	443	333	211	89
Coefficient of friction..........	0.00132	0.00168	0.00247	0.0044

The nominal load per square inch is the total load divided by the product of the diameter and length of the journal. At the low speed of 20 r.p.m. it was increased to 676 lbs. per sq. in. without any signs of heating or seizing.

Friction of Car-journal Brasses. (J. E. Denton, *Trans. A. S. M. E.* xii, 405.) — A new brass dressed with an emery-wheel, loaded with 5000 lbs., may have an actual bearing-surface on the journal, as shown by the polish of a portion of the surface, of only 1 square inch. With this pressure of 5000 lbs. per sq. in., the coefficient of friction may be 6%, and the brass may be overheated, scarred and cut, but, on the contrary, it may wear down evenly to a smooth bearing, giving a highly polished area of contact of 3 sq. ins., or more, inside of two hours of running, gradually decreasing the pressure per square inch of contact, and a coefficient of friction of less than 0.5%. A reciprocating motion in the direction of the axis is of importance in reducing the friction. With such polished surfaces any oil will lubricate, and the coefficient of friction then depends on the viscosity of the oil. With a pressure of 1000 lbs. per sq. in., revolutions from 170 to 320 per min., and temperatures of 75° to 113° F., with both sperm and paraffine oils, a coefficient of as low as 0.11% has been obtained, the oil being fed continuously by a pad.

Experiments on Overheating of Bearings. — Hot Boxes. (Denton.) — Tests with car brasses loaded from 1100 to 4500 lbs. per sq. in. gave 7 cases of overheating out of 32 trials. The tests show how purely a matter of chance is the overheating, as a brass which ran hot at 5000 lbs. load on one day would run cool on a later date at the same or higher pressure. The explanation of this apparently arbitrary difference of behavior is that the accidental variations of the smoothness of the surfaces, almost infinitesimal in their magnitude, cause variations of friction which are always tending to produce overheating, and it is solely a matter of chance when these tendencies preponderate over the lubricating influence of the oil. There is no appreciable advantage shown by sperm oil, when there is no tendency to overheat — that is, paraffine can lubricate under the highest pressures which occur, as well as sperm, when the surfaces are within the conditions affording the minimum coefficients of friction.

Sperm and other oils of high heat-resisting qualities, like vegetable oils and petroleum cylinder stocks, differ from the more volatile lubricants, like paraffine, only in their ability to reduce the chances of the continual accidental infinitesimal abrasion producing overheating.

The effect of emery or other gritty substance in reducing overheating of a bearing is thus explained:

The effect of the emery upon the surfaces of the bearings is to cover the latter with a series of parallel grooves, and apparently after such grooves are made the presence of the emery does not practically increase the friction over its amount when pure oil only is between the surfaces. The infinite number of grooves constitute a very perfect means of insuring a uniform oil supply at every point of the bearings. As long as grooves in the journal match with those in the brasses the friction appears to amount to only about 10% to 15% of the pressure. But if a smooth journal is placed between a set of brasses which are grooved, and pressure be applied, the journal crushes the grooves and becomes brazed or coated with brass, and then the coefficient of friction becomes upward of 40%. If then emery is applied, the friction is made very much less by its presence, because the grooves are made to match each other, and a uniform oil supply prevails at every point of the bearings, whereas before the application of the emery many spots of the bearing receive no oil between them.

Moment of Friction and Work of Friction of Sliding-surfaces, etc.

	Moment of Friction, inch-lbs.	Energy lost by Friction in ft.-lbs. per min.
Flat surfaces	....	fWS
Shafts and journals	$\frac{1}{2} fWd$	$0.2618 fWdn$
Flat pivots	$\frac{2}{3} fWr$	$0.349 fWrn$
Collar-bearing	$\frac{2}{3} fW \frac{r_2^3 - r_1^3}{r_2^2 - r_1^2}$	$0.349 fWn \frac{r_2^3 - r_1^3}{r_2^2 - r_1^2}$
Conical pivot	$\frac{2}{3} fWr \operatorname{cosec} a$	$0.349 fWrn \operatorname{cosec} a$
Conical journal	$\frac{2}{3} fWr \sec a$	$0.349 fWrn \sec a$
Truncated-cone pivot	$\frac{2}{3} fW \frac{r_2^3 - r_1^3}{r_2 \sin a}$	$0.349 fWn \frac{r_2^3 - r_1^3}{r_2 \sin a}$
Hemispherical pivot	fWr	$0.5236 fWrn$
Tractrix, or Schiele's "anti-friction" pivot	fWr	$0.5236 fWrn$

In the above f = coefficient of friction;
W = weight on journal or pivot in pounds;
r = radius, d = diameter, in inches;
S = space in feet through which sliding takes place;
r_2 = outer radius, r_1 = inner radius;
n = number of revolutions per minute;
a = the half-angle of the cone, i.e., the angle of the slope with the axis.

To obtain the horse-power, divide the quantities in the last column by 33,000. Horse-power absorbed by friction of a shaft $= \frac{fWdn}{126,050}$.

The formula for energy lost by shafts and journals is approximately true for loosely fitted bearings. Prof. Thurston shows that the correct formula varies according to the character of fit of the bearing; thus for loosely fitted journals, if U = the energy lost,

$$U = \frac{2 f\pi r}{\sqrt{1+f^2}} Wn \text{ inch-pounds} = \frac{0.2618 fWdn}{\sqrt{1+f^2}} \text{ foot-lbs.}$$

For perfectly fitted journals $U = 2.54 f\pi rWn$ inch-lbs. $= 0.3325 fWdn$ ft.-lbs.

For a bearing in which the journal is so grasped as to give a uniform pressure throughout, $U = f\pi^2 rWn$ inch-lbs. $= 0.4112 fWdn$ ft.-lbs.

Resistance of railway trains and wagons due to friction of trains:

$$\text{Pull on draw-bar} = f \times 2240 \div R \text{ pounds per gross ton,}$$

in which R is the ratio of the radius of the wheel to the radius of journal.

A cylindrical journal, perfectly fitted into a bearing, and carrying a total load, distributes the pressure due to this load unequally on the bearing, the maximum pressure being at the extremity of the vertical radius, while at the extremities of the horizontal diameter the pressure is zero. At any point of the bearing-surface at the extremity of a radius which makes an angle θ with the vertical radius the normal pressure is proportional to $\cos \theta$. If p = normal pressure on a unit of surface.

w = total load on a unit of length of the journal, and r = radius of journal,
$w \cos \theta = 1.57\, rp, \quad p = w \cos \theta \div 1.57\, r.$

Tests of Large Shaft Bearings are reported by Albert Kingsbury in *Trans. A. S. M. E.*, 1905. A horizontal shaft was supported in two bearings 9 × 30 ins., and a third bearing 15 × 40 ins., midway between the other two, was pressed upwards against the shaft by a weighed lever, so that it was subjected to a pressure of 25 to 50 tons. The journals were flooded with oil from a supply tank. The shaft was driven by an electric motor, and the friction H.P. was determined by measuring the current supplied. Following are the principal results:

Load, tons*									
25	25	25	25	25	33.6	42.3	47	47	50.5
Load per sq. in.*									
83	83	83	83	83	112	141	157	157	168
Speed, r.p.m.									
309	506	180	179	301	454	480	946	1243	1286
Speed, ft. per min.*									
1215	1990	708	704	1180	1785	1890	3720	4900	5050
Friction H.P.†

* On the large bearing. † Three bearings.

The last three tests were with paraffin oil; the others with heavy machine oil.

Clearance between Journal and Bearing. — John W. Upp, in *Trans. A. S. M. E.*, 1905 gives a table showing the diameter of bore of horizontal and vertical bearings according to the practice of one of the leading builders of electrical machinery. The maximum diameter of the journal is the same as its nominal diameter, with an allowable variation below maximum of 0.0005 in. up to 3 in. diam., 0.001 in. from 3½ to 9 in., and 0.0015 in. from 10 to 24 in. The maximum bore of a horizontal bearing is larger than the diam. of the journal by from 0.002 in. for a ½-in. journal to 0.009 for 6 in., for journals 7 to 15 in. it is 0.004 + 0.001 × diam., and for 16 to 24 in. it is uniformly 0.02 in. For vertical journals the clearance is less by from 0.001 to 0.004 in. according to the diameter. The allowable variation above the minimum bore is from 0.001 to 0.005.

Allowable Pressures on Bearings. — J. T. Nicholson, in a paper read before the Manchester Assoc. of Engrs. (*Am. Mach.*, Jan. 16, 1908, *Eng. Digest*, Feb., 1908), as a result of a theoretical study of the lubrication of bearings and of their emission of heat, obtains the formula $p = P/ld = 40\,(dN)^{1/4}$, in which p = allowable pressure per sq. in. of projected area, P = total pressure, l = length and d = diam. of journal, N = revs. per min. It appears from this formula that the greater the speed the greater the allowable pressure per sq. in., so that for a 1-in. journal the allowable pressure per sq. in. is 126 lbs. at 100 r.p.m. and 189 lbs. at 500 r.p.m., and for a 5-in. journal 189 lbs. at 100 and 283 lbs. at 500 r.p.m. W. H. Scott (*Eng. Digest*, Feb., 1908) says this is contrary to the teaching of practical experience, and therefore the formula is inaccurate. Mr. Scott, from a study of the experiments of Tower, Lasche, and Stribeck, derives the following formulæ for the several conditions named:

For main bearings of double-acting vertical engines. $p = 750\, D^{1/4}/N^{1/4}$
" " " " " " horizontal " . $p = 660\, D^{1/12}/N^{1/4}$
" " " " single-acting four-cycle gas engines . . . . $p = 1350\, D^{1/12}/N^{1/4}$
For crank pins of vert. and hor. double-acting engines. $p = 1560\, D^{1/4}/N^{1/4}$
" " " " single-acting four-cycle gas engines. $p = 3000\, D^{1/4}/N^{1/4}$
For dead loads with ordinary lubrication . . . . $p = 400\, N^{-1/5}$
" " " " forced " . . . . $p = 1600\, N^{-1/4}$

p = allowable pressure in lbs. per sq. in. of projected area; D = diam. in ins.; N = revs. per min.

F. W. Taylor (*Trans. A. S. M. E.*, 1905), as the result of an investigation of line shaft and mill bearings that were running near the limit of durability and heating yet not dangerously heating, gives the formula $PV = 400$. P = pressure in lbs. per sq. in. of projected area, V = velocity of circumference of bearing in ft. per sec.

The formula is applicable to bearings in ordinary shop or mill use on shafting which is intended to run with the care and attention which such bearings usually receive, and gives the maximum or most severe duty to which it is safe to subject ordinary *chain or oiled* ball and socket bearings which are *babbitted.* It is not safe for ordinary shafting to use *cast-iron boxes*, with either sight feed, wick feed, or grease-cup oiling, under as severe conditions as $P \times V = 200$.

Archbutt and Deeley's "Lubrication and Lubricants" gives the following allowable pressures in lbs. per sq. in. of projected area of bearings.

Crank-pin of shearing and punching machine, hard steel, intermittent load bearing	3000
Bronze crosshead neck journals	1200
Crank pins, large slow engine	800–900
Crank pins, marine engines	400–500
Main crankshaft bearing, fast marine	400
Same, slow marine	600
Railway coach journals	300–400
Flywheel shaft journals	150–200
Small engine crank pin	150–200
Small slide block, marine engine	100
Stationary engine slide blocks	25–125
Same, usual case	30– 60
Propeller thrust bearings	50– 70
Shafts in cast-iron steps, high speed	15

Bearing Pressures for Heavy Intermittent Loads. (Oberlin Smith, *Trans. A. S. M. E.*, 1905.) — In a punching press of about 84 tons capacity, the pressure upon the front journal of the main shaft is about 2400 lbs. per sq. in. of projected area. Upon the eccentric the pressure against the pitman driving the ram is some 7000 lbs. per sq. in. — both surfaces being of cast iron, and sometimes running at a surface speed of 140 feet per minute. Such machines run year in and year out with but little trouble in the way of heating or "cutting." An instance of excessive pressure may be cited in the case of a Ferracute toggle press, where the whole ram pressure of 400 tons is brought to bear upon hardened steel toggle-pins, running in cast iron or bronze bearings, 3 in. in diam. by nearly 14 in. long. These run habitually, for maximum work, under a load of 20,000 lbs. per sq. in.

Bearings for Very High Rotative Speeds. (*Proc. Inst. M. E.*, Oct., 1888, p. 482.) — In the Parsons steam-turbine, which has a speed as high as 18,000 rev. per min., as it is impossible to secure absolute accuracy of balance, the bearings are of special construction so as to allow of a certain very small amount of lateral freedom. For this purpose the bearing is surrounded by two sets of steel washers 1/16 in. thick and of different diameters, the larger fitting close in the casing and about 1/32 in. clear of the bearing, and the smaller fitting close on the bearing and about 1/32 in. clear of the casing. These are arranged alternately, and are pressed together by a spiral spring. Consequently any lateral movement of the bearing causes them to slide mutually against one another, and by their friction to check or damp any vibrations that may be set up in the spindle. The tendency of the spindle is then to rotate about its axis of mass, and the bearings are thereby relieved from excessive pressure, and the machine from undue vibration. The allowing of the turbine itself to find its own center of gyration is a well-known device in other branches of mechanics: as in the instance of the centrifugal hydro-extractor, where a mass very much out of balance is allowed to find its own center of gyration; the faster it runs the more steadily does it revolve and the less is the vibration Another illustration is to be found in the spindles of spinning machinery which run at about 10,000 or 11,000 revs. per min.: although of very small dimensions, the outside diameter of the largest portion or driving whorl being perhaps not more than 1 1/4 in., it is found impracticable to run them at that speed in what might be called a hard-and-fast bearing. They are therefore run with some elastic substance surrounding the bearing, such as steel springs, hemp, or cork. Any elastic substance is sufficient to absorb the vibration, and permit of absolutely steady running.

Bearing Pressures in Shafts of Parsons Turbines.—The product of the bearing pressure in lb. per sq. in. and the peripheral velocity in ft. per sec. is generally about 2500 (*Proc., Inst. Elect. Engrs.*, June, 1905).

Thrust Bearings in Marine Practice. (G. W. Dickie, *Trans. A. S. M. E.*, 1905.) — The approximate pressure on a thrust bearing of a propeller shaft assuming two thirds of the indicated horse-power to be effective on the propeller is $P = \text{I.H.P.} \times \frac{2 \times 60 \times 33000}{S \times 3 \times 6080} = \frac{\text{I.H.P.}}{S} \times 217.1$, in which S = speed of ship in knots per hour, P = total thrust in lbs. The following are data of water-cooled bearings which have given satisfactory service:

Speed in knots	22	22½	28	21
Thrust-ring surface, horse-shoe type, sq. ins.	1188	891	581	2268
Horse-power, one engine, I.H.P.	11,500	6,800	4,200	15,000
Indicated pressure on bearing, lbs.	112,700	89,000	33,600	154,000
Pressure per sq. in. of surface, lbs.	95	100	58	68.1
Mean speed of bearing surfaces, ft. per min.	642	610	827	504

Bearings for Locomotives. (G. M. Basford, *Trans., A. S. M. E.*, 1905.) — Bearing areas for locomotive journals are determined chiefly by the possibilities of lubrication. On driving journals the following figures of pressure in lbs. per sq. in. of projected area give good service: passenger, 190; freight, 200; switching, 220 lbs. Crank pins may be loaded from 1500 to 1700 lbs.; wrist pins to 4000 lbs. per sq. in. Car and tender bearings are usually loaded from 300 to 325 lbs. per sq. in.

Bearings of Corliss Engines. (P. H. Been, *Trans. A. S. M. E.*, 1905.) — In the practice of one of the largest builders the greatest pressure allowed per sq. in. of projected area for all shafts is 140 lbs. On most engines the pressure per sq. in. multiplied by the velocity of the bearing surface in ft. per sec. lies between 1000 and 1300.

Edwin Reynolds says that a main engine bearing to be safe against undue heating should be of such a size that the product of the square root of the speed of rubbing-surface in feet per second multiplied by the pounds per square inch of projected area, should not exceed 375 for a horizontal engine, or 500 for a vertical engine when the shaft is lifted at every revolution. Locomotive driving boxes in some cases give the product as high as 585, but this is accounted for by the cooling action of the air. (*Am. Mach.*, Sept. 17, 1903.)

Temperature of Engine Bearings. (A. M. Mattice, *Trans. A. S. M. E.*, 1905.)—An examination of the temperature of bearings of a large number of engines of various makes showed more above 135° F. than below that figure. Many bearings were running with a temperature over 150°, and in one case at 180°, and in all of these cases the bearings were giving no trouble.

PIVOT-BEARINGS.

The Schiele Curve. — W. H. Harrison (*Am. Mach.*, 1891) says the Schiele curve is not as good a form for a bearing as the segment of a sphere. He says: A mill-stone weighing a ton frequently bears its whole weight upon the flat end of a hard-steel pivot 1⅛ in. diam., or 1 sq. in. area of bearing; but to carry a weight of 3000 lbs. he advises an end bearing about 4 ins. diam., made in the form of a segment of a sphere about ½ in. in height. The die or fixed bearing should be dished to fit the pivot. This form gives a chance for the bearing to adjust itself, which it does not have when made flat, or when made with the Schiele curve. If a side bearing is necessary it can be arranged farther up the shaft. The pivot and die should be of steel, hardened; cross-gutters should be in the die to allow oil to flow, and a central oil-hole should be made in the shaft.

The advantage claimed for the Schiele bearing is that the pressure is uniformly distributed over its surface, and that it therefore wears uniformly. Wilfred Lewis (*Am. Mach.*, April 19, 1894) says that its merits as a thrust-bearing have been vastly overestimated; that the term "anti-friction" applied to it is a misnomer, since its friction is greater than that of a flat step or collar of the same diameter. He advises that flat thrust-bearings should always be annular in form, having an inside diameter one-half of the external diameter.

Friction of a Flat Pivot-bearing. — The Research Committee on Friction (*Proc. Inst. M. E.*, 1891) experimented on a step-bearing, flat-tended, 3 in. diam., the oil being forced into the bearing through a hole in its center and distributed through two radial grooves, insuring thorough lubrication. The step was of steel and the bearing of manganese-bronze.

At revolutions per min.	50	128	194	290	353
The coefficient of friction varied between	0.0181	0.0053	0.0051	0.0044	0.0053
and	0.0221	0.0113	0.0102	0.0178	0.0167

With a white-metal bearing at 128 revs. the coefficient of friction was a little larger than with the manganese-bronze. At the higher speeds the coefficient of friction was less, owing to the more perfect lubrication, as shown by the more rapid circulation of the oil. At 128 revs. the bronze-bearing heated and seized on one occasion with a load of 260 lbs., and on another occasion with 300 lbs. per sq. in. The white-metal bearing under similar conditions heated and seized with a load of 240 lbs. per sq. in. The steel footstep on manganese-bronze was afterwards tried, lubricating with three and with four radial grooves; but the friction was from one and a half times to twice as great as with only the two grooves.

Mercury-bath Pivot. — A nearly frictionless step-bearing may be obtained by floating the bearing with its superincumbent weight upon mercury. Such an apparatus is used in the lighthouses of La Heve, Havre. It is thus described in *Eng'g*, July 14, 1893, p. 41:

The optical apparatus, weighing about 1 ton, rests on a circular cast-iron table, which is supported by a vertical shaft of wrought iron 2.36 in. diameter. This is kept in position at the top by a bronze ring and outer iron support, and at the bottom in the same way, while it rotates on a removable steel pivot resting in a steel socket, which is fitted to the base of the support. To the vertical shaft there is rigidly fixed a floating cast-iron ring 17.1 in. diameter and 11.8 in. in depth, which is plunged into and rotates in a mercury bath contained in a fixed outer drum or tank, the clearance between the vertical surfaces of the drum and ring being only 0.2 in., so as to reduce as much as possible the volume of mercury (about 220 lbs.), while the horizontal clearance at the bottom is 0.4 in.

BALL-BEARINGS, ROLLER-BEARINGS, ETC.

Friction-rollers. — If a journal instead of revolving on ordinary bearings be supported on friction-rollers the force required to make the journal revolve will be reduced in nearly the same proportion that the diameter of the axles of the rollers is less than the diameter of the rollers themselves. In experiments by A. M. Wellington with a journal 3 1/2 in. diam. supported on rollers 8 in. diam., whose axles were 1 3/4 in. diam., the friction in starting from rest was 1/4 the friction of an ordinary 3 1/2-in bearing, but at a car speed of 10 miles per hour it was 1/2 that of the ordinary bearing. The ratio of the diam. of the axle to diam. of roller was 1 3/4: 8, or as 1 to 4.6.

Coefficients of Friction of Roller Bearings. C. H. Benjamin, *Machy.* Oct., 1905. — Comparative tests of plain babbitted, McKeel plain roller, and Hyatt roller bearings gave the following values of the coefficient of friction at a speed of 560 r.p.m.:

Diameter of Journal.	Hyatt Bearing.			McKeel Bearing.			Babbitt Bearing.		
	Max.	Min.	Ave.	Max.	Min.	Ave.	Max.	Min.	Ave.
1 15/16	.032	.012	.018	.033	.017	.022	.074	.029	.043
2 3/16	.019	.011	.014	......	......	......	.088	.078	.082
2 7/16	.042	.025	.032	.028	.015	.021	.114	.083	.096
2 15/16	.029	.022	.025	.039	.019	.027	.125	.089	.107

The friction of the roller-bearing is from one-fifth to one-third that of a plain bearing at moderate loads and speeds. It is noticeable that as the load on a roller-bearing increases the coefficient of friction decreases.

A slight change in the pressure due to the adjusting nuts was sufficient to increase the friction considerably. In the McKeel bearing the rolls bore on a cast-iron sleeve and in the Hyatt on a soft-steel one. If roller bearings are properly adjusted and not overloaded a saving of from 2-3 to 3-4 of the friction may be reasonably expected.

McKeel bearings contained rolls turned from solid steel and guided by spherical ends fitting recesses in cage rings at each end. The cage rings were joined to each other by steel rods parallel to the rolls.

Lubrication is absolutely necessary with ball and roller bearings, although the contrary claim is often advanced. Under favorable conditions an almost imperceptible film is sufficient; a sufficient quantity to immerse half the lowest ball should always be provided as a rust preventive. Rust and grit must be kept out of ball and roller bearings. Acid or rancid lubricants are as destructive as rust. (Henry Hess.)

Both ball and roller bearings, to give the best satisfaction, should be made of steel, hardened and ground; accurately fitted, and in proper alignment with the shaft and load; cleaned and oiled regularly, and fitted with as large-size balls or rollers as possible, depending upon the revolutions per minute and load to be carried. Oil is absolutely necessary on both ball and roller bearings, to prevent rust. (S. S. Eveland.)

Roller Bearings. — The Mossberg roller bearings for journals are made in the sizes given in the table below. D = diam. of journal; d = diam. of roll; N = number of rolls; P = safe load on journals, in lbs. The rolls are enclosed in a bronze supporting cage. (*Trans. A. S. M. E.*, 1905.)

D	d	N	P	D	d	N	P	D	d	N	P
2	1/4	20	3,500	6	11/16	24	50,000	15	1 3/8	28	255,000
2 1/2	5/16	22	7,000	7	13/16	22	70,000	18	1 3/8	32	325,000
3	3/8	22	13,000	8	7/8	22	90,000	20	1 1/2	34	400,000
4	7/16	24	24,000	9	1	24	115,000	24	1 1/2	38	576,000
5	9/16	24	37,000	12	1 1/4	26	175,000				

Surface speed of journal 0 to 50 ft. per min. Length of journal 1 1/2 diameters. The rolls are made of tool steel not too high in carbon, and of spring temper. The journal or shaft should be made not above a medium spring temper. The box should be made of high carbon steel and tempered as hard as possible.

Conical Roller Thrust Bearings. — The Mossberg thrust bearing is made of conical rollers contained in a cage, and two collars, one being stationary and the other fixed to the shaft and revolving with it. One side of each collar is made conical to correspond with the rollers which bear on it. The apex of the cones is at the center of the shaft. The angle of the cones is 6 to 7 degrees. Larger angles are objectionable, giving excessive end thrust. The following sizes are made:

Diameter of Shaft. Ins.	Outside Diameter of Ring. Ins.	No. of Rolls.	Safe Pressure on Bearing.		
			Area of Pressure Plate. Sq. ins.	Speed 75 Rev. Lbs.	Speed 150 Rev. Lbs.
2 1/16–2 1/4	5 9/16	30	10	19,000	9,500
3 1/16–3 1/4	8	30	20	40,000	20,000
4 1/16–4 1/4	10 5/16	30	35	70,000	35,000
5 1/16–5 1/4	12 3/8	30	54	108,000	56,000
6 1/16–6 1/2	14 7/8	30	78	125,000	62,000
8 1/16–8 1/2	18 3/4	32	132	200,000	100,000
9 1/16–9 1/2	20 1/2	32	162	300,000	150,000

Plain Roller Thrust Bearings. — S. S. Eveland, of the Standard Roller Bearing Co., contributes the following data of plain roller thrust bearings in use in 1903. The bearing consists of a large number of short cylindrical rollers enclosed in openings in a disk placed between two hardened steel plates. He says "our plain roller bearing is theoretically wrong, but in practice it works perfectly, and has replaced many thousand ball-bearings which have proven unsatisfactory."

Size of Bearing, Ins.	Number and Size of Rollers, Ins.	R.p.m.	Wt. on Bearings, Lbs.	Lineal Inches.	Weight per lin. in., Lbs.	Weight on each Roll, Lb.
$4\frac{3}{4} \times 6\frac{11}{16}$	36 $\frac{5}{8} \times \frac{5}{16}$	500	6,000	$11\frac{1}{4}$	546	167
$4\frac{3}{4} \times 7\frac{1}{4}$	32 $\frac{3}{4} \times \frac{5}{8}$	470	10,000	12	833	312

The Hyatt Roller Bearing. (A. L. Williston, *Trans. A. S. M. E.*, 1905.) — The distinctive feature of the Hyatt roller bearing is a flexible roller, made of a strip of steel wound into a coil or spring of uniform diameter. A roller of this construction insures a uniform distribution of the load along the line of contact of the roller and the surfaces on which it operates. It also permits any slight irregularities in either journal or box without causing excessive pressure. The roller is hollow and serves as an oil reservoir. For a heavy load, a roller of heavy stock can be made, while for a high-speed bearing under light pressure a roller of light weight, made from thin stock, can be used. Following are the results of some tests of the Hyatt bearing in comparison with other bearings:

A shaft 152 ft. long, $2\frac{15}{16}$ in. diam. supported by 20 bearings, belt-driven from one end, gave a friction load of 2.28 H.P. with babbitted bearings, and 0.80 H.P. with Hyatt bearings. With 88 countershafts running in babbitted bearings, the H.P. required was 8.85 when the main shaft was in babbitted bearings and 6.36 H.P. when it was in Hyatt bearings.

Comparative tests of solid rollers and of Hyatt rollers were made in 1898 at the Franklin Institute by placing two sets of rollers between three flat plates, putting the plates under load in a testing machine and measuring the force required to move the middle plate. All the rollers were $\frac{3}{4}$ in. diam., 10 ins. long. The Hyatt rollers were made of $\frac{1}{2} \times \frac{1}{8}$ in. steel strip. With 2000 lbs. load and plain rollers it took 26 lbs. to move the plate, and with the Hyatt rollers 9 lbs. With 3000 lbs. load and plain rollers the resistance was 34 lbs., with Hyatt rollers 17 lbs.

In tests with a pendulum friction testing machine at the Case Scientific School, with a bearing $1\frac{15}{16}$ in. diam. the coefficient of friction with the Hyatt bearing was from 0.0362 down to 0.0196, the loads increasing from 64 to 264 lbs.; with cast-iron bearings and the same loads the coefficient was from 0.165 to 0.098.

In tests at Purdue University with bearings $4 \times 1\frac{1}{2}$ ins. and loads from 1900 to 8300 lbs., the average coefficients with different bearings and different speeds were as follows:

Hyatt bearing	130 r.p.m.	0.0114	302 r.p.m.	0.0099	585 r.p.m.	0.0147
Cast-iron bearing	128 "	0.0548	302 "	0.0592	410 "	0.0683
Bronze bearing	130 "	0.0576	320 "	0.0661	582 "	0.140

The cast-iron bearing at 128 r.p.m. seized with 8300 lbs., and at 410 r.p.m. with 5900 lbs. The bronze bearing seized at 130 r.p.m. with 3500 lbs., at 320 r.p.m. with 5100 lbs., and at 582 r.p.m. with 2700 lbs.

The makers have found that the advantages of roller bearings of the type described are especially great with either high speeds or heavy loads. Generally, the best results are obtained for line-shaft work up to speeds of 600 rev. per min., when a load of 30 lbs. per square inch of projected area is allowed. For heavy load at slow speed, such as in crane and truck wheels, a load of 500 lbs. gives the best results.

The Friction Coefficient of a well-made annular ball-bearing is 0.001 and 0.002 of the load referred to the shaft diameter and is independent of the speed and load. The friction coefficient of a good roller bearing is from 0.0035 to 0.014; it rises very much if the load is light. It increases also when the speeds are very low, though not so much as with plain bearings. (Henry Hess.)

Notes on Ball Bearings. — The following notes are contributed by Mr. Henry Hess, 1910. Ball bearings in modern use date from the bicycle. That brought in the adjustable cup and cone and three-point contact type. Under the demands for greater load resistance and reliability the two-point contact type, without adjustability, was evolved; that is now used under loads from a few pounds to many tons. Such a bearing consists of an inner race, an outer race and the series of balls that roll in tracks of curved cross section. Various designs are used, differing chiefly in the devices for separating the balls and in the arrangement for introducing the balls between the races. The most widely used type has races that are of the same cross section throughout, unbroken by any openings for the introduction of balls. To introduce the balls the two races are first eccentrically placed; the balls will fill slightly more than a half circumference; elastic separators or solid cages are used to space the balls.

Another type has a filling opening of sufficient depth cut into one race; the race continuity is restored by a small piece that is let in. This type is usually filled with balls, without cages or separators. The filling opening is always placed at the unloaded side of the bearing, where the weakening of the race is not important. This type has been almost entirely discarded in favor of the one above described.

A third type has a filling opening cut into each race not quite deep enough to tangent the bottom of the ball track. As this weakened section necessarily comes under the load during each revolution, the carrying capacity is reduced. After slight wear there develops an interference of the balls with the edges of these openings, which seriously reduces the speeds and load capacity. This interference precludes the use of this type to take end thrust.

The carrying capacity of a ball-bearing is directly proportional to the number of balls and to the square of the ball diameter.

It may be written as:

$L = Knd^2$, in which L = load capacity in pounds; n = number of balls; d = ball diameter in eighths of an inch. K varies with the condition and type of bearing, as also with the material and speed.

For a certain special steel that hardens throughout and is also unusually tough, employed by "DWF" or "HB" (the originators of the modern two-point type), the following values apply. For other steels lesser values must be used.

I. *For Radial Bearings:*

$K = 9$ for uninterrupted race track, cross-section curvature = 0.52 and 9/16 in. ball diameter respectively for inner and outer races, separated balls, uniform load, and steady speed up to 3000 revs. per min.

$K = 5$ for full ball type, filling opening in one race at the unloaded side, otherwise as above.

$K = 2.5$ for both ball tracks interrupted by filling openings, inelastic cage separators for balls, or full ball, speeds not above 2000 revs. per min., uniform load.

$K = 0.9$ for thrust on a radial bearing of the first type, as above. The larger the balls the smaller K. The type with filling openings in each race is not suitable for end thrust.

The radial load bearing is, up to high speeds, practically unaffected by speed, as to carrying capacity.

II. *Thrust Bearings:*

With the thrust type, consisting of one flat plate and one seat plate with grooved ball races, the load capacity decreases with speed or

$$L = \frac{K_1 nd^2}{\sqrt[3]{R}}.$$

K_1 = constant for material and race cross-section, etc., R = revolutions per minute. R ranges from about 3000 revs. per min. down to 1 rev. per min. as for crane hooks and similar elements.

K_1 = 25 to 40 for material used by the *DWF* or *HB*, and race cross-section radius = approx. 1.66 ball radius.

K_1 = 0.5 for unhardened steel, occasionally used for very large races; a steel that is fairly hard without tempering must be used, and then only when there is no hammering or sharp load variation.

Balls must be carefully selected to make sure that all that are used in the same bearing do not vary among one another by more than 0.0001 inch. A ball that is more than that larger than its fellows will sustain more than its proportion of the load, and may therefore be overloaded and will in turn overload the races.

The usual test of ball quality, which consists in compressing a ball between flat plates and noting the load at rupture, gives the quality of the plates, but not of the balls. It is the ability of the ball to resist permanent deformation that is of importance. As the deformations involved are very small the test is a difficult one to carry out. Of even greater importance than a small deformation under load is uniformity of such deformation between the balls employed; a hard ball will deform less than its softer mate and so will carry more than its share of the load, and will therefore be overloaded and in turn overload the races.

Coned bearings for balls are objectionable. The defect in all these forms of bearings is their adjustable feature. A bearing properly proportioned with reference to a certain load may be enormously overloaded by a little extra effort applied to the wrench, or on the other hand the bearing may be adjusted with too little pressure, so that the balls will rattle, and the results consequently be unsatisfactory. The prevalent idea that coned ball-bearings can be adjusted to compensate for wear is erroneous.

Mr. Hess's paper, in *Trans. A. S. M. E.*, 1907, contains a great deal of useful information on the practical design of ball-bearings, including different forms of raceways. He prefers a two-point bearing, in which the ball races have a curved section, with sustaining surfaces at right angles with the direction of the load.

Formulæ for Number of Balls in a Bearing. (H. Rolfe, *Am. Mach.*, Dec. 3, 1896.)—Let D = diam. of ball circle (the circle passing through the centers of the balls); d = diam. of balls; n = number of balls; s = average clearance space between the balls. Then $D = (d + s) \div \sin (180°/n)$; $d = D \sin (180°/n) - s$; $s = D \sin (180°/n) - d$; $n = 180° \div$ angle whose sine is $(d + s) \div D$. The clearance s should be about 0.003 in.

VALUES OF 180°/n AND OF SIN 180°/n.

Grades of Balls for Bearings. (S. S. Eveland, *Trans. A. S. M. E.*, 1905.) — "A" grade balls vary about 0.0025 in. in diameter; "B" grade, 0.001 to 0.002 in.; while "high-duty" or special balls are furnished varying not over 0.0001 in. The crushing strength of balls is of little importance as to the load a bearing will carry, the revolutions per minute being quite as important as the load.

Saving of Power by Use of Ball-Bearings. — Henry Hess (*Trans. A. S. M. E.*, 1909) describes a series of tests made by Dodge and Day on a 2 15/16 in. line shaft 72 ft. long, alternately equipped with plain ring-oiling babbitted boxes and with Hess-Bright ball-bearings. Eight countershafts were driven from pulleys on the line shaft. The countershaft pulleys had plain bearings. The conclusions from the tests made under normal belt conditions of 44 and 57 lbs. per inch width of angle of single belt are as follows:

a. Savings due to the substitution of ball-bearings for plain bearings on line shafts may be safely calculated by using 0.0015 as the coefficient of ball-bearing friction, 0.03 as the coefficient of line shaft friction, and 0.08 as the coefficient of countershaft friction.

b. When the belts from line shaft to countershaft pull all in one direction and nearly horizontally the saving due to the substitution of ball-bearings for plain bearings on the line shaft may be safely taken as 35% of the bearing friction.

c. When ball-bearings are used also on the countershafts the savings will be correspondingly greater and may amount to 70% or more of the bearing friction.

d. These percentages of savings are percentages of the friction work lost in the plain bearings; they are not percentages of the total power transmitted. The latter will depend upon the ratio of the total power transmitted to that absorbed in the line and countershafts.

e. The power consumed in the plain line and countershafts varies, as is well known, from 10 to 60% in different industries and shops. The substitution of ball-bearings for plain bearings on the line shaft only, under conditions of paragraph "*a*," will thus result in saving of total power of $35 \times 0.10 = 3.5\%$ to $35 \times 0.60 = 21\%$. By using ball-bearings on the countershafts also, the saving of total power will be from $70 \times 0.10 = 7\%$ to $70 \times 0.60 = 42\%$.

KNIFE-EDGE BEARINGS.

Allowable loads on knife-edges vary with the manner in which the pivots or knife-edges are held in the lever and the pivot supports or seats secured to the base of weighing machines. The extension of the pivot beyond the solid support is practically worthless. A high-grade uniform tool steel with carbon 0.90% to 1.00% should be used. The temper of the seats should be drawn to a very light straw color; that of the pivots should be slightly darker. The angle of 90° for the knife-edge has given good results for heavy loads. For ordinary weighing machinery and most testing machinery 5000 lb. per in. of length is ample. Loads of 10,000 lb. per inch of length are permissible, but the pivot must be flat at its upper portion, normal to the load and supported its whole length, with a minimum deflection of parts to secure reasonable accuracy. The edge may be made perfectly sharp, for loads up to 1000 lb. per inch of length. For greater loads the sharp edge is rubbed with an oilstone, so that a smoothness is just visible. A pronounced radius of knife-edge will decrease the sensibility of the apparatus. (Jos. W. Bramwell, *Eng. News*, June 14, 1906.)

FRICTION OF STEAM-ENGINES.

Distribution of the Friction of Engines. — Prof. Thurston, in his "Friction and Lost Work," gives the following:

	1.	2.	3.
Main bearings	47.0	35.4	35.0
Piston and rod	32.9	25.0	21.0
Crank-pin	6.8	5.1	13.0
Cross-head and wrist-pin	5.4	4.1	
Valve and rod	2.5	26.4	22.0
Eccentric strap	5.3	4.0	
Link and eccentric	....	....	9.0
Total	100.0	100.0	100.0

No. 1, Straight-line, 6 × 12 in., balanced valve; No. 2, Straight-line, 6 × 12 in., unbalanced valve; No. 3, 7 × 10 in., Lansing traction, locomotive valve-gear.

Prof. Thurston's tests on a number of different styles of engines indicate that the friction of any engine is practically constant under all loads. (*Trans. A. S. M. E.*, viii, 86; ix, 74.)

In a straight-line engine, 8 × 14 in., I.H.P. from 7.41 to 57.54, the friction H.P. varied irregularly between 1.97 and 4.02, the variation being independent of the load. With 50 H.P. on the brake the I.H.P. was only 52.6, the friction being only 2.6 H.P., or about 5%.

A compound condensing-engine, tested from 0 to 102.6 brake H.P., gave I.H.P. from 14.92 to 117.8 H.P., the friction H.P. varying only from 14.92 to 17.42. At the maximum load the friction was 15.2 H.P., or 12.9%.

The friction increases with increase of the boiler-pressure from 30 to 70 lbs., and then becomes constant. The friction generally increases with increase of speed, but there are exceptions to this rule.

Prof. Denton (*Stevens Indicator*, July, 1890), comparing the calculated friction on a number of engines with the friction as determined by measurement, finds that in one case, a 75-ton ammonia ice-machine, the friction of the compressor, 17 1/2 H.P., is accounted for by a coefficient of friction of 7 1/2% on all the external bearings, allowing 6% of the entire friction of the machine for the friction of pistons, stuffing-boxes, and valves. In the case of the Pawtucket pumping-engine, estimating the friction of the external bearings with a coefficient of friction of 6% and that of the pistons, valves, and stuffing-boxes as in the case of the ice-machine, we have the total friction distributed as follows:

	Horse-power.	Per cent of whole.
Crank-pins and effect of piston-thrust on main shaft	0.71	11.4
Weight of fly-wheel and main shaft	1.95	32.4
Steam-valves	0.23	3.7
Eccentric	0.07	1.2
Pistons	0.43	7.2
Stuffing-boxes, six altogether	0.72	11.3
Air-pump	2.10	32.8
Total friction of engine with load	6.21	100.0
Total friction per cent of indicated power.	4.27	

The friction of this engine, though very low in proportion to the indicated power, is satisfactorily accounted for by Morin's law used with a coefficient of friction of 5%. In both cases the main items of friction are those due to the weight of the fly-wheel and main shaft and to the piston-thrust on crank-pins and main-shaft bearings. In the ice-machine the latter items are the larger owing to the extra crank-pin to work the pumps, while in the Pawtucket engine the former preponderates, as the crank-thrusts are partly absorbed by the pump-pistons, and only the surplus effect acts on the crank-shaft.

Prof. Denton describes in *Trans. A. S. M. E.*, x. 392, an apparatus by which he measured the friction of the piston packing-ring. When the parts of the piston were thoroughty devoid of lubricant, the coefficient of friction was found to be about 7 1/2%; with an oil-feed of one drop in two minutes the coefficient was about 5%; with one drop per minute it was about 3%. These rates of feed gave unsatisfactory lubrication, the piston groaning at the ends of the stroke when run slowly, and the flow of oil left upon the surfaces was found by analysis to contain about 50% of iron. A feed of two drops per minute reduced the coefficient of friction to about 1%, and gave practically perfect lubrication, the oil retaining its natural color and purity.

FRICTION BRAKES AND FRICTION CLUTCHES.

Friction Brakes are used for slowing down or stopping a moving machine by converting its energy of motion into heat, or for controlling the speed of a descending load. The simplest form is the block brake, commonly used for railway car wheels, which resists the motion of the wheel not only with the force due to ordinary sliding friction, but with that due to cutting or grinding away the surface of the metals in contact. If P = total pressure acting normal to the sliding surface, f = coefficient of friction, and v = velocity in feet per minute, then the energy absorbed, in foot-pounds per minute, is Pfv. If the surface is lubricated and the pressure per square inch not great enough to squeeze out the lubricant, then the value of f for different materials may be taken from Morin's tables for friction of motion, page 1221, but if the pressure is great enough to force out the lubricant, then the coefficient becomes much greater and the surfaces will cut and wear, with a rapid rise of temperature.

Other forms of brakes are disk brakes and cone brakes, in which a disk or cone is carried by the rotating shaft and a mating disk or cone is pressed against it by a lever or other means; and band brakes, also called strap or ribbon brakes, in which a flexible band encircles the cylindrical surface of a rotating drum or wheel, and tension applied to one end of the band brings it in contact with that surface. For band brakes the theory of friction of belts applies. See page 1138. For much information on the theory and practice of friction brakes see articles by C. F. Blake in *Mach'y*, Jan., 1901, Mar., 1905, and Aug., 1906, and by E. R. Douglas, *Am. Mach.*, Dec. 26, 1901, and R. B. Brown, *Mach'y*, April, 1909. For friction brake dynamometers see Dynamometers.

Friction Clutches are used for putting shafts in motion gradually, without shock. If two shafts, in line with each other, one in motion and the other at rest, each having a disk keyed to the end, and the disks almost touching, are moved toward each other so that the disks are brought in contact with some pressure, the shaft at rest will be put in motion gradually, while the disks rub on each other, until it acquires the velocity of the driving shaft, when the friction ceases and the disks may then be locked together. This is an elementary form of friction clutch. A great variety of styles are made in which the sliding surfaces may be disks, cones, and gripping blocks of various forms. The work done by a clutch while the surfaces are in sliding contact, and before they are locked together, is the overcoming of the inertia of the driven shaft and of all the mechanism driven by it, and giving it the velocity of the driving shaft. The principles of friction brakes apply to friction clutches. The sliding surfaces must be of sufficient area to keep the normal pressure below that at which they will overheat, cut and wear, and to dissipate the heat generated by friction. The following values of the coefficient of friction to be used in designing clutches are given by C. W. Hunt: cork on iron, 0.35; leather on iron, 0.3; wood on iron, 0.2; iron on iron, 0.25 to 0.3. Lower values than these should be assumed for velocities exceeding 400 ft. per minute. The pressure per square inch in disk clutches should not exceed 25 or 30 lbs., and wooden surfaces should not be loaded beyond 20 to 25 lbs. per sq. in. See Kimball and Barr on Machine Design, also *Trans. A. S. M. E.*, 1903 and 1908.

Electrically Operated Brakes are discussed by H. A Steen in a paper read before the Engrs. Socy. of W. Penna., reprinted in *Iron Trade Rev.*, Dec. 24, 1908. Formulæ are given for the time required for stopping, for the heat generated and the temperature rise, for different types of brakes.

Magnetic and Electric Brakes.—For braking the load on electric cranes a band brake is used which is held off the drum by the action of a magnet or solenoid, and is put on by the action of a spring or weight. The solenoid usually consists of a coil of wire connected in series with the motor, and a plunger working inside of the coil. It should be so proportioned that its action is not delayed by residual magnetism when the current is cut off. Too rapid action is prevented by making the end of the solenoid an air dash-pot.

For electric-driven machinery an electric motor makes a most efficient brake by reversing the direction of the electric current, causing the motor to become a generator supplying current to a rheostat in which it is converted into heat and dissipated. In some cases the electric current generated, instead of being absorbed in a rheostat, is fed into the main electric circuit. In this case the energy of the rotating mass, instead of being wasted in friction or in electrical heating, is converted into electric energy and thus conserved for further use.

Design of Band Brakes. (R. A. Greene, *Am. Mach.*, Oct. 8, 1908.)—In the practice of the Browning Engineering Co., Cleveland, O., in regard to the design of band brakes the equations are:

$T = PX$, $t = T - P$, $S = \dfrac{2T}{D \times F}$, $\vartheta = S \times D \times 0.262 \times$ revolutions per minute, in which T = the greater tension on the band, t = the lesser tension on the band, P = equivalent load on the brake drum, X = factor from the accompanying table, $X = \dfrac{N}{N-1}$ in which $N = 10^{2.7288\,fc}$, where f = the coefficient of friction and c the length of arc of contact in degrees divided by 360. D = diam. of brake drum, F = width of face of brake drum, S = a checking factor which has a maximum limit of 65, ϑ = a checking factor which has a limit of 54,000 (Yale & Towne practice) or 60,000 (Brown hoist practice).

Example.—A band brake is to be designed having an arc of contact of 260°, coefficient of friction = 0.2, drum diameter 30 ins., face 4 ins., speed 100 r.p.m., and a load of 3000 lbs. acting on a diameter of 20 ins. Then

$P = 3000 \times 20 \div 30 = 2000$ pounds, $X = 1.68$ (from table), $T = 2000 \times 1.68 = 3360$ pounds, $t = 3360 - 2000 = 1360$ pounds, $S = 2 \times 3360 \div (30 \times 4) = 56$ (within the limit), $\vartheta = 56 \times 30 \times 0.262 \times 100 = 44{,}000$ (within the limit).

Degrees.	Values of X.			Degrees.	Values of X.		
	$f=0.2.$	$f=0.3.$	$f=0.4.$		$f=0.2.$	$f=0.3.$	$f=0.4.$
180	2.14	1.64	1.40	260	1.68	1.35	1.19
195	2.03	1.56	1.35	270	1.64	1.32	1.18
210	1.93	1.50	1.30	280	1.60	1.30	1.17
240	1.76	1.40	1.23	290	1.57	1.28	1.15
250	1.72	1.37	1.21	300	1.54	1.26	1.14

FRICTION OF HYDRAULIC PLUNGER PACKING.

The "Taschenbuch der Hutte" (15th edition, vol. 1, p. 202) says: "For stuffing-boxes with hemp, cotton or leather packing, with water pressures between 1 and 50 atmospheres, the frictional loss is dependent upon the water pressure, the circumference of the packed surface, and a coefficient μ, which is constant for this range of pressure. The loss is independent of the depth of stuffing-box or leather ring, and is given by the formula $F=Kpd$, in which F = total frictional loss in pounds, p = pressure in pounds per sq. in., d = diameter of plunger in inches.

K is a coefficient, which depends on the kind and condition of the packing, and is given as follows for various cases.

For cotton or hemp, loose or braided, dipped in hot tallow; plungers smooth, glands not pulled down too tight, packing therefore retaining its elasticity; dimensions such as usually occur, $K=0.072$.

Same conditions, after packing is some months old, $K=0.132$.

Materials the same, but with hard packing, unfavorable conditions, etc., K = as much as 0.299.

Leather packing; soft leather, well made, etc., $K=0.036$ to 0.084.

Hard, stiffly tanned leather, $K=0.12$ to 0.156.

Unfavorable conditions; rough plungers, gritty water, etc., K = as much as 0.239.

Weisbach-Hermann, "Mechanics of Hoisting Machinery," gives a formula which when translated into the same notation as the one in "Hutte" is

$$F=0.0312\ pd \text{ to } 0.0767\ pd.$$

Since the total pressure on a plunger is $\frac{1}{4}\pi d^2p$, the ratio of the loss of pressure to the total pressure is $Kpd \div \frac{1}{4}\pi d^2p$, or, using the extreme values of K, 0.0312 and 0.299, the ratio ranges from $0.04 \div d$ to $0.38 \div d$, or from 4 to 38 per cent divided by the diameter in inches.

Walter Ferris (*Am. Mach.*, Feb. 3, 1898) derives from the formula given above the following formula for the pressure produced by a hemp-packed hydraulic intensifier made with two plungers of different diameters:

$$p_2=p_1\ \frac{A-KD}{a+kd},$$

in which p_2 = pressure per sq. in. produced by the intensifier, p_1 = initial pressure, A = area and D = diam. of the larger plunger, a = area and d = diam. of the smaller plunger, and K an experimental coefficient. He gives the following results of tests of an intensifier with a small plunger 8 ins. diam. and two large plungers, $14\frac{1}{4}$ and $17\frac{3}{4}$ ins., either one of which could be used as desired.

Diam. of large plunger, in.	$14\frac{1}{4}$	$14\frac{1}{4}$	$17\frac{3}{4}$	$17\frac{3}{4}$
Initial pressure, lbs. per sq. in.	285	475	335	350
Intensified pressure, lbs. per sq. in.	750	1450	1450	1510
Intensified if there were no friction	905	1505	1650	1725
Intensified calculated by formula*	806	1433	1572	1643
Efficiency of machine	0.83	0.965	0.88	0.875

LUBRICATION.

Measurement of the Durability of Lubricants. — (J. E. Denton, *Trans. A. S. M. E.*, xi, 1013.) — Practical differences of durability of lubricants depend not on any differences of inherent ability to resist being "worn out" by rubbing, but upon the rate at which they flow through and away from the bearing-surfaces. The conditions which

* Assuming $K=0.2$. The efficiency calculated by the formula in each case was 0.953.

control this flow are so delicate in their influence that all attempts thus far made to measure durability of lubricants may be said to have failed to make distinctions of lubricating value having any practical significance. In some kinds of service the limit to the consumption of oil depends upon the extent to which dust or other refuse becomes mixed with it, as in railroad-car lubrication and in the case of agricultural machinery. The economy of one oil over another, so far as the quality used is concerned — that is, so far as durability is concerned — is simply proportional to the rate at which it can insinuate itself into and flow out of minute orifices or cracks. Oils will differ in their ability to do this, first, in proportion to their viscosity, and, second, in proportion to the capillary properties which they may possess by virtue of the particular ingredients used in their composition. Where the thickness of film between rubbing-surfaces must be so great that large amounts of oil pass through bearings in a given time, and the surroundings are such as to permit oil to be fed at high temperatures or applied by a method not requiring a perfect fluidity, it is probable that the least amount of oil will be used when the viscosity is as great as in the petroleum cylinder stocks. When, however, the oil must flow freely at ordinary temperatures and the feed of oil is restricted, as in the case of crank-pin bearings, it is not practicable to feed such heavy oils in a satisfactory manner. Oils of less viscosity or of a fluidity approximating to lard-oil must then be used.

Relative Value of Lubricants. (J. E. Denton, *Am. Mach.*, Oct. 30, 1890.) — The three elements which determine the value of a lubricant are the cost due to consumption of lubricants, the cost spent for coal to overcome the frictional resistance caused by use of the lubricant, and the cost due to the metallic wear on the journal and the brasses.

The Qualifications of a Good Lubricant, as laid down by W. H. Bailey, in *Proc. Inst. C. E.*, vol. xlv, p. 372, are: 1. Sufficient body to keep the surfaces free from contact under maximum pressure. 2. The greatest possible fluidity consistent with the foregoing condition. 3. The lowest possible coefficient of friction, which in bath lubrication would be for fluid friction approximately. 4. The greatest capacity for storing and carrying away heat. 5. A high temperature of decomposition. 6. Power to resist oxidation or the action of the atmosphere. 7. Freedom from corrosive action on the metals upon which the lubricant is used.

The Examination of Lubricating Oils. (Prof. Thos. B. Stillman, *Stevens Indicator*, July, 1890.) — The generally accepted conditions of a good lubricant are as follows:

1. "Body" enough to prevent the surfaces to which it is applied from coming in contact with each other. (Viscosity.)
2. Freedom from corrosive acid, of either mineral or animal origin.
3. As fluid as possible consistent with "body."
4. A minimum coefficient of friction.
5. High "flash" and burning points.
6. Freedom from materials liable to produce oxidation or "gumming."

The examinations to be made to verify the above are both chemical and mechanical, and are usually arranged in the following order:

1. Identification of the oil, whether a simple mineral oil, or animal oil, or a mixture. 2. Density. 3. Viscosity. 4. Flash-point. 5. Burning-point. 6. Acidity. 7. Coefficient of friction. 8. Cold test.

Detailed directions for making all of the above tests are given in Prof. Stillman's article. See also Stillman's Engineering Chemistry, p. 366.

Notes on Specifications for Petroleum Lubricants. (C. M. Everest, Vice-Pres. Vacuum Oil Co., *Proc. Engineering Congress*, Chicago World's Fair, 1893.) — The specific gravity was the first standard established for determining quality of lubricating oils, but it has long since been discarded as a conclusive test of lubricating quality. However, as the specific gravity of a particular petroleum oil increases the viscosity also increases.

The object of the fire test of a lubricant, as well as its flash test, is the prevention of danger from fire through the use of an oil that will evolve inflammable vapors. The lowest fire test permissible is 300°, which gives a liberal factor of safety under ordinary conditions.

The cold test of an oil, i.e., the temperature at which the oil will congeal, should be well below the temperature at which it is used; otherwise the coefficient of friction would be correspondingly increased.

Viscosity, or fluidity, of an oil is usually expressed in seconds of time in which a given quantity of oil will flow through a certain orifice at the temperature stated, comparison sometimes being made with water, sometimes with sperm-oil, and again with rape-seed oil. It seems evident that within limits the lower the viscosity of an oil (without a too near approach to metallic contact of the rubbing surfaces) the lower will be the coefficient of friction. But we consider that each bearing in a mill or factory would probably require an oil of different viscosity from any other bearing in the mill, in order to give its lowest coefficient of friction, and that slight variations in the condition of a particular bearing would change the requirements of that bearing; and further, that when nearing the "danger point" the question of viscosity alone probably does not govern.

The requirement of the New England Manufacturers' Association, that an oil shall not lose over 5% of its volume when heated to 140° Fahr. for 12 hours, is to prevent losses by evaporation, with the resultant effects.

The precipitation test gives no indication of the quality of the oil itself, as the free carbon in improperly manufactured oils can be easily removed.

It is doubtful whether oil buyers who require certain given standards of laboratory tests are better served than those who do not. Some of the standards are so faulty that to pass them an oil manufacturer must supply oil he knows to be faulty; and the requirements of the best standards can generally be met by products that will give inferior results in actual serivce.

Penna. R. R. Specifications for Petroleum Products, 1900. — Five different grades of petroleum products will be used.

The materials desired under this specification are the products of the distillation and refining of petroleum unmixed with any other substances.

150° *Fire-test Oil.* — This grade of oil will not be accepted if sample (1) is not "water-white" in color; (2) flashes below 130° Fahrenheit; (3) burns below 151° Fahrenheit; (4) is cloudy or shipment has cloudy barrels when received, from the presence of glue or suspended matter; (5) becomes opaque or shows cloud when the sample has been 10 minutes at a temperature of 0° Fahrenheit.

300° *Fire-test Oil.* — This grade of oil will not be accepted if sample (1) is not "water-white" in color; (2) flashes below 249° Fahrenheit (3) burns below 298° Fahrenheit; (4) is cloudy or shipment has cloudy barrels when received, from the presence of glue or suspended matter; (5) becomes opaque or shows cloud when the sample has been 10 minutes at a temperature of 32° Fahrenheit; (6) shows precipitation when some of the sample is heated to 450° F. The precipitation test is made by having about two fluid ounces of the oil in a six-ounce beaker, with a thermometer suspended in the oil, and then heating slowly until the thermometer shows the required temperature. The oil changes color, but must show no precipitation.

Paraffine and Neutral Oils. — These grades of oil will not be accepted if the sample from shipment (1) is so dark in color that printing with long-primer type cannot be read with ordinary daylight through a layer of the oil 1/2 inch thick; (2) flashes below 298° F.; (3) has a gravity at 60° F., below 24° or above 35° Baumé; (4) from October 1st to May 1st has a cold test above 10° F., and from May 1st to October 1st has a cold test above 32° F.

The color test is made by having a layer of the oil of the prescribed thickness in a proper glass vessel, and then putting the printing on one side of the vessel and reading it through the layer of oil with the back of the observer toward the source of light.

Well Oil. — This grade of oil will not be accepted if the sample from shipment (1) flashes, from May 1st to October 1st, below 298° F., or from October 1st to May 1st, below 249° F.; (2) has a gravity at 60° F., below 28° or above 31° Baumé; (3) from October 1st to May 1st has a cold test above 10° F., and from May 1st to October 1st has a cold test above 32° F.; (4) shows any precipitation when 5 cubic centimeters are mixed with 95 c.c. of gasoline. The precipitation test is to exclude tarry and suspended matter. It is made by putting 95 c.c. of 88° B. gasoline, which must not be above 80° F. in temperature, into a 100 c.c. graduate, then adding the prescribed amount of oil and shaking thoroughly. Allow to stand ten minutes. With satisfactory oil no separated or precipitated material can be seen.

500° Fire-test Oil. — This grade of oil will not be accepted if sample from shipment (1) flashes below 494° F.; (2) shows precipitation with gasoline when tested as described for well oil.

Printed directions for determining flashing and burning tests and for making cold tests and taking gravity are furnished by the railroad company.

Penna. R. R. Specifications for Lubricating Oils (1894). (In force in 1902.)

Constituent Oils.	Parts by volume.

A, freight cars; engine oil on shifting-engines; miscellaneous greasing in foundries, etc. *B*, cylinder lubricant on marine equipment and on stationary engines. *C*, engine oil; all engine machinery; engine and tender truck boxes; shafting and machine tools; bolt cutting; general lubrication except cars. *D*, passenger-car lubrication. *E*, cylinder lubricant for locomotives. C_1, D_1, for use in Dec., Jan., and Feb.; C_2, D_2, in March, April, May, Sept., Oct., and Nov.; C_3, D_3, in June, July, and August. Weights per gallon, *A*, 7.4 lbs.; *B*, *C*, *D*, *E*, 7.5 lbs.

Grease Lubricants. — Tests made on an Olsen lubricant testing machine at Cornell University are reported in *Power*, Nov. 9, 1909. It was found that some of the commercial greases stood much higher pressures than the oils tested, and that the coefficients of friction at moderate loads were often as low as those of the oils. The journal of the testing machine was 3 3/4 in. diam., 3 1/2 in. long, and the babbitt bearing shoe had a projected area of 5.8 sq. in. The speed was 240 r.p.m. and each test lasted one hour, except when the bearing showed overheating. The following are the coefficients of friction obtained in the tests:

Lbs. per sq. in.	Mineral Grease.	Animal Grease.	Graphite Grease.	Mineral Grease.	Engine Oil.	Engine Oil.	Grease.	Grease.

Testing Oil for Steam Turbines. (Robert Job, *Trans. Am. Soc. for Testing Matls.*, 1909.) —

In some types of steam-turbines, the bearings are very closely adjusted and, if the oil is not clear and free from waxy substances, clogging and heating quickly results. A number of red engine and turbine oils some of which had given good service and others bad service were tested and it was found that clearness and freedom from turbidity were of importance, but mere color, or lack of color, seemed to have little influence, and good service results were obtained with oils which were of a red color, as well as with those which were filtered to an amber color.

Heating Test.—It was found that on heating the oils to 450° F. all which had given bad service showed a marked darkening of color, while those which had proved satisfactory showed little change. With oils that had been filtered or else had been chemically treated in such manner that the so-called "amorphous waxes" had been completely removed, on applying the heating test only a slight darkening of color resulted. It is of advantage in addition to other requirements to specify that an oil for steam turbines on being heated to 450° F. for five minutes shall show not more than a slight darkening of color. The test is that commonly used in test of 300° oil for burning purposes.

Separating Test.—It is known that elimination of the waxes causes an increase in the ease with which the oil separates from hot water when thoroughly shaken with it. This condition can be taken advantage of by prescribing that when one ounce of the oil is placed in a 4-oz. bottle with two ounces of boiling water, the bottle corked and shaken hard for one minute and let stand, the oil must separate from the water within a specified time, depending upon the nature of the oil, and that there must be no appearance of waxy substances at the line of demarcation between the oil and the water.

Quantity of Oil needed to Run an Engine. — The Vacuum Oil Co. in 1892, in response to an inquiry as to cost of oil to run a 1000-H.P. Corliss engine, wrote: The cost of running two engines of equal size of the same make is not always the same. Therefore, while we could furnish figures showing what it is costing some of our customers having Corliss engines of 1000 H.P., we could only give a general idea, which in itself might be considerably out of the way as to the probable cost of cylinder- and engine-oils per year for a particular engine. Such an engine ought to run readily on less than 8 drops of 600 W oil per minute. If 3000 drops are figured to the quart, and 8 drops used per minute, it would take about two and one half barrels (52.5 gallons) of 600 W cylinder-oil, at 65 cents per gallon, or about $85 for cylinder-oil per year, running 6 days a week and 10 hours a day. Engine-oil would be even more difficult to guess at what the cost would be, because it would depend upon the number of cups required on the engine, which varies somewhat according to the style of the engine. It would doubtless be safe, however, to calculate at the outside that not more than twice as much engine-oil would be required as of cylinder-oil.

The Vacuum Oil Co. in 1892 published the following results of practice with "600 W" cylinder-oil:

Corliss compound engine,	20 and 33 × 48; 83 revs. per min.; 1 drop of oil per min. to 1 drop in two minutes.
" triple exp. "	20, 33, and 46 × 48; 1 drop every 2 minutes.
Porter-Allen "	20 and 36 × 36; 143 revs. per min.; 2 drops of oil per min., reduced afterwards to 1 drop per min.
Ball "	15 and 25 × 16; 240 revs. per min.; 1 drop every 4 minutes.

Results of tests on ocean-steamers communicated to the author by Prof. Denton in 1892 gave: for 1200-H.P. marine engine, 5 to 6 English gallons (6 to 7.2 U. S. gals.) of engine-oil per 24 hours for external lubrication; and for a 1500-H.P. marine engine, triple expansion, running 75 revs. per min., 6 to 7 English gals. per 24 hours. The cylinder-oil consumption is exceedingly variable, — from 1 to 4 gals. per day on different engines, including cylinder-oil used to swab the piston-rods.

Cylinder Lubrication. — J. H. Spoor, in *Power*, Jan. 4, 1910, has made a study of a great number of records of the amount of oil used for lubricating cylinders of different engines, and has reduced them to a systematic basis of the equivalent number of pints of oil used in a 10-hour day for different areas of surface lubricated. The surface is determined in square inches by multiplying the circumference of the cylinder by the length of stroke. The results are plotted in a series of curves for different types of engines, and approximate average figures taken from these curves are given below:

Compound Engines.

Sq. ins. lubricated.......	2,000	4,000	6,000	8,000	10,000	12,000	18,000
Pints of oil used in 10 hrs.	2	3.5	4.3	5	5.5	6	6.5

Corliss Engines.

Sq. ins. lubricated....................	1,000	2,000	3,000	4,000
Pints of oil in 10 hrs. Avge............	0.9	1.65	2.25	3.75
Max............	1.2	2.25	....	....
Min............	....	1.00	....	....

Automatic high-speed engines, about 2 pints per 1,000 sq. in.

Simple slide-valve engines, about 0.5 pint per 1,000 sq. in.

As shown in the figures under 2,000 Corliss, a certain engine may take 2¼ times as much oil as another engine of the same size. The difference may be due to smoothness of cylinder surface, kind and pressure of piston rings, quality of oil, method of introducing the lubricant, etc. Variations in speed of a given type of engine and in steam pressure do not appear to make much difference, but the small automatic high-speed engine takes more oil than any other type. Vertical marine engines are commonly run without any cylinder oil, except that used occasionally to swab the piston rods.

Quantity of Oil used on a Locomotive Crank-pin. — Prof. Denton, *Trans. A. S. M. E.*, xi, 1020, says: A very economical case of practical oil-consumption is when a locomotive main crank-pin consumes about six cubic inches of oil in a thousand miles of service. This is equivalent to a consumption of one milligram to seventy square inches of surface rubbed over.

Soda Mixture for Machine Tools. (Penna. R. R. 1894.) — Dissolve 5 lbs. of common sal-soda in 40 gallons of water and stir thoroughly. When needed for use mix a gallon of this solution with about a pint of engine oil. Used for the cutting parts of machine tools instead of oil.

Water as a Lubricant. (C. W. Naylor, *Trans. A. S. M. E.*, 1905.) — Two steel jack-shafts 18 ft. long with bearings 5 × 14 ins. each receiving 175 H.P. from engines and driving 5 electric generators, with six belts all pulling horizontally on the same side of the shaft, gave trouble by heating when lubricated with oil or grease. Water was substituted, and the shafts ran for 11 years, 10 hours a day, without serious interruption. Oil was fed to the shaft before closing down for the night, to prevent rusting. The wear of the babbitted bearings in 11 years was about 1/4 in., and of the shaft nil.

Acheson's "Deflocculated" Graphite. (*Trans. A. I. E. E.*, 1907; *Eng. News*, Aug. 1, 1907.) — In 1906, Mr. E. G. Acheson discovered a process of producing a fine, pure, unctuous graphite in the electric furnace. He calls it deflocculated graphite. By treating this graphite in the disintegrated form with a water solution of tannin, the amount of tannin being from 3% to 6% of the weight of the graphite treated, he found that it would be retained in suspension in water, and that it was in such a fine state of subdivision that a large part of it would run through the finest filter paper, the filtrate being an intensely black liquid in which the graphite would remain suspended for months. The addition of a minute quantity of hydrochloric acid causes the graphite to flocculate and group together so that it will no longer flow through filter paper. The same effect has been obtained with alumina, clay, lampblack and siloxicon, by treatment with tannin. The graphite thus suspended in water, known as "*aquedag*," has been successfully used as a lubricant for journals with sight-feed and with chain-feed oilers. It also prevents rust in iron and steel. The deflocculated graphite has also been suspended in oil, in a dehydrated condition, making an excellent lubricant known as "*oildag*." Tests by Prof. C. H. Benjamin of oil with 0.5% of graphite showed that it had a lower coefficient of friction than the oil alone.

SOLID LUBRICANTS.

Graphite in a condition of powder and used as a *solid lubricant*, so called, to distinguish it from a liquid lubricant, has been found to do well where the latter has failed.

Rennie, in 1829, says: "Graphite lessened friction in all cases where it was used." General Morin, at a later date, concluded from experiments that it could be used with advantage under heavy pressures: and Prof. Thurston found it well adapted for use under both light and heavy pressures when mixed with certain oils. It is especially valuable to prevent abrasion and cutting under heavy loads and at low velocities.

For comparative tests of various oils with and without graphite, see paper on lubrication and lubricants, by C. F. Mabery, *Jour. A.S.M.E.*, Feb., 1910.

Soapstone, also called talc and steatite, in the form of powder and mixed with oil or fat, is sometimes used as a lubricant. Graphite or soapstone, mixed with soap, is used on surfaces of wood working against either iron or wood.

Metaline is a solid compound, usually containing graphite, made in the form of small cylinders which are fitted permanently into holes drilled in the surface of the bearing. The bearing thus fitted runs without any other lubrication.

Bushings fitted with graphite packed into grooves are made by the Graphite Lubricating Co., Bound Brook, N. J.

THE FOUNDRY.

Melting cap., lbs. per hr.	4820	10,760	13,850	16,940	21,200	26,070	37,530

Mr. Bolland says that the melting capacities in the table are not supposed to be all that can be melted in the hour by some of the best cupolas, but are simply the amounts which a common cupola under ordinary circumstances may be expected to melt in the time specified.

By height of cupola is meant the distance from the base to the bottom side of the charging door. The distance from the sand-bed, after it has been formed at the bottom of the cupola, up to the under side of the tuyeres is taken at 10 ins. in all cases.

All the amounts for fuel are based upon a bottom of 10 ins. deep. The quantity of fuel used on the bed is more in proportion as the depth is increased, and less when it is made shallower.

The amount of fuel required on the bed is based on the supposition that the cupola is a straight one all through, and that the bottom is 10 ins. deep. If the bottom be more, as in those of the Colliau type, then additional fuel will be needed.

First Charge of Iron. — The amounts given are safe figures to work upon in every instance, yet it will always be in order, after proving the ability of the bed to carry the load quoted, to make a slow and gradual increase of the load until it is fully demonstrated just how much burden the bed will carry.

Succeeding Charges of Fuel and Iron. — The highest proportions are not favored, for the simple reason that successful melting with any greater proportion of iron to fuel is not the rule, but, rather, the exception.

Diameter of Main Blast-pipe. — The sizes given are of sufficient area for all lengths up to 100 feet.

Tuyeres. — Any arrangement or disposition of tuyeres may be made, which shall answer in their totality to the areas given in the table. On no consideration must the tuyere area be reduced; thus, an 84-inch cupola must have tuyere area equal to 31 pipes 6 ins. diam., or 16 flat tuyeres $16 \times 3\frac{1}{2}$ ins. The tuyeres should be arranged in such a manner as will concentrate the fire at the melting-point into the smallest possible compass, so that the metal in fusion will have less space to traverse while exposed to the oxidizing influence of the blast.

To accomplish this, recourse has been had to the placing of additional rows of tuyeres in some instances — the "Stewart rapid cupola" having three rows, and the "Colliau cupola furnace" having two rows, of tuyeres.

[Cupolas as large as 84 inches in diameter are now (1906) built without boshes. The most recent development with this size cupola is to place a center tuyere in the bottom discharging air vertically upwards.]

Blast-pressure. — About 30,000 cu. ft. of air are consumed in melting a ton of iron, which would weigh about 2400 pounds, or more than both iron and fuel. When the proper quantity of air is supplied, the combustion of the fuel is perfect, and carbonic-acid gas is the result. When the supply of air is insufficient, the combustion is imperfect, and carbonic-oxide gas is the result. The amount of heat evolved in these two cases is as 15 to 4 1/2, showing a loss of over two-thirds of the heat by imperfect combustion. [Combustion is never perfect in the cupola except near the tuyeres. The CO_2 formed by complete combustion is largely reduced to CO in passing through the hot coke above the fusion zone.]

It is not always true that we obtain the most rapid melting when we are forcing into the cupola the largest quantity of air. Too much air absorbs heat, reduces the temperature, and retards combustion, and the fire in the cupola may be extinguished with too much blast.

Slag in Cupolas. — A certain amount of slag is necessary to protect the molten iron which has fallen to the bottom from the action of the blast; if it was not there, the iron would suffer from decarbonization.

When slag from any cause forms in too great abundance, it should be led away by inserting a hole a little below the tuyeres, through which it will find its way as the iron rises in the bottom.

With clean iron and fuel, slag seldom forms to any appreciable extent in small heats; but when the cupola is to be taxed to its utmost capacity it is then incumbent on the melter to flux the charges all through the heat, carrying it away in the manner directed.

The best flux for this purpose is the chips from a white-marble yard. About 6 pounds to the ton of iron will give good results when all is clean. [Fluor-spar is now largely used as a flux.]

When fuel is bad, or iron is dirty, or both together, it becomes imperative that the slag be kept running all the time.

Fuel for Cupolas. — The best fuel for melting iron is coke, because it requires less blast, makes hotter iron, and melts faster than coal. When coal must be used, care should be exercised in its selection. All anthracites which are bright, black, hard, and free from slate, will melt iron admirably. For the best results, small cupolas should be charged with the size called "egg," a still larger grade for medium-sized cupolas, and what is called "lump" will answer for all large cupolas, when care is taken to pack it carefully on the charges.

Melting Capacity of Different Cupolas. — The following figures are given by W. B. Snow, in *The Foundry*, Aug., 1908, showing the records of capacity and the blast pressure of several cupolas:

Diam. of lining, ins.	44	44	47	49	54	54	54	60	60	60	74
Tons per hour	6.7	7.3	8.4	9.1	7.7	8.8	10.2	12.4	14.8	13.8	13.0
Pressure, oz. per sq. in.	12.9	16.4	17.5	11.8	13.6	11.0	20.8	15.5	16.8	12.6	8.7

From plotted diagrams of records of 46 tests of different cupolas the following figures are obtained:

Diam. of lining, ins.	30	36	42	48	54	60	66	72
Max. tons per hour	3	5	7.3	9.5	12	15	18	21
Avge. " " "	2.5	4	5.5	7.5	9	11	13	16
Max. pressure, oz.	11	12	13.5	14	14.6	15.2	15.7	16

For a given cupola and blower the melting rate increases as the square root of the pressure. A cupola melting 9 tons per hour with 10 ounces pressure will melt about 10 tons with 12.5 ounces, and 11 tons with 15 ounces. The power required varies as the cube of the melting rate, so that it would require $(11/9)^3 = 1.82$ times as much power for 11 tons as for 9 tons. Hence the advantage of large cupolas and blowers with light pressures.

Charging a Cupola. — Chas. A. Smith (*Am. Mach.*, Feb. 12, 1891) gives the following: A 28-in. cupola should have from 300 to 400 lbs. of coke on bottom bed; a 36-in. cupola, 700 to 800 lbs.; a 48-in. cupola, 1500 lbs.; and a 60-in. cupola should have one ton of fuel on bottom bed.

To every pound of fuel on the bed, three, and sometimes four pounds of metal can be added with safety, if the cupola has proper blast; in after-charges, to every pound of fuel add 8 to 10 pounds of metal; any well-constructed cupola will stand ten.

F. P. Wolcott (*Am. Mach.*, Mar. 5, 1891) gives the following as the practice of the Colwell Iron-works, Carteret, N. J.: "We melt daily from twenty to forty tons of iron, with an average of 11.2 pounds of iron to one of fuel. In a 36-in. cupola seven to nine pounds is good melting, but in a cupola that lines up 48 to 60 inches, anything less than nine pounds shows a defect in arrangement of tuyeres or strength of blast, or in charging up."

"The Molder's Text-book," by Thos. D. West, gives forty-six reports in tabular form of cupola practice in thirty States, reaching from Maine to Oregon.

Improvement of Cupola Practice. — The following records are given by J. R. Fortune and H. S. Wells (*Proc. A. S. M. E.*, Mar., 1908) showing how ordinary cupola practice may be improved by making a few changes. The cupola is 13 ft. 4 in. in height from the top of the sand bottom to the charging door, and of three diameters, 50 in. for the first 3 ft. 6 in., then 54 in. for the next 2 ft. 4 in., then 60 in. to the top. When driven with a No. 8 Sturtevant blower, the maximum melting rate, from iron down to blast off, was 8.5 tons per hour. A No. 11 high-pressure blower was then installed. Test No. 1 in the table below gives the result with cupola charges as follows in pounds: Bed, 590 coke, followed by 826 coke, 2000 iron; 400 coke, 2000 iron; 300 coke, 2000 iron; and thereafter all charges were 200 coke, 2000 iron. The time between starting fire and starting blast was 2 hr. 30 min., and the time from blast on to iron down, 11 min. The melting rate, tons per hour, is figured for the time from iron down to blast off. The tuyeres were eight rectangular openings 11 1/4 in. high and of a total area of 1/9.02 of the area of the 54-in. circle.

No. of Test.	1	2	3	4	5	6	7	8	9	10
Total tons...	22.7	24.	22.15	24.25	24.25	22.65	24.	20.30	23.85	22.35
Tons per hr..	9.45	8.88	8.86	9.15	9.66	10.24	10.43	10.91	11.35	11.17
Lbs. per min*	19.81	18.61	18.55	19.17	20.25	21.44	21.82	22.95	23.77	23.39
Iron ÷ coke†	7.54	7.40	7.28	8.58	8.94	8.71	9.02	9.02	10.02	9.49
Blast, oz.....	11.60	10.63	10.00	9.47	9.80	9.86	10.00	10.13	10.55	10.55

* Per sq. ft. cupola area at 54 in. diam. from iron down to blast off.
† Including bed.

The tuyeres were then enlarged, making their area 1/5.98 of the cupola (54 in.) area, and the results are shown in tests No. 2 and 3 of the table. The iron was too hot, and the coke charge was decreased to a ratio of 1/13.33 instead of 1/10, the bed of coke being increased. The result, test No. 4, was an increased rate of melting, a decrease in the amount of coke, and a decrease in the blast pressure. Tests 5, 6, 7, 8 and 9 were then made, the coke being decreased, while the blast pressure was increased, resulting in a decided increase in the melting speed. In tests 5, 6 and 7 the iron layer was 13.33 times the weight of the coke layer; in test 8, 14.28 times; and in test 9, 15.38 times. In test 9 it was noticed that the iron was not at the proper temperature, and in test 10 the coke layer was increased to a ratio of 1 to 14.28 without altering the blast pressure; this resulted in a decreased melt per hour. It has been found that a coke charge of 150 lbs. to 2000 lbs. of iron, with a blast pressure of 10.5 ounces, results in a melt of 11.5 tons per hour, the iron coming down at the proper temperature.

An excess of coke decreases the melting rate. Iron in the cupola is melted in a fixed zone, the first charge of iron above the bed being melted by burning coke in the bed. As this iron is melted, the charge of coke above it descends and restores to the bed the amount which has been burned away. If there is too much coke in the charge, the iron is held above the melting zone, and the excess coke must be burned away before it can be melted, and this of course decreases the economy and the melting speed.

Cupola Charges in Stove-foundries. (*Iron Age*, April 14, 1892.) — No two cupolas are charged exactly the same. The amount of fuel on the bed or between the charges differs, while varying amounts of iron are used in the charges. Below will be found charging-lists from some of the prominent stove-foundries in the country:

	lbs.		lbs.
A—Bed of fuel, coke	1,500	Four next charges of coke, each	150
First charge of iron	5,000	Six next charges of coke, each	120
All other charges of iron	1,000	Nineteen next charges of coke, each	100
First and second charges of coke, each	200		

Thus for a melt of 18 tons there would be 5120 lbs. of coke used, giving a ratio of 7 to 1. Increase the amount of iron melted to 24 tons, and a ratio of 8 pounds of iron to 1 of coal is obtained.

	lbs.		lbs.
B—Bed of fuel, coke	1,600	Second and third charges of fuel	130
First charge of iron	1,800	All other charges of fuel, each	100
First charge of fuel	150		
All other charges of iron, each	1,000		

For an 18-ton melt 5060 lbs. of coke would be necessary, giving a ratio of 7.1 lbs. of iron to 1 pound of coke.

	lbs.		lbs.
C—Bed of fuel, coke	1,600	All other charges of iron	2,000
First charge of iron	4,000	All other charges of coke	150
First and second charges of coke	200		

In a melt of 18 tons 4100 lbs. of coke would be used, or a ratio of 8.5 to 1.

	lbs.		lbs.
D—Bed of fuel, coke	1,800	All charges of coke, each	200
First charge of iron	5,600	All other charges of iron	2,900

In a melt of 18 tons, 3900 lbs. of fuel would be used, giving a ratio of 9.4 pounds of iron to 1 of coke. Very high, indeed, for stove-plate.

	lbs.		lbs.
E—Bed of fuel, coal	1,900	All other charges of iron, each	2,000
First charge of iron	5,000	All other charges of coal, each	175
First charge of coal	200		

In a melt of 18 tons 4700 lbs. of coal would be used, giving a ratio of 7.7 lbs. of iron to 1 lb. of coal.

These are sufficient to demonstrate the varying practices existing among different stove-foundries. In all these places the iron was proper for stove-plate purposes, and apparently there was little or no difference in the kind of work in the sand at the different foundries.

Foundry Blower Practice. (W. B. Snow, *Trans. A. S. M. E.*, 1907.) — The velocity of air produced by a blower is expressed by the formula $V = \sqrt{2\,gp/d}$. If p, the pressure, is taken in ounces per sq. in., and d, the density, in pounds per cu. ft. of dry air at 50° and atmospheric pressure of 14.69 lbs. or 235 ounces, = 0.77884 lb., the formula reduces to $V = \sqrt{1{,}746{,}700\ p/(235 + p)}$, no allowance being made for change of temperature during discharge. From this formula the following figures are obtained. Q = volume discharged per min. through an orifice of 1 sq. ft. effective area, H.P. = horse-power required to move the given volume under the given conditions, p = pressure in ounces per sq. in.

p	Q	H.P.	p	Q	H.P.	p	Q	H.P.	p	Q	H.P.
1	35.85	0.00978	6	86.89	0.1422	11	116.45	0.3493	16	139.03	0.6067
2	50.59	0.02759	7	93.66	0.1788	12	121.38	0.3972	17	143.03	0.6631
3	61.83	0.05058	8	99.92	0.2180	13	126.06	0.4470	18	146.88	0.7211
4	71.24	0.07771	9	105.76	0.2596	14	130.57	0.4986	19	150.61	0.7804
5	79.48	0.1084	10	111.25	0.3034	15	134.89	0.5518	20	154.22	0.8412

The greatest effective area over which a fan will maintain the maximum velocity of discharge is known as the "capacity area" or "square inches of blast." As originally established by Sturtevant it is represented by $DW/3$, D = diam. of wheel in ins., W = width of wheel at circumference, in inches. For the ordinary type of fan at constant speed maximum efficiency and power are secured at or near the capacity area; the power per unit of volume and the pressure decrease as the discharge area and volume increase; with closed outlet the power is approximately one-third of that at capacity area.

The following table is calculated on these bases: Capacity area per inch of width at periphery of wheel = 1/3 of diam. Air, 50° F. Velocity of discharge = circumferential speed of the wheel. Power = double the theoretical. In rotary positive blowers, as well as in fans, the velocity and the volume vary as the number of revolutions, the pressure varies as the square, and the power as the cube of the number of revolutions. In the fan, however, increase of pressure can be had only by increasing the revolutions, while in the rotary blower a great range of pressure is obtainable with constant speed by merely varying the resistance. With a rotary blower at constant speed, theoretically, and disregarding the effect of changes in temperature and density, the volume is constant; the velocity varies inversely as the effective outlet area; the pressure varies inversely as the square of the outlet area, hence as the square of the velocity; and the power varies directly as the pressure. The maximum power is required when a fan discharges against the least, and when a rotary blower discharges against the greatest resistance.

Performance of Cupola Fan Blowers at Capacity Area per Inch of Peripheral Width.

Diam. of Wheel, ins.	Item.	Total Pressure in Ounces per Square Inch.

The air supply required by a cupola varies with the melting ratio, the density of the charges, and the incidental leakage. Average practice is represented by the following:

Lbs. iron per lb. coke..........	6	7	8	9	10
Cu. ft. air per ton of iron.......	33,000	31,000	29,000	27,000	25,000

It is customary to provide blower capacity on a basis of 30,000 cu. ft., which corresponds to 75 to 80% of the chemical requirements for complete combustion with average coke, and a melting ratio of 7.5 to 1.

In comparative tests with a 54-inch lining cupola under identical conditions as to contents, alternately run with a No. 10 Sturtevant fan and a 33 cu. ft. Connersville rotary, with the fan the pressure varied between 12 1/2 and 14 1/8 ounces in the wind box, the net power from 25 to 38.5 H.P., while with the rotary blower the pressure varied between 10 1/2 and 25 ounces, and the power between 19 and 45 H.P. With the fan 28.84 tons were melted in 3.77 hours, or 7.65 tons per hour, while with the rotary blower 2.82 hours were required to melt 31.5 tons, an hourly rate of 10.6 tons, an increase of nearly 40 per cent in output. This reduces to a net input of 4.09 H.P. per ton melted per hour with the fan, and 2.98 H.P. with the rotary blower; an apparent advantage of 27% in favor of the rotary. Had the rotary been of smaller capacity such excessive pressures would not have been necessary, the power would have been decreased, and the duration of the heat prolonged, with probable decrease in the H.P. hours per ton. Had the fan been run at higher speed the H.P. would have increased, the time decreased and the power per ton per hour would have more closely approached that required by the rotary blower.

Theoretically, for otherwise constant conditions, the following relations hold for cupolas and melting rates within the range of practical operation:

For a given cupola:	For a given melting rate:	For a given volume:
$M \propto V, \sqrt{P}$, or $\sqrt[3]{\text{H.P.}}$	$V \propto 1 \div D^2$	$M \propto D$
$V \propto M$	$P \propto d$	For a given cupola
$P \propto V^2$	$\text{H.P.} \propto P$ or $1 \div D^4$	$E \propto M^2$, or P
$\text{H.P.} \propto M^3$ or $\sqrt{P^3}$	$E \propto M, P$, or $1 \div D^4$	Duration of heat $\propto 1 \div \sqrt{P}$

M = melting rate; V = volume; P = pressure; H.P. = horse-power; D = diam. of lining; E = operating efficiency = power per ton per hour; d = depth of the charge; $\propto$, varies as.

These relations might be the source of formulæ for practical use were it possible to establish accurate coefficients. But the variety in cupolas, tuyere proportions, character of fuel and iron, and difference in charging practice are bewildering and discouraging. Maximum efficiency in a given case can only be assured after direct experiment. Something short of the maximum is usually accepted in ignorance of the ultimate possibilities.

The actual melting range of a cupola is ordinarily between 0.6 and 0.75 ton per hour per sq. ft. of cross section. The limits of air supply per minute per sq. ft. are roughly 2500 and 4000 cu. ft. The possible power required varies even more widely, ranging from 1.5 to 3.75 H.P. per sq. ft., corresponding to 2.5 and 5 H.P. per ton per hour for the melting rates specified. The power may be roughly calculated, from the theoretical requirement of 0.27 H.P. to deliver 1000 cu. ft. per minute against 1 oz. pressure. The power increases directly with the pressure, and depends also on the efficiency of the blower. Current practice can only be expressed between limits as in the following table.

Range of Performance of Cupola Blowers.

Diameter inside Lining, in.	Capacity per Hour, tons.	Pressure per sq. in., oz.	Volume of Air per min., cu. ft.	Horse-power.
18	0.25– 0.5	5– 7	150– 300	0.5– 1.5
24	1.00– 1.5	7– 9	600– 900	2.0– 6.0
30	2.00– 3.5	8–11	1,200– 2,000	5.0– 15.0
36	4.00– 5.0	8–12	2,200– 2,800	10.0– 23.0
42	5.00– 7.0	8–13	2,700– 3,700	12.0– 32.0
48	8.00–10.0	8–13	4,000– 5,000	18.0– 45.0
54	9.00–12.0	9–14	4,500– 6,000	22.0– 60.0

78	19.00–24.0	10–16	9,500–12,000	52.0–130.0
84	21.00–27.0	10–16	10,500–13,500	60.0–150.0

Results of Increased Driving. (Erie City Iron-works, 1891.) — May–Dec., 1890: 60-in. cupola, 100 tons clean castings a week, melting 8 tons per hour; iron per pound of fuel, $7\frac{1}{2}$ lbs.; per cent weight of good castings to iron charged, $75\frac{3}{4}$. Jan.–May, 1891: Increased rate of melting to $11\frac{1}{2}$ tons per hour; iron per lb. fuel, $9\frac{1}{2}$; per cent weight of good castings, 75; one week, $13\frac{1}{4}$ tons per hour, 10.3 lbs. iron per lb. fuel; per cent weight of good castings, 75.3. The increase was made by putting in an additional row of tuyeres and using stronger blast, 14 ounces. Coke was used as fuel. (W. O. Webber, *Trans. A. S. M. E.*, xii, 1045.)

Power Required for a Cupola Fan. (Thos. D. West, *The Foundry*, April, 1904.) — The power required when a fan is connected with a cupola depends on the length and diameter of the piping, the number of bends, valves, etc., and on the resistance to the passage of blast through the cupola. The approximate power required in everyday practice is the difference between the power required to run the fan with the outlet open and with it closed. Another rule is to take 75% of the maximum power or that with the outlet open. A fan driving a cupola 66 ins. diam., 1800 r.p.m., driven by an electric motor required horse-power and gave pressures as follows: Outlet open, 146.6; outlet closed, 37.2, pressure 15 oz.; attached to cupola, with no fuel in it, 120.5, 5 oz.; after kindling and coke had been fired, 101.0, 10 oz.; during the run 70.8 to 76.7, 11 to 13 oz., the variations being due to changes in the resistances to the passage of the blast.

Utilization of Cupola Gases. — Jules De Clercy, in a paper read before the Amer. Foundrymen's Assn., advises the return of a portion of the gases from the upper part of the charge to the tuyeres, and thus utilizing the carbon monoxide they contain. He says that A. Baillot has thereby succeeded in melting 15 lbs. of iron per lb. of coke, and at the same time obtained a greater melting speed and a superior quality of castings.

Loss in Melting Iron in Cupolas. — G. O. Vair, *Am. Mach.*, March 5, 1891, gives a record of a 45-in. Colliau cupola as follows:

Ratio of fuel to iron, 1 to 7.42.

Good castings	21,314 lbs.
New scrap	3,005 "
Millings	200 "
Loss of metal	1,481 "
Amount melted	26,000 lbs.

Loss of metal, 5.69%. Ratio of loss, 1 to 17.55.

Use of Softeners in Foundry Practice. (W. Graham, *Iron Age*, June 27, 1889.) — In the foundry the problem is to have the right proportions of combined and graphitic carbon in the resulting casting; this is done by getting the proper proportion of silicon. The variations in the proportions of silicon afford a reliable and inexpensive means of producing a cast iron of any required mechanical character which is possible with the material employed. In this way, by mixing suitable irons in the right proportions, a required grade of casting can be made more cheaply than by using irons in which the necessary proportions are already found.

Hard irons, mottled and white irons, and even steel scrap, all containing low percentages of silicon and high percentages of combined carbon, could be employed if an iron having a large amount of silicon were mixed with them in sufficient amount. This would bring the silicon to the proper proportion and would cause the combined carbon to be forced into the graphitic state, and the resulting casting would be soft. High-silicon irons used in this way are called "softeners."

Mr. Keep found that more silicon is lost during the remelting of pig of over 10% silicon than in remelting pig iron of lower percentages of silicon. He also points out the possible disadvantage of using ferro-silicons containing as high a percentage of combined carbon as 0.70% to overcome the bad effects of combined carbon in other irons.

The Scotch irons generally contain much more phosphorus than is desired in irons to be employed in making the strongest castings. It is a mistake to mix with strong low-phosphorus irons an iron that would increase the amount of phosphorus for the sake of adding softening qualities, when softness can be produced by mixing irons of the same low phosphorus.

(For further discussion of the influence of silicon, see pages 438 and 447.)

Weakness of Large Castings. (W. A. Bole, *Trans. A. S. M. E.*, 1907.) — Thin castings, by virtue of their more rapid cooling, are almost certain to be stronger per unit section than would be the case if the same metal were poured into larger and heavier shapes. Many large iron castings are of questionable strength, because of internal strains and lack of harmony between their elements, even though the casting is poured out of iron of the best quality. This may be due to lack of experience on the part of the designer, especially in the cooling and shrinking of the various parts of a large casting after being poured.

Castings are often designed with a useless multiplicity of ribs, walls, gussets, brackets, etc., which, by their asynchronous cooling and their inharmonious shrinkage and contraction, may entirely defeat the intention of the designer.

There are some castings which, by virtue of their shapes, can be specially treated by the foundryman, and artificial cooling of certain critical parts may be effected in order to compel such parts to cool more rapidly than they would naturally do, and the strength of the casting may by such means be beneficially affected. As for instance in the case of a fly-wheel with heavy rim but comparatively light arms and hub; it may be beneficial to remove the flask and expose the rim to the air so as to hasten its natural rate of cooling, while the arms and hub are still kept muffled up in the sand of the mold and their cooling retarded as much as possible.

Large fillets are often highly detrimental to good results. Where two walls meet and intersect, as in the shape of a *T*, if a large fillet is swept at the juncture, there will be a pool of liquid metal at this point which will remain liquid for a longer time than either wall, the result being a void, or "draw," at the juncture point.

Risers and sink heads should often be employed on iron castings. In large iron-foundry work interior cavities may exist without detection, and some of these may be avoided by the use of suitable feeding devices, risers and sink heads.

Specimens from a casting having at one point a tensile strength as high as 30,250 lbs. per sq. in. have shown as low as 20,500 in another and heavier section. Large sections cannot be cast to yield the high strength of specimen test pieces cast in smaller sections.

The paper describes a successful method of artificial cooling, by means of a coil of pipe with flowing water, of portions of molds containing cylinder heads with ports cast in them. Before adopting this method the internal ribs in these castings always cracked by contraction.

Shrinkage of Castings. — The allowance necessary for shrinkage varies for different kinds of metal, and the different conditions under which they are cast. For castings where the thickness runs about one inch, cast under ordinary conditions, the following allowance can be made:

For cast iron,	1/8 inch per foot.		For zinc,	5/16 inch per foot.
" brass,	3/16 " " "		" tin,	1/12 " " "
" steel,	1/4 " " "		" aluminum,	3/16 " " "
" mal. iron,	1/8 " " "		" britannia,	1/32 " " "

Thicker castings, under the same conditions, will shrink less, and thinner ones more, than this standard. The quality of the material and the manner of molding and cooling will also make a difference. (See also Shrinkage of Cast Iron, page 447.)

Mr. Keep (*Trans. A. S. M. E.*, vol. xvi) gives the following "approximate key for regulating foundry mixtures" so as to produce a shrinkage of 1/8 in. per ft. in castings of different sections:

Size of casting	1/2	1	2	3	4	in. sq.
Silicon required, per cent	3.25	2.75	2.25	1.75	1.25	per cent.
Shrinkage of a 1/2-in. test-bar	0.125	.135	.145	.155	.165	in per. ft.

Growth of Cast Iron by Heating. (*Proc. I. and S. Inst.*, 1909.) — Investigations by Profs. Rugan and Carpenter confirm Mr. Outerbridge's experiments. (See page 449) They found: 1. Heating white iron causes it to become gray, and it expands more than sufficient to overcome the original shrinkage. 2. Iron when heated increases in weight, probably due to absorption of oxygen. 3. The change in size due to heating is not only a molecular change, but also a chemical one. 4. The growth of one bar was shown to be due to penetration of gases. When heated in vacuo it contracted.

Hard Iron due to Excessive Silicon. — W. J. Keep in *Jour. Am. Foundrymen's Assn.*, Feb., 1898, reports a case of hard iron containing graphite, 3.04; combined C, 0.10; Si, 3.97; P, 0.61; S, 0.05; Mn, 0.56. He says: For stove plate and light hardware castings it is an advantage to have Si as high as 3.50. When it is much above that the surface of the castings often become very hard, though the center will be very soft.

The surface of heavier parts of a casting having 3.97 Si will be harder than the surface of thinner parts. Ordinarily if a casting is hard an increase of silicon softens it, but after reaching 3.00 or 3.50 per cent, silicon hardens a casting.

Ferro-Alloys for Foundry Use. E. Houghton (*Iron Tr. Rev.*, Oct. 24, 1907.) — The objects of the use of ferro-alloys in the foundry are: 1, to act as deoxidizers and desulphurizers, the added element remaining only in small quantities in the finished casting; 2, to alter the composition of the casting and so to control its mechanical properties. Some of these alloys are made in the blast furnace, but the purest grades are made in the electric furnace. The following table shows the range of composition of blast furnace alloys made by the Darwen & Mostyn Iron Co. All of these alloys may be made of purer quality in the electric furnace.

	Ferro-Mn.	Spiegel-eisen.	Silicon Spiegel.	Ferro-sil.	Ferro-phos.	Ferro-Chrome.
Mn......	41.5– 87.9	9.25–29.75	17.50–20.87	1.17– 2.20	3.00– 5.90	1.55– 2.30
Si.......	0.10– 0.63	0.42– 0.95	9.45–14.23	8.10–17.00	0.50– 0.84	0.13– 0.36
P.......	0.09– 0.20	0.06– 0.09	0.07– 0.10	0.06– 0.08	15.71–20.50	0.04– 0.07
C........	5.62– 7.00	3.94– 5.20	1.05– 1.89	0.90– 1.75	0.27– 0.30	5.34– 7.12
S	nil	nil-trace	nil	0.02– 0.05	0.16– 0.33	Cr, 13.50–41.39

The following are typical analyses of other alloys made in the electric furnace:

	Si	Fe	Mn	Al	Ca	Mg	C	S	P	Ti
Ferro-titanium..............	1.21	.....	....	0.30	.....	....	3.28	0.03	0.02	53.0
Ferro-aluminum-silicide.....	45.65	44.15	tr.	9.45	nil	nil	0.55	0.01	0.03	....
Ferro-calcium-silicide.......	69.80	11.15	0.22	2.55	15.05	0.26	1.14	0.01	0.04	....

Ferro-aluminum, Al, 5, 10 and 20%. Metallic manganese, Mn, 95 to 98; Fe, 2 to 4; C, under 5. Do. refined, Mn, 99; Fe, 1; C, 0.

Dangerous Ferro-silicon. — Phosphoretted and arseniuretted hydrogen, highly poisonous gases, are said to be disengaged in a humid atmosphere from ferro-silicon containing between 30 and 40% and between 47 and 65% of Si, and there is therefore danger in transporting it in passenger steamships. A French commission has recommended the abandonment of the manufacture of FeSi of these critical percentages. (*La Lumiere Electrique*, Dec. 11, 1909. *Elec. Rev.*, Feb. 26, 1910.)

Quality of Foundry Coke. (R. Moldenke, *Trans. A. S. M. E.*, 1907.) — Usually the sulphur, ash and fixed carbon are sufficient to give a fair idea of the value of coke, apart from its physical structure, specific gravity, etc. The advent of by-product coke will necessitate closer attention to moisture Beehive coke, when shipped in open cars, may, through inattention, cause the purchase of from 6 to 10 per cent of water at coke prices.

Concerning sulphur, very hot running of the cupola results in less sulphur in the iron. In good coke, the amount of S should not exceed 1.2 per cent; but, unfortunately, the percentage often runs as high as 2.00. If the coke has a good structure, an average specific gravity, not over 11 per cent of ash and over 86 per cent of fixed carbon, it does not matter much whether it be of the "72 hour" or "24 hour" variety. Departure from the normal composition of a coke of any particular region should place the foundryman on his guard at once, and sometimes the plentiful use of limestone at the right moment may save many castings.

Castings made in Permanent Cast-Iron Molds. — E. A. Custer, in a paper before the Am. Foundrymen's Assn. (*Eng. News*, May 27, 1909). describes the method of making castings in iron molds, and the quality of these castings. Very heavy molds are used, no provision is made against shrinkage, and the casting is removed from the mold as soon as it has set, giving it no time to chill or to shrink by cooling. Over 6000 pieces have been cast in a single mold without its showing any signs of failure. The mold should be so heavy that it will not become highly heated in use. Casting a 4-in. pipe weighing 65 lbs. every seven minutes in a mold weighing 6500 lbs. did not raise the temperature above 300° F. In using permanent molds the iron as it comes from the cupola should be very hot. The best results in casting pipe are had with iron containing over 3% carbon and about 2% silicon. Iron when cast in an iron mold and removed as soon as it sets, possesses some unusual properties. It will take a temper, and when tempered will retain magnetism. If the casting be taken from the mold at a bright heat and suddenly quenched in cold water, it has the cutting power of a good high-carbon steel, whether the iron be high or low in silicon, phosphorus, sulphur or manganese. There is no evidence of "chill"; no white crystals are shown.

Chilling molten iron swiftly to the point of setting, and then allowing it to cool gradually, produces a metal that is entirely new to the art. It has the chemical characteristics of cast iron, with the exception of combined carbon, and it also possesses some of the properties of high-carbon steel. A piece of cast iron that has 0.44% combined, and over 2% free carbon, has been tempered repeatedly and will do better service in a lathe than a good non-alloy steel. Once this peculiar property is imparted to the casting, it is impossible to eliminate it except by remelting. A bar of iron so treated can be held in a flame until the metal drips from the end, and yet quenching will restore it to its original hardness.

The character of the iron before being quenched is very fine, close-grained, and yet it is easily machined. If permanent molds can be used with success in the foundry, and a system of continuous pouring be inaugurated which in duplicate work would obviate the necessity of having molders, why is it necessary to melt pig iron in the cupola? What could be more ideal than a series of permanent molds supplied with molten iron practically direct from the blast furnace? The interposition of a reheating ladle such as is used by the steel makers makes possible the treatment of the molten iron.

The molten iron from the blast furnace is much hotter than that obtained from the cupola, so that there is every reason to believe that the castings obtained from a blast furnace would be of a better quality than when the pig is remelted in the cupola.

It is immaterial whether an iron contains 1.75 or 3% silicon, so long as the molten mass is at the proper temperature, so that the high temperatures obtained from the blast furnace would go far toward offsetting the variations in the impurities.

R. H. Probert (*Castings*, July, 1909) gives the following analysis of molds which gave the best results: Si, 2.02; S, 0.07; P, 0.89; Mn, 0.29; C.C., 0.84; G.C., 2.76. Molds made from iron with the following analysis were worthless: Si, 3.30; S, 0.06; P, 0.67; Mn, 0.12; C.C., 0.19; G.C., 2.98.

Weight of Castings determined from Weight of Pattern.
(Rose's Pattern-makers' Assistant.)

Molding Sand. (Walter Bagshaw, *Proc. Inst. M. E.*, 1891.) — The chemical composition of sand will affect the nature of the casting, no matter what treatment it undergoes. Stated generally, good sand is composed of 94 parts silica, 5 parts alumina, and traces of magnesia and oxide of iron. Sand containing much of the metallic oxides, and especially lime, is to be avoided. Geographical position is the chief factor governing the selection of sand; and whether weak or strong, its deficiencies are made up for by the skill of the molder. For this reason the same sand is often used for both heavy and light castings, the proportion of coal varying according to the nature of the casting. A common mixture of facing-sand consists of six parts by weight of old sand, four of new sand, and one of coal-dust. Floor-sand requires only half the above proportions of new sand and coal-dust to renew it. German founders adopt one part by measure of new sand to two of old sand; to which is added coal-dust in the proportion of one-tenth of the bulk for large castings, and one-twentieth for small castings. A few founders mix street-sweepings with the coal in order to get porosity when the metal in the mold is likely to be a long time in setting. Plumbago is effective in preventing destruction of the sand; but owing to its refractory nature, it must not be dusted on in such quantities as to close the pores and prevent free exit of the gases. Powdered French chalk, soapstone, and other substances are sometimes used for facing the mold; but next to plumbago, oak charcoal takes the best place, notwithstanding its liability to float occasionally and give a rough casting.

For the treatment of sand in the molding-shop the most primitive method is that of hand-riddling and treading. Here the materials are roughly proportioned by volume, and riddled over an iron plate in a flat heap, where the mixture is trodden into a cake by stamping with the feet; it is turned over with the shovel, and the process repeated. Tough sand can be obtained in this manner, its toughness being usually tested by squeezing a handful into a ball and then breaking it; but the process is slow and tedious. Other things being equal, the chief characteristics of a good molding-sand are toughness and porosity, qualities that depend on the manner of mixing as well as on uniform ramming.

Toughness of Sand. — In order to test the relative toughness, sand mixed in various ways was pressed under a uniform load into bars 1 in. sq. and about 12 in. long, and each bar was made to project further and further over the edge of a table until its end broke off by its own weight. Old sand from the shop floor had very irregular cohesion, breaking at all lengths of projections from 1/2 in. to 1 1/2 in. New sand in its natural state held together until an overhang of 2 3/4 in. was reached. A mixture of old sand, new sand, and coal-dust

Mixed under rollers................	broke at	2	to 2 1/4	in. of overhang.
" in the centrifugal machine...	" "	2	" 2 1/4	" " "
" through a riddle............	" "	1 3/4	" 2 1/8	" " "

showing as a mean of the tests only slight differences between the last three methods, but in favor of machine-work. In many instances the fractures were so uneven that minute measurements were not taken.

Heinrich Ries (*Castings*, July, 1908) says that chemical analysis gives little or no information regarding the bonding power, texture, permeability or use of sand, the only case in which it is of value being in the selection of a highly silicious sand for certain work such as steel casting.

Dimensions of Foundry Ladles. — The following table gives the dimensions, inside the lining, of ladles from 25 lbs. to 16 tons capacity. All the ladles are supposed to have straight sides. (*Am. Mach.*, Aug. 4, 1892.)

Cap'y.	Diam.	Depth.	Cap'y.	Diam.	Depth.	Cap'y.	Diam.	Depth.
	in.	in.		in.	in.		in.	in.
16 tons	54	56	3 tons	31	32	300 lbs.	11 1/2	11 1/2

THE MACHINE-SHOP.

SPEED OF CUTTING-TOOLS IN LATHES, MILLING MACHINES, ETC.

Relation of diameter of rotating tool or piece, number of revolutions and cutting-speed:

Let d = diam. of rotating piece in inches, n = No. of revs. per min.; S = speed of circumference in feet per minute;

$$S = \frac{\pi dn}{12} = 0.2618\,dn; \quad n = \frac{S}{0.2618\,d} = \frac{3.82\,S}{d}; \quad d = \frac{3.82\,S}{n}.$$

Approximate rule: Number of revolutions per minute = 4 × speed in feet per minute ÷ diameter in inches.

Table of Cutting-speeds.

Diameter, Inches	Feet per minute.

The Speed of Counter-shaft of the lathe is determined by an assumption of a slow speed with the back gear, say 6 feet per minute, on the largest diameter that the lathe will swing.

Example. — A 30-inch lathe will swing 30 inches =, say, 90 inches circumference = 7 feet 6 inches; the lowest triple gear should give a speed of 5 or 6 feet per minute.

Spindle Speeds of Lathes. — The spindle speeds of lathes are usually in geometric progression, being obtained either by a combination of cone-pulley and back gears, or by a single pulley in connection with a gear train. Either of these systems may be used with a variable speed motor, giving a wide range of available speeds.

It is desirable to keep work rotating at a rate that will give the most economical cutting speed, necessitating, sometimes, frequent changes in spindle speed. A variable speed motor arranged for 20 speeds in geometric progression, any one of which can be used with any speed due to the mechanical combination of belts and back gears, gives a fine gradation of cutting speeds. The spindle speeds obtained with the higher speeds of the motor in connection with a certain mechanical arrangement of belt and back gears may overlap those obtained with the lower speeds available in the motor in connection with the next higher speed arrangement of belt and gears, but about 200 useful speeds are possible. E. R. Douglas (*Elec. Rev.*, Feb. 10, 1906) presents an arrangement of variable speed motor and geared head lathe, with 22 speed variations in the motor and 3 in the head. The speed range of the spindle is from 4.1 to 500 r.p.m. By the use of this arrangement, and taking advantage of the speed changes possible for different diameters of the work, a saving of 35.4 per cent was obtained in the time of turning a piece ordinarily requiring 289 minutes.

Rule for Gearing Lathes for Screw-cutting. (Garvin Machine Co.) — Read from the lathe index the number of threads per inch cut by equal gears, and multiply it by any number that will give for a product a gear on the index; put this gear upon the stud, then multiply the number of threads per inch to be cut by the same number, and put the resulting gear upon the screw.

Example. — To cut 11½ threads per inch. We find on the index that 48 into 48 cuts 6 threads per inch, then $6 \times 4 = 24$, gear on stud, and $11\frac{1}{2} \times 4 = 46$, gear on screw. Any multiplier may be used so long as the products include gears that belong with the lathe. For instance, instead of 4 as a multiplier we may use 6. Thus, $6 \times 6 = 36$, gear upon stud, and $11\frac{1}{2} \times 6 = 69$, gear upon screw.

Rules for Calculating Simple and Compound Gearing where there is no Index. (*Am. Mach.*) — If the lathe is simple-geared, and the stud runs at the same speed as the spindle, select some gear for the screw, and multiply its number of teeth by the number of threads per inch in the lead-screw, and divide this result by the number of threads per inch to be cut. This will give the number of teeth in the gear for the stud. If this result is a fractional number, or a number which is not among the gears on hand, then try some other gear for the screw. Or, select the gear for the stud first, then multiply its number of teeth by the number of threads per inch to be cut, and divide by the number of threads per inch on the lead-screw. This will give the number of teeth for the gear on the screw. If the lathe is compound, select at random all the driving-gears, multiply the numbers of their teeth together, and this product by the number of threads to be cut. Then select at random all the driven gears except one; multiply the numbers of their teeth together, and this product by the number of threads per inch in the lead-screw. Now divide the first result by the second, to obtain the number of teeth in the remaining driven gear. Or, select at random all the driven gears. Multiply the numbers of their teeth together, and this product by the number of threads per inch in the lead-screw. Then select at random all the driving-gears except one. Multiply the numbers of their teeth together, and this result by the number of threads per inch of the screw to be cut. Divide the first result by the last, to obtain the number of teeth in the remaining driver. When the gears on the compounding stud are fast together, and cannot be changed, then the driven one has usually twice as many teeth as the other, or driver, in which case in the calculations consider the lead-screw to have twice as many threads per inch as it actually has, and then ignore the compounding entirely. Some lathes are so constructed that the stud on which the first driver is placed revolves only half as fast as the spindle. This can be ignored in the calculations by doubling the number of threads of the lead-screw. If both the last conditions are present ignore them in the calculations by multiplying the number of threads per inch in the lead-screw by four. If the thread to be cut is a fractional one, or if the pitch of the lead-screw is fractional, or if both are fractional, then reduce the fractions to a common denominator, and use the numerators of these fractions as if they equaled the pitch of the screw to be cut, and of the lead-screw, respectively. Then use that part of the rule given above which applies to the lathe in question. For instance, suppose it is desired to cut a thread of $^{25}/_{32}$-inch pitch, and the lead-screw has 4 threads per inch. Then the pitch of the lead-screw will be $^{1}/_{4}$ inch, which is equal to $^{8}/_{32}$ inch. We now have two fractions, $^{25}/_{32}$ and $^{8}/_{32}$, and the two screws will be in the proportion of 25 to 8, and the gears can be figured by the above rule, assuming the number of threads to be cut to be 8 per inch, and those on the lead-screw to be 25 per inch. But this latter number may be further modified by conditions named above, such as a reduced speed of the stud, or fixed compound gears. In the instance given, if the lead-screw had been $2\,^{1}/_{2}$ threads per inch, then its pitch being $^{4}/_{10}$ inch, we have the fractions $^{4}/_{10}$ and $^{25}/_{32}$, which, reduced to a common denominator, are $^{64}/_{160}$ and $^{125}/_{160}$, and the gears will be the same as if the lead-screw had 125 threads per inch, and the screw to be cut 64 threads per inch.

On this subject consult also "Formulas in Gearing," published by Brown & Sharpe Mfg. Co., and Jamieson's Applied Mechanics.

Change-gears for Screw-cutting Lathes.—There is a lack of uniformity among lathe-builders as to the change-gears provided for screw-cutting. W. R. Macdonald, in *Am. Mach.*, April 7, 1892, proposed the following series, by which 33 whole threads (not fractional) may be cut by changes of only nine gears:

Screw.	Spindle.									Whole Threads.			
	20	30	40	50	60	70	110	120	130				
20	...	8	6	4 4/5	4	3 3/7	2 2/11	2	1 11/13	2	11	22	44
30	18	...	9	7 1/5	6	5 1/7	3 3/11	3	2 10/13	3	12	24	48
40	24	16	12	9 3/5	8	6 6/7	4 4/11	4	3 9/13	4	13	26	52
50	30	20	15	...	10	8 4/7	5 5/11	5	4 8/13	5	14	28	66
60	36	24	18	14 2/5	...	10 2/7	6 6/11	6	5 7/13	6	15	30	72
70	42	28	21	16 4/5	14	...	7 7/11	7	6 6/13	7	16	33	78
110	66	44	33	26 2/5	22	18 6/7	...	11	10 2/13	8	18	36	
120	72	48	36	28 4/5	24	20 4/7	13 1/11	..	11 1/13	9	20	39	
130	78	52	39	31 1/5	26	22 3/7	14 2/11	13	...	10	21	42	

Ten gears are sufficient to cut all the usual threads, with the exception of perhaps $11\,^{1}/_{2}$, the standard pipe-thread; in ordinary practice any fractional thread between 11 and 12 will be near enough for the customary short pipe-thread; if not, the addition of a single gear will give it.

In this table the pitch of the lead-screw is 12, and it may be objected to as too fine for the purpose. This may be rectified by making the real pitch 6 or any other desirable pitch, and establishing the proper ratio between the lathe spindle and the gear-stud.

"Quick Change Gears."—About 1905, lathe manufacturers began building "quick change" lathes in which gear changing for screw cutting is eliminated. The lead-screw carries a cone of gears, one of which is in mesh with a movable gear in a nest of gears driven from the spindle. By changing the position of this movable gear, in relation to the cone of gears, the proper ratio of speeds between the spindle and lead-screws is obtained for cutting any desired thread usual in the range of the machine. About 16 different numbers of threads per inch can usually be cut by means of the "quick change" gear train. Different threads from those usually available can be cut by means of change gears between the spindle and "quick change" gear train. The threads per inch usually available range from 2 to 46 in a 12-in. lathe to 1 to 24 in a 30-in. lathe. Catalogs of lathe manufacturers should be consulted for constructional details.

Shapes of Tools. For illustrations and descriptions of various forms of cutting-tools, see Taylor's Experiments, below; also see Standard Planer Tools, p. 1271, and articles on Lathe Tools in Appleton's Cyc. Mech., vol. ii, and in Modern Mechanism.

Cold Chisels.—Angle of cutting-faces (Joshua Rose): For cast steel, about 65 degrees; for gun-metal or brass, about 50 degrees; for copper and soft metals, about 30 to 35 degrees.

Metric Screw-threads may be cut on lathes with inch-divided leading-screws, by the use of change-wheels with 50 and 127 teeth; since 127 centimeters = 50 inches (127 × 0.3937 = 49.9999 in.).

Rule for Setting the Taper in a Lathe. (*Am. Mach.*) — No rule can be given which will produce exact results, owing to the fact that the centers enter the work an indefinite distance. If it were not for this circumstance the following would be an exact rule, and it is an approximation as it is. To find the distance to set the center over: Divide the difference in the diameters of the large and small ends of the taper by 2, and multiply this quotient by the ratio which the total length of the shaft bears to the length of the tapered portion. EXAMPLE: Suppose a shaft three feet long is to have a taper turned on the end one foot long, the large end of the taper being two inches and the small end one inch diameter,

$$\frac{2-1}{2} \times \frac{3}{1} = 1\tfrac{1}{2} \text{ inches.}$$

Lubricants for Lathe Centers.—*Machinery* recommends as lubricants for lathe centers to prevent cutting or abrasion: 1. Dry or powdered red lead mixed with a good mineral oil to the consistency of cream. 2. White lead mixed with sperm oil, together with enough graphite to give the mixture a dark red color. 3. One part graphite, four parts tallow, thoroughly mixed.

TAYLOR'S EXPERIMENTS.

Fred W. Taylor directed a series of experiments, extending over 26 years, on feeds, speeds, shape of tool, composition of tool steel, and heat treatment. His results are given in *Trans. A. S. M. E.*, xxviii, "The Art of Cutting Metals." The notes below apply mainly to tools of high speed steel and to heavy work requiring tools not less than 1/2 by 3/4 inch in cross-section.

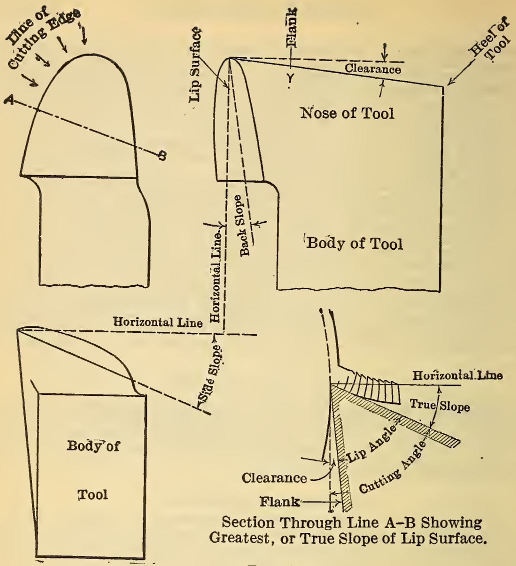
Proper Shape of Lathe Tool.—Mr. Taylor discovered the best shape for lathe tools to be as shown in Fig. 194 with the angles given in the following table, when used on materials of the class shown. The exact outline of the nose of the tool is shown in Fig. 195. The actual dimensions of a 1-inch roughing tool are shown in Fig. 196. Let R = radius of point of tool, A = width of tool, L = length of shank, and H = height of shank, all in inches. Then $L = 14A + 4$; $H = 1.5A$; $R = 0.5A - 0.3125$ for cutting hard steel and cast iron; $R = 0.5A - 0.1875$ for soft steel. The meaning of the terms back slope, etc., is shown in Fig. 194.

Angles for Tools.

* Material cut.	a = clearance.	b = back slope.	c = side slope.
Cast iron; Hard steel.	6 degrees.	8 degrees.	14 degrees.
Medium or Soft steel.	6 degrees.	8 degrees.	22 degrees.
Tire steel.	6 degrees.	5 degrees.	9 degrees.

* As far as the shape of the tool is concerned, Taylor divided metals to be cut into general classes: (*a*) cast iron and hard steel, steel of 0.45–0.50 per cent carbon, 100,000 pounds tensile strength, and 18 per cent stretch, being a low limit of hardness; (*b*) soft steel, softer than above; (*c*) chilled iron; (*d*) tire steel; (*e*) extremely soft steel of carbon, say, 0.10–0.15 per cent.

The table presupposes the use of an automatic tool grinder. If tools are ground by hand the clearance angle should be 9 degrees. The lip angles for tools cutting hard steel and cast iron should be 68 degrees;



Section Through Line A–B Showing Greatest, or True Slope of Lip Surface.

FIG. 194.

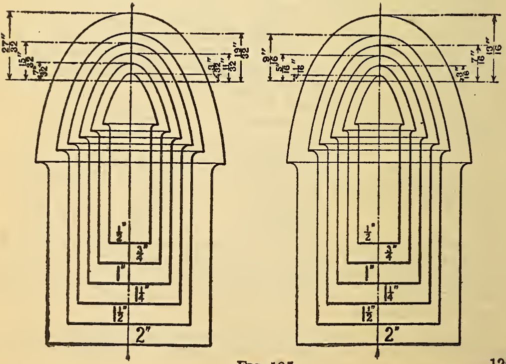


FIG. 195.

for soft steel, 61 degrees; for chilled iron, 86 to 90 degrees; for tire steel, 74 degrees; for extremely soft steel, keener than 61 degrees. A tool should be given more side than back slope; it can then be ground more times without weakening, the chip does not strike the tool post or clamps,

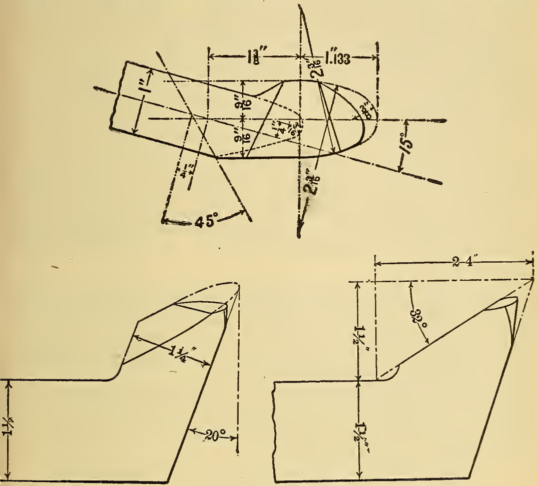

Fig. 196.

and it is also easier to feed. The nose of the tool should be set to one side, as in Fig. 196 above, to avoid any tendency to upset. To use a tool of this shape, lathe tool posts should be set lower below the center of the work than is now (1907) customary.

Forging and Grinding Tools.—The best method of dressing a tool is to turn one end up nearly at right angles to the shank, so that the nose will be high above the top of the body of the tool. Dressing can be thus done in two heats. Tools should leave the smith shop with a clearance angle of 20 degrees. Detailed directions for dressing a tool are given in Mr. Taylor's paper. To avoid overheating the tool in grinding, a stream of water, of at least five gallons a minute, should be thrown at low velocity on the nose of the tool where it is in contact with the emery wheel. In hand grinding, tools should not be held firmly against the wheel, but should be moved over its surface. It is of the utmost importance that high speed steel tools should not be heated above 1200° F. in grinding. Automatic tool grinders are economical, even in a small shop. Grinding machines should have some means for automatically adjusting the pressure of the tool against the grinding wheel. Each size of tool should have adapted to it a pressure, automatically adjusted, and which is just sufficient to grind rapidly without overheating the tool. Standard shapes should be adopted, to which all tools should be ground. there being no economy in automatic grinding without standard shapes,

Best Grinding Wheel. — The best grinding wheel was found to be a corundum wheel, of a mixture of 24 and 30 grit,

Pressure of Tool, etc. — Mr. Taylor found that there is no definite relation between the cutting speed of tools and the pressure with which the chip bears on the lip surface of the tool. He found, however, that the pressure per square inch of sectional area of the chip increases slightly as the thickness of the chip decreases. The feeding pressure of the tool is sometimes equal to the entire driving pressure of the chip against the lip surface of the tool, and the feed gears should be designed to deliver a pressure of this magnitude at the nose of the tool.

Chatter. — Chatter is caused by: too small lathe dogs; imperfect bearing at the points where the face plate drives the dogs; badly made or badly fitted gears; shafts in the machine of too small diameter, or of too great length; loose fits in bearings. A tool which chatters must be run at a cutting speed about 15 per cent slower than can be used if the tool does not chatter, irrespective of the use or non-use of water on the tool. A higher cutting speed can be used with an intermittent cut, as occurs on a planer, or shaper, or in turning, say, the periphery of a gear, than with a steady cut. To avoid chatter, tools should have curved cutting edges, or two or more tools should be used at the same time in the same machine. The body of the tool should be greater in height than width, and should have a true, solid bearing on the tool support, which latter should extend to almost beneath the cutting edge of the tool. Machines should be made massive beyond the metal needed for strength alone, and steady rests should be used on long work. It is advisable to use a steady rest, when turning any cylindrical piece of diameter D, when the length exceeds 12 D.

Use of Water on Tool. — With the best high speed steel tools, a gain of 14 per cent in cutting speed can be made in cutting cast-iron and hard steel to 35 per cent on very soft steel by throwing a heavy stream of water directly on the chip at the point where it is being removed from the forging by the tool. Not less than three gallons a minute should be used for a $2 \times 2\,1/2$-in. tool. The gain is practically the same for all qualities of steel, regardless of hardness and whether thick or thin chips are being cut.

Interval between Grindings. — Mr. Taylor derived a table showing how long various sizes of tools should run without regrinding to give the maximum work for the lowest all-around cost. Time a tool should run continuously without regrinding equals 7 × (time to change tool + proper portion of time for redressing + time for grinding + time equivalent to cost of the tool steel ground off).

INTERVAL BETWEEN GRINDINGS, AT MAXIMUM ECONOMICAL CUTTING SPEEDS.

Size of tool.					
Inches.	$1/2 \times 3/4$	$5/8 \times 1$	$3/4 \times 1\,1/8$	$7/8 \times 1\,3/8$	$1 \times 1\,1/2$
Hours.	1.25	1.25	1.25	1.5	1.5

Size of tool.				
Inches.	$1\,1/4 \times 1\,7/8$	$1\,1/2 \times 2\,1/4$	$1\,3/4 \times 2\,3/4$	2×3
Hours.	1.75	2.0	2.5	2.75

If the proper cutting speed (A) is known for a cut of given duration, the speed for a cut (B) of different duration can be obtained by multiplying (A) by the factor given in the following table:

Duration of cut in minutes:						
At known speed (A)	20	40	20	40	80	80
At derived speed (B)	40	80	80	20	40	20
Factor	0.92	0.92	0.84	1.09	1.09	1.19

For cutting speeds of high-speed lathe tools to last $1\,1/2$ hours, see tables on pages 1266 and 1267.

Effect of Feed and Depth of Cut on Cutting Speed.—With a given depth of cut, metal can be removed faster with a coarse feed and slow speed, than with fine feed and high speed. With a given depth of cut, a cutting speed of S, and a feed of F, S varies approximately as $1/\sqrt{F}$. With tools of the best high speed steel, varying the feed and depth of cut varies the cutting speed in the same ratio when cutting hard steel as when cutting soft steel.

Best High Speed Tool Steel — Composition — Heat Treatment. — Mr. Taylor and Maunsel White developed a number of high speed steels, the one showing the best all-around qualities having the following chemical composition: Vanadium, 0.29; tungsten, 18.19; chromium, 5.47; carbon, 0.674; manganese, 0.11; silicon, 0.043. The use of vanadium materially improves high speed steel. The following method of treatment is described as the best for this or any other composition of high speed steel. The tool should be forged at a light yellow heat, and, after forging slowly and uniformly heated to a bright cherry red, allowing plenty of time for the heat to penetrate to the center of the tool, in order to avoid danger of cracking due to too rapid heating. The tool should then be heated from a bright cherry red to practically its melting-point as rapidly as possible in an intensely hot fire; if the extreme nose of the tool is slightly fused no harm is done. Time should be allowed for the tool to become uniformly hot from the heel to the lip surface.

After the high heat has been given the tools, as above described, they should be cooled rapidly until they are below the "breaking-down point," or, say, down to or below 1550° F. The quality of the tool will be but little affected whether it is cooled rapidly or slowly from this point down to the temperature of the air. Therefore, after all parts of a tool from the outside to the center have reached a uniform temperature below the breaking-down point, it is the practice sometimes to lay it down in any part of the room or shop which is free from moisture, and let it cool in the air, and sometimes to cool it in an air blast to the temperature of the air.

The best method of cooling from the high heat to below the breaking-down point is to plunge the tools into a bath of red-hot molten lead below the temperature of 1550° F. They should then be plunged into a lead bath maintained at a uniform temperature of 1150° F., because the same bath is afterward used for reheating the tools to give them their second treatment. This bath should contain a sufficiently large body of the lead so that its temperature can be maintained uniform; and for this purpose should be used preferably a lead bath containing about 3600 lb. of lead.

Too much stress cannot be laid upon the importance of never allowing the tool to have its temperature even slightly raised for a very short time during the process of cooling down. The temperature must either remain absolutely stationary or continue to fall after the operation of cooling has once started, or the tool will be injured. Any temporary rise of temperature during cooling, however small, will injure the tool. This, however, applies only to cooling the tool to the temperature of about 1240° F. Between the limits of 1240 degrees and the temperature of the air, the tool can be raised or lowered in temperature time after time and for any length of time without injury. And it should also be noted that during the first operation of heating the tool from its cold state to the melting-point, no injury results from allowing it to cool slightly and then reheating. It is from reheating during the operation of cooling from the high heat to 1240° F. that the tool is injured.

The above-described operation is commonly known as the first or high-heat treatment.

To briefly recapitulate, the first or high-heat treatment consists of heating the tool —

(*a*) slowly to 1500° F.;
(*b*) rapidly from that temperature to just below the melting-point.
(*c*) cooling fast to below the breaking-down point, i.e., 1550°F.
(*d*) cooling either fast or slowly from 1550° F. to temperature of the air.

Second Treatment, Reheating the Cooled Tool. — After air-temperature has been reached the tool should be reheated to a temperature of from 700 to 1240° F., preferably by plunging it in the before-mentioned lead bath at 1150° F. and kept at that temperature at least five minutes. To avoid danger of fire cracks, the tool should be heated slowly before immersing in the bath. The above tool heated in this fashion possesses a high degree of "red hardness" (ability to cut steel with the nose of the tool at red heat), while it is not extraordinarily hard at ordinary temperatures. It is difficult to injure it by overheating on the grindstone or in the lathe. It will operate at 90 per cent of its maximum cutting speed, even without the second or low-heat treatment. A coke fire is preferable for giving the first heat, and it should be made as deep as possible.

Cutting Speeds in Feet per Minute of Standard Taylor-White Tools. Tool to Last $1\frac{1}{2}$ Hours between Grindings.

Cooling the tool by plunging it in oil or water, renders it liable to fire cracks and to brittleness in the body. Next to the lead bath an air blast is preferable for cooling.

Best Method of Treating Tools in Small Shops. — For small shops, in treating high-speed tools, Mr. Taylor considers the best method to be as follows for the blacksmith who is equipped only with the apparatus ordinarily found in a smith-shop.

After the tools have been forged and before starting to give them their heat, fuel should be added to the smith's fire so as to give a good deep bed either of coke about the size of a walnut or of first-class blacksmiths' soft coal. A number of tools should then be laid with their noses at a slight distance from the hotter portion of the fire, so that they may all be pre-heating while the fire is being blown up to its proper intensity. After reaching its proper intensity, the tools should be heated one at a time over the hottest part of the fire as rapidly as practicable up to just below their melting-point. During this operation they should be repeatedly turned over and over so as to insure a uniform high heat throughout the whole end of the tool. As soon as each tool reaches its high heat, it should be placed with its nose under a heavy air blast and allowed to cool to the temperature of the air before being removed from the blast.

Unfortunately, however, the blacksmith's fire is so shallow that it is incapable of maintaining its most intense heat for more than a comparatively few minutes, and, therefore, it is only through these few minutes that first-class high-speed tools can be properly heated in the smith's fire. Great numbers of high-speed tools are daily turned out from smiths' fires which are not sufficiently intense in their heat, and they are therefore inferior in red hardness and produce irregular cutting tools.

On the whole, a blacksmith's fire made from coke may be regarded as better for giving the high heat to tools than a soft-coal fire, merely because a coke fire can be more easily made by the smith which will remain capable for a longer period of heating the tools quickly to their melting-points.

Quality of Different Tool Steels. — Mr. Taylor in a letter to the author, Dec. 30, 1907, says:

First. Any of a half dozen makes of high speed tools now on the market are amply good, and but little attention need be paid to the special directions for heating and cooling high speed tools given by the makers of the tool steel. The most important matter is that an intensely hot fire should be used for giving the tools their high heat, and that they should not be allowed to soak a long time in this fire. They should be heated as fast as possible and then cooled in an air blast.

Second. The greatest number of tools are ruined on the emery wheel through overheating, either because a wheel whose surface is glazed is used, or because too small a stream of water is run upon the nose of the tool. The emery wheel should be kept sharp through frequent dressings with a diamond tool.

Third. Uniformity is the most important quality in high speed tools. For this reason, only one make of high speed tool steel should be used in each shop.

Economical Cutting Speeds.—Tools shaped as in Fig. 196, and of the chemical composition and heat treatment given in the preceding paragraphs, should be run at the cutting speeds given in the tables on pages 1266 and 1267 in order to last one hour and 30 minutes without re-grinding.

Cutting Speed of Parting and Thread Tools.—To find the economical cutting speed of a parting tool of the best high-speed steel, first ascertain the thickness of chip which is to be cut by the tool. Then from the tables on pages 1266 and 1267, under the standard 7/8-in. tool and 3/16 in. depth of cut, and opposite the feed which most nearly corresponds to the thickness of chip to be taken by the parting tool, find the speed. Divide the figure so found by 2.7 to ascertain the speed for the parting tool. For thread tools, the process is the same, except that the divisor is 4. The thickness of chip in the latter case is the advance in inches per revolution of the tool toward the center of the work

Durability of Cutting Tools.—E. G. Herbert (*Am. Mach.*, June 24 1909) shows that the durability of a tool depends mainly on the temperature to which its extreme edge is raised, and that the rate of evolution of heat and consequently the durability is proportional to the thickness and to the area of the chip and to the cube of the cutting speed. Or if t_1 = thickness or feed, c_1 = depth of cut, a_1 = area of the cut and s_1 = cutting speed, for any given set of working conditions, and $t_2c_2a_2$ and s_2 values for another set of conditions, then the durability of the tool will be the same when $t_1a_1s_1^3 = t_2a_2s_2^3$, or for constant durability $s_2 = s_1\sqrt[3]{(t_1^2c_1) \div (t_2^2c_2)}$.

Other High-Speed Steels.—*Am. Mach.* April 8, May 20 and 27, 1909, describes the operations of some new varieties of high-speed steel made by Sheffield manufacturers, which show results superior to those of the earlier high-speed steels in endurance of tool, ability to cut very hard metals, and higher speeds. The following are the results of some of the tests in lathe-work:

Tool size. in.	Material Cut.	Diam. in.	Depth. cut in.	Feed in.	Speed ft. per min.	Length of Cut.
1 1/4	Steel, 2.00 C..........	....	3/8	1/16	36	4 3/4 in.*
1 1/4	Steel, 0.70 C..........	....	1/4	1/16	48	13 in.†
1 1/4	Steel, 0.70 C..........	....	3/16	1/16	65	8 7/8 in.
7/8	Steel, 0.40 C..........	4	1/8	1/16	65	28 ins., ‡
7/8	Steel, 0.40 C..........	4	1/8	1/32	120	28 ins., §
7/8	Cast iron.............	5 ft.	1/8 to 3/16	1/10	56	4 1/2 ins.
1 1/4	Cast iron.............	5 ft.	5/16	1/32	107	6 ins.
1 1/2	Cast iron.............	5 ft.	1/8	1/8	55	8 ins.
1 1/4	Steel, 0.40 C..........	5 3/8 in.	1/8	1/10	90	54 ins.

1 1/4	Steel casting, 0.45 C..	20 in.	3/8	1/8	50	15 to 20 min.‖
1 1/4	Steel, 0.60 C..........	7 1/2 in.	9/64	1/26	115	18 in.

* Then 1 3/4 in. at 50 ft. per min. † Then 1 1/8 in. at 65 ft. per min.
‡ Then 28 ins. at 98 ft. § Then 22 ins. at 160 ft. ‖ Required 28 H.P.

Chilled rolls, too hard for ordinary high-speed steel, were cut at a speed of 80 ft. per min., with 5/16 in. depth of cut and 1/8 in. feed.

The following results were obtained in drilling:

Drill size.	Material.	Rev. per min.	Feed per rev.	Speed per min.	Drilled without Re-grinding.
3/4 in.	Close cast iron.......	466	0.018	8 1/2 in.	70 holes, 3 ins. deep.
3/4	Steel, 0.25 C..........	247	0.011	......	60 holes, 2 3/4 ins. deep.
3/4	Hard steel............	526	......	6 in.	12 holes, 2 1/2 ins. deep.
13/16	Steel.................	400	......	3 1/2	14 in. at one operation.

A milling cutter 5 in. diam., with 54 teeth, milling teeth in saw-blanks, at a cutting speed of 56 ft. per min. and a feed of 1 in. per min., cuts 80 blanks (three or more together), each 32 in. diam., 3/8 in. thick, 240 teeth, before re-grinding.

Stellite.—An alloy of 25% chromium, 65% cobalt and 10% molybdenum, to which the name "stellite" has been given, is described in *Ir. Tr. Review*, Mar. 5, 1914. This alloy is extremely hard, and retains its hardness even when red hot, thus making it useful as a substitute for tool steel. Tests made with stellite as a cutting tool on various materials showed the following cutting speeds, the speed attained by high-speed steel in the same tests being given for comparison:

Material Cut.	Cutting Speed, Ft. per Min. Stellite.	Steel.	Material Cut.	Cutting Speed, Ft. per Min. Stellite.	Steel.
Phosphor-bronze...	900	125	Seamless tubing...	400	100
Tool steel.........	133	80	Cast iron.........	200	100

A circular issued by the Midvale Steel Co. gives the following directions for the use of stellite, with a 1/2-in. square lathe tool: For cutting steel of 0.30 carbon or under, the limits will be: Depth of cut, 1/8 in.; feed, 1/16 in. per revolution; speed, 100 to 300 ft. per min., depending on the other conditions. For steel of 0.35 to 1.00 carbon, with the same depth of cut and feed as above the speed should be from 50 to

150 ft. per min. In cutting cast iron it is recommended that light cuts, and heavy feeds, say up to 1/4 in., be used. The depth of cut can run to 1/4 or 3/8 in. under moderate feeds. Stellite cannot be forged, but is cast and ground to shape. It is extremely brittle, and its use is restricted to such tools as can be supported close to the cutting edge. It should not be used when the cut is one that will subject the tool to heavy shocks. The fields for which it is recommended are: For turning steel, where turning represents a large proportion of the work to be done, and where the capacity of the lathe has not been reached with the steel tool; for turning cast iron that is not so hard that a slow speed with a steel tool is necessary, and where the capacity of the machine has not been reached with a steel tool; for inserted teeth in milling cutters and reamers in a limited field where speed is important.

For other data on the heat treatment, forging, etc., of tool steels, see also pages 491 to 497.

PLANER WORK.

Work that Should be Planed.—The planer is adapted for finishing flat surfaces where great accuracy is required. The Cincinnati Planer Co. gives (1912) in "A Treatise on Planing" the following list of work which should be planed: Locomotive frames, cylinders, shoes, wedges, and driving-boxes; printing-press tables, frames, bearings, bases; laundry frames, mangle chests; engine steam chests, valves, frames, pillow blocks, connecting-rods; rolling-mill guides, frames, bearings, keyways, tables; woodworking saw tables, frames, knife arbors, knives, bases; textile machinery frames, guides, bearing stands, legs; electric motor and generator bases and frame segments; forging machinery dies, guides, arches, header frames, bases; machine tool beds, tables, carriages, rails, slides, knees, columns.

Cutting and Return Speeds.—A cutting speed of about 55 ft. per minute is about as high as it is practical to use on the planer, and this should be decreased for most materials. The table below shows the speeds recommended by the Cincinnati Planer Co. The lower cutting speed of the planer tool, as compared with the lathe, is probably due to the absence of a cooling lubricant on long cuts. If the cut is intermittent, as in planing a series of castings with gaps in between, the cutting speed can be higher than with a continuous cut of equal total length, probably due to the partial cooling of the tool during the intervals of cutting. Return speeds of 75 to 100 ft. per minute are as high as are recommended, although the author has seen planers operating at a return speed as high as 135 ft. per minute. An increase in the cutting speed is much more effective in increasing the capacity of the machine than an increase in the return speed, and it is better to increase the cutting speed by 25% than to double the return speed.

Planer Cutting Speeds, Feet per Minute.

Iron, cast, roughing.....	40 to 50	Steel, cast, roughing....	30 to 35
Iron, cast, finishing......	20 to 25	Steel, cast, finishing.....	20
Iron, wrought, roughing..	30 to 45	Steel machinery........	30 to 35
Iron wrought, finishing..	20	Bronze and Brass.......	50 to 60

Planer Feeds.—For rough planing cast-iron feeds range from 1/8 to 3/16 in.; for steel 1/16 to 1/8 in. For finishing cast iron with a broad nose tool the feed may range from 1/2 to 3/4 in. per stroke. The feed should be as heavy as possible, in order to decrease the time required, although when planing to a finished edge, a feed of as low as 1/16 in. must be used to avoid breaking the edge at the end of the stroke.

Power Requirements for Planing.—The principal power requirement in planing is that required for reversing at the end of the stroke. The largest portion is used in reversing the planer pulleys, which, running at high speeds, store up considerable energy. The substitution of aluminum alloy pulleys by some planer builders for the cast-iron ones usually employed has reduced the power requirements for reversal and has increased the capacity of the machine by increasing the number of strokes which can be made per hour. The Cincinnati Planer Co. (1912) reports that with a 35-ft. cutting speed and an 85-ft. return speed, on a 4-ft. cut, 165 strokes were made in 30 minutes with cast-iron pulleys and 189 in the same time with aluminum pulleys. In another test, cast-iron pulleys required 39 horse-power at the reverse while aluminum pulleys required 30 horse-power. For other data on power required, see pages 1296, 1302 and 1303.

Time Required for Planing.—The Cincinnati Planer Co. has devised a slide rule, shown in Fig. 197, for determining the time required to machine work in a variable speed planer. It is adapted for use with cutting speeds of 20 to 60 ft. per min., return speeds of 50 to 130 ft. per min. and a feed range of from $1/16$ to 1 in. per stroke. The feed which is to be used (scale B) is set opposite the intersection of the

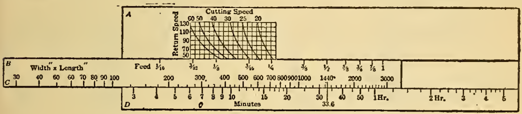

FIG. 197. PLANER TIME SLIDE RULE.

cutting-speed curve with the return speed line (Scale A). The time is read on scale D underneath the figure representing the area in square inches to be planed (width $\times$ length) on scale C. To the time so determined must be added the time required for setting up the work in the machine.

The following tables have also been prepared by the Cincinnati Planer Co. for determining times for planer operation.

Planer Table Travel, Feet per Hour.

Standard Planer Tools.—Carl G. Barth designed for the use of the Watertown Arsenal a full line of planer tools, as shown in the drawings, Figs. 198 to 213, and in the tables below. These tools were developed according to the principles discovered by Taylor and Barth in the investigation into the "Art of Cutting Metals" (see p. 1261), and may be regarded as forming a standard line of tools of the best shape for their respective purposes. They are described in *Am. Mach.*, Jan. 21 and 28, 1915.

MILLING MACHINE PRACTICE.

Forms of Milling Cutters.—Milling cutters are made from either high speed or carbon steel. The former can be subjected to the more severe service and are especially adapted to the removal of large amounts of metal, thus dictating their use as roughing cutters. The varieties of cutters in common use and the work to which they are adapted are as follows:

The Plain Milling Cutter is a cylinder with teeth on the periphery only, and is used for producing a flat surface parallel to the axis of the cutter. Plain milling cutters are made in a wide variety of diameters and widths for the various requirements of slab milling, keyway cutting, sawing, etc. Cutters less than 3/4 in. wide are usually made with straight teeth, while wider cutters have teeth that are a portion of a spiral. The spiral form enables each tooth to take a shearing cut, reduces the stress on the teeth, and prevents shock as each tooth engages the work, thus producing smoother surfaces on wide work. The spiral cutter requires less power to operate, and as it is under less strain, the tendency to chatter is reduced. Cutters for milling wide surfaces, whether of the spiral or straight type sometimes have nicks cut in the teeth, the nicks being staggered in the consecutive teeth. It is claimed that such cutters can be run with coarser feeds than plain cutters, as the nicks break up the chips and prevent jamming of the teeth. Nicked cutters are condemned by many authorities, however, for the reason that that portion of a following tooth opposite a nick is required to do double the usual amount of work with a resulting tendency to breakage.

The Side Milling Cutter is a plain milling cutter with the addition of teeth on both sides. Side milling cutters are used in a large variety of work. Two or more are often placed on the same arbor with a space between them, in which case they are known as straddle mills. Straddle mills are advantageously used where the work has to be milled on two parallel sides, as in bolt heads, tongues, etc. Side milling cutters are often made with interlocking side teeth for milling slots to a standard width, the width of the slot being maintained by means of packing washers between the two parts of the cutter.

Face Milling Cutters have teeth cut on the periphery and on one face of a disk. The face mill is fastened to the end of the machine spindle and the teeth on the face come in full contact with the work, only a small portion of the peripheral teeth being in action. Some face mills have no teeth at all on the periphery.

The End Mill, like the face mill, has teeth on the periphery and on one end. It is used for light milling operations, such as the milling of slots, facing narrow surfaces, and for making cuts on the periphery of pieces. End mills are of four general types: The solid end mill, the end mill with center cut, the slotting end mill with two lips, and the shell end mill. The first and the last have either straight or spiral teeth. In the solid end mill the teeth are cut in the same piece that forms the shank. The shell end mill has a hole through its center so that it can be mounted on an arbor, and it should be used in preference to the solid mill whenever possible, as it is cheaper to replace when worn out or broken. The teeth of end mills with center cut are designed to cut at the inner end, whereas the teeth of solid mills have no cutting edge at this point. Center cut end mills are used for milling shallow recesses in surfaces where there has been no hole bored previously for starting the cut, for milling squares on the ends of shafts and for similar work. They have fewer teeth and can take heavier cuts than solid end mills or shell end mills. Slotting end mills are adapted to the rapid milling of deep slots from the solid where there has been no hole bored for starting the cut. A depth of cut equal to one-half the diameter of the mill can usually be taken from solid stock.

The T-Slot cutter has teeth on its periphery and alternating teeth on its sides, the teeth being cut on the same piece that forms the shank. In making a T-slot, a groove is first cut with an ordinary side milling cutter or a two-lipped end mill, after which the wide groove at the bottom is cut with the T-slot cutter.

Angular Cutters have teeth that are at some oblique angle to the axis. The cutter may have more than one angle. They are used for milling the edge of a piece to a required angle, or for cutting teeth in cutters or reamers. In work such as dovetailing where the cutter cannot be fastened to the arbor with a nut, it is made with a threaded hole or with the cutter in one piece with the shank.

Form Cutters are of irregular outline for exactly duplicating pieces. In one style of form cutter the teeth are sharpened by grinding on the tops of the teeth, which necessarily changes the contour of the teeth and therefore the outline produced. The usual style is so made that it may be sharpened by grinding the face of the tooth, without altering the contour. This permits the cutter to be used for duplicate interchangeable work until it has been ground to a point where the teeth are too slender to stand the strain of the work.

Fly Cutters consist of a single cutter similar in shape to a planer tool, held in and rotated by an arbor. As they have but a single cutting edge, they are used but rarely outside of the experiment room or tool-room. The fly cutter can be formed exactly to any desired shape and will reproduce this shape exactly. Its field is those operations that would not bear the expense of special shaped commercial cutters, as where but one or two teeth are to be made of a special form.

Inserted Tooth Cutters.—When it is required to use plain milling cutters of a greater diameter than about 8 in., or side milling cutters of greater than 6 in. diameter, it is preferable to insert the teeth in a disk or head, so as to avoid the expense of making solid cutters and the difficulty of hardening them. not merely because of the risk of breakage in hardening them, but also on account of the difficulty in obtaining a uniform degree of hardness or temper. The face of the inserted tooth should be undercut a few degrees from the radial line, thereby giving a smoother cut and consuming less power than would be the case were the face of the tooth flush with the radial line. Drawings of inserted tooth cutters furnished the author by the Cincinnati Milling Machine Co., show a rake of the teeth of from 10 to 15 degrees.

Number of Teeth.—There is no standard rule for the number of teeth in milling cutters. The sizes offered commercially by cutter manufacturers have been found as a rule satisfactory for most purposes, but in roughing out work where as much metal is to be removed as possible in a given time, cutters with a smaller number of teeth than the standard mills are advisable. Furthermore, a short lead spiral on coarse tooth cutters adapts them to a large range of work that is not in the heavier class. Such cutters show a considerable saving of power over cutters with a larger number of teeth. The number of teeth in cutters of various types is given in *Machinery*, April, 1907, as follows:

Plain milling cutters are usually manufactured in sizes from 2 to 5 in. diameter, and up to 6-in. face. The use of solid plain milling cutters of over 5-in. face is not advised, and cutters over 5-in. face should be made in two or more interlocking sections.

NUMBER OF TEETH AND AMOUNT OF SPIRAL OF PLAIN MILLING CUTTERS

$$\text{No. of teeth} = \frac{5 \times \text{diam.} + 24}{2}; \text{ Length of Spiral} = 9 \times \text{diam.} + 4.$$

Diameter of cutter,
2 2 1/4 2 1/2 2 3/4 3 3 1/2 4 4 1/2 5 5 1/2 6 6 1/2 7 7 1/2 8

A cutter with an included angle of 60° (12° on one side and 48° on the other) is recommended for fluting plain milling cutters, although cutters of 52° (12° and 40°) are commonly furnished by manufacturers. The angle of relief of milling cutters should be between 5° and 7°.

The teeth of side milling cutters should have the same general form as those of plain milling cutters, excepting that the cutter used to form them should have an included angle of about 75°.

Width W	1/8	3/16	1/4	5/16	3/8	7/16	1/2
Depth, D	1/16	3/32	1/8	5/32	3/16	7/32	1/4

Diameter of Cutters.—It is advisable to use cutters of as small a diameter as the strength will admit. The smaller the cutter, the shorter the distance it will have to travel in milling a given length. With small mills also there is less liability to chatter than with large ones. In addition they require less power and are not as expensive as large ones. The Brown & Sharpe Mfg. Co. states that a difference of 1/2 in. in the diameter of the mills made a difference of 10% in the cost of their work. In surface milling the cutter should, if possible, be wider than the work.

Clearance and Rake of Cutters.—The clearance of milling cutters, or the amount of material removed from the top of the teeth back of the cutting edge to permit it to clear the surface of the work instead of scraping over it, depends on the diameter of the cutters. It must be greater for small cutters than for large ones. For plain cutters over 3 in. diameter, the clearance angle should be 4 degrees, and for cutters of less than 3 in. it should be 6 degrees. For end mills it should be about 2 degrees. It is considered advisable to have the teeth of end mills from 0.001 to 0.002 in. lower at the center than at the outside. The Cincinnati Milling Machine Co. has furnished the author with drawings of cutters of various types. In these the teeth have a front rake of 10 degrees..

Power Required for Milling. (*Mech. Engr.*, Oct. 26, 1907.) — Mr. S. Strieff made a series of experiments to determine the power required to drive milling cutters of high-speed steel. The results are shown in the table below. A proportionately higher amount of power is required for light than heavy milling, as the power to drive the machine is the same at all loads. The table also shows that the depth of cut does not increase the power required in the same proportion as the width, and that work with a quick feed and a deep but comparatively narrow cut requires less power than a wide cut of moderate depth with slow feed, the amount of metal removed being the same in both cases.

P. V. Vernon reports (*En'gr*, Mar. 9, 1909) some milling machine tests made by Alfred Herbert, Ltd., showing the horse-power required to slab mild steel and cast iron. The tests reported include 44 on steel and 38 on cast iron. The horse-power was determined from the current readings and includes the motor losses and also a constant loss of 1.8 H.P. in the jack shaft and countershaft of the machine.

Horse-power per Cu. In. per Minute required for slabbing.

Steel	3.02	1.95	2.52
Cast iron	1.25	0.89	1.10

Later tests reported to the Manchester Assoc. of Engrs., Nov. 23, 1912, by Mr. Vernon, embodied the following conclusions: (1) A 5-in. double belt, driving a 16-in. pulley at 400 r.p.m. (100,531 sq. in. of belt per min.) geared to drive 4 1/2-in. high-speed cutter at 70 ft. per min. is able to remove as much as 48.1 cu. in. of cast iron or 24.31 cu. in. of mild steel per minute. (2) 2090 sq. in. of double belt passing over a pulley per minute will remove 1 cu. in. of cast iron in a milling machine. To remove 1 cu. in. of steel the belt surface passing should be 4135 sq. in. (3) A 4 1/2-in. high-speed cutter on a 2-in. arbor, running at 70 ft. per min. is capable of removing at least 3.63 cu. in. of cast iron, and possibly as much as 6.01 cu. in., and at least 2.125 cu. in. of mild steel, and possibly as much as 3.03 cu. in. per min. for each inch of width of belt, up to 8 in. From the earlier tests noted above the conclusion was reached that 1 H.P. would remove as much as 1.84 cu. in. of cast iron per min., and 0.74 cu. in. of mild steel. In these tests the feed in cast iron ranged between 1 27/32 and 10 9/16 in. per min., the depth of cut from 0.14 to 1.10 in., while in steel the feeds ranged from 5/8 to 10 3/8 in. per min. and the depth of cut from 0.10 to 1.10 in. per min.

A. L. De Leeuw gives in *Am. Mach.*, Aug. 8, 1912, the results of a large number of tests to determine the horse-power consumed in cutting machinery steel in the milling machine. From the tests there reported the following table has been compiled, the figures given showing the test in each class in which the maximum amount of metal per horse-power per minute was removed. The figures for horse-power are net, the motor losses having been deducted.

NOTE 1.—Cutter No. 1 is an 8-in., 12-blade face mill; No. 2 is a 10-in., 16-blade high-power face mill; No. 3 is a 4 1/2 in., 10-tooth spiral nicked cutter.

NOTE 2.—Material *A*, Elastic Limit 36,400 lb. per sq. in., elongation 36%, reduction of area 66%; material *B*, E. L. 36,200 lb. per sq. in., elong. 36.5%, red. of area 59.6%; material *C*, E. L. 37,400 lb. per sq. in., elong. 36.5%, red. of area 60%; material *D*, E. L. 55,000 lb. per sq. in., elong. and red. of area not given; 0.26 carbon, 0.5% manganese.

Modern Milling Practice (1914).—The limit of milling operations is determined by the strength and durability of the cutter. A rigid frame on the machine and powerful feed mechanism increase these. The chief causes of low output are: Improperly constructed cutters; insufficient rigidity in the machine; and timidity, due to lack of experience, of both builders and operators. The principal cause of cutter failures is insufficient space for chips between the cutter teeth. Fixed rules cannot be laid down for proper feeds and speeds of milling cutters, these depending on the character and hardness of the metal being cut. On roughing cuts it is desirable to run the cutter at a speed well within its limit, and use as heavy a feed as the machine can pull. The size of chip taken by each tooth of the cutter with the heaviest feeds is comparatively light, and with properly sharpened cutters there is little danger of breaking the cutter by giving too great a feed. It is considered better practice, however, to break an occasional cutter than to run machines at a low rate. It is not considered desirable to run even high speed steel cutters at excessive speeds. The great value of these cutters is their long life and ability to hold a cutting edge as compared with carbon steel cutters. It is important to keep the cutters sharp, as accurate or fast work is impossible with dulled teeth, and a dull cutter will wear away faster than a sharp one. Cutter grinders should always be used for sharpening cutters.

The following speeds in feet per minute are a good basis for roughing the materials indicated:

	Cast Iron.	Machinery Steel.	Tool Steel.	Brass and Bronze.
Carbon steel cutters,	40 to 60	30 to 40	20 to 30	80 to 100
High speed steel cutters,	80 to 100	80 to 100	60 to 80	150 to 200

On cast-iron work a jet of air delivered to the cutter with sufficient force to blow the chips away as fast as made permits faster feeds and prolongs the cutter's life. A stream of oil fed under heavy pressure to wash the chips away has the same effect when cutting steel. On finishing cuts the rate of feed used determines the grade of the finish. If a spiral mill is used the feed should range from 0.036 in. to 0.05 in. per revolution of a 3-in. diameter cutter. As such cuts are light the speed of cutting can be much higher than that used for roughing cuts. The nature of the cut is a factor in determining speeds; a saw can run twice as fast as a surface mill. (See paragraph, p. 1282, on high-speed milling.) Keyseating and similar work can be best done with a plain cutter rather than a side mill.

Castings should be pickled in a solution of sulphuric acid, diluted with water to a specific gravity of 25 deg. (Baumé), before milling, to remove the hard skin and sand which are destructive to cutters. If the castings are later to be painted, they should not be immersed in the pickling bath. It is better to pour the solution over them, allowing it to dry before making another application. This should be repeated 4 or 5 times. Forgings should be pickled in a solution of sulphuric acid and water of a specific gravity of 30 deg. (Baumé), for from 3 to 12 hours. After pickling, forgings and castings should be washed with hot water to remove the sand and acid.

Milling "with" or "against" the Feed.—Tests made with the Brown & Sharpe No. 5 milling-machine (described by H. L. Arnold, in *Am. Mach.*, Oct. 18, 1884) to determine the relative advantage of running the milling cutter with or against the feed — "with the feed" meaning that the teeth of the cutter strike on the top surface or "scale" of cast-iron work in process of being milled, and "against the feed" meaning that the teeth begin to cut in the clean, newly cut surface of the work and cut upwards toward the scale — showed a decided advantage in favor of running the cutter against the feed. The result is directly opposite to that obtained in tests of a Pratt & Whitney machine by experts of the Pratt & Whitney Co.

In the tests with the Brown & Sharpe machine the cutters used were 6 inches face by $4\frac{1}{2}$ and 3 inches diameter, respectively, 15 teeth in each mill, 42 revolutions per minute in each case, or nearly 50 feet per minute surface speed for the $4\frac{1}{2}$-inch and 33 feet per minute for the 3-inch mill. The revolution marks were 6 to the inch, giving a feed of 7 inches per minute, and a cut per tooth of 0.011 inch. When the machine was forced to the limit of its driving the depth of cut was $\frac{11}{32}$ inch when the cutter ran in the "old" way, or against the feed, and only $\frac{1}{4}$ inch when it ran in the "new" way, or with the feed. The endurance of the milling cutters was much greater when they were run in the "old" way. The Brown & Sharpe Mfg. Co. says that it is sometimes advisable to mill with the feed, as in surfacing two sides of a piece with straddle mills, the cutters will then tend to hold the work down. In milling deep slots or cutting off stock with thin cutters or saws, milling with the feed is less likely to crowd the cutter sidewise and make a crooked slot.

Lubricant for Milling Cutters. (Brown & Sharpe Mfg. Co., 1907.)—An excellent lubricant, to use with a pump, for milling cutters is made by mixing together and boiling for one-half hour, 1/4 lb. sal soda, 1/2 pint lard oil, 1/2 pint soft soap and water enough to make 10 quarts. Oil is also frequently used in milling steel, wrought iron, malleable iron or tough bronze.

Typical Milling Jobs—Speeds—Feeds.—The notes below compiled from data furnished by the Brown & Sharpe Mfg. Co. and the Cincinnati Milling Machine Co. (1915) show examples of what is considered good commercial milling practice.

Bars of 0.60 Carbon steel, 5/8 in. thick, 2 1/2 in. wide, 11 3/4 in. long, had 22 rack teeth, 7/16 in. pitch and 1/8 in. deep milled in the edge. The bars were locked four at a time in a vise. A gang of four cutters was used, at 41 r.p.m. and a feed of 0.023 in. per revolution, equivalent to 15/16 in. per minute. Two vises were used, the operator loading one while the bars in the other were being machined. The time required per piece including chucking and removing, was 0.71 minute. For milling two recesses in the upper edges of these same bars, after the rack teeth were cut, they were mounted two in a vise with distance pieces between, and a gang of four 31/2-in. side mills was used, milling all four recesses at once. The mills rotated at 50 r.p.m., and the feed was 0.068 per revolution, equivalent to 3.4 in. per minute. Two vises were used as before, and the total time per rack was 2.2 minutes. The final operation was the milling of a slot in the bar, for which purpose it was held at the ends in two vises. Two holes were first drilled in the piece through one of which the cutter was threaded. The slot was 1-in. wide and 9 in. long. A 15/16-in. helical cutter was used at 160 r.p.m. A roughing cut was first taken at a feed of 0.015 per revolution, equivalent to 2.4 in. per min., after which the piece was removed and allowed to cool before the finishing cut was taken at a feed of 0.068 in. per revolution, or 10.8 in. per minute. The roughing cut removed 11/2 cu. in. of steel per minute. The total time, including chucking, removing, etc., was 7.5 minutes.

Gray iron castings 8 1/4 in. long, 8 1/2 in. wide, 4 1/4 in. thick, with two flanges 7/8 in. high and 7/8 in. thick projecting above the upper face, were milled on the entire upper surface and the two sides, including top and sides of flanges at one operation by a gang of straddle mills, the largest cutter being 10 1/2 in. diameter and running at 21 r.p.m., with 6.3 in. feed per minute. Metal was removed at the rate of 19 cu. in. per minute, the maximum depth of cut being 3/16 in. The pieces were held in a string jig, removed as fast as they were traversed by the gang of cutters, and others were chucked in their places. They were milled in lots of 125 without resharpening of the cutters. Time per piece, 2 minutes.

A gray iron casting 22 in. wide and 9 in. long was milled on its upper surface by a gang of three 6-in. spiral mills with a total face width of 24 in., mounted on a 2-in. arbor. The depth of cut was 3/8 in. and the table feed was 7 3/4 in. per minute.

A surface about 1 in. wide all around an aluminum transmission case 12 × 14 in. was milled by means of a 10 1/2-in. inserted tooth face mill at 236 r.p.m. Depth of cut, 1/8 in., table feed, 0.068 in. per revolution or 20 in. per minute. A double fixture was used, one piece being inserted while the other was being milled. Time, including chucking and removal, 2 1/2 minutes per piece.

Gray iron castings, 10 1/4 in. wide, 14 in. long × 1 3/4 in. thick, finished all over, and a slot 5/8 × 1 in. cut from the solid. A gang of five cutters was used, two of 8 in., two of 3 1/2 in. and one of 5 3/4 in. diameter, respectively. These took a cut 3/16 in. deep across the top, and two edges, and milled the slot in one operation. The table travel was 4.2 in. per minute. The average time, including chucking, was 15.6 minutes.

Gray iron castings, 3 in. and 6 1/2 in. wide × 25 1/4 in. long, 1 1/4 in. thick, were surfaced by a face mill 8 in. diameter at a surface speed of 80 feet per minute. The cut was 3/16 in., and the table travel 11.4 in. per minute in the 3-in. part and 8 in. per minute in the 6 1/2-in. part. The total time for finishing, including chucking, was seven minutes. The planer required 23 minutes for the same operation. In finishing the opposite side of these castings, two castings were milled at one setting, 3/16 in. of stock being removed all over and two slots 5/8 × 5/8 in. milled from the solid. A gang of seven cutters, 3 of 3 in., 2 of 4 1/4 in., and 1 of 8 1/4 in. diameter was used at 38 r.p.m. and a feed of 0.1 in., giving a table travel of 3.8 in. per minute. These two castings were finished in 18 minutes, including chucking, the actual milling time being eight minutes on each piece. A planer working at 55 ft. cutting speed finished the same job in 36 minutes.

An inserted-tooth face mill 12 in. diameter took a 9-in. cut, 1/8 in. deep across the entire face of a gray iron casting at a table travel of 5 in. per minute. The length of cut was 18 in. and the time required 6 1/2 minutes.

The following table summarizes a number of typical jobs of milling:

Typical Milling Jobs.

[1] Inserted teeth, high-speed steel. [2] Maximum. [3] Chrome nickel steel. [4] Carbon steel, nicked spiral cutter. [5] High-speed steel, spiral nicked cutter. [6] Machinery steel, tensile strength, 65,000 lb. [7] End mill. [8] End mill with spiral teeth; work done by peripheral teeth. [9] Both sides of cutter engaged, making slot width equal to cutter diameter; slot 11/16 × 1/2 in. [10] Milling slots from solid plate 13/16 in. thick. [11] Helical end mill, front of which is formed as a regular twist drill. Operator first drills through the plate with it, and then uses it as a milling cutter.

High Speed Milling.—L. P. Alford describes (*Am. Mach.*, April 16, 1914) a system of high-speed milling developed by the Cincinnati Milling Machine Co., which permits of cutter speeds and feeds from 8 to 12 times as great as are ordinarily used. The fundamental condition for this practice is the provision of ample lubrication of the cutter and work. The cutter is deluged with about 12 gal. per minute of lubricant, which is delivered through a hood which completely surrounds the cutter. The lubricant is delivered under pressure, and in addition to cooling the cutter and work, washes away the chips from the teeth of the cutter, preventing them from being carried back into the cut, clogging it, dulling the cutter and marring the finished surface. Other requisites for high-speed milling are powerful, heavy and rigid machines, and cutters with wide spaced teeth which will permit the use of heavy feeds and high speeds. The following tests were cited to show what is possible with this system of milling. The material cut was machinery steel, 0.2 carbon, 0.5 manganese, with a tensile strength of 55,000 to 65,000 lb. per sq. in. The cutters were of high speed steel.

[1] Diametral Pitch. [2] Same cutter and block as in Test No. 1, but run without lubricant. Test stopped when cutter showed signs of distress after cutting $2\frac{1}{2}$ in. Edges of teeth blued.

NOTE.—*S*, spiral mill; *H*, helical mill; *L*, slotting cutter; *G*, gear cutter.

As a criterion of the life of cutters under the above conditions, a cutter of the type used in test No. 5, was run to destruction. It milled 6700 in., not including cutter approach, the equivalent of cutting 223 gears of 1-in. face, 7 pitch, 30 teeth.

Limiting Factors of Milling Practice.—Discussing the above tests Mr. Alford gives the following as the limiting factors of milling machine practice: (1) Power of the machine. Increased speed requires greater power per cubic inch of metal removed; according to the Cincinnati Milling Machine Co., doubling the speed necessitates a 10% increase of power per cubic inch of metal removed. (2) Ability of the cutter to remove metal. Increased speed, with the same feed increases the ability of the cutter to cut, due to the smaller chip removed by each tooth. This means a decrease of strain, wear and heating effect. The total or final heating effect is increased, but this may be counteracted by copious lubrication. (3) Size and spring of arbor. The size of the arbor is limited by the size of commercial cutters. The strain on the arbor depends on the feed per minute. An increase of speed, lessening the pressure per tooth, reduces the arbor strain, and tends to do away with the limitation imposed by the arbor. (4) Heating of the cutter, often the most important limitation. This can be overcome by sufficient lubricant to remove all heat as fast as it is generated. (5) Wear of the cutter. This is dependent on the number of lineal inches milled, depth of cut and feed per revolution being constant. Increased speed increases the wear per unit of time. Wear may be somewhat reduced with high speed by copious lubrication which washes away the chips, thus preventing the grinding action due to cutting up chips. (6) Breakage of cutters. Frail cutters limit production, as only a certain maximum feed per revolution, dependent on their strength, can be taken. Increased speed, with constant feed, will increase production without increasing the cutter strain or danger of breakage. (7) Heating of work. Uneven local heating when milling will produce uneven surfaces, for the swelled portions will be cut away. This action is progressive as the total heat increases as the cut advances. The absence or prevention of heating by copious lubrication does away with this limitation. (8) Spring of work. This limitation is minimized for the same reasons given in (6). (9) Spring of fixture. The same analysis applies as in (6). If the pressure per tooth is reduced, the pressure for holding may be reduced, and clamping fixtures may be made to operate more quickly. An increase in cutting speed therefore will tend to increase the speed of operation of the clamping devices and fixtures. (10) Spring of the machine. The same arguments apply as in (9). (11) Distance of revolution marks on the work. This is the limiting feature in perhaps 90% of milling work, which is governed by polishing or some subsequent operation. If the marks are far apart, polishing cannot be satisfactorily done. Increased speed, with constant feed will bring these marks closer together. (12) Smoothness of cut. High speed milling, both by the action of centrifugal force and by copious flooding removes the chips completely from the cutter and eliminates the grinding effect on the finished surface. With a given distance between revolution marks, high speed will give a smoother surface.

Speeds and Feeds for Gear Cutting.—The speeds and feeds which can be used in gear cutting are affected by many variables, among which may be noted: The material and shape of the cutter, the latter condition involving both the strength and the ability of the teeth to clear themselves of chips; the material and shape of the gear, shape influencing the speed and feed in that a heavy rugged gear will permit higher speeds and heavier feeds, even in hard material than will a light springy one; accuracy of finish required; quality of lubricant used; rigidity of machine. The following table shows tentative speeds recommended by Gould and Eberhardt, which may serve as a preliminary guide, pending the determination of the best combination for each particular case. They represent average practice in medium grades of cast iron and steel.

	High-Speed Steel Cutters.			Carbon Steel Cutters.		
	Min.	Average.	Max.	Min.	Average.	Max.
Cast iron, ft. per min..	60	70	80	35	45	60
Steel, ft. per min......	45	50	55	25	30	40

The feeds in inches per minute recommended by the same company, depend on the capacity of the machine and on the size of the teeth. Thus, in a machine whose maximum capacity is for gears with teeth of one diametral pitch in cast iron and of 1 1/4 diametral pitch in steel, the feeds range from 2.3 in. per minute in cast iron for gears of 1 diametral pitch to 6.9 in. for gears of 6 diametral pitch, carbon steel cutters being used. For high-speed steel cutters, the corresponding figures are 3.5 and 11.0 in. In steel, the feeds under the same conditions are 1.9 in. and 4.5 in. per minute with carbon steel cutters and 2.8 in. and 6.9 in. per minute with high-speed steel cutters. Likewise in a machine whose maximum capacity is teeth of 4 diametral pitch for cast-iron gears and 5 diametral pitch for steel gears, the feed given for carbon steel cutters for gears of 4 diametral pitch is 2.6 in. per minute in cast iron and 1.5 in. per minute in steel. For gears of 24 diametral pitch the figures are for cast iron 7.6 in. per minute, and for steel 5.8 in. per minute. Using high-speed steel cutters, the corresponding figures are: 4 diametral pitch, cast iron 4.5 in. per minute; steel, 3.5 in. per minute; 24 diametral pitch, cast iron 10 in. per minute; steel, 7.6 in. per minute. These figures merely show the range of feeds that are possible in gear cutting, and the tables furnished by the manufacturers of gear-cutting machines should be consulted for the proper feeds for particular cases.

DRILLS AND DRILLING.

Constant for Finding Speeds of Drills.—For finding the speed in feet when the number of revolutions is given; or the number of revolutions, when the speed in feet is given.

Constant = 12 ÷ (size of drill × 3.1416).
Number of revolutions = Constant × speed in feet.
Speed in feet = Number of revolutions ÷ constant.

Size Drill, In.	Constant.	Size Drill, In.	Constant.	Size Drill, In.	Constant.	Size Drill, In.	Constant.	Size Drill, In.	Constant.

The Cleveland Twist Drill Co., Cleveland, states (1915) that it is safe to start carbon steel drills with a peripheral speed of 30 ft. per minute in soft tool and machinery steel, 35 ft. per min. in cast iron, and 60 ft. per min. in brass. In all cases a feed of from 0.004 to 0.007 in. per revolution should be used for drills 1/2 in. diam. and smaller, and of from 0.005 to 0.015 in. per revolution for drills larger than ½ in. In the case of high speed steel drills these feeds should not be changed, but the peripheral speed may be increased from 2 to 2 1/2 times. The table below is calculated on the basis of the speeds given above for carbon steel drills, and on the basis of speeds 2 1/3 times higher for high-speed drills. The running speed may be higher or lower than the starting speed, and must be determined by good individual judgment for each case.

Starting Speeds for Carbon and High-Speed Steel Drills in Steel, Cast Iron and Brass, R. P. M.

A drill with a tendency to wear away on the outside is running too fast; if it breaks or chips on the cutting edges it has too much feed.

Forms of Drills.—The common form of twist drill is a cylinder with two spiral flutes milled in it. Another type, for heavy duty, consists of a twisted bar of flat steel. The angle that the cutting edges makes with the axis of the drill has been fixed at about 59°. A decrease in this angle decreases the pressure required for feeding the drill, but increases the power required to turn it. The cutting edge of a spotting drill should make an angle of about 50° with the axis of the drill. The clearance angle, that is, the angle between the surface back of the cutting edge and a plane perpendicular to the axis of the drill, ranges from 12 to 15°, the angle increasing slightly toward the center. In general, the small clearance is best for hard metals and the large clearance for soft metals.

Drilling Compounds.—The following drilling compounds or lubricants are recommended when drilling the materials given below:

Steel (hard)—kerosene, turpentine, soda water.
Steel (soft)—soda water, lard oil.
Iron (wrought)—soda water, lard oil.
Iron (malleable)—soda water.
Iron (cast)—none or air blast.
Brass—paraffine oil.
Aluminum—soda water, kerosene.

Warming the lubricant before applying it to high-speed drills is recommended, and precautions should be taken against suddenly chilling high-speed drills by the lubricant after they have become heated.

Twist Drill and Steel Wire Gages.—Three standards of gages for twist drills and steel wire are in use—the Manufacturers' Standard, used by the Morse Twist Drill Co., Brown & Sharpe, and other manufacturers, the Stubs gage, and that of the Standard Tool Co. The Stubs and Manufacturers' gages are given in the table on page 30. The Standard Tool Co. gage agrees with the Manufacturers' gage for sizes from Nos. 1 to 60, inclusive, and with the Stubs gage for sizes from Nos. 61 to 80. In addition it has additional ½ sizes interpolated at Nos. 60½, 68½, 69½, 71½, 73½, 74½, 78½, and 79½.

Power Required to Drive High-Speed Drills.—H. M. Norris, mechanical engineer of the Cincinnati-Bickford Tool Co., found (1914) that the power absorbed by a 6-foot, high-speed, high-power, plain radial drill fitted with a variable speed motor, in driving drills in machine steel under a stream of water, varied in accordance with the formula:

$$\text{H.P.} = 0.152\ (R + 2.1)\ d^{1.25} f^{0.74} \left[r - \left(\frac{52.2}{d} + 6.8\right)\right]$$

R = ratio between speed of the intake shaft and speed of the spindle; d = diameter of drill, in.; f = feed in thousandths of an inch per revolution; r = rev. per min.

The values deduced from this formula are given in the table, p. 1287; the figures 1, 2, and 4 in the column "Ratio R" represent the ratios of 1 to 1, 1 to 2, and 1 to 4 respectively. The table also gives the results obtained in drilling medium cast-iron, but these, at this writing, have not been reduced to a formula.

The American Tool Works Co., Cincinnati, has furnished the author with the tests given in the table below, made in 1912, showing the power required to drive drills in a 6-foot plain triple-geared radial drill made by that company. This table shows the results obtained with speeds and feeds higher than those given by Mr. Norris.

Feeds for Drills.— According to Mr. Norris, the rate at which a drill may be advanced per revolution depends upon the toughness of the material to be drilled, the ability of the machine to resist thrust without forfeiture of alignment and upon the knowledge that is exercised in the grinding of the drill—the size of its included angle, the width of its chisel point, and the keenness and evenness of its cutting edges, all being deciding factors. Were it not for the weakening effect on the drill it could be said that the stiffer the machine, the less the included angle; the narrower the chisel point, the smaller the degree of the spiral; the greater the uniformity of the cutting lips and the more efficacious the lubricant in minimizing the frictional resistance of the chips, the coarser becomes the feed it is permissible to use. But, inasmuch as the durability of the drill must not be impaired, the advantage obtainable through the application of these axioms has its limitations. The keenness of edges needed to attain maximum efficiency in cutting cast-iron disqualifies for work in steel a drill suitable for use in cast-iron. The highest rate of feed at which drills of from 3/8 to 3 in. diam. may be operated in steel appears to be about 0.060 in. per revolution, but the employment of such feeds increases, rather than decreases the cost of work. The feeds provided in the product of the Cincinnati-Bickford Tool Co. range from 0.006 in. to 0.040 in. per revolution, which, under favorable conditions, may be utilized as follows:

Steel		Cast Iron	
Hard..........	0.006 to 0.010 in.	Hard.........	0.015 to 0.020 in.
Medium.......	0.012 to 0.018 in.	Medium......	0.020 to 0.030 in.
Soft...........	0.020 to 0.028 in.	Soft..........	0.030 to 0.040 in.

Speed of Drills.—Mr. Norris says further that while an occasional drill is found that will withstand for days a cutting speed of 150 ft. per minute, in either cast-iron or steel (the latter under a lubricant), it is rarely expedient to drive any but very small ones faster than 100 ft. per min. Operating drills at an excessive speed is an expensive fad. It is more economical to err in the other direction. The most satisfactory results have been obtained at a cutting speed of 80 ft. per min. in cast-iron and $\frac{12}{d} + 76$ ft. in steel. This formula will decrease the cutting speed from 100 ft. per min. for a ½-in. drill to 80 ft. for a 3-in. drill. The reason for this reduction is that a stream of liquid sufficient to keep a small drill cool is insufficient to prevent overheating in a large one.

In order to facilitate the use of the formulæ for horse-power there is given in the following table the deduced values for $f^{0.74}$, $d^{1.25}$, $\frac{52.2}{d} + 6.8$ and $\frac{12}{d} + 76$.

Values of $f^{0.74}$, $d^{1.25}$, $\frac{52.2}{d} + 6.8$ and of $\frac{12}{d} + 76$.

Extreme Results with Drills.— The Cleveland Twist Drill Co. furnishes the following table of results of drilling tests made at the convention of Railway Master Mechanics' Association at Atlantic City, N. J., June, 1911. The object of the tests was to demonstrate good shop practice, drilling being done at speeds and feeds considered economical under average shop conditions, and also to show what were the ultimate possibilities of drills and machines. The drills used were flat twisted drills, and the ordinary milled drill. The record performance for high-speed drilling is test No. 4, in which a 1 1/4 in. drill repeatedly drilled through a casting at 57 1/2 in. per minute. In the tests to demonstrate good shop conditions, the drill in test No. 17 drilled 68 holes, removing 1418 cu. in. of metal without being reground, and was in good condition at the close of the test. The Cleveland Twist Drill Co. does not recommend the high speeds and heavy feeds attained as economical shop practice, but points out that the results can be duplicated by carefully established ideal conditions of absolute rigidity in the machine, solid clamping of the work, perfect grinding of the drill and expert handling.

Record Performances of High-Speed Drills.

* Milled drills; all other drills are flat twisted drills.

Experiments on Twist Drills.—An extensive series of experiments on the forces acting on twist drills of high-speed steel when operating on cast-iron and steel is reported by Dempster Smith and A. Poliakoff, in *Proc. Inst. M. E.*, 1909. Abstracted in *Am. Mach.*, May, 1909, and *Indust. Eng.*, May, 1909. Approximate equations derived from the first set of experiments are as follows:

Torque in pounds-feet, $I = (1800\,t + 9)d^2$, for medium cast-iron; $T = (3200\,t + 20)d^2$, for medium steel. End thrust, lb., $P = 115{,}000\,t - 200$, for medium cast-iron; $P = 160{,}000(d - 0.5)t - 1000$, for medium steel; d = diam., t = feed per revolution of drill, both in inches. The steel was of medium hardness, 0.29 C, 0.625 Mn.

The end thrust in enlarging holes in medium steel from one size to a larger was as follows: 3/4 in. to 1 in., $P = 15{,}200\,t + 60$; 1 in. to 1 1/2 in., $P = 25{,}500\,t +$; 3/4 in. to 1 1/2 in., $P = 30{,}000\,t + 200$.

A second series of experiments with soft cast-iron of C.C., 0.2; G.C., 2 9; Si, 1.41; Mn, 0.68; S, 0.035; P, 1.48, and medium steel of C, 0.31;

Si, 0.07; Mn, 0.50; S, 0.018; P, 0.033; tensile strength, 72,600 lb. per sq. in., gave results from which were derived the following approximate equations:

Torque, lb.-ft., $T = 740\ d^{1.8} t^{0.7}$, or $10\ d^2 + 100\ t(14\ d^2 + 3)$ for cast iron,
$T = 1640\ d^{1.8} t^{0.7}$, or $28\ d^2(1 + 100\ t)$ for medium steel,
End thrust, lb. $P = 35,500\ d^{0.7} t^{0.75}$, or $200\ d + 10,000\ t$ for cast iron,
$P = 35,500\ d^{0.7} t^{0.6}$, or $750\ d + 1000\ t\ (75\ d + 50)$ for medium steel,

and for different sizes of drill the following equations:

Drill.	3/4	1	1 1/2
Cast iron T = ...	$5 + 1,100\ t$	$10 + 1,750\ t$	$25 + 3,700\ t$
Cast iron P = ...	$125 + 82,000\ t$	$200 + 89,000\ t$	$350 + 103,000\ t$
Steel T = ...	$7.5 + 3,350\ t$	$17.5 + 4,400\ t$	$40 + 9,000\ t$
Steel P = ...	$550 + 109,000\ t$	$750 + 131,000\ t$	$1,250 + 162,000\ t$

Drill.	2	2 1/2	3
Cast iron T = ...	$40 + 5,900\ t$	$60 + 8,800\ t$	$90 + 12,900\ t$
Cast iron P = ...	$500 + 110,000\ t$	$600 + 126,000\ t$	$850 + 140,000\ t$
Steel T = ...	$75 + 12,500\ t$	$112.5 + 19,050\ t$	$175 + 26,250\ t$
Steel P = ...	$1,500 + 181,250\ t$	$1,725 + 224,375\ t$	$2,350 + 280,000\ t$

The tests above referred to were made without lubricants. When lubricants were used in drilling steel the average torque varied from 72% with 1/400 in. feed to 92% with 1/35 in. feed of that obtained when operating dry. The thrust for soft, medium and hard steel is 26%, 37%, and 12% respectively less than when operating dry, no marked difference being found, as in the torque, with different feeds. The horse-power varies as $t^{.07}$ and as $d^{0.8}$ for a given drill and speed. The torque and horse-power when drilling medium steel is about 2.1 times that required for cast iron with the same drill speed and feed. The horse-power per cu. in. of metal removed is inversely proportional to $d^{0.2}\ t^{0.3}$, and is independent of the revolutions.

While the chisel point of the drill scarcely affects the torque it is accountable for about 20% of the thrust. Tests made with a preliminary hole drilled before the main drill was used to enlarge the hole showed that the work required to drill a hole where only one drill is used is greater than that required to drill the hole in two operations, with drills of different diameter.

For economy of power a drill with a larger point angle than 120° is to be preferred, but the increased end thrust strains the machine in proportion, and there is more danger of breaking the drill.

Cutting Speeds for Tapping and Threading. (*Am. Mach.*, Aug. 3, 1911.)—The National Machine Co., for tapping and threading, uses speeds of 233 r.p.m. for sizes and holes up to 1/4 in. diameter, and 140 r.p.m. for sizes from 1/4 in. to 1/2 in. diameter, with a lubricant of screw-cutting oil. Both the Bignall & Keeler Co. and the Standard Engineering Co. recommend a cutting speed of 15 ft. per minute. The former recommends lard oil as a lubricant. The practice of the F. E. Wells Co. in tapping and the Landis Machine Co. in threading in machines of the bolt cutter type is as follows:

Speeds for Tapping and Threading—r. p. m.

SAWING METALS.

Speeds and Feeds for Cold Sawing Metals.—(*Mach'y*, Jan., 1914). —For sawing 0.30 carbon, open-hearth machine steel bars in a cold sawing machine, a feed of 1 in. per minute and a peripheral speed of approximately 45 ft. per minute was used. The bars were 5 in. diameter, and an average of 145 were sawed with one sharpening of the saw. For some classes of work a feed of 2 in. per minute can be used, but 3/4 in. per minute is advisable for 0.30 carbon steel with the saw in good condition. For tool steel and alloy steel the best economy will be obtained with a feed of 1/2 in. per minute and a surface speed of 30 ft. per minute, with a grinding every 100 pieces.

Hack Sawing Machines.—Charles Wicksteed (*Proc. Inst. Mech. Engrs.*, 1912) says that the important considerations to be observed in using hack sawing machines are: For ordinary work, a coarse pitch tooth, not less than 10 to the inch is best; extra strength of the saw is to be obtained by extra depth, not extra thickness, of blade; the greatest weight that a blade will take without injury is 7 lb. per tooth or 70 lb. per in.; a 6-in. machine thus will use the full capacity of the blade on 4-in. bars with a weight of 210 lb. on the blade. As the size of the machine increases, the weight increases proportionately, a 15-in. machine employing 700 lb. and using the full capacity of the blade when sawing a 10-in. surface. A hack sawing machine will cut true to 0.01 in. in a mild steel bar at a speed roughly of 1 to 2 sq. in. per minute.

Saws for Copper.—A special saw for cutting copper has teeth with a front rake of 10°. The metal is ground away at the sides of the teeth to provide clearance. The number of teeth should be comparatively small. A pitch of about 1 in. giving 10 teeth in 3-in. saw renders good service.

CASE-HARDENING, ETC.

Case-hardening of Iron and Steel, Cementation, Harveyizing.—When iron or soft steel is heated to redness or above in contact with charcoal or other carbonaceous material, the carbon gradually penetrates the metal, converting it into high carbon steel. The depth of penetration and the percentage of carbon absorbed increase with the temperature and with the length of time allowed for the process. In the old cementation process for converting wrought iron into "blister steel" for re-melting in crucibles flat bars were packed with charcoal in an oven which was kept at a red heat for several days. In the Harvey process of hardening the surface of armor plate, the plate is covered with charcoal and heated in a furnace, and then rapidly cooled by a spray of water.

In case-hardening, a very hard surface is given to articles of iron or soft steel by covering them or packing them in a box or oven with a material containing carbon, heating them to redness while so covered, and then chilling them. Many different substances have been used for the purpose, such as wood or bone charcoal, charred leather, sugar, cyanide of potassium, bichromate of potash, etc. Hydrocarbons, such as illuminating gas, gasolene or naphtha, are also used. *Amer. Machinist*, Feb. 20, 1908, describes a furnace made by the American Gas Furnace Company of Elizabeth, N. J., for case-hardening by gas. The best results are obtained with soft steel, 0.12 to 0.15 carbon, and not over 0.35 manganese, but steel of 0.20 to 0.22 carbon may be used. The carbon begins to penetrate the steel at about 1300° F., and 1700° F. should never be exceeded with ordinary steels. A depth of carbonizing of 1/64 in. is obtained with gas in one hour, and 1/4 in. in 12 hours. After carbonizing the steel should be annealed at about 1625° F. and cooled slowly, then re-heated to about 1400° F. and quenched in water. Nickel-chrome steels may be carbonized at 2000° F. and tungsten steels at 2200° F.

Change of Shape due to Hardening and Tempering. — J. E. Storey, *Am. Mach.*, Feb. 20, 1908, describes some experiments on the change of dimensions of steel bars 4 in. long, 7/8 in. diam. in hardening and tempering. On hardening the length increased in different pieces .0001 to .0014 in., but in two pieces a slight shrinkage, maximum .00017, was found. The diameters increased .0003 to .0036 in. On tempering the length decreased .0017 to .0108 in. as compared with the original 4 ins. length, while the diameter was increased .0003 to .0029; a few samples showing a decrease, max. 0009 in. The general effect of hardening is a slight increase in bulk, which increase is reduced by tempering.

POWER REQUIRED FOR MACHINE TOOLS.

Resistance Overcome in Cutting Metal. (*Trans. S. M. E.*, viii, 308.)—Some experiments made at the works of William Sellers & Co. showed that the resistance in cutting steel in a lathe would vary from 180,000 to 700,000 pounds per square inch of section removed, while for cast iron the resistance is about one-third as much. The power required to remove a given amount of metal depends on the shape of the cut and on the shape and sharpness of the tool used. If the cut is nearly square in section, the power required is a minimum; if wide and thin, a maximum. The dullness of a tool affects but little the power required for a heavy cut.

F. W. Taylor, in the Art of Cutting Metals (*Trans. A. S. M. E.*, xviii) gives the tangential pressure of the chip on the tool as ranging from 70,000 lb. per sq. in. when cutting soft cast iron with a coarse feed, to 198,000 lb. per sq. in. when cutting hard cast iron with a fine feed. In cutting steel, the pressure of the chip on the tool per sq. in. ranged from 184,000 lb. to 376,000 lb. The pressure, he found, is independent of the speed, and in the case of steel is independent of the hardness of the steel. It increases as the quality of the steel grows finer; that is, high grade steel, whether hard or soft, will give higher pressures than low grade steel. He also found that an increase in the tensile strength and ductility of the steel increases the pressure, the former having the greater effect.

Horse-power Required to Run Lathes.—The power required to do useful work varies with the depth and breadth of chip, with the shape of tool and with the nature and density of metal operated upon; and the power required to run a machine empty is often a variable quantity. For instance, when the machine is new, and the working parts have not become worn or fitted to each other as they will be after running a few months, the power required will be greater than will be the case after the running parts have become better fitted.

Another cause of variation of the power absorbed is the driving-belt; a tight belt will increase the friction.

A third cause is the variation of journal-friction, due to slacking up or tightening the cap-screws, and also the end-thrust bearing screw.

Owing to the demand imposed by high speed tool steels stouter machines are more necessary than formerly; these possess more rigid frames and powerful driving gears. The most modern (1915) forms of lathes obtain all speed changes by means of geared head-stocks, power being delivered at a single speed by a belt, or by a motor. If a motor drive is used, a speed variation may be obtained in addition to those available in the head, by using a variable speed motor, whose range usually is about 3:1. The tables on p. 1293 show the results of tests made by the Lodge & Shipley Co. in 1906 to determine the power required to remove metal in a 20-in. lathe with a cone pulley drive, and also in a similar lathe with a geared head.

Power Required to Drive Machine Tools.—The power required to drive a machine tool varies with the material to be cut. There is considerable lack of agreement among authorities on the power required. Prof. C. H. Benjamin (*Mach'y*, Sept., 1902) gives a formula H.P. = cW, c being a constant and W the pounds of metal removed per hour. c varies both with the quality of metal and the type of machine.

Values of c.

	Lathe.	Planer.	Shaper.	Milling Machine.
Cast iron	0.035	0.032	0.030	0.14
Machinery steel	0.067	....	....	....
Tool steel	....	....	....	0.30
Bronze	....	....	....	0.10

In each case the power to drive the machine without load should be added. G. M. Campbell (Proc. Engr. Soc. W., Pa., 1906) gives, exclusive of friction losses, H.P. = Kw, K being a constant and w the pounds of metal removed per minute. For hard steel $K = 2.5$; for soft

Average H.P. running idle 1.543; average H.P. with cut 10.55.

steel $K = 1.8$; for wrought iron, $K = 2.0$; for cast iron, $K = 1.4$. This formula gives results about 50% lower than Prof. Benjamin's.

L. L. Pomeroy (*Gen. Elec. Rev.*, 1908) gives: H.P. required to drive = 12 $FDSNC$, in which F = feed and D = depth of cut, in inches, S = speed in ft. per min., N = number of tools cutting, C = a constant, whose values with ordinary carbon steel tools are: for cast iron, 0.35 to 0.5; soft steel or wrought iron, 0.45 to 0.7; locomotive driving-wheel tires, 0.7 to 1.0; very hard steel, 1.0 to 1.1. This formula is based on Prof. Flather's dynamometer tests. An analysis of experiments by Dr. Nicholson of Manchester, which confirm the formula, showed the average H.P. required at the motor per pound of metal removed per minute to be as follows: Medium or soft steel, or wrought iron, 2.4 H.P.; hard steel, 2.65 H.P.; cast iron, soft or medium, 1.00 H.P.; cast iron, hard, 1.36 H.P.

Actual tests (1906) of a number of machine tools in the shops of the Pittsburg and Lake Erie R.R. showed the horse-power absorbed in driving under the conditions given in the table on p. 1295. The results obtained are compared with those computed by Campbell's formula on p. 1292. It will be observed that the sizes of motors actually used on the various machines in the table agree quite closely with the sizes recommended in the tables, pp. 1294 to 1298.

Sizes of Motors for Machine Tools.—The size of motor applied to machine tools which are driven by an individual motor is usually determined by the experience of the manufacturer, rather than by any formula. The same lathe, for instance, will be fitted with a larger motor if it is required to take heavy roughing cuts continuously in tough steel, than if it is to have a more general run of lighter work in cast iron. Even if it does, under the latter conditions of service, occasionally receive a job up to the limit of its capacity, the motor will be able to stand the temporary overload, whereas a continuous overload would soon ruin it. The conditions under which the machine will operate should therefore be stated when it or the motor to drive it is purchased. The tables given on pages 1294 to 1298 show the sizes of motors for machine tools as recommended by the Westinghouse Elect. & Mfg. Co. The sizes given embody average practice. The type of motor to be used varies with the conditions of service, and the type suitable for the different classes of machinery are indicated by the following symbols:

A. Adjustable speed, shunt wound, direct current motor; used where a number of speeds are essential.

B. Constant speed, shunt wound, direct current motor; used when the desired speeds are obtainable by a cone pulley or gear box, or where only a single speed is required.

C. Squirrel cage induction motor; used where direct current is not available. A cone pulley or gear box is necessary if more than one speed is desired.

D. Constant speed, compound wound, direct-current motor, used when different speeds are obtainable by means of a cone pulley or gear box, or where but one speed is necessary.

E. Wound secondary or squirrel cage induction motor with about 10% slip; used where direct current is not available, or where one speed is required.

F. Adjustable speed, compound wound, direct current motor; used where a number of speeds are necessary.

G. Standard bending roll motor.

H. Standard machine tool traverse motor.

Turning and Boring Machines.

MISCELLANEOUS GRINDERS—Motor *B* or *C*.

Wet tool grinder, 2 to 3 H.P.; flexible swinging grinding and polishing machine, 3 H.P.; angle cock grinder, 3 H.P.; piston rod grinder, 3 H.P.; twist drill grinder, 2 H.P.; automatic tool grinder, 3 to 5 H.P.

In selecting a motor for a machine tool, advantage should be taken of the fact that motors will stand considerable overloads for short periods. This will lead to the selection of smaller motors than are usual. The tendency is to select a motor to fit the maximum capacity of the machine, rather than one whose capacity is more nearly that of the average capacity of the tool.

A. G. Popcke (*Am. Mach.*, Sept. 26 and Oct. 3, 1912) outlines more accurate methods of determining the sizes of motors required for driving machine tools, based upon an analysis of the working conditions, and also the considerations other than those of power which govern the selection of the motor. To determine motor capacity, the following data are necessary: Horse-power, speed and voltage; and in addition for alternating current, frequency and phase. To estimate the horse-power the following must be known: Type of tool; depth of cut (all tools being considered), inches; feed, in. per revolution; speed, ft. per minute; duration of both average and maximum cuts; duration of peak of maximum load; number of peaks per hour. From the area of the cut (depth × feed) and the cutting speed, the cubic inches of metal removed per minute can be calculated for both average and maximum cuts, and these figures, multiplied by the constants below give the horse-power required, to which the friction load of the machine must be added.

HORSE-POWER CONSTANTS FOR CUTTING METAL.

	H.P. per Cu. In. per Min.		H.P. per Cu. In. per Min.
Cast iron	0.3 to 0.5	Steel, 50 carbon or more	1.0 to 1.25
Wrought iron	0.6	Brass and similar alloys	0.2 to 0.25
Machinery steel	0.6		

These constants apply to round nose tools used in accordance with the conditions recommended by F. W. Taylor (see p. 1261). For twist drills the power requirements per cubic inch are about double the figures given above.

The size of the motor selected will depend on the heating of the motor while under load, and as the load is usually intermittent, the heating will depend upon the square root of the mean square value of the power required. In a given cycle in which the several power values are P_1, P_2, P_3, utilized during periods of t_1, t_2, t_3, respectively, the square root of the mean square will be

$$\sqrt{\frac{P_1^2 t_1 + P_2^2 t_2 + P_3^2 t_3}{t_1 + t_2 + t_3}}$$

The heating of the motor will be the same as if it were run constantly at a load equal to the square root of the mean square load. In making the motor selection, however, it should be observed whether or not the duration of the maximum load will be greater than the motor can successfully withstand. Thus a 100% overload for a period of 10 seconds can easily be carried by a properly designed motor, while if prolonged such a load may burn it out. When selecting motors for widely fluctuating intermittent loads, the limits above rated load which must be taken into consideration are for alternating current, pull at starting torque, and speed regulation; and for direct current motors. commutation, speed regulation and stability. The pull at the starting torque of an induction motor is from 2.5 to 3.5 times the full-load torque, and the speed regulation, or percentage drop in speed between no load and full load, known as the slip, is, at full load, from 5 to 7%. At other loads it is approximately proportional to the load. Commutating pole, direct current motors will stand 100% to 125% overload without sparking. The speed regulation at full load is 10 to 15%, depending on the speed of the motor. With non-commutating pole motors the speed decreases with overloads in proportion to the loads, while on commutating pole motors it increases up to 100% overload, thus giving approximately the same speed at double load as at full load. A commutating pole motor can be made stable at overloads, which will increase the drop in speed. The better the speed regulation, however, the less certain is the stability and the motor for driving machine tools must be a compromise between these two factors. Motors, however, are available which can be safely operated on intermittent loads where the maximum load is 200% of the rated load. In machine tool work, a large speed reduction, giving a stable motor is advisable when variations occur in the work done by the cutting tool on long jobs, thus protecting the cutting tools, the machines and the work. An adjustable speed motor with a speed reduction of 25% is of advantage under such circumstances.

In applying the principles outlined above to the selection of a machine tool motor, the average and maximum conditions of service of the machine should be determined by laying out typical jobs in which these conditions are present. The power cycles are determined from the amount of metal removed on each cut as previously explained and the duration of each cut is ascertained from the length of the cut, the spindle speed and the feed per revolution. The square root of the mean square value of the power required is next determined, the time while the machine is idle during the periods of adjustment being added in the denominator of the formula for this value. A motor whose capacity is in the neighborhood of the value ascertained is then selected, and the relation of the maximum load to the rated motor capacity is observed to ascertain whether or not the motor, in addition to carrying the average load, is capable of carrying the maximum load without injury. For instance, if the square root of the mean square value is 5.5 H.P. a 5-H.P. motor would be under an overload of 10%, which is well within the capacity of a well designed machine. If the maximum load requires 8.3 H.P. for a period of three minutes the motor will be overloaded 66% for this period which is also within the limits set by good motor design.

According to Mr. Popcke, other questions than horse-power govern the selection of a motor for a machine tool. The speed of the motor depends upon the speed of the machine shaft, which ranges from 50 to 60 r.p.m. on forging machines to 200 to 300 r.p.m. on machine tools, and as high as 1000 to 2000 r.p.m. on grinding and wood-working machinery. The speeds usually obtainable with 60-cycle alternating current motors are 1700–1800, 1100–1200, 850–900, 650–720 and 550–600 r.p.m. The speeds available on standard direct current motors are approximately the same. On 25-cycle alternating current motors the usual speeds are 700–750, 550–600, and 350-375 r.p.m. The following factors are considered in selecting motors for belt drives: Speed reductions, pulley sizes, belt speeds, motor speeds, distance between pulley centers, arc of contact, use of idler pulleys, mounting of motor. Involved in the speed reductions are the sizes of the motor and machine pulleys and the belt speed. The standard sizes of motor pulleys which have been adopted in connection with standard speed ratings of the various sizes of motors have standardized the belt speeds. The maximum and minimum standard speed ratings of the motors, together with the maximum and minimum pulley diameters are given in the following table:

Horse-Power of Motor.	1	2	3	5	7 1/2	10	15	20	25	30	35	40	50
R.P.M., Maximum.	1700	1700	1800	1800	1700	1700	1700	1700	1400	1700	1700	1700	1700
Pulley Diameter, standard.	3 1/2	3 1/2	4	4	5	6	7	8	9	9	10	11	11
Pulley Diameter, minimum.	3	3	3	3 1/2	4	4 1/2	5	6	6 1/2	6 1/2	7	7 1/2	8
R.P.M., Minimum.	....	850	850	850	650	600	600	650	600	600	675	600	565
Pulley Diameter, standard.	....	4	5	6	8	9	11	11	12	13	13	14	16
Pulley Diameter, minimum.	....	3 1/2	4	4 1/2	6	6 1/2	7 1/2	8	9	10	10	12	13 1/2

The minimum size of pulley is specified on account of the reduction of pulley size increasing the strains on the motor bearings and shaft. The arc of contact has great effect on the success of a belt-driven motor installation. The arc of contact depends on the distance between the pulley centers and on the speed reduction. Where it is necessary to increase the arc of contact, idler pulleys are of service. In machine work the size of the motor pulley is sometimes fixed by the necessity of belting the motor to the machine flywheel, in which case care must be taken that the diameter of the motor pulley is not less than the minimum size specified. The arc of contact must also be considered, as in a large speed reduction this will be decreased and will seriously affect the amount of power transmitted. The effect of decreasing the arc of contact is shown below, the power transmitted by a 180 deg. arc of contact being taken as 100.

Arc of contact, deg....	180	170	160	150	140	130	120
Power transmitted, %..	100	94	89	83	78	72	67

The cost of a motor per horse-power increases as the speed decreases. Therefore, for maximum economy in first cost as high a speed as possible should be selected without, however, going below the minimum pulley diameter. Back geared motors are useful where extremely low speeds are required. A speed ratio of 6:1 between the armature and the motor countershaft is usually satisfactory, any further speed reduction to the machine pulley being obtained by means of the pulley

on the motor countershaft. Back geared motors are used where the machine speed is below 150 to 100 r.p.m. The initial speed of the back geared motor should not exceed 1200 r.p.m. when the horse-power is from 10 to 20 and should not exceed 900 or even 720 r.p.m. when the horse-power is greater than this figure.

For equipment where the motor is geared to the machine, the following are the governing considerations: Speed reduction, pitch line speed, number of teeth on gears, width of face of gears, center distances, use of idler gears, motor mounting. Noise limits the pitch line speed to about 1000 feet per minute with steel gears. For speeds of 1000 to 2000 feet per minute, cloth or rawhide pinions should be used and speeds in excess of 2000 feet per minute should be avoided if possible. Stresses in bearings and motor shafts limit the minimum size of motor pinions just as they limit the size of pulleys. The maximum and minimum speed ratings and the corresponding standard and minimum sizes of pinions for constant speed and adjustable speed motors are given in the tables on the preceding page. The second table also gives the minimum pulley diameters for adjustable speed motors.

For additional data on machine tool motors see Electrical Engineering, p. 1466.

Motor Requirements for Milling Machines.—See p. 1278.

Power Required for Drilling.—See p. 1286.

Motor Requirements of Planers. (A. G. Popcke, *Am. Mach.*, Sept. 26, 1912.)—Manufacturers usually specify motors for planers that are larger than necessary, due to the heavy peak load imposed at the instant of reversal. Before the advent of interpole, commutating motors, this peak load caused sparking unless a large motor was used. The commutating motor eliminates this trouble and permits the use of a smaller motor. A flywheel on the countershaft, from which the forward and reverse belts are driven, will assist in the carrying of the peak loads, and will allow the use of a smaller driving motor than otherwise. The table below shows the results of tests of planers with a graphic recording ammeter, and gives the power required at different portions of the planer cycle. It also shows the motors recommended and installed, which are handling the work satisfactorily, and also the size of motors specified by the makers of the tools.

Power Required for Wood-Working Machinery. (E. G. Fox, *El. Rev.*, June 13, 1914.).—The factors influencing the power required for wood-working machines are: Design, speed of working, including feed and depth of cut, condition of machine and cutters, nature of material. Machines handling one kind of material may be motored for their ordinary load, while those having diverse work must be motored for their heaviest service. The data below are based upon tests as well as on figures furnished by manufacturers.

Band Saws.—The motors should have good starting torque, and with resaws should be capable of developing 1.5 full load torque at starting, and should have good overload characteristics. Belted motors are recommended for most installations.

BAND-SAWS.

Wheel diameter, in.	42	38	36	36	34	30
R.P.M.	400–500	450	500	400	500	500
Maximum depth of timber, in.	20	16	16	14	12	12
H.P. of motor	5	5	5	3	3	3

BAND-RESAWS.

Wheel diameter, in.	60	54	48	44	42	40	38
R.P.M.	550	600	650	650	650	700	450
Width saw blade, in.	8	6	5	4	4	3	2
Maximum depth of timber, in.	36	30	26	24	24	20	12
H.P. of motor	50	40	30	20	15	15	7.5
R.P.M. of motor	600	600	720	720	720	720	514

Add for jointing attachment on 48-in. saw, 7.5 H.P.

BAND RIP SAWS—POWER FEED.

Wheel Diam., in.	R.P.M.	Max. Timber Depth, in.	Motor H.P.	Motor R.P.M.
42	650	12	15	720
40	600	15	10	600

Add 2 H.P. for return rolls, if used. Speeds given are for direct connection.

Circular Saws.—Circular saws are not as widely used as band-saws for resawing, as they require more power, run at lower speeds and waste more stock. Splitting with circular saws requires from 15 to 20% more power than cross-cutting. Band-saws require about the same power for both.

CIRCULAR SAWS.

Maximum diameter of saw, in.	42	36	32	30	24
R.P.M. of saw	900	1000	1225	1200	1225
Maximum capacity, in., horizontal	17	14	11	10	8
" " " vertical	...	....	8	6	6
Horse-power	25	25	20	20	20

CIRCULAR RIP-SAWS.

Maximum diameter of saw, in.	20	16	12
Maximum R.P.M. of saw	2100	2600	2400
Maximum thickness of stock, in.	6	5	2
Feed, ft. per min.	60–180	64–194	50–100
Horse-power	15	15	7.5

HAND-FEED CIRCULAR RIP-SAWS.

Maximum diameter of saw, in.	14	16	20	24	30	36
R.P.M. of saw	2700	2400	2000	1600	1250	1000
Horse-power	7.5	10	15	15	20	20

POWER-FEED GANG RIPPING-MACHINE.

Number of saws	2	3	4	8
Maximum R.P.M.	3400	2300	2500	2500
Diameter of saws, in.	10	15	14	14
Feed, ft. per min.	180	200	100–180	90–200
Horse-power	15	30	25	35

CIRCULAR CUT-OFF SAWS.

Maximum saw diameter, in.	14	16
R.P.M. of saws	2700	2600
Horse-power	5	7.5

INSIDE MOLDERS.

Maximum capacity, in.	8 × 4	10 × 4	12 × 6	14 × 6
Horse-power	25	25	35	35

OUTSIDE MOLDERS.

Maximum capacity, in.	4 × 4	6 × 4	8 × 4	10 × 4	12 × 5	14 × 6
Horse-power	10	15	20	25	30	35

STICKERS.

Maximum size of timber, in.	16 × 4	18 × 4	20 × 4
Horse-power	5	7.5	10

JOINTERS.

Maximum width of timber, in.	8	12	16	20	24	36
Horse-power	2	2	3	5	7.5	7.5

The recommendations for molders, stickers and jointers are based on a maximum depth of cut of 3/32 in. If the cut is greater, the size of motor should be correspondingly increased.

Surfacers.—The motor sizes given below are for medium work with maximum depths of cut of 1/8 in. For planing mill work, on heavy stock with deep cuts the sizes should be increased about 5 H.P.

SINGLE SURFACERS.

Maximum width of timber, in.	16	20	24	30	36
Horse-power	7.5	10	10	15	15

DOUBLE SURFACERS.

Maximum width of timber, in.	26	30	36
Horse-power, heavy work	35	35	..
Horse-power, medium work	20	25	30

Timber Sizers.—The following figures apply to heavy service in dressing timber to size, surfacing four sides simultaneously.

Max. size of timber, in.	20 × 16	20 × 18	20 × 20	30 × 18	30 × 20
Horse-power	60	60–75	60–75	75	75

DRUM SANDERS.

Number of drums	1	1	1	2	2	2	2
Max. Width of Stock, in.	30	36	42	30	36	42	48
Horse-power	10	15	15	20	20	20	25
Number of drums	3	3	3	3	3	3	3
Maximum width of stock, in.	30	36	42-48	54-66	72	78	84
Horse-power	20	25	30	35	40	40	50

When material is sanded to size and full width of sander is used with panels fed continuously, add 5 H.P. to above motor sizes.

TENONERS—HAND-FEED.

Length of tenon, in.	7 single	7 double
Horse-power	7.5	10

Shapers.—For ordinary service on reversible single- or two-spindle machines, use a 5 H.P. motor. For extra heavy work, as in carriage factories, railroad shops, etc., use a 7.5 H.P. motor.

SCRAPING MACHINES.

Maximum width of stock, in...	12	26	30	42
Horse-power	2	3	3	5

AUTOMATIC LATHES.

Maximum diameter and length of stock, in.	2.75 × 72	3 × 50	5 × 50
Horse-power	10	15–20	20

BORERS.

Number of bits	1	1	2	3	4	8
Maximum diameter of bits, in	1	2	0.75	0.75	0.5	0.5
Horse-power	3	5	3	5	5	10

CHISEL MORTISING-MACHINES.

Maximum number of chisels	1	1	1	1	2
Maximum size of chisel square, in	0.5	0.75	0.75	1.25	1
Horse-power	2	2	3	5	3
Maximum number of chisels	3	4	5	6	7
Maximum size of chisel square, in	1	1	13/16	13/16	13/16
Horse-power	5	5	5	7.5	7.5

PLANERS AND MATCHERS.

For planing and matching timber at one operation.

Maximum size of timber. in..	9 × 6	15 × 6	20 × 6	24 × 6	26 × 8
Horse-power	35	40	45	45	45

Box board matchers are similar to planers and matchers, but the work is much lighter. Hand-fed machines usually require a 7.5 H.P. motor, while power-fed machines require 10 H.P.

Horse-power Required to Drive Shafting.—Samuel Webber in his "Manual of Power" gives, among numerous tables of power required to drive textile machinery, a table of results of tests of shafting. A line of 2 1/8-in. shafting, 342 ft. long, weighing 4098 lb., with pulleys weighing 5331 lb., or a total of 9429 lb., supported on 47 bearings, 216 revolutions per minute, required 1.858 H.P. to drive it. This gives a coefficient of friction of 5.52%. In seventeen tests the coefficient ranged from 3.34% to 11.4%, averaging 5.73%. J. T. Henthorn states (*Trans. A. S. M. E.*, vi, 462) that in print-mills which he examined the friction of the shafting and engine was in 7 cases below 20% and in 35 cases between 20% and 30%, in 11 cases from 30% to 35% and in 2 cases above 35%, the average being 25.9%. Mr. Barrus in eight cotton-mills found the range to be between 18% and 25.7%, the average being 22%. Mr. Flather (Dynamometers) believes that for shops using heavy machinery the percentage of power required to drive the shafting will average from 40% to 50% of the total power expended. Under the head of shafting are included elevators, fans and blowers.

Power Required to Drive Machines in Groups. — L. P. Alford (*Am. Mach.*, Oct. 31, 1907) gives the results of an investigation to determine the power required to drive machinery in groups. The method employed comprised disconnecting parts of the shafting in a belt-driven plant, and driving the disconnected portion with its machines by an electric motor, readings of the power required being taken every 5 minutes. The average power required for the entire factory was considerably less than the sum of the power required for the individual machines, due to tools being stopped at some portion of the day for adjustment, replacement of work, etc. The conditions of group driving are such that fixed rules cannot be laid down, but a study must be made of each individual case. The results of the several thousand observations made in the investigation are given in the accompanying table. The observations were made before the introduction of high speed steel, and the figures probably should be modified somewhat for more modern practice. The sum of the individual horse-power values as given in the table is about 20% higher than the power actually used in the factory, due to a lessening of the average horse-power in each department. The reason for this is the working conditions existing, in that all tools were not used to their maximum or even average capacity at the same time. In determining the size of motor for each department, the total horse-power required by the tools in that department, as given in the table, was diminished by 20%, and the friction load of line and countershafts was added.

A similar investigation, reported by H. C. Spillman (*Mach'y*, June, 1913), showed that but 20% of the total power supplied to the motor is applied in useful work in the machines, 72% being absorbed in friction losses in machines and shafting, and 8% disappearing as electrical losses.

MACHINE TOOL DRIVES, SPEEDS AND FEEDS.

Geometrical Progression of Speeds and Feeds.—It has become generally accepted that the speeds available on a given machine tool should be in a geometric progression. There is, however, by no means a uniformity in the ratio of the various geometric series adopted by the different makers. This ratio will be found to range from 1.3 to 1.7 on the usual types of cone-driven machines, and the speeds available under different conditions of open belt and back gear operation present many duplications and are often far from a true geometric progression when considered over the entire range of speeds. Carl G. Barth (*Am. Mach.*, Jan. 11, 1912) suggests a ratio of $\sqrt[4]{2} = 1.189$. With this ratio, the revolutions per minute of the spindle are doubled every fourth speed. An editorial (*Am. Mach.*, Dec. 3, 1914) discussing the advantage of adopting this ratio for a speed series shows that it will fulfill all the ordinary requirements of machine tool work, and that practically any desired speed in either lathe or drill press can be obtained when the machine is speeded according to a geometric progression based on the ratio 1.189. At the present writing (1915) this ratio has been adopted by several machine tool builders.

The necessity for the adoption of a standard ratio for speeds and feeds on machine tools is discussed in *Am. Mach.*, Dec. 3 and 10, 1914, in describing the respeeding of machines at the Watertown arsenal and elsewhere. The speeds originally available on many of the machines presented many duplications of open belt speeds when back-geared, and the speeds on any one machine considered as a whole were not in any regular series. Thus a lathe with supposedly 20 speeds had practically, due to duplication of speeds in the open belt and back-gear series, only 12 speeds. The rearrangement of the gearing and the pulleys made all 20 speeds available, and in practical accord with a geometric series with a ratio of 1.189. In the same article there are tabulated the speeds of nine 16-in. lathes offered in response to a request for bids. In no case did the speeds available on one lathe correspond with those on any other, nor did any set of speeds even approximate the ideal speeds. Even three machines offered by one maker had wide variations in their speeds. Such a condition precludes the possibility of using machines interchangeably for the same service, and, as stated by Mr. Barth, is the basis of much of the trouble regarding piece rates in machine shop work. See also article by Robert T. Kent, *Iron Age*, July 3, 1913.

A geometrical progression of the feeds available on machine tools is also desirable, and Mr. Barth has recommended the same ratio for the feed series as for the speed series, $\sqrt[4]{2} = 1.189$. The reasons for adopting this ratio are given in the article above cited, *Am. Mach.*, Jan. 11, 1912.

Methods of Driving Machine Tools.—F. A. Halsey in a lecture at Columbia University (*Indust. Eng.*, Sept., 1914) compares the relative advantages of the ordinary 5-step cone pulley, the 3-step cone pulley, the constant speed pulley and the individual motor as a drive for machine tools. In the 5-step cone pulley drive the large intervals between the speeds available on the different cone steps decrease the output of the machine, due to the fact that except in those few cases where the cone speed is nearly equal to the cutting speed the next lower cone speed must be used. Also on account of the proportions of the cone, the belt speed is unnecessarily low, and as the belt is moved to the largest cone step its speed is still further decreased. On the larger steps the belt is frequently incapable of delivering the power required by the heavier cuts which go with large work. This defect is remedied in the 3-step cone pulley, in which the difference in the diameters of the steps is not so pronounced, the additional number of speed changes being obtained by double back gears.

Mr. Halsey compares two specific cases: (1) A 5-step cone with single back gears, the cone step diameters being respectively 4, 6, 8, 10, and 12 in. (2) A 3-step cone with double back gears, the cone step diameters being respectively $11\,^{17}/_{32}$, $12\,^{9}/_{32}$, and 13 in. In case 1 a $2\,^{1}/_{2}$-in. belt, and in case 2 a 4-in. belt, is used. The change from 3 to 5 steps reduces the ratio of the highest to the lowest speed on the cone, and it increases the belt speed and therefore the power on all steps, but particularly on the large ones where it is most needed. The effect of these changes can be shown by calculating the respective powers with the belts on the largest steps of the two cones. Assume (case 1) that the speed with the belt on the 4-in. step is 100. Then the speed with the belt on the largest step will be $100 \times {}^{4}/_{12} = 33\,^{1}/_{3}$. To maintain the same cone speed in case 2, the highest belt speed will be $100\ (11\,^{17}/_{32} \div 4) = 288 +$; the lowest will be $288\ (11\,^{17}/_{32} \div 13) = 255 +$. The smallest step in case 1 is too small for a double belt, while in case 2 a double belt can be used on the smallest step. In order to compare the power capacities of the two machines the belt speed must be multiplied by a factor representing the greater pulling power of the double belt, say 1.43, and also by the ratio of the belt widths, 1.6. If L_1 and L_2 represent respectively the power capacities of the large steps of cases 1 and 2, and S_1 and S_2 the power capacities of the small steps, then

$$\frac{S_2}{S_1} = \frac{288}{100} \times 1.43 \times 1.6 = 6.5$$

$$\frac{L_2}{L_1} = \frac{255}{33.33} \times 1.43 \times 1.6 = 17.5$$

That is, the power capacity of the 3-step cone is 6.5 times as great as that of the 5-step cone with the belt on the small step, and 17.5 times as great with the belt on the large step. The defect of the arrangement given in case 2 is that it provides a smaller number of speeds and a smaller range of speeds than does case 1. The remedy is the provision of additional back gears if the additional speeds or greater range is necessary. Mr. Halsey further points out that direct connection between the cone pulley and the work spindle has been retained in many cases where it should have been discarded, since with large work the belt speed will become too low to transmit adequate power, and it is better practice to interpose gearing between the pulley and the spindle, and thus speed up the belt and pulley. In changing machines in accordance with the above suggestions, it is advisable to so design the gearing as to obtain speeds which will be in geometric progression as explained in a previous paragraph. For methods of laying out cone pulleys, see p. 1136. For methods of laying out the driving gears of machine tools see "Halsey's Handbook for Machine Designers and Draftsmen," p. 77.

In the Constant Speed Pulley drive, the belt pulley of the machine is driven at a constant speed and the power is transmitted to the machine from the pulley through a train of gears arranged in a gear box. By the shifting of appropriate levers any particular set of gears can be put in engagement, thus making instantly available any speed in the range of the machine. This arrangement makes the obtaining of a geometric series of speeds a particularly easy matter. The constant speed pulley drive possesses the advantage of giving a self-contained machine, particularly adapted to the individual motor drive. It has found wide application in the milling machine and in certain types of lathes.

The Individual Motor Drive has, according to Mr. Halsey, a field in the driving of portable floor plate tools, for machines in isolated positions, or for tools so located that line shafts cannot be conveniently laid out for them, and for large machines where the cost of the motor is a relatively small part of the total cost of the tool. The disadvantage of the individual motor for the small or medium size tool is that the power capacity of the motor must be equal to the maximum power requirement of the machine and that no advantage can be taken of the average power requirements of several machines as is possible in the group drive where one motor drives several machines. This increases the first cost of the motors, and they are also usually worked at low efficiency, due to the fact that they are most of the time underloaded.

ABRASIVE PROCESSES.

Abrasive cutting is performed by means of stones, sand, emery, glass, corundum, carborundum, crocus, rouge, chilled globules of iron, and in some cases by soft, friable iron alone. (See paper by John Richards, read before the Technical Society of the Pacific Coast, *Am. Mach.*, Aug. 20, 1891, and *Eng. & M. Jour.*, July 25 and Aug. 15, 1891.)

The "Cold Saw." — For sawing any section of iron while cold the cold saw is sometimes used. This consists simply of a plain soft steel or iron disk without teeth, about 42 inches diameter and 3/16 inch thick. The velocity of the circumference is about 15,000 feet per minute. One of these saws will saw through an ordinary steel rail cold in about one minute. In this saw the steel or iron is ground off by the friction of the disk, and is not cut as with the teeth of an ordinary saw. It has generally been found more profitable, however, to saw iron with disks or band-saws fitted with cutting-teeth, which run at moderate speeds and cut the metal as do the teeth of a milling-cutter.

Reese's Fusing-disk. — Reese's fusing-disk is an application of the cold saw to cutting iron or steel in the form of bars, tubes, cylinders, etc., in which the piece to be cut is made to revolve at a slower rate of speed than the saw. By this means only a small surface of the bar to be cut is presented at a time to the circumference of the saw. The saw is about the same size as the cold saw above described, and is rotated at a velocity of about 25,000 feet per minute. The heat generated by the friction of this saw against the small surface of the bar rotated against it is so great that the particles of iron or steel in the bar are actually fused, and the "sawdust" welds as it falls into a solid mass. This disk will cut either cast iron, wrought iron, or steel. It will cut a bar of steel 1 3/8 inch diameter in one minute, including the time of setting it in the machine, the bar being rotated about 200 turns per minute.

Cutting Stone with Wire. — A plan of cutting stone by means of a wire cord has been tried in Europe. While retaining sand as the cutting agent, M. Paulin Gay, of Marseilles, has succeeded in applying it by mechanical means, and as continuously as formerly the sand-blast and band-saw, with both of which appliances his system — that of the "helicoidal wire cord" — has considerable analogy. An engine puts in motion a continuous wire cord (varying from five to seven thirty-seconds of an inch in diameter, according to the work), composed of three mild-steel wires twisted at a certain pitch, that is found to give the best results in practice, at a speed of from 15 to 17 feet per second.

The Sand-blast. — In the sand-blast, invented by B. F. Tilghman, of Philadelphia, and first exhibited at the American Institute Fair, New York, in 1871, common sand, powdered quartz, emery, or any sharp cutting material is blown by a jet of air or steam on glass, metal, or other comparatively brittle substance, by which means the latter is cut, drilled, or engraved. To protect those portions of the surface which it is desired shall not be abraded it is only necessary to cover them with a soft or tough material, such as lead, rubber, leather, paper, wax, or rubber-paint. (See description in App. Cyc. Mech.; also U. S. report of Vienna Exhibition, 1873, vol. iii. 316.)

A "jet of sand" impelled by steam of moderate pressure, or even by the blast of an ordinary fan, depolishes glass in a few seconds; wood is cut quite rapidly; and metals are given the so-called "frosted" surface with great rapidity. With a jet issuing from under 300 pounds pressure, a hole was cut through a piece of corundum 1 1/2 inches thick in 25 minutes.

The sand-blast has been applied to the cleaning of metal castings and sheet metal, the graining of zinc plates for lithographic purposes, the frosting of silverware, the cutting of figures on stone and glass, and the cutting of devices on monuments or tombstones, the recutting of files, etc. The time required to sharpen a worn-out 14-inch bastard file is about four minutes. About one pint of sand, passed through a No. 120 sieve, and 4 H.P. of 60-lb. steam are required for the operation. For cleaning castings, compressed air at from 8 to 10 pounds pressure per square inch is employed. Chilled-iron globules instead of quartz or flint-sand are used with good results, both as to speed of working and cost of material, when the operation can be carried on under proper conditions. With the expenditure of 2 H.P. in compressing air, 2 square feet of ordinary scale on the surface of steel and iron plates can be removed per minute. The surface thus prepared is ready for tinning, galvanizing, plating, bronzing, painting, etc. By continuing the operation the hard skin on the surface of castings, which is so destructive to the cutting edges of milling and other tools, can be removed. Small castings are placed in a sort of slowly rotating barrel, open at one or both ends, through which the blast is directed downward against them as they tumble over and over. No portion of the surface escapes the action of the sand. Plain cored work, such as valve-bodies, can be cleaned perfectly both inside and out. One hundred lbs. of castings can be cleaned in from 10 to 15 minutes with a blast created by 2 H.P. The same weight of small forgings can be scaled in from 20 to 30 minutes. — *Iron Age*, March 8, 1894.

Polishing and Buffing.—The type of polishing wheel to be used depends on the class of work. For rough polishing on flat surfaces or where the corners are to be square, a paper or a wooden wheel, faced with leather to which emery or some other abrasive is glued is used. For large flat work, or curved surfaces, bull neck, solid canvas, solid sheepskin, paper or wooden wheels are used. These wheels are also used for such work as stove trimmings, agricultural implements, tools, cast iron and brass parts, etc. Loose or stitched sheepskin, loose or stitched canvas and solid or stitched laminated felt wheels are used for roughing irregular shapes requiring a soft faced wheel which will come in contact with every crevice of the work. Bull neck or wooden wheels are used whenever coloring or finishing is to be done on cast or sheet metal. For work requiring a high polish, as guns, cutlery, etc., sea horse is often employed. The hardness of the wheel depends on the service in which it is to be used, and in the case of linen, canvas, leather, or other built-up wheels on steel centers, is governed by the depth of the flanges clamping the wheel on the arbor; the larger the flanges the harder is the wheel. For most polishing operations, a peripheral speed of the wheel of from 3000 to 6000 ft. per minute is sufficient, and 4000 ft. will serve for most purposes. These are the speeds recommended for muslin, felt or sea horse wheels, although some claims are advanced for speeds as high as 7500 ft., it being stated that lower speeds will scratch the work.

Buffing is the process of obtaining a grainless finish of high luster on plated surfaces. The degree of luster depends on the finish of the surface prior to plating. The work is done on a soft wheel to which a polishing composition has been applied. The polishing composition comprises a heavy grease containing polishing material, as flour-emery, rouge, tripoli, crocus, etc. According to the Chicago Wheel and Mfg. Co. the following compositions are adapted to the different varieties of work. For cutting down and polishing brass, bronze and Britannia metal preparatory to plating, tripoli composition; for smooth surfaces on nickel and brass, crocus composition; for coloring brass, copper, nickel, bronze, German silver, etc., either in solid or plated metal, White Diamond XXX composition; for chased or embossed parts, or for cutting down silver-plated pieces which are afterward to be colored with rouge and alcohol, White Diamond XXXX composition is used; for nickel-plated pieces with a high luster, White Coloring composition, made of Vienna lime is used. Where rapid, sharp, even cutting is desired, emery cake is used. Chandelier rouge is used to produce a deep color on brass and bronze parts.

Laps and Lapping.—A series of tests was made by W. A. Knight and A. A. Case (*Jour. A. S. M. E.*, Aug., 1915) to determine the effect on the rate of cutting with different combinations of abrasive lubricant and lap material. The tests were made with hardened steel specimens, and comparative results were obtained with emery, alundum and carborundum used in connection with lard oil, machine oil, gasoline, kerosene, turpentine, alcohol and soda water. The lap materials were cast iron, soft steel and copper. The following conclusions were derived from the invesigation: The initial rate of cutting is not greatly different for the different abrasives; carborundum maintains its rate better than either of the others, alundum next, and emery the least; carborundum wears the lap about twice as fast, and alundum 1¼ times as fast as emery; there is no advantage in using an abrasive coarser than No.150; the rate of cutting is practically proportional to the pressure; the wear of the laps is in the proportions of cast iron 1.00, steel 1.27, copper 2.62, and this wear is inversely proportional to the hardness by the Brinell test; in general, copper and steel cut faster than cast iron, but where permanence of form is a consideration, cast iron is the superior metal; gasoline and kerosene are the best lubricants to use with cast-iron lap, kerosene, on account of its non-evaporative qualities, being first choice; machine and lard oil are the best lubricants to use with copper or steel lap, but they are least effective on the cast lap; for all laps and all abrasives (of those tested) the cutting is faster with lard oil than with machine oil; alcohol shows no particular merit for the work; turpentine does fairly good work with carborundum, but in general, is not as good as kerosene or gasoline; soda water compares favorably with other lubricants, and on the whole it is slightly better than alcohol or turpentine; wet lapping is from 1.2 to 6 times as fast as dry lapping, depending on the material of the lap and the method of charging.

EMERY WHEELS AND GRINDSTONES.

Co.; "Table of Causes of Grinding Wheel Accidents;" Independence Inspection Bureau; "Safeguarding Grinding Wheels," Report of Committee of National Machine Tool Builders' Association; Bulletin, "Safeguarding High Speed Grinding Wheels," National Founders' Association; "Operation of Grinding Wheels in Machine Grinding," Geo. I. Alden, *Journal A.S.M.E.*, Jan., 1915.

Selection of Abrasive Wheels. (Contributed by the Norton Company, 1915.) — The user of a modern grinding wheel should thoroughly understand these essential features; the definition of grain and grade, the particular conditions of grinding which cause them to vary; the methods of balancing and mounting; truing and dressing; the effect of machine vibration and arc of contact upon grain and grade; the relation of work speed and wheel speed for production and finish; safeguards and dust removal systems.

Grain.— Abrasive grains are numbered according to the meshes per lineal inch of the screen through which they have been graded. The numbers used in wheels are 8, 10, 12, 14, 16, 20, 24, 30, 36, 46, 54, 60, 70, 80, 90, 120, 150, 180, 200; when finer than 200, the grains are termed flours, being designated as F, 2F, 3F, 4F, XF, 65C, 65F, F being the coarsest and 65F, the finest. Grits from 12 to 30 are generally used on all heavy work such as snagging; 36 to 80 cover nearly all tool grinding, saw gumming, and other operations where precision in measurement is sought; 90 and finer are used for special work such as grinding steel balls and fine edge work; the flour sizes are used mostly for sharpening and rubbing stones. The number representing the grades of abrasive leave a degree of smoothness of surface which may be compared to that left by files as follows: 8 and 10 represent the cut of a wood rasp; 16, 20, coarse-rough file; 24, 30, ordinary rough file; 36, 40, bastard file; 46, 60, second-cut file; 70, 80, smooth file; 90, 100, superfine file; 120F, 2F, dead-smooth file.

Grade. — When the retentive properties of the bond are great, the wheel is called hard; when the grains are easily broken out, it is called soft. A wheel is of the proper grade when its cutting grains are automatically replaced when dulled. Wheels that are too hard glaze. Dressing re-sharpens them, the points of the dresser breaking out and breaking off the cutting grains by percussion.

Soft wheels are used on hard materials, like hardened steel. Here the cutting particles are quickly dulled and must be renewed. On softer materials, like mild steel and wrought iron, harder grades can be used, the grains not dulling so quickly.

The area of surface to be ground in contact with the wheel is of the utmost importance in determining the grade. If it is a point contact like grinding a ball or if an extremely narrow fin is to be removed, we must use a very strongly bonded wheel, on account of the leverage exerted on its grain, which tends to tear out the cutting particles before

Revolutions per Minute Required for Specified Rates of Periphery Speed. Also Stress per Square Inch on Norton Wheels at the Specified Rates.

To find surface speed, in feet, per minute, of a wheel.

RULE. — Multiply the circumference (see above table) by its revolutions per minute.

Surface speed and diam. of wheel being given, to find number of revolutions of wheel spindle.

RULE. — Multiply surface speed, in feet, per min., by 12 and divide the product by 3.14 times the diam. of the wheel in inches.

they have done their work. If the contact is a broad one, as in grinding a hole, or where the work brings a large part of the surface of the wheel into operation, softer grades must be used, because the depth of cut is so infinitely small that the cutting points in work become dulled quickly and must be renewed, or the wheel glazes and loses its efficiency.

Vibrations in grinding machines cause percussion on the cutting grains, necessitating harder wheels. Wheels mounted on rigid machines can be softer in grade and are much more efficient.

Speeds of Grinding Wheels.— The factor of safety in vitrified wheels is proportional to the grade of hardness. Bursting limits are from 12,000 to 25,000 feet per minute, surface speed. Wheels are tested by standard makers at speeds in excess of 9000 feet surface speed per minute. Running speeds in practice are from 4000 to 6000 feet, depending on work, condition of machine, and mounting.

Generally speaking, grinding of tools, reamers, cutters, and surface grinding is done at about 4000 feet, snagging and rough forms of hand grinding at 5000 to 5500 feet, cylindrical grinding, or where the work is rigidly held and where the wheel feed is under control, from 5500 to 6500 feet, and in some instances as high as 7500 feet.

These speeds are all for vitrified wheels. The same speeds will apply to wheels made by the elastic and silicate processes.

Grain Depth of Cut.—An analysis of the action of the wheel when in operation shows how theoretical considerations bear out the truth of the empirical rules for the use of grinding wheels in machine grinding. A paper by Geo. I. Alden (*Jour. Am. Soc. M. E.*, Jan., 1915) gives the essential distinction between the radial or real depth at which the wheel cuts and the depth which the abrasive grain in the wheel cuts into the material being ground. The latter depth is termed the "grain depth of cut." This grain depth of cut is the controlling factor in securing the correct working of the wheel. A formula is deduced for computing the grain depth of cut, the application of the analysis is explained and these conclusions reached by Prof. Alden: 1—Other factors remaining constant, increase of work speed increases grain depth of cut, and makes a wheel appear softer. 2—A decrease of wheel speed increases grain depth of cut. 3—Diminishing the diameter of the wheel increases the grain depth of cut; increasing the diameter of the wheel decreases the grain depth of cut. 4—Decreasing the diameter of work increases the grain depth of cut; conversely, increasing the diameter of work decreases the grain depth of cut.

A table of arcs of contact of wheel and work for a limited range of diameters is given, also a table of values of one of the factors in the formula for grain depth of cut.

Artificial Abrasives.—Since 1900 artificial abrasives, made in various types of electric furnaces, have been displacing natural abrasives, and they are to-day almost exclusively used. This has been due largely to the ability to control the purity of the raw material and to insure uniformity of cutting action of the finished products. Artificial abrasives are divided into the aluminous group (examples, Alundum, Aloxite and Boro-Carbone), and the silicon carbide group (examples, Crystolon, Carborundum, Carbolite). The abrasive action of the aluminous group is due to the amount of oxide of aluminum, which in these artificial abrasives is in excess of 90%, slightly more than the best corundum and considerably in excess of the alumina content of emery, which rarely exceeds 70%. The aluminous abrasives are characterized by a high degree of toughness and are particularly adapted for grinding materials of high tensile strength such as steel and its alloys. The silicate carbide group is not duplicated by Nature and is somewhat harder and more brittle than the aluminous group. The silicon carbide abrasives are now recognized as standard for grinding materials of low tensile strength such as cast iron, brass pearl, marble, granite and leather.

Selection of Emery Wheels.— The Norton Co. (1915) publishes the accompanying table showing the proper grain and grade of wheel for different services. The column headed grain indicates the coarseness of the material composing the wheel, being designated by the number of meshes per inch of a sieve through which the grains pass. A No. 20 grain will pass through a 20-mesh sieve, but not through a 30-mesh, etc.

EXPLANATION OF GRADE LETTERS.

Extremely Soft.	Soft.	Medium Soft.	Medium.	Medium Hard.	Hard.	Extremely Hard.

B	F	J	N	R	W	Z
C	G	K	O	S		
D	H	L	P	T		

For Grinding High-speed Tool Steel, The American Emery Wheel Co. recommends a wheel one number coarser and one grade softer than a wheel for grinding carbon steel for the same service.

Balancing.— The standard makers of grinding wheels send out wheels balanced within narrow limits, accomplished by inserting lead near the hole. As the wheels wear down it frequently becomes necessary for the user to balance them by removing some of the lead.

Mounting Grinding Wheels—Safety Devices.— A code for the mounting of grinding wheels was adopted by 23 manufacturers of grinding wheels in the U. S. and Canada in 1914, and approved by the National Machine Tool Builders' Association. An abstract of the code is given in *Indust. Eng.*, Jan., 1915. The code recognizes as safety devices protection flanges, protection hoods, and protection chucks.

Protection flanges of the double or single concave type, used in conjunction with wheels having double or single convex tapered sides or side are recommended. For double tapered wheels they shall have a taper of not less than 3/4 in. per foot for each flange. For single tapered wheels they shall have a taper of not less than 3/4 in. per foot. Each flange, whether straight or tapered, shall be recessed at the center at least 1/16 in. on the side next to the wheel. All tapered flanges over 10 in. diameter shall be of steel or material of equal strength. Both flanges in contact with the wheels shall be of the same diameter. Wheels should never be run without flanges.

The following table gives the dimensions of flanges to be used where no hoods are provided: A = Maximum flat spot at center of flange. B = Flat spot at center of wheel. C = Minimum diameter of flange. D = thickness of flange at bore. E = minimum diameter of recess. F = Minimum thickness of each flange at bore; all dimensions are in inches.

Dia. of Wheel.	6	8	10	12	14	16	18	20	22	24	26	28	30
A	0	0	0	4	4	4	4	4	4	4	4	4	4
B	1	1	2	4 1/2	4 1/2	6	6	6	6	6	6	6	6
C	3	5	6	6	8	10	12	14	16	18	20	22	24
D	3/8	3/8	1/2	5/8	5/8	5/8	3/4	3/4	3/4	3/4	3/4	7/8	7/8
E	2	3 1/2	4	4	5 1/2	7	8	9	10 1/2	12	13 1/2	14 1/2	16
F	3/8	3/8	1/2	5/8	3/4	7/8	1	1	1 1/8	1 1/8	1 1/8	1 1/4	1 1/4

Where protection hoods are provided, straight flanges and straight wheels may be used, the dimensions being as follows, and the reference letters having the same meaning as above:

Dia. of Wheel.	6	8	10	12	14	16	18	20	22	24	26	28	30
C	2	3	3 1/2	4	4 1/2	5 1/2	6	7	7 1/2	8	8 1/2	10	10
E	1	2	2 1/4	2 3/4	3	3 1/2	4	4 1/2	5	5 1/2	6	7	7
F	3/8	3/8	3/8	1/2	1/2	1/2	5/8	5/8	5/8	5/8	5/8	3/4	3/4

Protection hoods shall be used where practical with wheels not provided with protection flanges, and shall be sufficiently strong to retain all pieces of a broken grinding wheel. They shall conform as nearly as possible to the periphery of the wheel, and leave exposed the

least portion of the wheel compatible with the work. A sliding tongue to close the opening in the hood as the wheel is reduced in diameter should be provided. Protruding ends of the wheel arbors and their nuts shall be guarded.

Cups, cylinders and sectional ring wheels shall be either protected with hoods, enclosed in protection chucks, or surrounded with protection bands. Not more than one-quarter of the height of such grinding wheels shall protrude beyond the provided protection.

Grinding wheels shall fit freely on the spindles. Wheel arbor holes shall be made 0.005 in. larger than the machine arbor. The soft metal bushing shall not extend beyond the sides of the wheel at the center. Ends of spindles shall be threaded left and right so that the nuts on both ends will tend to tighten as the spindles revolve. Care should be taken that the spindles are arranged to revolve in the proper direction.

Wheel washers of compressible material, such as blotting paper, rubber or leather, not thicker than 0.025 in., shall be fitted between the wheel and its flanges. It is recommended that the wheel washers be slightly larger than the diameter of the flanges used.

When tightening clamping nuts, care shall be taken to tighten them only enough to hold the wheel firmly. Flanges must be frequently inspected to guard against the use of those which have become bent or out of balance. If a tapered wheel has broken, the flanges must be carefully inspected for truth before using with a new wheel. Clamping nuts shall also be inspected.

Minimum Sizes of Machine Spindles in Inches for Various Diameters and Thickness of Grinding Wheels.

Safe Speeds.—A peripheral speed of 5,000 ft. per min. is recommended as the standard operating speed for vitrified and silicate straight wheels, tapered wheels and shapes other than those known as cup and cylinder wheels, which are used on bench, floor, swing frame and other machines for rough grinding. In no case shall a peripheral speed of 6500 ft. be exceeded.

A peripheral speed of 4500 ft. per min. is recommended as the standard operating speed for vitrified and silicate wheels of the cup and cylinder shape, used on bench, floor, swing frame, and other machines for rough grinding. In no case shall 5500 ft. be exceeded.

For elastic, vulcanite and wheels of other organic bonds, the recommendations of individual wheel manufacturers shall be followed.

For precision grinding an operating peripheral speed of 6500 ft. per min. may be recommended.

If a wheel spindle is driven by a variable-speed motor some device shall be used which will prevent the motor from being run at too high speeds. Cone pulleys determining the speed of a wheel should never be used unless belt-locking devices are provided. Machines should be provided with a stop or some method of fixing the maximum size of wheel which may be used, at the speed at which the wheel spindle is running.

If wheels become out of balance through wear and cannot be balanced by truing or dressing, they should be removed from the machine.

A wheel used in wet grinding shall not be allowed to stand partly immersed in the water. The water-soaked portion may throw the wheel dangerously out of balance.

Wheel dressers shall be equipped with rigid guards over the tops of the cutters, to protect operator from flying pieces of broken cutters.

Goggles shall be provided for use of grinding wheel operators where there is danger of eye injury.

Work shall not be forced against a cold wheel, but applied gradually, giving the wheel an opportunity to warm and thereby eliminate possible breakage. This applies to starting work in the morning in grinding rooms which are not heated in winter and new wheels which have been stored in a cold place.

Grinding as a Substitute for Finish Turning in the Lathe.— C. H. Norton (*Trans. Am. Soc. M. E.* 1912) recommends the use of the grinding machine as a substitute for the lathe for many forms of cylindrical work. He advocates the elimination of the finishing cut in the lathe, claiming it is more economical to grind to size immediately after the roughing cut than to finish turn and then grind. For this practice, work should not be turned closer than 1/32 in. of finish diameter, and coarse feeds, often as coarse as four to the inch, should be used. He cites instances where this method produced pieces in 18 minutes, where the former method of rough and finish turning and then grinding to size required 28 ½ minutes. In 1913, the Norton Grinding Co. was using the grinding machine to the exclusion of the lathe for automobile crank-shafts and similar pieces, grinding to size from the rough forging. Instances and methods are shown in *Indust. Eng.*, April, 1913.

Truing and Dressing.—(Norton Co., 1915).—A wheel is trued to make it concentric and to give it an accurate surface. Dressing is to sharpen or renew the surface of the wheel when glazed or loaded. Truing on precision grinding machines is performed by a diamond held rigidly in a fixed tool post — never in the hand. There should always be a liberal supply of lubricant or water flowing on the diamond while the truing is being done. In modern practice, truing is for two other purposes, as well as to make the wheel perfectly true: one for sharpening the wheel to obtain production and the other for dulling the wheel to obtain finish. Truing in rough grinding operations is performed by using a dresser, usually an instrument containing steel-cutting wheels, and in practice the rest is adjusted to form a rigid support for the lugs on the dresser, care being taken to see that the dresser is not caught between the wheel and the rest. In using the dresser to sharpen up the surface of the wheel, the rest is left in its usual close adjustment to the wheel. Truing and dressing are two of the most neglected and least understood features in the proper use of grinding wheels.

Special Wheels.—Rim wheels and iron-center wheels are specialties that require the maker's guarantee and assignment of speed.

Safe Speeds for Grindstones and Emery Wheels.—G. D. Hiscox (*Iron Age*, April 7, 1892), by an application of the formula for centrifugal force in fly-wheels (see Fly-wheels), obtains the figures for strains in grindstones and emery wheels which are given in the tables below. His formulæ are:

Stress per sq. in. of section of a grindstone $= (0.7071D \times N)^2 \times 0.0000795$

Stress per sq. in. of section of an emery wheel $= (0.7071D \times N)^2 \times 0.00010226$

D = diameter in feet, N = revolutions per minute.

He takes the weight of sandstone at 0.078 lb. per cubic inch, and that of an emery wheel at 0.1 lb. per cubic inch; Ohio stone weighs about 0.081 lb. and Huron stone about 0.089 lb. per cubic inch. The Ohio stone will bear a speed at the periphery of 2500 to 3000 ft. per min., which latter should never be exceeded. The Huron stone can be trusted up to 4000 ft., when properly clamped between flanges and not excessively wedged in setting. Apart from the speed of grindstones as a cause of bursting, probably the majority of accidents have really been caused by wedging them on the shaft and over-wedging to true them. The holes being square, the excessive driving of wedges to true the stones starts cracks in the corners that eventually run out until the centrifugal strain becomes greater than the tenacity of the remaining solid stone. Hence the necessity of great caution in the use of wedges, as well as the holding of large quick-running stones between large flanges and leather washers.

The *Iron Age* says the strength of grindstones when wet is reduced 40 to 50%. A section of a stone soaked all night in water broke at a stress of 80 lb. per sq. in. A section of the same stone dry broke at 146 lb. per sq. in. A better quality stone broke at stresses of 186 and 116 lb. per sq. in. when dry and wet respectively.

Strains in Grindstones.

LIMIT OF VELOCITY AND APPROXIMATE ACTUAL STRAIN PER SQUARE INCH OF SECTIONAL AREA FOR GRINDSTONES OF MEDIUM TENSILE STRENGTH.

Diameter.	Revolutions per Minute.						
	100	150	200	250	300	350	400
feet.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.
2	1.58	3.57	6.35	9.93	14.30	18.36	25.42
2 1/2	2.47	5.57	9.88	15.49	22.29	28.64	39.75
3	3.57	8.04	14.28	22.34	32.16	....	....
3 1/2	4.86	10.93	19.44	30.38	....	....	....
4	6.35	14.30	27.37	....	....	....	....
4 1/2	8.04	18.08	32.16	Approximate breaking strain ten times the strain for size opposite the bottom figure in each column.			
5	9.93	22.34	....				
6	14.30	32.17	....				
7	19.44	....	....				

The figures at the bottom of columns designate the limit of velocity (in revolutions per minute at the head of the columns) for stones of the diameter in the first column opposite the designating figure.

A general rule of safety for any size grindstone that has a compact and strong grain is to limit the peripheral velocity to 47 feet per second.

Joshua Rose (Modern Machine-shop Practice) says: The average circumferential speed of grindstones in workshops may be given as follows:

For grinding machinists' tools, about.......900 feet per minute.
" " carpenters' " " ....600 " " ".

The speeds of stones for file-grinding and other similar rapid grinding is thus given in the "Grinders' List."

Diam. ft.........	8	7 1/2	7	6 1/2	6	5 1/2	5	4 1/2	4	3 1/2	3

TAPER BOLTS, PINS, REAMERS, ETC.

Standard Steel Mandrels. (The Pratt & Whitney Co.) — These mandrels are made of tool-steel, hardened, and ground true on their centers. Centers are also ground to true 60 degree cones. The ends are of a form best adapted to resist injury likely to be caused by driving. They are slightly taper. Sizes, 1/4 inch diameter by 3 3/4 inches long to 4 inches diameter by 17 inches long, diameters advancing by 16ths.

Taper Bolts for Locomotives. — Bolt-threads, U. S. Standard, except stay-bolts and boiler-studs, V-threads, 12 per inch; valves, cocks, and plugs, V-threads, 14 per inch, and 1/8-inch taper per 1 inch. Standard bolt taper 1/16 inch per foot.

Taper Reamers.—The Pratt & Whitney Co. makes standard taper reamers for locomotive work taper 1/16 inch per foot from 1/4 inch diameter; 4-inch length of flute to 2-inch diameter, 18-inch length of flute, diameters advancing by 16ths and 32ds. P. & W. Co.'s standard taper pin reamers taper 1/4 inch per foot, are made in 15 sizes of diameters, 0.135 to 1.250 inches; length of flute, 1 7/16 inches to 14 inches.

Brown & Sharpe Mfg. Co. publishes (*Machy's* Data Sheets) a list of 18 sizes of tapers ranging from 0.20 in. to 3 in. diam. at the small end; taper 0.5 in. to 1 ft., except No. 10, which is 0.5161 in. per ft.

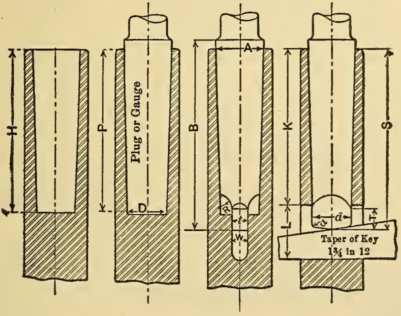

FIG. 216.—Morse Tapers. See table above.

The Jarno Taper is 0.05 inch per inch = 0.6 inch per foot. The number of the taper is its diameter in tenths of an inch at the small end, in eighths of an inch at the large end, and the length in halves of an inch. Thus, No. 3 Jarno taper is 1 1/2 inches long, 0.3 inch diameter at the small end and 3/8 inch diameter at the large end.

PUNCHES AND DIES, PRESSES, ETC.

Clearance between Punch and Die. — For computing the amount of clearance that a die should have, or, in other words, the difference in size between die and punch, the general rule is to make the diameter of die-hole equal to the diameter of the punch, plus 2/10 the thickness of the plate. Or, $D = d + 0.2t$, in which D = diameter of die-hole, d = diameter of punch, and t = thickness of plate. For very thick plates some mechanics prefer to make the die-hole a little smaller than called for by the above rule. For ordinary boiler-work the die is made from 1/10 to 3/10 of the thickness of the plate larger than the diameter of the punch; and some boiler-makers advocate making the punch fit

* Lengths vary by 1/4 inch each size.

† Taken 1/2 inch from extreme end. Each size overlaps smaller one about 1/2 inch.

the die accurately. For punching nuts, the punch fits in the die. (*Am. Mach.*)

The clearance between the punch and die when blanking, perforating and forming flat thin stock of different materials in the power press for light machine parts such as typewriters, adding machines, etc., are shown in the following table compiled by E. Dean (*Am. Mach.*, May 4, 1905). In using the table, the class of work to be done must be considered. For perforating work, the punch is made to the desired size, and the clearance is made on the die. For blanking, the die is of the desired size and the clearance is obtained by making the punch smaller.

Kennedy's Spiral Punch. (The Pratt & Whitney Co.) — B. Martell, Chief Surveyor of Lloyd's Register, reported tests of Kennedy's spiral punches in which a 7/8-inch spiral punch penetrated a 5/8-inch plate at a pressure of 22 to 25 tons, while a flat punch required 33 to 35 tons. Steel boiler-plates punched with a flat punch gave an average tensile strength of 58,579 pounds per square inch, and an elongation in two inches across the hole of 5.2 per cent, while plates punched with a spiral punch gave 63,929 pounds, and 10.6 per cent elongation.

The spiral shear form is not recommended for punches for use in metal of a thickness greater than the diameter of the punch. This form is of greatest benefit when the thickness of metal worked is less than two thirds the diameter of punch.

Size of Blanks used in the Drawing-press. — Oberlin Smith (*Jour. Frank. Inst.*, Nov. 1886) gives three methods of finding the size of blanks. The first is a tentative method, and consists simply in a series of experiments with various blanks, until the proper one is found. This is for use mainly in complicated cases, and when the cutting portions of the die and punch can be finally sized after the other work is done. The second method is by weighing the sample piece, and then, knowing the weight of the sheet metal per square inch, computing the diameter of a piece having the required area to equal the sample in weight. The third method is by computation, and the formula is $x = \sqrt{d^2 + 4dh}$ for a sharp-cornered cup, where x = diameter of blank, d = diameter of cup, h = height of cup. For a round-cornered cup where the corner is small, say radius of corner less than 1/4 height of cup, the formula is $x = (\sqrt{(d^2 + 4\,dh)} - r$, about; r being the radius of the corner. This is based upon the assumption that the thickness of the metal is not to be altered by the drawing operation.

Pressure attainable by the Use of the Drop-press. (R. H. Thurston, *Trans. A. S. M. E.*, v, 53.) — A set of copper cylinders was prepared, of pure Lake Superior copper; they were subjected to the action of presses of different weights and of different heights of fall. Companion specimens of copper were compressed to exactly the same amount, and measures were obtained of the loads producing compression, and of the amount of work done in producing the compression by the drop. Comparing one with the other it was found that the work done with the hammer was 90 per cent. of the work which should have been done with perfect efficiency. That is to say, the work done in the testing-machine was equal to 90 per cent of that due the weight of the drop falling the given distance.

Formula: Mean pressure in pounds $= \dfrac{\text{Weight of drop} \times \text{fall} \times \text{efficiency}}{\text{compression}}$.

For pressures per square inch, divide by the mean area opposed to crushing action during the operation.

Similar experiments on Bessemer steel plugs by A. W. Moseley and J. L. Bacon (*Trans. A. S. M. E.*, xxvii, 605) indicated an efficiency for the drop hammer of about 70 per cent.

An extensive series of experiments is reported in *Am. Mach.*, Mar. 10, 1910. These were made by W. T. Sears, and consisted of the compression of lead plugs under a falling weight, ranging from 20 to 200 lb., dropped from heights ranging up to 360 in. The tests showed that after a certain velocity of the falling weight had been attained, the speed had little effect on the compression of the plug. This speed was fixed at 10 ft. per second, but its exact value is uncertain.

Flow of Metals. (David Townsend, *Jour. Frank. Inst.*, March, 1878.) — In punching holes 7/16-inch diameter through iron blocks 1 3/4 inches thick, it was found that the core punched out was only 1 1/16 inches thick, and its volume was only about 32 per cent of the volume of the hole. Therefore, 68 per cent of the metal displaced by punching the hole flowed into the block itself, increasing its dimensions.

Fly-wheels for Presses, Punches, Shears, etc.—The function of the fly-wheel on punching and other machinery in which action is intermittent is to store up energy during that portion of the stroke when no work is being done and to give it out during the period of actual working. The giving up of energy is accompanied by a reduction in the velocity of the fly-wheel.

Notation:

E = total energy in the wheel at maximum velocity, ft.-lb.
E_1 = energy given out by the wheel during speed reduction, ft.-lb.
v_1 = initial velocity of the center of gravity of fly-wheel rim, ft. per sec.
v_2 = velocity of center of gravity of fly-wheel rim at end of period in which energy is given out.
$H.P.$ = horse-power required.
N = strokes of press or shear per min.
T = time required per stroke, secs.
t = time required for actual cutting of metal per stroke, secs.
w = weight of fly-wheel rim, lb.
d = diameter of rim at center of gravity.
R = r.p.m. of fly-wheel at initial velocity.
c and c_1 = constants.
a = width of fly-wheel rim, in.
b = depth of fly-wheel rim, in.
y = ratio of depth to width of rim.
g = acceleration due to gravity = 32.2

Formulæ:

$$E = \frac{w\,v_1^2}{2\,g} = \frac{w\,v_1^2}{64.4}$$

$$E_1 = \frac{(v_1^2 - v_2^2) \times W}{64.4}$$

$$w = \frac{E_1 \times 64.4}{v_1^2 - v_2^2}$$

$$v = \frac{2\,\pi\,R\,N}{60}$$

A simplified method for calculating fly-wheels for punches and shears is given in *Machinery's Handbook*, p. 289. Using the notation as above,

$$H.P. = \frac{E\,N}{33{,}000} = \frac{E}{T \times 550}\,;\ E_1 = E\left(1 - \frac{t}{T}\right);$$

$$W = \frac{E_1}{c\,D^2\,R^2}\,;\ a = \sqrt{\frac{1.22\,W}{12\,Dy}}\,;\ b = a\,y.$$

For cast-iron fly-wheels with maximum stresses of 1000 lb. per sq. in.; $W = c_1 E_1$; $R = 1940 \div D$.

VALUES OF c AND c_1.

Per Cent Reduction.	2 1/2	5	7 1/2	10	15	20
c	0.00000213	0.00000426	0.00000617	0.00000810	0.00001180	0.00001535
c_1	0.1250	0.0625	0.0432	0.0328	0.0225	0.0173

For belt-driven machines, the limiting low velocity v_2 is the speed at which the belt will run off the pulley. Wilfred Lewis, *Trans. A. S. M. E.*, vol. vii, shows that this takes place when the slip exceeds 20 per cent of the belt speed. This gives a limiting condition for belt drives of punches and shears of $W = 180 \left(\frac{E}{v_1^2}\right)$

FORCING, SHRINKING AND RUNNING FITS.

Forcing Fits of Pins and Axles by Hydraulic Pressure. — A 4-inch axle is turned 0.015 inch diameter larger than the hole into which it is to be fitted. They are pressed on by a pressure of 30 to 35 tons. (Lecture by Coleman Sellers, 1872.)

For forcing the crank-pin into a locomotive driving-wheel, when the pinhole is perfectly true and smooth, the pin should be pressed in with a pressure of 6 tons for every inch of diameter of the wheel fit. When the hole is not perfectly true, which may be the result of shrinking the tire on the wheel center after the hole for the crank-pin has been bored, or if the hole is not perfectly smooth, the pressure may have to be increased to 9 tons for every inch of diameter of the wheel-fit. (*Am. Machinist.*)

* Tires on.			8	65-70	102-110	9 1/2	95	135-143			

CRANK AXLES.
All crank discs, 110–150 tons.
All center webs 150–200 tons.

NOTE.—In mounting wheels and crank pins, care should be taken to see that for at least two-thirds of the wheel fit the pressure required shall be between the maximum and minimum limits given in the table, or if only one pressure is shown in the table, the actual pressure required should be as near as possible to that pressure.

In mounting driving wheels with tires on, the maximum pressures given in the tables or even 10 per cent higher pressure than the maximum pressure may be used.

Shrinkage of Tires.—Allow 1/64 inch for each 12 in. in diameter.

Ground Fits for Machine Parts.—The practice of the Brown & Sharpe Mfg. Co. in tolerances and allowances for ground fits is given in a paper by W. A. Viall (*Trans. A. S. M. E.*, xxxii) from which the table below has been prepared. The limits given can be recommended for satisfactory commercial work in the production of machine parts and may be followed under ordinary conditions. In special cases it may be necessary to vary slightly from the tables.

Running Fits.—Wm. Sangster (*Am. Mach.*, July 8, 1909) gives the practice of different manufacturers as follows:

An electric manufacturing Co. allows a clearance of 0.003 to 0.004 in. for shafts 1 1/2 to 2 1/4 in. diam.; 0.003 to 0.006 for 2 1/2 in.; 0.004 to 0.006 for

$2^3/_4$ to $3^1/_2$ ins.; 0.005 to 0.007 in. for 4 and $4^1/_2$ ins.; 0.006 to 0.008 in. for 5 ins.; 0.009 to 0.011 in. for 6 ins. Dodge Mfg. Co. allows from $^1/_{64}$ for 1-in. ordinary bearings to a little over $^1/_{32}$ in. for 6-in. Clutch sleeves, 0.008 to 0.015 in.; loose pulleys as close as 0.003 in. in the smaller sizes, and about $^1/_{64}$ in. on a $2^1/_2$-in. hole.

Watt Mining Car Wheel Co. allows $^1/_{16}$ in. for all sizes of wheels, and $^1/_{16}$ in. end play. A large fan-blower concern allows 0.005 to 0.01 in. on fan journals from $^9/_{16}$ to $2\,^7/_{16}$ ins.

Limits of Diameters for Fits. C. W. Hunt Co. (*Am. Mach.*, July 16, 1903.) — For parallel shafts and bushings (shafts changing): d = diam. in ins.

Shafts: Press fit, $+ 0.001\,d + (0 \text{ to } 0.001 \text{ in.})$. Drive fit, $+ 0.0005\,d + (0. \text{ to } 0.001 \text{ in.})$.
Shafts: Hand fit, + 0.001 to 0.002 in. for shafts 1 to 3 in.; 0.002 to 0.003 in. for 4 to 6 in.; 0.003 to 0.004 in. for 7 to 10 in.
Holes: all fits 0 to − 0.002 in. for 1 to 3 in.; 0 to − 0.003 in. for 4 to 6 in.; 0 to − 0.004 in. for 7 to 10 in.

Parallel journals and bearings (journals changing):

Close fit $- 0.001\,d + (0.002 \text{ to } 0.004 \text{ in.})$; Free fit $- 0.001\,d + (0.007 \text{ to } 0.01 \text{ in.})$; Loose fit, $- 0.003\,d + (0.02 \text{ to } 0.025)$. Limits of diameters for taper shaft and bushings (holes changing). Shaft turned to standard taper $^3/_{16}$ in. per ft., large end to nominal size ± 0.001 in. Holes are reamed until the large end is small by from $0.001\,d + 0.004$ to 0.005 in. for press fit, from $0.0005\,d + 0.001$ in. for drive fit, and from 0 to 0.001 in. for hand fit. In press fits the shaft is pressed into the hole until the true sizes match, or $^1/_{16}$ in. for each $^1/_{1000}$ in. that the hole is small. The above formulæ apply to steel shafts and cast-iron wheels or other members.

Shaft Allowances for Electrical Machinery.—The General Electric Co. (1915) gives the following table of allowances for sliding and press fits.

Nominal Diam., In.	Sliding Fit.	Commutator and Split Hub.	Press Fit for Armature Spider Solid Steel.	Press Fit for Armature Spider Solid Cast Iron.	Press Fit for Coupling.	Shrink Fit.
2	−0.0015	+0.0005	+0.00075	+0.0015	+0.00175	+0.0025

44	− .0095	+ .002	+ .005	+ .0085	+ .0105	+ .0145
48	− .010	+ .002	+ .0055	+ .009	+ .011	+ .015

Pressure Required for Press Fits. (*Am. Mach.*, March 7, 1907.) — The following approximate formulæ give the pressures required for press fits of cranks and crank-pins, as used by an engine-building firm. P = total pressure on ram, tons; D = diameter inches.

Crank fits up to D = 10.	$P = 9.9\,D - 14.$
Crank fits D = 12 to 24.	$P = 5\,D + 40.$
Straight crank-pins.	$P = 13\,D.$
Taper crank-pins.	$P = 14\,D - 7.$

The allowance for cranks and straight pins is 0.0025 inch per inch of diameter Taper cranks, taper $^1/_{16}$ inch per inch, are fitted on the lathe to within $^1/_8$ inch of shoulder and then forced home.

Stresses due to Force and Shrink Fits. — S. H. Moore, *Trans. A. S. M. E.*, vol. xxiv, gives the following allowances for different fits:

For shrinkage fits, $d = (17/16\,D + 0.5) \div 1000$. For forced fits, $d = (2\,D + 0.5) \div 1000$. For driven fits, $d = (1/2\,D + 0.5) \div 1000$. d = allowance or the amount the diameter of the shaft exceeds the diameter of the hole in the ring and D = nominal diameter of the shaft. A. L. Jenkins, *Eng. News*, Mar. 17, 1910, says the values obtained from the formula for forced fits are about twice as large as those frequently used in practice, and in many cases they lead to excessive stresses in the ring. He calculates from Lamé's formula for hoop stress in a ring subjected to internal pressure the relation between the stress and the allowance for fit, and deduces the following formulæ.

$S_{h_1} = 15{,}000{,}000\,d \div (k + 0.6)$; $S_{h_2} = 15{,}000{,}000\,d \div (1 + 0.6/k)$; for a cast-iron ring on a steel shaft.
$S_{h_1} = 30{,}000{,}000\,d \div (1 + k)$; $S_{h_2} = 30{,}000{,}000\,d \div (1 + 1/K)$; for a steel ring on a steel shaft.
S_{h_1} = radial unit pressure between the surfaces; S_{h_2} = unit tensile or hoop stress in the ring;
d = allowance per inch of diameter, K a constant whose value depends on t, the thickness, and r, the radius of the ring, as follows.

Values of $t \div r$,
0.4 0.5 0.6 0.7 0.8 0.9 1.0 1.25 1.5 1.75 2.0 3.0
Values of K,
3.083 2.600 2.282 2.058 1.892 1.766 1.666 1.492 1.380 1.300 1.250 1.133.

The allowances for forced and shrinkage fits should be based on the stresses they produce, as determined by the above formula, and not on the diameter of the shaft.

Force Required to Start Force and Shrink Fits. (*Am. Mach.*, Mar. 7, 1907.) — A series of experiments was made at the Alabama Polytechnic Institute on spindles 1 in. diam. pressed or shrunk into cast-iron disks 6 in. diam., $1\frac{1}{4}$ in. thick. The disks were bored and finished with a reamer to 1 in. diam. with an error believed not to exceed 0.00025 in. The shafts were ground to sizes 0.001 to 0.003 in. over 1 in. Some of the spindles were forced into the disks by a testing machine, the others had the disks shrunk on. Some of each sort were tested by pulling the spindle from the disk in the testing machine, others by twisting the disk on the spindle,. The force required to start the spindle in the twisting tests was reduced to equivalent force at the circumference of the spindle, for comparison with the tension tests. The results were as follows: D = diam. of spindle; F = force in lbs.:

Force Fits, Tension.			Force Fits, Torsion.			Shrink Fits, Tension.			Shrink Fits, Torsion.		
D	F, lbs.	Per sq. in.	D	F, lbs.	Per sq. in.	D	F, lbs.	Per sq. in.	D	F, lbs.	Per sq. in.

KEYS.

Formulæ for Flat and Square Keys.—Great divergence exists in the dimensions of square and flat keys as given by various authorities. The following are the formulæ in common use:

Notation.—D = diameter of shaft; w = width of key; t = thickness of key; l = length of key, all dimensions being in inches.

E. G. Parkhurst's rule: $w = 1/8\,D$; $t = 1/9\,D$; taper $1/8$ in. per ft.
Michigan saw-mill practice: $w = 1/4\,D$; $t = w$.
J. T. Hawkins's rule: $w = 1/3\,D$; $t = 1/4\,D$.
Machinery's Handbook, rule 1: $w = 1/4\,D$; $t = 1/6\,D$; $l = 1.5\,D$.
Machinery's Handbook, rule 2: $w = 3/16\,D + 1/16$; $t = 1/8\,D + 1/8$; $l = 0.3\,D^2 \div t$.

For splines or feather keys interchange w and t.

F. W. Halsey ("Handbook for Machine Designers and Draftsmen") says: The common driven key for securing a crank or gear to a shaft is commonly made with a width of $1/4\,D$ up to about a 4-in. shaft, about $1\,3/8$ in. for a 6-in., $1\,3/4$ in. for an 8-in., and $2\,1/4$ in. for a 10-in. shaft. The depth should be from $5/8\,w$ to $3/4\,w$. If the work is at all severe the length should be at least 1.5 D. The taper is commonly $1/8$ in. per ft.

Unwin ("Elements of Machine Design") gives: Width $= 1/4\,D + 1/8$ in. Thickness $= 1/8\,D + 1/8$ in. When wheels or pulleys transmitting only a small amount of power are keyed on large shafts, he says, these dimensions are excessive. In that case, if H.P. = horse-power transmitted by the wheel or pulley, N = r.p.m., P = force acting at the circumference, in pounds, and R = radius of pulley in inches, take

$$D = \sqrt[3]{\frac{100\text{ H.P.}}{N}} \text{ or } \sqrt{\frac{PR}{630}}.$$

John Richards, in an article in *Cassier's Magazine*, writes as follows: There are two kinds or systems of keys, both proper and necessary, but widely different in nature. 1. The common fastening key, usually made in width one fourth of the shaft's diameter, and the depth five eighths to one-third the width. These keys are tapered and fit on all sides, or, as it is commonly described, "bear all over." They perform the double function in most cases of driving or transmitting and fastening the keyed-on member against movement endwise on the shaft. Such keys, when properly made, drive as a strut, diagonally from corner to corner.

2. The other kind or class of keys are not tapered and fit on their sides only, a slight clearance being left on the back to insure against wedge action or radial strain. These keys drive by shearing strain.

For fixed work where there is no sliding movement such keys are commonly made of square section, the sides only being planed, so the depth is more than the width by so much as is cut away in finishing or fitting.

For sliding bearings, as in the case of drilling-machine spindles, the depth should be increased, and in cases where there is heavy strain there should be two keys or feathers instead of one.

The following tables are from proportions adopted in practical use.

Flat keys, as in the first table, are employed for fixed work when the parts are to be held not only against torsional strain, but also against movement endwise; and in case of heavy strain the strut principle being the strongest and most secure against movement when there is strain each way, as in the case of engine cranks and first movers generally. The objections to the system for general use are, straining the work out of truth, the care and expense required in fitting, and destroying the evidence of good or bad fitting of the keyed joint. When a wheel or other part is fastened with a tapering key of this kind there is no means of knowing whether the work is well fitted or not. For this reason such keys are not employed by machine-tool-makers, and in the case of accurate work of any kind, indeed, cannot be, because of the wedging strain, and also the difficulty of inspecting completed work.

I. DIMENSIONS OF FLAT KEYS, IN INCHES.

Diam. of shaft....	1	1 1/4	1 1/2	1 3/4	2	2 1/2	3	3 1/2	4	5	6	7	8

Depth of keys.....	3/16	1/4	5/16	3/8	7/16	1/2	9/16	5/8	3/4

III. DIMENSIONS OF SLIDING FEATHER KEYS, IN INCHES.

Diameter of shaft..	1 1/4	1 1/2	1 3/4	2	2 1/4	2 1/2	3	3 1/2	4	4 1/2
Breadth of keys...	1/4	1/4	5/16	5/16	3/8	3/8	1/2	9/16	9/16	5/8
Depth of keys.....	3/8	3/8	7/16	7/16	1/2	1/2	5/8	3/4	3/4	7/8

Depth of Key Seats.—The depth of a flat or square key is equally divided between the shaft and the hub. The depth to which a milling cutter is sunk into the shaft in milling a keyway is equal to one-half the depth of the key plus the height of the arc projecting above the intersection of the side of the keyway with the circumference of the shaft. This height can be calculated from the formula

$$h = r - \sqrt{r^2 - (1/2\, w)^2}$$

in which r is the radius of the shaft, h the height of the arc, and w the width of the key.

The Lewis Key.—The disadvantage of the ordinary flat key is that it must be carefully fitted. A key fitting tight on top and bottom of the keyway drives partly by friction. If fitted only on the sides of the keyway it exerts a prying action on the hub and shaft, and is subjected to severe bending and shearing stresses. Square or flat keys should fit tight on all four sides, but in practice this is prohibitive on account of the expense. To avoid the difficulty inherent in ordinary flat keys, the Lewis key shown in Fig. 217 was devised by Wilfred Lewis. It is subject to compression only, but is expensive to fit.

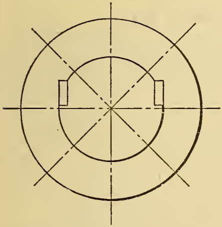

FIG. 217.

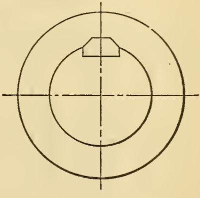

FIG. 218.

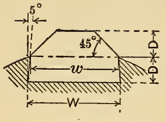
The Barth Key. (Fred. Oyen, *Am. Mach.*, Nov. 14, 1907, and Feb. 20, 1908.)—The key shown in Fig. 218 was devised by Carl G. Barth to combine the advantages of the Lewis key with those of the ordinary rectangular key. The Barth key is rectangular with one-half of both sides bevelled at 45°. The key does not need to fit tightly, as pressure tends to drive it into its seat. There is no tendency to turn it, and the only stress to which it is subject is compression. This key has been used in many cases as a feather to replace rectangular feather keys which have given trouble. It has found wide application as a feather key in drill sockets and drill shanks, reamers, etc., which are commonly driven with a tang.

Reducing sockets for drill presses are fitted with a Barth key dovetailed inside and a similar keyway on the outside. No. 1 Morse taper shank has a keyway for No. 1 Barth key and fits into a No. 1 reducing socket. No. 2 shank has No. 2 Morse taper and a keyway for No. 2 Barth key, etc. Dimensions of the various sizes of the Barth key are shown in the following table:

Dimensions of Dovetailed Barth Keys.



No. of Barth Key.	No. of Morse Taper in Which Used.	w, In.	W, In.	D, In.
1	1	1/8	0.132	5/128
2	2	5/32	0.165	3/64
3	3	3/16	0.199	1/16
4	4	1/4	0.264	5/64
5	5	5/16	0.329	3/23

The Barth key has been adapted to a complete line of standard taper sockets, shanks, driving keys, holdback keys, drifts, adapters, and reducers at the Watertown Arsenal. The standards, which cover both Brown & Sharpe and Morse tapers are given in *Am. Mach.*, Dec. 24, 1914.

Detrick & Harvey Keys. (*Am. Mach.*, Feb. 11, 1915.)—The Detrick & Harvey Machine Co., Baltimore, uses square keys of dimensions shown in Fig. 219 and the following table. Although these are smaller than the square key generally used, there is no case known in which one of them has sheared off. The dimension C is for setting the key, and the dimension B gives the diameter across the corners of the key. All dimensions are in inches.

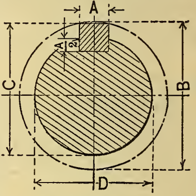


Fig. 219.

Dimensions of Detrick & Harvey Keys.

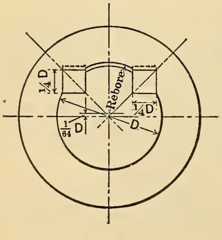

Fig. 220.

The Kennedy Key. — The Kennedy key, largely used in rolling mill work, is shown in Fig. 220. In these keys $w = t = 1/4\ D$. They are tapered 1/8 in. per ft. on top, while the sides are a neat fit. The keys are so set in the shaft that diagonals through them intersect at the axis of the shaft. The hub is bored for a press fit and then is rebored eccentrically about $1/_{64}\ D$ off center. The keyways are cut in the eccentric side. General practice is to use single keys for diameters up to and including 6 in. where the torque is constant and the power transmitted always in one direction. For shafts above 6 in. diameter double keys should be used, and if the torque is intermittent and in alternate directions, double keys should be used down to shaft diameters of 4 in.

The Nordberg Key.—The Nordberg Mfg. Co. has adopted for the ends of shafts round keys shown in Fig. 221. The advantages of this key are: No tendency toward deformation; they are a driven fit in the direction of the shear; they are always in true shear and are cheaper than the square key. In manufacturing a hole *A* is drilled in the joint and next a hole *B* as large as the size of the keyway will admit is drilled in the shaft in order to avoid the tendency of the drill used for drilling the keyway to size to crowd into the soft cast iron. In the table the reamer diameters given are of the small end. The taper is 1/16 in. per ft., measured on the diameter.

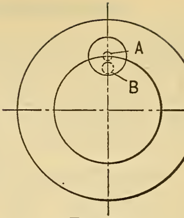

Fig. 221.

The Woodruff Key.—The Woodruff key shown in Fig. 222 is extensively used in machine construction. Dimensions are given in the following table. The key should project above the shaft a distance equal to one-half the thickness. For ordinary practice medium-sized keys should be used:

Gib Keys.—"Machinery's Handbook" gives the following formulæ for dimensions of gib keys. (See Fig. 223). All dimensions are in inches. D = diameter of shaft; w = width of key; T = thickness of key, large end; S = safe shearing strength of material in key; G = length of gib; h = projection of gib above top of key.

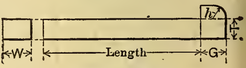

FIG. 223.

$w = 1/4\,D$ up to 6 in.; over 6 in. $w = 0.211\,D$.

$T = 1/6\,D$ up to 6 in.; over 6 in. $T = 1/8\,D$. Minimum value 3/16 in. $G = w$.

Length = length of hub + 1/2 in. Taper 1/8 in. per ft.

Safe twisting moment per in. of length of key = $1/2\,D \times W \times S$.

Keyways for Milling Cutters.—For keyways for milling cutters see p. 1277.

HOLDING-POWER OF KEYS AND SET-SCREWS.

Tests of the Holding-power of Set-screws in Pulleys. (G. Lanza, *Trans. A. S. M. E.*, x, 230.)—These tests were made by using a pulley fastened to the shaft by two set-screws with the shaft keyed to the holders; then the load required at the rim of the pulley to cause it to slip was determined, and this being multiplied by the number 6.037 (obtained by adding to the radius of the pulley one-half the diameter of the wire rope, and dividing the sum by twice the radius of the shaft, since there were two set-screws in action at a time) gives the holding-power of the set-screws. The set-screws used were of wrought iron, 5/8 of an inch in diameter, and ten threads to the inch; the shaft used was of steel and rather hard, the set-screws making but little impression upon it. They were set up with a force of 75 pounds at the end of a ten-inch monkey-wrench. The set-screws used were of four kinds, marked respectively A, B, C, and D. The results were as follows:

A, ends perfectly flat, 9/16-in. diam.	1412 to 2294 lbs.; average	2064.
B, radius of rounded ends about 1/2-in.	2747 to 3079 lbs.; average	2912.
C, radius of rounded ends about 1/4-in.	1902 to 3079 lbs.; average	2573.
D, ends cup-shaped and case-hardened	1962 to 2958 lbs.; average	2470.

REMARKS. — A. The set-screws were not entirely normal to the shaft; hence they bore less in the earlier trials, before they had become flattened by wear.

B. The ends of these set-screws, after the first two trials, were found to be flattened, the flattened area having a diameter of about 1/4 inch.

C. The ends were found, after the first two trials, to be flattened, as in B.

D. The first test held well because the edges were sharp, then the holding-power fell off till they had become flattened in a manner similar to B, when the holding-power increased again.

Tests of the Holding-power of Keys. (Lanza.) — The load was applied as in the tests of set-screws, the shaft being firmly keyed to the holders. The load required at the rim of the pulley to shear the keys was determined, and this, multiplied by a suitable constant, determined in a similar way to that used in the case of set-screws, gives us the shearing strength per square inch of the keys.

The keys tested were of eight kinds, denoted, respectively, by the letters A, B, C, D, E, F, G and H, and the results were as follows: A, B, D, and F, each 4 tests; E, 3 tests; C, G, and H, each 2 tests.

A, Norway iron, $2'' \times 1/4'' \times 15/32''$,	40,184 to	47,760 lbs.; average,	42,726
B, refined iron, $2'' \times 1/4'' \times 15/32''$,	36,482 to	39,254 lbs.; average,	38,059
C, tool steel, $1'' \times 1/4'' \times 15/32''$,	91,344 &	100,056 lbs.;	
D, mach'y steel, $2'' \times 1/4'' \times 15/32''$	64,630 to	70,186 lbs.; average,	66,875
E, Norway iron, $1\,1/3'' \times 3/8'' \times 7/16''$	36,850 to	37,222 lbs.; average,	37,036
F, cast-iron, $2'' \times 1/4'' \times 15/32''$,	30,278 to	36,944 lbs.; average,	33,034
G, cast-iron, $1\,1/3'' \times 3/8'' \times 7/16''$,	37,222 &	38,700.	
H, cast-iron, $1'' \times 1/2'' \times 7/16''$,	29,814 &	38,978.	

The first dimension is the length, the second the width and the third the height.

In A and B some crushing took place before shearing. In E, the keys, being only 7/16 inch deep, tipped slightly in the key-way. In H, in the first test, there was a defect in the key-way of the pulley.

DYNAMOMETERS.

Dynamometers are instruments used for measuring power. They are of several classes, as: 1. Traction dynamometers, used for determining the power required to pull a car or other vehicle, or a plow or harrow. 2. Brake or absorption dynamometers, in which the power of a rotating shaft or wheel is absorbed or converted into heat by the friction of a brake; and 3. Transmission dynamometers, in which the power in a rotating shaft is measured during its transmission through a belt or other connection to another shaft, without being absorbed.

Traction Dynamometers generally contain two principal parts: (1) A spring or series of springs, through which the pull is exerted, the extension of the spring measuring the amount of the pulling force; and (2) a paper-covered drum, rotated either at a uniform speed by clockwork, or at a speed proportional to the speed of the traction, through gearing, on which the extension of the spring is registered by a pencil. From the average height of the diagram drawn by the pencil above the zero-line the average pulling force in pounds is obtained, and this multiplied by the distance traversed, in feet, gives the work done, in foot-pounds. The product divided by the time in minutes and by 33,000 gives the horse-power.

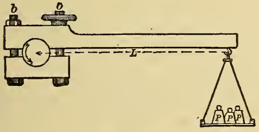

FIG. 224.

The Prony brake is the typical form of absorption dynamometer. (See Fig. 224, from Flather on Dynamometers.)

Primarily this consists of a lever connected to a revolving shaft or pulley in such a manner that the friction induced between the surfaces in contact will tend to rotate the arm in the direction in which the shaft revolves. This rotation is counterbalanced by weights P, hung in the scale-pan at the end of the lever. In order to measure the power for a given number of revolutions of pulley, we add weights to the scale-pan and screw up on bolts b,b, until the friction induced balances the weights and the lever is maintained in its horizontal position while the revolutions of the shaft per minute remain constant.

For small powers the beam is generally omitted — the friction being measured by weighting a band or strap thrown over the pulley. Ropes or cords are often used for the same purpose.

Instead of hanging weights in a scale-pan, as in Fig. 224, the friction may be weighed on a platform-scale; in this case, the direction of rotation being the same, the lever-arm will be on the opposite side of the shaft.

In a modification of this brake, the brake-wheel is keyed to the shaft, and its rim is provided with inner flanges which form an annular trough for the retention of water to keep the pulley from heating. A small stream of water constantly discharges into the trough and revolves with the pulley—the centrifugal force of the particles of water overcoming the action of gravity; a waste-pipe with its end flattened is so placed in the trough that it acts as a scoop, and removes all surplus water. The brake consists of a flexible strap to which are fitted blocks of wood forming the rubbing-surface; the ends of the strap are connected by an adjustable bolt-clamp, by means of which any desired tension may be obtained.

The horse-power or work of the shaft is determined from the following:

Let W = work of shaft, equals power absorbed, per minute;
P = unbalanced pressure or weight in pounds, acting on lever-arm at distance L;
L = length of lever-arm in feet from center of shaft;
V = velocity of a point in feet per minute at distance L, if arm were allowed to rotate at the speed of the shaft;
N = number of revolutions per minute;
H.P. = horse-power.

Then will $W = PV = 2\,\pi LNP$.

Since H.P. $= PV \div 33{,}000$, we have H.P. $= 2\,\pi LNP \div 33{,}000$.

If $L = 33 \div 2\,\pi$, we obtain H.P. $= NP \div 1000$. $33 \div 2\,\pi$ is practically 5 ft. 3 in., a value often used in practice for the length of arm.

If the rubbing-surface be too small, the resulting friction will show great irregularity — probably on account of insufficient lubrication — the jaws being allowed to seize the pulley, thus producing shocks and sudden vibrations of the lever-arm.

Soft woods, such as bass, plane-tree, beech, poplar, or maple, are all to be preferred to the harder woods for brake-blocks. The rubbing-surface should be well lubricated with a heavy grease.

The Alden Absorption-dynamometer. (G. I. Alden, *Trans. A. S. M. E.*, vol. xi, 958; also xii, 700 and xiii, 429.) — This dynamometer is a friction-brake, which is capable in quite moderate sizes of absorbing large powers with unusual steadiness and complete regulation. A smooth cast-iron disk is keyed on the rotating shaft. This is inclosed in a cast-iron shell, formed of two disks and a ring at their circumference, which is free to revolve on the shaft. To the interior of each of the sides of the shell is fitted a copper plate, inclosing between itself and the side a water-tight space. Water under pressure from the city pipes is admitted into each of these spaces, forcing the copper plate against the central disk. The chamber inclosing the disk is filled with oil. To the outer shell is fixed a weighted arm, which resists the tendency of the shell to rotate with the shaft, caused by the friction of the plates against the central disk. Four brakes of this type, 56 in. diam., were used in testing the experimental locomotive at Purdue University (*Trans. A. S. M. E.*, xiii, 429). Each was designed for a maximum moment of 10,500 foot-pounds with a water-pressure of 40 lbs. per sq. in. The area in effective contact with the copper plates on either side is represented by an annular surface having its outer radius equal to 28 ins. and its inner radius equal to 10 ins. The apparent coefficient of friction between the plates and the disk was 3½%.

Capacity of Friction-brakes. — W. W. Beaumont (*Proc. Inst. C. E.*, 1889) has deduced a formula by means of which the relative capacity of brakes can be compared, judging from the amount of horse-power ascertained by their use.

If W = width of rubbing-surface on brake-wheel in inches; V = vel. of point on circum. of wheel in feet per minute; K = coefficient; then

$$K = WV \div \text{H.P.}$$

Prof. Flather obtains the values of K given in the last column of the subjoined table:

Horse-power.	R.P.M. Brake-pulley.	Brake-pulley. Face, in inches.	Brake-pulley. Diameter, in feet.	Length of Arm, inches.	Design of Brake.	Value of K.
21	150	7	5	33	Royal Ag. Soc., compensating................	785
19	148.5	7	5	33.38	McLaren, compensating.....................	858
20	146	7	5	32.19	McLaren, water-cooled and comp	802
40	180	10.5	5	32	Garrett, water-cooled and comp	741
33	150	10.5	5	32	Garrett, water-cooled and comp	749
150	150	10	9	......	Schoenheyder. water-cooled	282
24	142	12	6	38.31	Balk	1385
180	100	24	5	126.1	Gately & Kletsch, water-cooled	209
475	76.2	24	7	191	Webber, water-cooled	847
125 250	290 250	24	4	63	Westinghouse, water-cooled	465
40 125	322 290	13	4	27¾	Westinghouse, water-cooled	847

The above calculations for eleven brakes give values of K varying from 84.7 to 1385 for actual horse-powers tested, the average being $K = 655$.

Instead of assuming an average coefficient, Prof. Flather proposes the following:

Water-cooled brake, non-compensating, $K = 400$; $W = 400$ H.P. $\div V$.

Water-cooled brake, compensating, $K = 750$; $W = 750$ H.P. $\div V$.

Non-cooling brake, with or without compensating device, $K = 900$; $W = 900$ H.P. $\div V$.

A brake described in *Am. Mach.*, July 27, 1905, had an iron water-cooled drum, 30 in. diam., 20 in. face, with brake blocks of maple attached to an iron strap nearly surrounding the drum. At 250 r.p.m., or a circumferental speed of 1963 ft. per min., the limit of its capacity was about 140 H.P.; above that power the blocks took fire. At 140 H.P. the total surface passing under the brake blocks per minute was 3272 sq. ft., or 23.37 per H.P. This corresponds to a value of $K = 285$.

Several forms of Prony brake, including rope and strap brakes, are described by G. E. Quick in *Am. Mach.*, Nov. 17, 1908. Some other forms are shown in *Am. Electrician*, Feb., 1903.

A 6000 H.P. Hydraulic Absorption Dynamometer, built by the Westinghouse Machine Co., is described by E. H. Longwell in *Eng. News*, Dec. 30, 1909. It was designed for testing the efficiency of the Melville and McAlpine turbine reduction gear (see page 1095). This dynamometer consists of a rotor mounted on a shaft coupled to the reduction gear and rotating within a closed casing which is prevented from turning by a 6½ ft. lever arm, the end of which transmits pressure through an I-beam lever to a platform scale. The rotor carries several rows of steam turbine vanes and the casing carries corresponding rows of stationary vanes, so arranged as to baffle and agitate the water passing through the brake, which is heated to boiling temperature by the friction. The dynamometer was run for 40 hours continuously, and proved to be a highly accurate instrument.

Transmission Dynamometers are of various forms, as the Batchelder dynamometer, in which the power is transmitted through a "train-arm" of bevel gearing, with its modifications, as the one described by the author in *Trans. A. I. M. E.*, viii, 177, and the one described by Samuel Webber in *Trans. A. S. M. E.*, x, 514; belt dynamometers, as the Tatham; the Van Winkle dynamometer, in which the power is transmitted from a revolving shaft to another in line with it, the two almost touching, through the medium of coiled springs fastened to arms or disk keyed to the shafts; the Brackett and the Webb cradle dynamometers, used for measuring the power required to run dynamo-electric machines. Descriptions of the four last named are given in Flather on Dynamometers.

The Kenerson transmission dynamometer is described in *Trans. A. S. M. E.*, 1909. It has the form of a shaft coupling, one part of which contains a cavity filled with oil and covered by a flexible copper diaphragm. The other part, by means of bent levers and a thrust ball-bearing, brings an axial pressure on the diaphragm and on the oil, and the pressure of the oil is measured by a gauge.

Much information on various forms of dynamometers will be found in *Trans. A. S. M. E.*, vols. vii to xv, inclusive, indexed under Dynamometers.

ICE-MAKING OR REFRIGERATING MACHINES.

References.—An elaborate discussion of the thermodynamic theory of the action of the various fluids used in the production of cold was published by M. Ledoux in the *Annales des Mines*, and translated in *Van Nostrand's Magazine* in 1879. This work, revised and additions made in the light of recent experience by Professors Denton, Jacobus, and Riesenberger, was reprinted in 1892. (Van Nostrand's Science Series, No. 46.) The work is largely mathematical, but it also contains much information of immediate practical value, from which some of the matter given below is taken. Other references are Wood's Thermodynamics, Chap. V. and numerous papers by Professors Wood, Denton, Jacobus, and Linde in *Trans. A. S. M. E.*, vols. x to xiv; Johnson's Cyclopædia, article on Refrigerating-machines; and the following books: Siebel's Compend of Mechanical Refrigeration; Modern Refrigerating Machinery, by Lorenz, translated by Pope; Refrigerating Machines, by Gardner T. Voorhees; Refrigeration, by J. Wemyss Anderson, and Refrigeration, Cold Storage and Ice-making, by A. J. Wallis-Taylor. For properties of Ammonia and Sulphur Dioxide, see papers by Professors Wood and Jacobus, *Trans. A. S. M. E.*, vols. x and xii.

For illustrated descriptions of refrigerating-machines, see catalogues of builders, as Frick & Co., Waynesboro, Pa.; De La Vergne Refrigerating-machine Co., New York; Vilter Mfg. Co., Milwaukee; York Mfg., York, Co., Pa.; Henry Vogt Machine Co., Louisville, Ky.; Carbondale Machine Co., Carbondale, Pa.; and others. See also articles in *Ice* and *Refrigeration*.

Operations of a Refrigerating-machine. — Apparatus designed for refrigerating is based upon the following series of operations:

Compress a gas or vapor by means of some external force, then relieve it of its heat so as to diminish its volume; next, cause this compressed gas or vapor to expand so as to produce mechanical work, and thus lower its temperature. The absorption of heat at this stage by the gas, in resuming its original condition, constitutes the refrigerating effect of the apparatus.

A refrigerating-machine is a heat-engine reversed.

From this similarity between heat-motors and freezing-machines it results that all the equations deduced from the mechanical theory of heat to determine the performance of the first, apply equally to the second.

The efficiency depends upon the difference between the extremes of temperature.

The useful effect of a refrigerating-machine depends upon the ratio between the heat-units eliminated and the work expended in compressing and expanding.

This result is independent of the nature of the body employed.

Unlike the heat-motors, the freezing-machine possesses the greatest efficiency when the range of temperature is small, and when the final temperature is elevated.

If the temperatures are the same, there is no theoretical advantage in employing a gas rather than a vapor in order to produce cold.

The choice of the intermediate body would be determined by practical considerations based on the physical characteristics of the body, such as the greater or less facility for manipulating it, the extreme pressures required for the best effects, etc.

Air offers the double advantage that it is everywhere obtainable, and that we can vary at will the higher pressures, independent of the temperature of the refrigerant. But to produce a given useful effect the apparatus must be of larger dimensions than that required by liquefiable vapors.

The maximum pressure is determined by the temperature of the condenser and the nature of the volatile liquid; this pressure is often high.

When a change of volume of a saturated vapor is made under constant pressure, the temperature remains constant. The addition or subtraction of heat, which produces the change of volume, is represented by an increase or a diminution of the quantity of liquid mixed with the vapor.

On the other hand, when vapors, even if saturated, are no longer in contact with their liquids, and receive an addition of heat either through compression by a mechanical force, or from some external source of heat, they comport themselves nearly in the same way as permanent gases. and become superheated.

It results from this property, that refrigerating-machines using a liquefiable gas will afford results differing according to the method of working, and depending upon the state of the gas, whether it remains constantly saturated, or is superheated during a part of the cycle of working.

The temperature of the condenser is determined by local conditions. The interior will exceed by 9° to 18° the temperature of the water furnished to the exterior. This latter will vary from about 52° F., the temperature of water from considerable depth below the surface, to about 95° F., the temperature of surface-water in hot climates. The volatile liquid employed in the machine ought not at this temperature to have a tension above that which can be readily managed by the apparatus.

On the other hand, if the tension of the gas at the minimum temperature is too low, it becomes necessary to give to the compression-cylinder large dimensions, in order that the weight of vapor compressed by a single stroke of the piston shall be sufficient to produce a notably useful effect.

These two conditions, to which may be added others, such as those depending upon the greater or less facility of obtaining the liquid, upon the dangers incurred in its use, either from its inflammability or unhealthfulness, and finally upon its action upon the metals, limit the choice to a small number of substances.

The gases or vapors generally available are: sulphuric ether, sulphurous oxide, ammonia, methylic ether, and carbonic acid.

The following table, derived from Regnault, shows the tensions of the **vapors of these substances at temperatures between − 22° and + 104°.**

Pressures and Boiling-points of Liquids available for Use in Refrigerating-machines.

104	17.59	90.32	227.76	....	1338.2	82.9	37.12

The table shows that the use of ether does not readily lead to the production of low temperatures, because its pressure becomes then very feeble. Ammonia, on the contrary, is well adapted to the production of low temperatures.

Methylic ether yields low temperatures without attaining too great pressures at the temperature of the condenser. Sulphur dioxide readily affords temperatures of − 14 to − 5, while its pressure is only 3 to 4 atmospheres at the ordinary temperature of the condenser. These latter substances then lend themselves conveniently for the production of cold by means of mechanical force.

The "Pictet fluid" is a mixture of 97% sulphur dioxide and 3% carbonic acid. At atmospheric pressure it affords a temperature 14° lower than sulphur dioxide. (It is not now used — 1910.)

Carbonic acid is in use to a limited extent, but the relatively greater compactness of compressor that it requires, and its inoffensive character, are leading to its recommendation for service on shipboard.

Certain ammonia plants are operated with a surplus of liquid present during compression, so that superheating is prevented. This practice is known as the "cold" or "wet" system of compression.

Ethyl chloride, C_2H_5Cl, is a colorless gas which at atmospheric pressure condenses to a liquid at 54.5° F. The latent heat at 23° F. is given at 174 B.T.U. Density of the gas (air = 1) = 2.227. Specific heat at constant pressure, 0.274; at constant volume, 0.243.

Nothing definite is known regarding the application of methylic ether or of the petroleum product chymogene in practical refrigerating service. The inflammability of the latter and the cumbrousness of the compressor required are objections to its use.

PROPERTIES OF SULPHUR DIOXIDE AND AMMONIA GAS.

Ledoux's Table for Saturated Sulphur-dioxide Gas.

Heat-units expressed in B.T.U. per pound of sulphur dioxide.

Temperature of Ebullition in deg. E. F. Miller (*Trans. A. S. M. E.*, 1903) reports a series of tests on the pressure of SO_2 at various temperatures, the results agreeing closely with those of Regnault up to the highest figure of the latter, 149° F., 178 lbs. absolute. He gives a table of pressures and temperatures for every degree between — 40° and 217°. The results obtained at temperatures between 113° and 212° are as below:

Temp. °F.	113	122	131	140	149	158	167	176	194	203	212
Pres. lbs. per sq. in.	104.4	120.1	137.5	156.7	179.5	203.8	230.7	260.5	331.1	371.8	418.

Properties of Ammonia.—For a discussion of the properties of ammonia and a bibliography of investigations of ammonia, see Bulletin 66 of the University of Illinois Experiment Station. See also "Properties of Steam and Ammonia," by G. A. Goodenough (John Wiley & Sons, 1915). Prof. Goodenough says that experiments on the properties of ammonia are by no means as complete or as concordant as the experiments on water vapor; hence any formulation for ammonia must be regarded as tentative and subject to revision as further experimental evidence becomes available.

Properties of Saturated Ammonia.

(From Goodenough's Tables.)

The figures for CO_2 in the above table differ widely from those of Regnault, and are no doubt more reliable.

Heat Generated by Absorption of Ammonia. (Berthelot, from Siebel.) — Heat developed when a solution of 1 lb. NH_3 in n lbs. water is diluted with a great amount of water = $Q = 142/n$ B.T.U. Assuming 925 B.T.U. to be developed when 1 lb. NH_3 is absorbed by a great deal (say 200 lbs.) of water, the heat developed in making solutions of different strengths (1 lb. NH_3 to n lbs. water) = $Q_1 = 925 - 142/n$ B.T.U. Heat developed when b lbs. NH_3 is added to a solution of 1 lb. $NH_3 + n$ lbs. water = $Q_3 = 925b - 142\ (2\,b + b^2)/n$ B.T.U.

Let the weak liquor enter the absorber with a strength of 10%, = 1 lb. NH_3 + 9 lbs. water, and the strong liquor leave the absorber with a strength of 25%, = 3 lbs. NH_3 + 9 lbs. water, $b = 2$, $n = 9$; $Q_3 = 925 \times 2 - 142\ (4 + 4)/9 = 1724$ B.T.U. Hence by dissolving 2 lbs. of ammonia gas or vapor in a solution of 1 lb. ammonia in 9 lbs. water we obtain 12 lbs. of a 25% solution, and the heat generated is 1724 B.T.U.

Cooling Effect, Compressor Volume, and Power Required. — The following table gives the theoretical results computed on the basis of a temperature in the evaporator of 14° F. and in the condenser of 68° F.; in the first three columns of figures the cooling agent is supposed to flow through the regulating valve with this latter temperature; in the last three it is previously cooled to 50° F.

From the stroke-volume per 100,000 B.T.U. the minimum theoretical horse-power is obtained as follows: Adiabatic compression is assumed for the ratio of the absolute condenser pressure to that of the vaporizer, and the mean pressure through the stroke thus found, in lbs. per sq ft.; multiplying this by the stroke volume per hour and dividing by 1,980,000 gives the net horse-power. The ratio of the mean effective pressure, M.P., to the vaporizer pressure, V.P., for different ratios of condenser pressure, C.P., to vaporizer pressure is given on the next page.

Cooling Effect, Compressor Volume, and Power Required, with Different Cooling Agents. (Lorenz.)

1.4	0.350	2.4	0.970	3.4	1.414	4.4	1.766	5.4	2.062	8.0	2.666
1.6	0.487	2.6	1.070	3.6	1.491	4.6	1.829	5.6	2.116	9.0	2.858
1.8	0.630	2.8	1.163	3.8	1.564	4 8	1.891	5.8	2.168	10.0	3.036

The minimum theoretical horse-power thus obtained is increased by the ratio of the heat of evaporation to the available cooling action (line 4 ÷ line 6, = line 10 of the table) and by an allowance for the resistance of the valves taken at 7.5% to obtain the total H.P. given in the table.

To the theoretical horse-power given in line 12 Lorenz makes numerous additions, viz.: friction of the compression and driving machine 0.90, 1.10, 0.90, 0.85, 0.95, 0.85 respectively for the six columns in the table; also H.P. for stirring 0.3; for cooling-water pumps, 0.45; for brine pumps, 2.2; for transmission of power, 0.6, making the total H.P. for the six cases 10.30, 12.18, 10.44, 10.07, 10.98, 10.15. He also makes deductions from the theoretical generation of cold of 100,000 B.T.U. per hour, for a brewery cooling installation, for irregularities of valves, etc., for NH_3 and SO_2 machines 10% and for CO_2 machines 5%; for cooling loss through stirring 765 B.T.U., through brine pumps 5610 B.T.U., and through radiation 4500 B.T.U., making the net cooling for NH_3 and SO_2 machines 79,125 B.T.U. and for CO_2 machines 84,125 B.T.U., and the cold generated per effective H.P. in the six cases, 7682, 6908, 7578, 7848, 7662, and 7796 B.T.U.

The figures given in the tables are not to be considered as holding generally or extended to other condenser and evaporator temperatures. Each change of condition requires a separate calculation. The final results indicate that for the various cooling systems no appreciable difference exists in the work required for the same amount of cold delivered at the place where it is to be applied.

Properties of Brine Used to Absorb Refrigerating Effect of Ammonia. (J. E. Denton, *Trans. A. S. M. E.*, x, 799).—A solution of Liverpool salt in well-water having a specific gravity of 1.17, or a weight per cubic foot of 73 lbs., will not sensibly thicken or congeal at 0° F.

The mean specific heat between 39° and 16° Fahr. was found by Denton to be 0.805. Brine of the same specific gravity has a specific heat of 0.805 at 65° Fahr., according to Naumann.

Naumann's values (*Lehr-und Handbuch der Thermochemie*, 1882) are:

Specific heat......	0.791	0.805*	0.863	0.895	0.941	0.962	0.978
Specific gravity....	1.187	1.170	1.103	1.072	1.044	1.023	1.012

Properties of Salt Brine (Carbondale Calcium Co.)

Deg. Baumé 60° F.........	1	5	10	15	19	23
Deg. Salinometer 60° F.....	4	20	40	60	80	100

Specific heat.............	0.992	0.960	0.892	0.855	0.829	0.783

Chloride of Calcium solution is commonly used instead of brine. According to Naumann, a solution of 1.0255 sp. gr. has a specific heat of 0.957. A solution of 1.163 sp. gr. in the test reported in *Eng'g*, July 22, 1887, gave a specific heat of 0.827.

H. C. Dickinson (*Science*, April 23, 1909) gives the following values of the specific heat of solutions of chemically pure calcium chloride.

Density	Specific Heat	Temperature, *C.*
1.07................	$0.869 + 0.00057\,t$	(− 5° to + 15°)
1.14................	$0.773 + 0.00064\,t$	(− 10° to + 20°)
1.20................	$0.710 + 0.00064\,t$	(− 20° to + 20°)
1.26................	$0.662 + 0.00064\,t$	(− 25° to + 20°)

The advantages of chloride of calcium solution are its lower freezing point and that it has little or no corrosive action on iron and brass. Calcium chloride is sold in the fused or granulated state, in steel drums, containing about 75% anhydrous chloride and 25% water, or in solution containing 40 to 50% anhydrous chloride, in tank cars. The following data are taken from the catalogue of the Carbondale Calcium Co.

* Interpolated.

"Ice-melting Effect."—It is agreed that the term "ice-melting effect" means the cold produced in an insulated bath of brine, on the assumption that each 144 B.T.U. represents one pound of ice, this being the latent heat of fusion of ice, or the heat required to melt a pound of ice at 32° to water at the same temperature. The performance of a machine, expressed in pounds or tons of "ice-melting capacity," does not mean that the refrigerating-machine would make the same amount of actual ice, but that the cold produced is equivalent to the effect of the melting of ice at 32° to water of that temperature.

In making artificial ice the water frozen is generally about 70° F. when submitted to the refrigerating effect of a machine; second, the ice is chilled from 12° to 20° below its freezing-point; third, there is a dissipation of cold, from the exposure of the brine tank and the manipulation of the ice-cans: therefore the weight of actual ice made, multiplied by its latent heat of fusion, 144 thermal units, represents only about three-fourths of the cold produced in the brine by the refrigerating fluid per I.H.P. of the engine driving the compressing-pumps. Again, there is considerable fuel consumed to operate the brine-circulating pump, the condensing-water and feed-pumps, and to reboil, or purify, the condensed steam from which the ice is frozen. This fuel, together with that wasted in leakage and drip water, amounts to about one-half that required to drive the main steam-engine. Hence the pounds of actual ice manufactured from distilled water is just about half the equivalent of the refrigerating effect produced in the brine per indicated horse-power of the steam-cylinders.

When ice is made directly from natural water by means of the "plate system," about half of the fuel, used with distilled water, is saved by avoiding the reboiling, and using steam expansively in a compound engine.

Ether-machines, used in India, are said to have produced about 6 lbs. of actual ice per pound of fuel consumed.

The ether machine is obsolete, because the density of the vapor of ether, at the necessary working-pressure, requires that the compressing-cylinder shall be about 6 times larger than for sulphur dioxide, and 17 times larger than for ammonia.

Air-machines require about 1.2 times greater capacity of compressing cylinder, and are, as a whole, more cumbersome than ether machines, but they remain in use on shipboard. In using air the expansion must take place in a cylinder doing work, instead of through a simple expansion-cock which is used with vapor machines. The work done in the expansion-cylinder is utilized in assisting the compressor.

The Allen Dense Air Machine takes for compression air of considerable pressure which is contained in the machine and in a system of pipes. The air at 60 or 70 lbs. pressure is compressed to 210 or 240 lbs. It is then passed through a coil immersed in circulating water and cooled to nearly the temperature of the water. It then passes into an expander, which is, in construction, a common form of steam-engine with a cut-off valve. This engine takes out of the air a quantity of heat equivalent to the work done by the air while expanding, to the original pressure of 60 or 70 lbs., and reduces its temperature to about 90° to 120° F. below the temperature of the cooling water supply. The return stroke of the piston pushes the air out through insulated pipes to the places that are to be refrigerated, from which it is returned to the compressor.

The air pushed out by the expander is commonly about 35 to 55 below zero F. In arrangements where not all the cold is taken out of the air by the refrigerating apparatus, the highly compressed air after cooling in the coil is further cooled by being brought in surface contact with the returning and still cold air, before entering the expander. By this means temperatures of 70 to 90 below zero may be obtained.

The refrigerating effect in B.T.U. per minute is: Lbs. of air handled per min. $\times$ 0.2375 $\times$ difference of temperature of air passing out of expander and of that returning to the machine.

Carbon-dioxide Machines are in extensive use on shipboard. S. H. Bunnell (*Eng. News*, April 9, 1903) says there are over 1500 CO_2 plants on shipboard. He describes a large duplex CO_2 compressor built by the Brown-Cochrane Co., Lorain, O. Tests of CO_2 machines by a committee of the Danish Agricultural Society were reported in 1899, in "Ice and

Cold Storage," of London. Carbon-dioxide machines are built also by Kroeschel Bros., Chicago.

Ethyl-Chloride machines are made by the Clothel Co., New York City. The compressor is a rotary pump. When driven by an electric motor the complete apparatus is very compact, and is therefore suitable for refrigerator cars or other places where space is restricted.

Sulphur-Dioxide Machines.—Results of theoretical calculations are given in a table by Ledoux showing an ice-melting capacity per hour per horse-power ranging from 134 to 63 lbs., and per pound of coal ranging from 44.7 to 21.1 lbs., as the temperature corresponding to the pressure of the vapor in the condenser rises from 59° to 104° F. The theoretical results do not represent the actual.

Prof. Denton says concerning Ledoux's theoretical results: The figures given are higher than those obtained in practice, because the effect of superheating of the gas during admission to the cylinder is not considered. This superheating may cause an increase of work of about 25%. There are other losses due to superheating the gas at the brine-tank, and in the pipe leading from the brine-tank to the compressor, so that in actual practice a sulphur-dioxide machine, working under the conditions of an absolute pressure in the condenser of 56 lbs. per sq. in. and the corresponding temperature of 77° F., will give about 22 lbs. of ice-melting capacity per pound of coal, which is about 60% of the theoretical amount neglecting friction, or 70% including friction.

Sulphur-dioxide machines are not (1910) used in the United States.

Refrigerating-Machines using Vapor of Water. (Ledoux.)—In these machines, sometimes called vacuum machines, water, at ordinary temperatures, is injected into, or placed in connection with, a chamber in which a strong vacuum is maintained. A portion of the water vaporizes, the heat to cause the vaporization being supplied from the water not vaporized, so that the latter is chilled or frozen to ice. If brine is used instead of pure water, its temperature may be reduced below the freezing-point of water. The water vapor is compressed from, say, a pressure of 0.1 lb. per sq. in. to 1 ½ lbs. and discharged into a condenser. It is then condensed and removed by means of an ordinary air-pump. The principle of action of such a machine is the same as that of volatile-vapor machines.

A theoretical calculation for ice-making, assuming a lower temperature of 32° F., a pressure in the condenser of 1 ½ lbs. per sq. in. and a coal consumption of 3 lbs. per I.H.P. per hour, gives an ice-melting effect of 34.5 lbs. per pound of coal, neglecting friction. Ammonia for ice-making conditions gives 40.9 lbs. The volume of the compressing cylinder is about 150 times the theoretical volume for an ammonia machine for these conditions.

[The Patten Vacuum Ice Co., of Baltimore, has a large plant on this system in operation (1910).]

Ammonia Compression-machines.—"*Cold*" *vs.* "*Dry*" *Systems of Compression.*—In the "cold" system or "humid" system some of the ammonia entering the compression cylinder is liquid, so that the heat developed in the cylinder is absorbed by the liquid and the temperature of the ammonia thereby confined to the boiling-point due to the condenser-pressure. No jacket is therefore required about the cylinder.

In the "dry" or "hot" system all ammonia entering the compressor is gaseous, and the temperature becomes by compression several hundred degrees greater than the boiling-point due to the condenser-pressure. A water-jacket is therefore necessary to permit the cylinder to be properly lubricated.

Dry, Wet and Flooded Systems. (York Mfg. Co.)—An expansion system, or one where the ammonia leaves the coil slightly superheated, requires about 33 ⅓% more pipe surface than a wet compression system, in which the ammonia leaves the coils containing sufficient entrained liquid to maintain a wet compression condition in the compressor.

The flooded system is one where the ammonia is allowed to flow through the coils and into a trap, where the gas is separated from the liquid, the gas passing on to the compressor, while the liquid goes around through the coils again, together with the fresh liquid, which is fed into the trap. Such a system requires only about one-half the evaporating surface that an expansion system does to do the same work. The relative proportions of the three systems may be expressed as follows:

A Dry Compression plant will need, with an Expansion Evaporating System, a medium size compressor, a large size evaporating system, a small amount of ammonia.

A Dry Compression plant will need, with a Flooded Evaporating System, a small size compressor, a small size evaporating system, a large amount of ammonia.

A Wet Compression plant will need, with a Wet Compression Evaporating System, a large size compressor, a medium size evaporating system, a medium amount of ammonia.

The Ammonia Absorption-machine comprises a generator which contains a concentrated solution of ammonia in water; this generator is heated either directly by a fire, or indirectly by pipes leading from a steam-boiler. The vapor passes first into an "analyzer," a chamber connected with the upper part of the generator which separates some of the water from the vapor, then into a rectifier, where the vapor is partly cooled, precipitating more water, which returns to the generator, and then to the condenser. The upper part of the cooler or brine-tank is in communication with the lower part of the condenser.

An absorption-chamber is filled with a weak solution of ammonia; a tube puts this chamber in communication with the cooling-tank.

The absorption-chamber communicates with the boiler by two tubes: one leads from the bottom of the generator to the top of the chamber, the other leads from the bottom of the chamber to the top of the generator. Upon the latter is mounted a pump, to force the liquid from the absorption-chamber, where the pressure is maintained at about one atmosphere into the generator, where the pressure is from 8 to 12 atmospheres.

To work the apparatus the ammonia solution in the generator is first heated. This releases the gas from the solution, and the pressure rises. When it reaches the tension of the saturated gas at the temperature of the condenser there is a liquefaction of the gas, and also of a small amount of steam. By means of a cock the flow of the liquefied gas into the refrigerating coils contained in the cooler is regulated. It is here vaporized by absorbing the heat from the substance placed there to be cooled. As fast as it is vaporized it is absorbed by the weak solution in the absorbing-chamber.

Under the influence of the heat in the boiler the solution is unequally saturated, the stronger solution being uppermost. The weaker portion is conveyed by the pipe entering the top of the absorbing-chamber, the flow being regulated by a cock, while the pump sends an equal quantity of strong solution from the chamber back to the boiler.

The working of the apparatus depends upon the adjustment and regulation of the flow of the gas and liquid; by these means the pressure is varied, and consequently the temperature in the cooler may be controlled.

The working is similar to that of compression-machines. The absorption-chamber fills the office of aspirator, and the generator plays the part of compressor. The mechanical force producing exhaustion is here replaced by the affinity of water for ammonia gas, and the mechanical force required for compression is replaced by the heat which severs this affinity and sets the gas at liberty.

Reece's absorption apparatus (1870) is thus described by Wallis-Taylor. The charge of liquid ammonia (26° Baumé) is vaporized by the application of heat, and the mixed vapor passed to the analyzer and rectifier, wherein the bulk of the water is condensed at a comparatively elevated temperature and returned to the generator. The ammoniacal vapor or gas is then passed to the condenser, where it is liquefied under the combined action of the cooling-water and of the pressure maintained in the generator. The liquid ammonia, practically anhydrous, is then used in the refrigerator, and the vapor therefrom, still under considerable pressure, is admitted to the cylinder of an engine used to drive a pump for returning the strong solution to the generator, after which it is passed to the absorber, where it meets and is absorbed by the weak liquor from the generator, and the strong liquor so formed is forced back into the generator by means of the pump. The temperature exchanger, introduced in 1875, provides for the hot liquor on its way from the generator to the absorber giving up its heat to the cooler liquid from the absorber on its way to the generator.

Wallis-Taylor describes also marine refrigerating, ice-making cold storage, the application of refrigeration in breweries, dairies, etc.; and the management and testing of apparatus.

For the best results the following conditions are necessary (Voorhees): 1. The generator should have ample liquid evaporating surface to make dry gas. 2. The temperature of the gas to the rectifier should be as low as possible. 3. The drip liquor returned to the generator from the rectifier should be as hot as possible. 4. The gas from the rectifier to the condenser should not be over 10° to 50° hotter than the condensing temperature of the gas. 5. The exchanger should exchange upwards of 90% of the heat of the hot weak liquor to the cold strong liquor. The weight of strong liquor pumped should be from 7 to 8 times that of the anhydrous ammonia circulated in the refrigerator.

To produce one ton of refrigeration at 8.5 lbs. suction and 170 lbs. gauge condenser pressure, about 3.5 times as many heat units are actually used by an absorption machine as by a compression machine (compound condensing engine driven), but, owing to the low efficiency of the steam engine, due to the heat wasted in the exhaust and in cylinder condensation, the actual weight of steam used per hour per ton of refrigeration is the same for both the absorption machine and the compressor.

Relative Performance of Ammonia Compression- and Absorption- machines, assuming no Water to be Entrained with the Ammonia-gas in the Condenser. (Denton and Jacobus, *Trans. A. S. M. E.*, xiii.) — It is assumed in the calculation for both machines that 1 lb. of coal imparts 10,000 B.T.U. to the boiler. The condensed steam from the generator of the absorption-machine is assumed to be returned

*5% of water entrained in the ammonia will lower the economy of the absorption-machine about 15% to 20% below the figures given in the table.

to the boiler at the temperature of the steam entering the generator. The engine of the compression-machine is assumed to exhaust through a feed-water heater that heats the feed-water to 212° F. The engine is assumed to consume 26 1/4 lbs. of water per hour per horse-power. The figures for the compression-machine include the effect of friction, which is taken at 15% of the net work of compression.

(For discussion of the efficiency of the absorption system, see Ledoux's work; paper by Prof. Linde, and discussion on the same by Prof. Jacobus, *Trans. A. S. M. E.*, xiv, 1416, 1436; and papers by Denton and Jacobus, *Trans. A. S. M. E.*, x, 792, xiii, 507.

Relative Efficiency of a Refrigerating-Machine.—The efficiency of a refrigerating-machine is sometimes expressed as the quotient of the quantity of heat received by the ammonia from the brine, that is, the quantity of useful work done, divided by the heat equivalent of the mechanical work done in the compressor. Thus in column 1 of the table of performance of the 75-ton machine (page 1363) the heat given by the brine to the ammonia per minute is 14,776 B.T.U. The horse-power of the ammonia cylinder is 65.7, and its heat equivalent = 65.7 × 33,000 ÷ 778 = 2786 B.T.U. Then 14,776 ÷ 2786 = 5.304, efficiency. The apparent paradox that the efficiency is greater than unity, which is impossible in any machine, is thus explained. The working fluid, as ammonia, receives heat from the brine and rejects heat into the condenser. (If the compressor is jacketed, a portion is rejected into the jacket-water.) The heat rejected into the condenser is greater than that received from the brine; the difference (plus or minus a small difference radiated to or from the atmosphere) is heat received by the ammonia from the compressor. The work to be done by the compressor is not the mechanical equivalent of the refrigeration of the brine, but only that necessary to supply the difference between the heat rejected by the ammonia into the condenser and that received from the brine. If cooling water colder than the brine were available, the brine might transfer its heat directly into the cooling water, and there would be no need of ammonia or of a compressor; but since such cold water is not available, the brine rejects its heat into the colder ammonia, and then the compressor is required to heat the ammonia to such a temperature that it may reject heat into the cooling water.

The maximum theoretical efficiency of a refrigerating machine is expressed by the quotient $T_0 \div (T_1 - T_0)$, in which T_1 is the highest and T_0 the lowest temperature of the ammonia or other refrigerating agent.

The efficiency of a refrigerating plant referred to the amount of fuel consumed is

$$\left.\begin{array}{c}\text{Ice-melting capacity}\\ \text{per pound of fuel}\end{array}\right\} = \frac{\left\{\begin{array}{c}\text{Pounds circulated per hour}\\ \times\text{ specific heat }\times\text{ range}\\ \text{of temperature}\end{array}\right\}\begin{array}{c}\text{of brine or other}\\ \text{circulating fluid}\end{array}}{144 \times \text{pounds of fuel used per hour}}$$

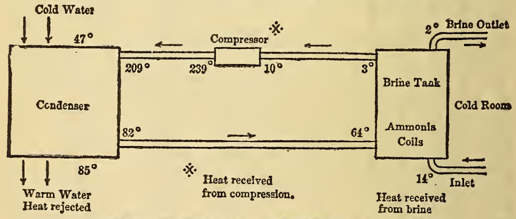

DIAGRAM OF AMMONIA COMPRESSION MACHINE.

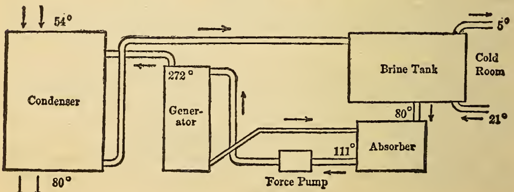

DIAGRAM OF AMMONIA ABSORPTION MACHINE.

The ice-melting capacity is expressed as follows:

$$\left.\begin{array}{l}\text{Tons (of 2000 lbs.)}\\ \text{ice-melting ca-}\\ \text{pacity per 24 hours}\end{array}\right\} = \frac{\left\{\begin{array}{l}24 \times \text{pounds}\\ \times \text{specific heat}\\ \times \text{range of temp.}\end{array}\right\} \text{of brine circulated per hour}}{144 \times 2000}$$

The analogy between a heat-engine and a refrigerating-machine is as follows: A steam-engine receives heat from the boiler, converts a part of it into mechanical work in the cylinder, and throws away the difference into the condenser. The ammonia in a compression refrigerating-machine receives heat from the brine-tank or cold room, receives an additional amount of heat from the mechanical work done in the compression-cylinder, and throws away the sum into the condenser. The efficiency of the steam-engine = work done ÷ heat received from boiler. The efficiency of the refrigerating-machine = heat received from the brine-tank or cold-room ÷ heat required to produce the work in the compression-cylinder. In the ammonia absorption-apparatus, the ammonia receives heat from the brine-tank and additional heat from the boiler or generator, and rejects the sum into the condenser and into the cooling water supplied to the absorber. The efficiency = heat received from the brine ÷ heat received from the boiler.

The Efficiency of Refrigerating Systems depends on the temperature of the condenser water, whether there is sufficient condenser surface for the compressor and whether or not the condenser pipes are free from uncondensable foreign gases. With these things right, condenser pressure for different temperatures of cooling water should be approximately as follows:

1 gallon per minute per ton per 24 hours —Cooling water, ° F.	60	65	70	75	80	85	90
Condenser pressure, gage, lb.	183	200	220	235	255	280	300
Condensed liquid ammonia, ° F.	95	100	105	110	115	120	125
2 gallons per minute per ton per 24 hours—Condenser pressure, gage, lb.	130	153	168	183	200	220	235
Condensed liquid ammonia, ° F.	77	85	90	93	100	105	110
3 gallons per minute per ton per 24 hours—Condenser pressure, gage, lb.	125	140	155	170	185	200	215
Condensed liquid ammonia, ° F.	75	85	90	93	95	100	105

The evaporating or back pressure within the expansion coils of a refrigerating system depends upon the temperatures on the outside of such coils, i.e., the air or brine to be cooled. For average practice back pressures for the production of required temperatures should be approximately as follows:

Temperature of room, ° F.	10	15	20	28	32	36	40	50	60
Back pressure, gage, lb.	10	12	15	22	25	27	30	35	40
Temperature of ammonia, ° F.	—10	—5	0	8	12	14	17	22	26

The condenser pressure should be kept as low as possible and the back pressure as high as possible, narrow limits between such pressures being as important to the efficiency of a refrigerating system as wide ones are to that of a steam engine in which the economy increases with the range between boiler pressure and condenser pressure. (F. E. Matthews, *Power*, Jan. 26, 1909.)

Cylinder-heating.—In compression-machines employing volatile vapors the principal cause of the difference between the theoretical and the practical result is the heating of the ammonia, by the warm cylinder walls, during its entrance into the compressor, thereby expanding it, so that to compress a pound of ammonia a greater number of revolutions must be made by the compressing-pumps than corresponds to the density of the ammonia-gas as it issues from the brine-tank.

Volumetric Efficiency.—The volumetric efficiency of a compressor is the ratio of the actual weight of ammonia pumped to the amount calculated from the piston displacement. Mr. Voorhees deduces from Denton's experiments the formula: Volumetric efficiency = $E = 1 - (t_1 - t_0)/1330$, in which t_1 = the theoretical temperature of gas after compression and t_1 = temperature of gas delivered to the compressor. The temperature t_1, $= T_1 - 460$, is calculated from the formula for adiabatic compression, $T_1 = T_0 (P_1/P_0)^{0.24}$, in which T_1 and T_0 are absolute temperatures and P_1 and P_0 absolute pressures. In eight tests by Prof. Denton the volumetric efficiency ranged from 73.5% to 84%, and they vary less than 1% from the efficiencies calculated by the formula. The temperature of the gas discharged from the compressor averaged 57° less than the theoretical.

The volumetric efficiency of a dry compressor is greatest when the vapor comes to the compressor with little or no superheat; 30° superheat of the suction gas reduces the capacity of the compressor 4%, and 100° 9%.

The following table (from Voorhees) gives the theoretical discharge. temperatures (t_1) and volumetric efficiencies (E) by the formula, and the actual cubic feet of displacement of compressor (F) per ton of refrigeration per minute for the given gage pressures of suction and condenser.

Mean Effective Pressure, and Horse-power.—Voorhees deduces the following (*Ice and Refrig.*, 1902): M.E.P. = $4.333\,p_0\,[(p_1/p_0)^{0.231}-1]$, p_0 = suction and p_1 condenser pressure, abs. lbs. per sq. in. The maximum M.E.P. occurs when $p_0 = p_1 \div 3.113$. The percentage of stroke during which the gas is discharged from the compressor is $V_1 = (p_0/p_1)^{0.769}$.

The compressor horse-power, C.H.P., is $0.00437\,F \times$ M.E.P.

The friction of the compressor and its engine combined is given by Voorhees as 33⅓% of the compressor H.P. or 25% of the engine H.P. Values of the mean effective pressure per ton of refrigeration (M), the compressor horse-power (C) and the engine horse-power (E) are given below for the conditions named.

Suction Pressure.	0			15			30		
	(M)	(C)	(E)	(M)	(C)	(E)	(M)	(C)	(E)
Cond. press., 140...	46.5	2.10	2.80	59.5	1.19	1.59	64.5	0.83	1.11
Cond. press., 170...	50.5	2.42	3.23	67.0	1.40	1.87	75.0	1.00	1.33
Cond. press., 200...	55.0	2.78	3.71	74.5	1.64	2.19	85.0	1.19	1.59

By cooling the liquid between the condenser and the expansion valve the capacity will be increased and the horse-power per ton reduced. With compression from 15 to 170 lbs., if the liquid at the expansion valve is cooled to 76° instead of 90° the H.P. per ton will be reduced 3%.

Prof. Lucke deduces a formula for the I.H.P. per ton of refrigerating capacity, as follows:

p = mean effective pressure, lbs. per sq. in.; L = length of stroke in ft.; a = area of piston in sq. ins.; n = no. of compressions per minute; E_c = apparent volumetric efficiency, the ratio of the volume of ammonia apparently taken in per stroke to the full displacement of the piston; w_c = weight of 1 cu.ft. of ammonia vapor at the back pressure, as it exists in the cylinder when compression begins; L_c = latent heat of vaporization available for refrigeration; 288,000 = B.T.U. equivalent to 1 ton of refrigeration; T = tons refrigeration per 24 hours.

$$\frac{\text{I.H.P.}}{T} = \frac{pLan \div 33{,}000}{\dfrac{LaE_c\,nw_c \times L_c \times 60 \times 24}{144 \times 288{,}000}} = \frac{0.87}{W_cL_c} \times \frac{p}{E_c}$$

The Voorhees Multiple Effect Compressor is based upon the fact that both the economy and the capacity of a compression machine vary with the back pressure. In the past it has always been necessary to run a compressor at a gas suction pressure corresponding to the lowest required temperature. The multiple effect compressor takes in gas from two or more refrigerators at two or more different suction pressures and temperatures on the same suction stroke of the compressor. The suction gas of the higher pressure helps to compress the lower suction pressure gas. There are two sets of suction valves in the compressor cylinder; the low temperature and corresponding low back pressure being connected to one suction port, usually in the cylinder head, and the high back pressure connected to the other. At the beginning of the stroke the cylinder is filled with the low pressure gas and as the piston reaches the end of its suction stroke, the second or high back pressure port is uncovered, the low pressure suction valve closing automatically, and the cylinder is completely filled with gas at the high pressure. By this means the compressor operates with an economy and capacity corresponding to the higher back pressure, making a gain in capacity of often 50% or more. (*Trans. Am. Soc. Refrig. Engrs.*, 1906.)

Quantity of Ammonia Required per Ton of Refrigeration. — The following table is condensed from one given by F. E. Matthews in *Trans. A. S. M. E.*, 1905. The weight in lbs. per minute is calculated from the formula $P = (144 \times 2000) \div [1440\,l - (h_1 - h_0)]$ in which l is the latent heat of evaporation at the back pressure in the cooler, and h_1 and h_0 the heat of the liquid at the temperatures of the condenser and the cooler respectively. The specific heat of the liquid has been taken at unity. The ton of refrigeration is 2000 lbs. in 24 hours = 288,000 B.T.U.

B = Pounds of ammonia evaporated per minute.
C = Cubic feet of gas to be handled per minute by the compressor.

* Cu. in. Displacement per Min. per Ton of Refrigeration.

The volumetric efficiency ranges from 63.5 to 76.5% for double-acting and from 74.5 to 85.5% for single-acting compressors, increasing with the decrease of condenser pressure and with the increase of suction pressure.

Where the liquid is cooled lower than the temperature corresponding to the condensing pressure, there will be a reduction in horse-power and displacement proportional to the increase of work done by each pound of liquid handled. The I.H.P. is that of the compressor. For Engine Horse-power add 17% up to 20 tons capacity and 15% for larger machines.

Rated Capacity of Refrigerating-Machines. — It is customary to rate refrigerating machines in tons of refrigerating capacity in 24 hours, on the basis of a suction pressure of 15.67 lbs. gauge, corresponding to 0° F. temperature of saturated ammonia vapor, and a condensing pressure of 185 lbs. gauge, corresponding to 95.5° F. The actual capacity increases with the increase of the suction pressure, and decreases with the increase of the condensing pressure. The following table shows the calculated capacities and horse-power of a machine rated at 40 H.P., when run at different pressures. (York Mfg. Co.) The horse-power required increases with the increase of both the suction and the condensing pressure.

Condenser Press. Temp.	Suction Gauge Pressure and Corresponding Temp.											
	5 lb. = −17.5° F		10 lb. = −8.5° F.		15.67 lb. = 0° F.		20 lb. = 5.7° F.		25 lb. = 11.5° F.		30 lb. = 16.8° F.	
	Tons.	H.P.	Tons.	H.P.	Tons.	H.P.	Tons.	H.P.	Tons.	H.P.	Tons.	H.P.
145 lb. = 82° F......	26.6	50.6	34.2	55.1	42.8	58.8	49.6	60.7	57.5	62.3	65.3	63.4

185 lb. = 95.5° F.....	24.8	57.4	32	63.3	40	68.6	46.5	71.4	53.9	74.2	61.3	76.5
205 lb. = 101.4° F.....	24	60.5	31	67	38.9	72.9	45	76.1	52.3	79.6	59.4	86.2

Piston Speeds and Revolutions per Minute.—There is a great diversity in the practice of different builders as to the size of compressor, the piston speed and the number of revolutions per minute for a given rated capacity. F. E. Matthews, *Trans. A. S. M. E.*, 1905, has plotted a diagram of the various speeds and revolutions adopted by four prominent builders, and from average curves the following figures are obtained:

Tons.........	20	30	40	50	60	80	100	120	140	160	180	200	240	300	400	500
R.P.M........	90	78	73	68	64	60	58 1/2	57	56	55	54	53	52	51	48 1/2	46
Piston speeds.	200	215	228	240	250	270	280	286	290	293	296	300	315	340	378	425

Mr. Matthews recommends a standard rating of machines based on these revolutions and speeds and on an apparent compressor displacement of 4.4 cu. ft. per minute per ton rating.

Condensers for Refrigerating-Machines are of two kinds: submerged, and open-air evaporative. The submerged condenser requires a large volume of cooling water for maximum efficiency. According to Siebel the amount of condensing surface, the water entering at 70° and leaving at 80°, is 40 sq ft. for each ton of refrigerating capacity, or 64 lineal feet of 2-in. pipe. Frequently only 20 sq. ft., or 90 ft. of 1 1/4-in. pipe, is used, but this necessitates higher condenser pressures. If F = sq. ft. of cooling surface, h = heat of evaporation of 1 lb. ammonia at the condenser temperature, K = lbs. of ammonia circulated per minute, m = B.T.U. transferred per minute per sq. ft. of condenser surface, t = temperature of the ammonia in the coils and t_1 the temperature of the water outside, $F = hK \div m(t - t_1)$. For $t = 80$ and $t_1 = 70$, m may be taken at 0.5. Practically the amount of water required will vary from 3 to 7 gallons per minute per ton of refrigeration. When cooling water is scarce, cooling towers are commonly used.

E. T. Shinkle gives the average surface of several submerged condensers as equal to 167 lineal feet of 1-in. pipe per ton of refrigeration.

Open air or evaporation surface condensers are usually made of a stack of parallel tubes with return bends, and means for distributing the water so that it will flow uniformly over the pipe surface. Shinkle gives as the average surface of open-air coolers 142 ft. of 1-in. pipe, or 99 ft. of 1 1/4 in. pipe per ton of refrigerating capacity.

Capacity of Condensers. (York Mfg. Co.) — The following table shows the capacities and horse-power per ton refrigeration of one section counter-current double-pipe condenser, 1 1/4-in. and 2-in. pipe, 12 pipes high, 19 feet in length outside of water bends, for water velocities 100 ft. to 400 ft. per minute: initial temperature of condensing water 70°.

The horse-power per ton is for single-acting compressor with 15.67 lbs. suction pressure.

The friction in water pump and connections should be added to water horse-power and to total horse-power.

Capacity of Condensers

Cooling-Tower Practice in Refrigerating-Plants. (B. F. Hart, Jr., *Southern Engr.*, Mar., 1909.)—The efficiency of a cooling-tower depends on exposing the greatest quantity of water surface to the cooling air-currents. In a tower designed to handle 100 gallons per minute the ranges of temperature found when handling different quantities of water were as follows:

Gallons of water per minute	148	109	58
Temperature of the atmosphere	78°	78.5°	78°
Relative humidity, %	47	49	47
Initial temperature	85.5°	85°	86°
Final temperature	78°	76°	75°
Range	7.5°	9°	11°

The final temperatures which may be obtained when the initial temperature does not exceed 100° are as follows:

Atmosphere Temp.		95°	90°	85°	80°	75°	70°
		Final temperature of water leaving tower.					
Humidity, %	90	100	95	90	85	80	75
	80	98	92	88	83	78	73
	70	95	90	86	80	76	71
	60	92	88	83	78	74	69
	50	89	84	79	75	70	66
	40	85	80	76	71	67	63

For ammonia condensers we figure on supplying 3 gallons per minute of circulating water per ton of refrigeration, or 6 gallons per minute per ton of ice made per 24 hours, and guarantee a reduction range from 150° to 160° down to about 100° when the temperature of the atmosphere does not exceed 80° nor the relative humidity 60%. When the temperature of the atmosphere and the humidity are both above 90° the speed of the pumps and the ammonia pressure must be increased.

The Refrigerating-Coils of a Pictet ice-machine described by Ledoux had 79 sq. ft. of surface for each 100,000 theoretic negative heat-units produced per hour. The temperature corresponding to the pressure of the dioxide in the coils is 10.4° F., and that of the bath (calcium chloride solution) in which they were immersed is 19.4°.

Comparison of Actual and Theoretical Ice-melting Capacity.— The following is a comparison of the theoretical ice-melting capacity of an ammonia compression machine with that obtained in some of Prof. Schröter's tests on a Linde machine having a compression-cylinder 9.9-in. bore and 16.5 in. stroke, and also in tests by Prof. Denton on a machine having two single-acting compression-cylinders, 12 in. × 30 in.:

No. of Test.		Temp. in Degrees F. Corresponding to Pressure of Vapor.		Ice-melting Capacity per lb. of Coal, assuming 3 lbs. per hour per Horse-power.		
		Condenser.	Suction.	Theoretical Friction* Included.	Actual.	Per cent of Loss Due to Cylinder Superheating.
Schröter	1	72.3	26.6	50.4	40.6	19.4
	2	70.5	14.3	37.6	30.0	20.2
	3	69.2	0.5	29.4	22.0	25.2
	4	68.5	−11.8	22.8	16.1	29.4
Denton	24	84.2	15.0	27.4	24.2	11.7

	25	84.6	−10.8	18.8	14.5	22.9

* Friction taken at figures observed in the tests, which range from 14% to 20% of the work of the steam-cylinder.

TEST-TRIALS OF REFRIGERATING-MACHINES.

(G. Linde, *Trans. A. S. M. E.*, xiv, 1414.)

The purpose of the test is to determine the ratio of consumption and production, so that there will have to be measured both the refrigerative effect and the heat (or mechanical work) consumed, also the cooling water. The refrigerative effect is the product of the number of heat-units (Q) abstracted from the body to be cooled, and the quotient $(T_c - T) \div T$: in which T_c = absolute temperature at which heat is transmitted to the cooling water, and T = absolute temperature at which heat is taken from the body to be cooled.

The determination of the quantity of cold will be possible with the proper exactness only when the machine is employed during the test to refrigerate a liquid; and if the cold be found from the quantity of liquid circulated per unit of time, from its range of refrigeration, and from its specific heat. Sufficient exactness cannot be obtained by the refrigeration of a current of circulating air, nor from the manufacture of a certain quantity of ice, nor from a calculation of the fluid circulating within the machine (for instance, the quantity of ammonia circulated by the compressor). Thus the refrigeration of brine will generally form the basis for tests making any pretension to accuracy. The degree of refrigeration should not be greater than necessary for allowing the range of temperature to be measured with the necessary exactness; a range of temperature of from 5° to 6° Fahr. will suffice.

The condenser measurements for cooling water and its temperatures will be possible with sufficient accuracy only with submerged condensers.

The measurement of the quantity of brine circulated, and of the cooling water, is usually effected by water-meters inserted into the conduits. If the necessary precautions are observed, this method is admissible. For quite precise tests, however, the use of two accurately gauged tanks which are alternately filled and emptied must be advised.

To measure the temperatures of brine and cooling water at the entrance and exit of refrigerator and condenser respectively, the employment of specially constructed and frequently standardized thermometers is indispensable; no less important is the precaution of using at each spot simultaneously two thermometers, and of changing the position of one such thermometer series from inlet to outlet (and *vice versa*) after the expiration of one-half of the test, in order that possible errors may be compensated.

It is important to determine the specific heat of the brine used in each instance for its corresponding temperature range, as small differences in the composition and the concentration may cause considerable variations. (*Continued on page* 1358.)

Ammonia Compression-machines.—Ammonia gas possesses the advantage of affording about three times the useful effect of sulphur dioxide for the same volume described by the piston.

The perfection of ammonia apparatus now renders it so convenient and reliable that no practical advantage results from the lower pressures afforded by sulphur dioxide.

The results of the calculations for ammonia are given in the table below:

PERFORMANCE OF AMMONIA COMPRESSION-MACHINES.

Gas superheated during compression as in ordinary practice. Temperature of condenser, 64.4° Fahr. Pressure in condenser, 117.44 lbs per sq. in. (Ledoux.)

Temperature Corresponding to Pressure of Vapor in Refrigerating-coils.	Absolute Pressure in Refrigerating-coils.	Temperature of Gas at End of Compression.	Per Cubic Foot of Piston Displacement. The theoretical results for ammonia are higher than the actual, for the same reasons that have been stated for sulphur dioxide. In the case of ammonia the action of the cylinder-walls in superheating the entering vapor has been determined experimentally by Prof. Denton, and the amount found to agree with that indicated by theory. In these experiments the ammonia circulated in a 75-ton refrigerating machine was measured directly by means of a special meter, so that, in addition to determining the effect of superheating, the latent heats can be calculated at the suction and condenser pressure.

As regards the measurement of consumption, the programme will not have any special rules in cases where only the measurement of steam and cooling water is undertaken, as will be mainly the case for trials of absorption-machines. For compression-machines the steam consumption depends both on the quality of the steam-engine and on that of the refrigerating-machine, while it is evidently desirable to know the consumption of the former separately from that of the latter. As a rule steam-engine and compressor are coupled directly together, thus rendering a direct measurement of the power absorbed by the refrigerating-machine impossible, and it will have to suffice to ascertain the indicated work both of steam-engine and compressor. By further measuring the work for the engine running empty, and by comparing the differences in power between steam-engine and compressor resulting for wide variations of condenser-pressures, the effective consumption of work L_e for the refrigerating-machine can be found very closely. In general, it will suffice to use the indicated work found in the steam-cylinder, especially as from this observation the expenditure of heat can be directly determined. Ordinarily the use of the indicated work in the compressor-cylinder, for purposes of comparison, should be avoided; firstly, because there are usually certain accessory apparatus to be driven (agitators, etc.), belonging to the refrigerating-machine proper; and secondly, because the external friction would be excluded.

Report of Test.—Reports intended to be used for comparison with the figures found for other machines will have to embrace at least the following observations:

Refrigerator:

Quantity of brine circulated per hour....................
Brine temperature at inlet to refrigerator....................
Brine temperature at outlet of refrigerator.................... T
Specific gravity of brine (at 64° Fahr.)....................
Specific heat of brine....................
Heat abstracted (cold produced).................... Q_e
Absolute pressure in the refrigerator....................

Condenser:

Quantity of cooling water per hour....................
Temperature at inlet to condenser....................
Temperature at outlet of condenser.................... T_c
Heat abstracted .... Q_1
Absolute pressure in the condenser....................
Temperature of gases entering the condenser....................

ABSORPTION-MACHINE.

Still:

Steam consumed per hour.........
Abs. pressure of heating steam.....
Temperature of condensed steam at outlet ....
Heat imparted to still .... Q'_e

Absorber:

Quantity of cooling water per hour..
Temperature at inlet ....
Temperature at outlet ....
Heat removed.................. Q_2

Pump for Ammonia Liquor:

Indicated work of steam-engine ....
Steam-consumption for pump ......
Thermal equivalent for work of pump .... ALp
Total sum of losses by radiation and convection................ $\pm Q_3$

Heat Balance:

$$Q_e + Q'_e = Q_1 + Q_2 \pm Q_3.$$

COMPRESSION-MACHINE.

Compressor:

Indicated work .... L_t
Temperature of gases at inlet
Temperature of gases at exit

Steam-engine:

Feed-water per hour........
Temperature of feed-water ..
Absolute steam-pressure before steam-engine ....
Indicated work of steam-engine .... L_e
Condensing water per hour..
Temperature of do.........
Total sum of losses by radiation and convection.. $\pm Q_3$

Heat Balance:

$$Q_e + AL_c = Q_1 \pm Q_3.$$

For the calculation of efficiency and for comparison of various tests, the actual efficiencies must be compared with the theoretical maximum of efficiency $Q \div (AL)$ max. $= T \div (T_c - T)$ corresponding to the temperature range.

Heat Balance. — We possess an important aid for checking the correctness of the results found in each trial by forming the balance in each case for the heat received and rejected. Only those tests should be regarded as correct beyond doubt which show a sufficient conformity in the heat balance. It is true that in certain instances it may not be easy to account fully for the transmission of heat between the several parts of the machine and its environment by radiation and convection, but generally (particularly for compression-machines) it will be possible to obtain for the heat received and rejected a balance exhibiting small discrepancies only.

Temperature Range. — For the temperatures (T and T_c) at which the heat is abstracted in the refrigerator and imparted to the condenser, it is correct to select the temperature of the brine leaving the refrigerator and that of the cooling water leaving the condenser, because it is in principle impossible to keep the refrigerator pressure higher than would correspond to the lowest brine temperature, or to reduce the condenser pressure below that corresponding to the outlet temperature of the cooling water.

Prof. Linde shows that the *maximum theoretical* efficiency of a compression-machine may be expressed by the formula

$$Q \div (AL) = T \div (T_c - T),$$

in which Q = quantity of heat abstracted (cold produced);
AL = thermal equivalent of the mechanical work expended;
L = the mechanical work, and $A = 1 \div 778$;
T = absolute temperature of heat abstraction (refrigerator);
T_c = absolute temperature of heat rejection (condenser).

If u = ratio between the heat equivalent of the mechanical work AL and the quantity of heat Q' which must be imparted to the motor to produce the work L, then

$$AL \div Q' = u, \text{ and } Q'/Q = (T_c - T) \div (uT).$$

It follows that the expenditure of heat Q' necessary for the production of the quantity of cold Q in a compression-machine will be the smaller, the smaller the difference of temperature $T_c - T$.

Metering the Ammonia. — For a complete test of an ammonia refrigerating-machine it is advisable to measure the quantity of ammonia circulated, as was done in the test of the 75-ton machine described by Prof. Denton. (*Trans. A. S. M. E.*, xii, 326.)

ACTUAL PERFORMANCES OF ICE-MAKING MACHINES.

The table given on page 1360 is abridged from Denton, Jacobus, and Riesenberger's translation of Ledoux on Ice-making Machines. The following shows the class and size of the machines tested, referred to by letters in the table, with the names of the authorities:

Class of Machines.	Authority.	Dimensions of Compression-cylinder in inches.	
		Bore.	Stroke.

In class A, a German double-acting machine with compression cylinder 9.9 in. bore, 16 in. stroke, tested by Prof. Schröter, the ice-melting capacity ranges from 46.29 to 16.14 lbs. of ice per pound of coal, according as the suction pressure varies from about 45 to 8 lbs. above the atmosphere, this pressure being the condition which mainly controls the economy of compression machines. These results are equivalent to realizing from 72% to 57% of theoretically perfect performances. The higher per cents appear to occur with the higher suction-pressures, indicating a greater loss from cylinder-heating (a phenomenon the reverse of cylinder condensation in steam-engines), as the range of the temperature of the gas in the compression-cylinder is greater.

In E, an American single-acting compression-machine, two compression cylinders each 12 × 30 in., operating on the "dry system," tested by Prof. Denton, the percentage of theoretical effect realized ranges from 69.5% to 62.6%. The friction losses are higher for the American machine. The latter's higher efficiency may be attributed, therefore, to more perfect displacement.

The largest "ice-melting capacity" in the American machine is 24.16 lbs.

Actual Performance of Ice-making Machines.

* Temperature of air at entrance and exit of expansion-cylinder.

† On a basis of 3 lbs. of coal per hour per H.P. of steam-cylinder of compression-machine and an evaporation of 11.1 lbs. of water per pound of combustible from and at 212° F. in the absorption-machine.

‡ Per cent of theoretical with no friction.

§ Loss due to heating during aspiration of gas in the compression-cylinder and to radiation and superheating at brine-tank.

‖ Actual, including resistance due to inlet and exit valves.

This corresponds to the highest suction-pressures used in American practice for such refrigeration as is required in beer-storage cellars using the direct-expansion system. The conditions most nearly corresponding to American brewery practice in the German tests are those in line 5, which give an "ice-melting capacity" of 19.07 lbs.

For the manufacture of artificial ice, the conditions of practice are those of lines 3 and 4, and lines 25 and 26. In the former the condensing pressure used requires more expense for cooling water than is common in American practice. The ice-melting capacity is therefore greater in the German machine, being 22.03 and 16.14 lbs. against 17.55 and 14.52 for the American apparatus.

Class B. Sulphur Dioxide or Pictet Machines. — No records are available for determination of the "ice-melting capacity" of machines using pure sulphur dioxide. In the "Pictet fluid," a mixture of about 97% of sulphur dioxide and 3% of carbonic acid, the presence of the carbonic acid affords a temperature about 14 Fahr. degrees lower than is obtained with pure sulphur dioxide at atmospheric pressure. The latent heat of this mixture has never been determined, but is assumed to be equal to that of pure sulphur dioxide.

For brewery refrigerating conditions, line 17, we have 26.24 lbs. "ice-melting capacity," and for ice-making conditions, line 13, the "ice-melting capacity" is 17.47 lbs. These figures are practically as economical as those for ammonia, the per cent of theoretical effect realized ranging from 65.4 to 57.8. At extremely low temperatures, – 15° Fahr., lines 14 and 18, the per cent realized is as low as 42.5.

Performance of a 75-ton Ammonia Compression-machine. (J. E. Denton, *Trans. A. S. M. E.*, xii, 326.)—The machine had two single-acting compression cylinders 12 × 30 in., and one Corliss steam-cylinder, double-acting, 18 × 36 in. It was rated by the manufacturers as a 50-ton machine, but it showed 75 tons of ice-refrigerating effect per 24 hours during the test.

The most probable figures of performance in eight trials are as follows:

No. of Trials.	Ammonia Pressures, lbs. above Atmosphere.		Brine Temperatures, Degrees F.		Capacity Tons Refrigerating Effect per 24 hours.	Efficiency lbs. of Ice per lb. of Coal at 3 lbs. Coal per hour per H.P.	Water-consumption, gals. of Water per min. per ton of Capacity.	Ratio of Actual Weights of Ammonia circulated.	Ratio of Capacities.
	Condensing	Suction.	Inlet.	Outlet.					
1	151	28	36.76	28.86	70.3	22.60	0.80	1.0	1.0
8	161	27.5	36.36	28.45	70.1	22.27	1.09	1.0	1.0
7	147	13.0	14.29	2.29	42.0	16.27	0.83	1.70	1.60

6	105	7.6	6.40	–2.22	37.20	17.00	2.00	1.91	1.88
2	135	15.7	4.62	3.22	27.2	13.20	1.25	2.59	2.57

The principal results in four tests are given in the table on page 1363. The fuel economy under different conditions of operation is shown in the following table:

Condensing Pressure, lbs.	Suction-pressure, lbs.	Pounds of Ice-melting Effect with Engines —						B.T.U. per lb. of Steam with Engines —		
		Non-condensing.		Non-compound Condensing.		Compound Condensing.		Non-condensing.	Condensing.	Compound Condensing.
		Per lb. Coal.	Per lb. Steam.	Per lb. Coal.	Per lb. Steam.	Per lb. Coal.	Per lb. Steam.			
150	28	24	2.90	30	3.61	37.5	4.51	393	513	640
150	7	14	1.69	17.5	2.11	21.5	2.58	240	300	366
105	28	34.5	4.16	43	5.18	54	6.50	591	725	923
105	7	22	2.65	27.5	3.31	34.5	4.16	376	470	591

The non-condensing engine is assumed to require 25 lbs. of steam per I.H.P. per hour, the non-compound condensing 20 lbs., and the compound condensing 16 lbs., and the boiler efficiency is assumed at 8.3 lbs. of water per lb. coal under working conditions. The following conclusions were derived from the investigation:

1. The capacity of the machine is proportional, almost entirely, to the weight of ammonia circulated. This weight depends on the suction-pressure and the displacement of the compressor-pumps. The practical suction-pressures range from 7 lbs. above the atmosphere, with which a temperature of 0° F. can be produced, to 28 lbs. above the atmosphere, with which the temperatures of refrigeration are confined to about 28° F. At the lower pressure only about one-half as much weight of ammonia can be circulated as at the upper pressure, the proportion being about in accordance with the ratios of the absolute pressures, 22 and 42 lbs. respectively. For each cubic foot of piston-displacement per minute a capacity of about one-sixth of a ton of refrigerating effect per 24 hours can be produced at the lower pressure, and of about one-third of a ton at the upper pressure. No other elements practically affect the capacity of a machine, provided the cooling-surface in the brine-tank or other space to be cooled is equal to about 36 sq. ft. per ton of capacity at 28 lbs. back pressure. For example, a difference of 100% in the rate of circulation of brine, while producing a proportional difference in the range of temperature of the latter, made no practical difference in capacity.

The brine-tank was $10\frac{1}{2} \times 13 \times 10\frac{2}{3}$ ft., and contained 8000 lineal feet of 1-in. pipe as cooling-surface. The condensing-tank was $12 \times 10 \times 10$ ft., and contained 5000 lineal feet of 1-in. pipe as cooling-surface.

2. The economy in coal-consumption depends mainly upon both the suction-pressures and condensing-pressures. Maximum economy with a given type of engine, where water must be bought at average city prices, is obtained at 28 lbs. suction-pressure and about 150 lbs. condensing-pressure. Under these conditions, for a non-condensing steam-engine consuming coal at the rate of 3 lbs. per hour per I.H.P. of steam-cylinders, 24 lbs. of ice-refrigerating effect are obtained per lb. of coal consumed. For the same condensing-pressure, and with 7 lbs. suction-pressure, which affords temperatures of 0° F., the possible economy falls to about 14 lbs. of refrigerating effect per lb. of coal consumed. The condensing-pressure is determined by the amount of condensing-water supplied to liquefy the ammonia in the condenser. If the latter is about 1 gallon per minute per ton of refrigerating effect per 24 hours, a condensing-pressure of 150 lbs. results, if the initial temperature of the water is about 56° F. Twenty-five per cent less water causes the condensing-pressure to increase to 190 lbs. The work of compression is thereby increased about 20%, and the resulting "economy" is reduced to about 18 lbs. of "ice effect" per lb. of coal at 28 lbs. suction-pressure and 11.5 at 7 lbs. If, on the other hand, the supply of water is made 3 gallons per minute, the condensing-pressure may be confined to about 105 lbs. The work of compression is thereby reduced about 25%, and a proportional increase of economy results. Minor alterations of economy depend on the initial temperature of the condensing-water and variations of latent heat, but these are confined within about 5% of the gross result, the main element of control being the work of compression, as affected by the back pressure and condensing-pressure, or both. If the steam-engine supplying the motive power may use a condenser to secure a vacuum, an increase of economy of 25% is available over the above figures, making the lbs. of "ice effect" per lb. of coal for 150 lbs. condensing-pressure and 28 lbs. suction-pressure 30.0, and for 7 lbs. suction-pressure, 17.5. It is, however, impracticable to use a condenser in cities where water is bought. The latter must be practically free of cost to be available for this purpose. In this case it may be assumed that water will also be available for condensing the ammonia to obtain as low a condensing-pressure as about 100 lbs., and the economy of the refrigerating-machine becomes, for 28 lbs. back pressure, 43.0 lbs. of "ice-effect" per lb. of coal, or for 7 lbs. back pressure 27.5 lbs. of ice effect per lb. of coal. If a compound condensing-engine can be used with a steam-consumption per hour per horse-power of 16 lbs. of water, the economy of the refrigerating-machine may be 25% higher than the figures last named, making for 28 lbs. back pressure a refrigerating-effect of 54.0 lbs. per lb. of coal, and for 7 lbs. back pressure a refrigerating effect of 34.0 lbs. per lb. of coal.

Performance of a 75-ton Refrigerating-machine. (Denton.)

A test of a 35-ton absorption-machine in New Haven, Conn., by Prof. Denton (*Trans. A. S. M. E.*, x, 792), gave an ice-melting effect of 20.1 lbs. per lb. of coal on a basis of boiler economy equivalent to 3 lbs. of steam per I.H.P. in a good non-condensing steam-engine. The ammonia was worked between 138 and 23 lbs. pressure above the atmosphere.

Performance of a Single-acting Ammonia Compressor. — Tests were made at the works of the Eastman Kodak Co., Rochester, N.Y., of a machine fitted with two York Mfg. Co.'s single-acting compressors, 15 in. diam., 22 in. stroke, to determine the horse-power per ton of refrigeration. Following are the principal average results (Bulletin of York Mfg. Co.):

Date of Test, 1908	Mar. 6	Mar. 7	Mar. 8	Mar. 9	Mar. 10.	Mar. 11.	Mar. 14.
Temp. dischg. gas, av.	216.2	217.8	250.6	245.8	253.0	242.9	255.5

Indicated H.P.	69.35	69.80	70.05	52.57	89.48	105.11	68.61
Tons Refrig. Capy, 24 hrs.	49.08	48.79	50.38	37.01	61.39	66.65	49.31
I.H.P. per ton capacity	1.418	1.427	1.389	1.422	1.425	1.439	1.375

Full details of these tests were reported to the Am. Socy. of Refrig. Engrs. and published in *Ice and Refrigeration*, 1908.

Performance of Absorption Machines. — From an elaborate review by Mr. Voorhees of the action of an absorption machine under certain stated conditions, showing the quantity of ammonia circulated per hour per ton of refrigeration, its temperature, etc., at the several stages of the operation, and its course through the several parts of the apparatus, the following condensed statement is obtained:

Generator. — 30.9 lbs. dry steam, 38 lbs. gauge pressure condensed, evaporates 32.2% strong liquor to 22.3% weak liquor.

Exchanger. — 3.01 lbs. weak liquor at 264° cools to 111°.

Absorber. — Adds 0.43 lbs. vapor from the brine cooler, making 3.44 lbs. strong liquor at 111° to go to the pump.

Exchanger. — 3.44 lbs. heated to 224°, some of it is now gas, and the rest liquor of a little less than 32% NH_3.

Analyzer. — (A series of shelves in a tank above the generator) delivers strong liquor to the generator, while the vapor, 91% NH_3, 0.4982 lb., goes to the rectifier.

Rectifier. — Cools the gas to 110° separating water vapor as 0.0682 lb. drip liquor which returns through a trap to the generator.

Condenser. — 0.43 lb. NH_3 gas at 110° cooled and condensed to liquid at 90° by 2 gals. of water per min. heated from 73° to 86°.

Expansion Valve and Cooler. — Reduces liquid to 0° and boils it at 0°, cooling 3 gals. of brine per min. from 12° to 3°. Gas passes to absorber and the cycle is repeated.

Of the 2 gals. per min. of cooling water flowing from the condenser, 0.2 gal. goes to the rectifier, where it is heated to 142°, and 1.8 gal. through the absorber, where it is heated to 110°.

Heat Balance. — Absorbed in the generator 496; in the brine cooler, 200, Total 696 B.T.U. Rejected; condenser, 220; absorber, 383; rectifier, 93; Total 696 B.T.U.

The following table shows the strength of the liquors and the quantity of steam required per hour per ton of refrigeration under the conditions stated:

	Condenser Pressures.								
	140			170			200		
	Suction Pressures.								
	0	15	30	0	15	30	0	15	30
Sl per cent.......	24	35	42	22	32	38	18	28	36
Wl per cent......	13.13	25.75	33.70	10.85	22.3	29.15	6.28	17.7	26.9
SG, pounds......	30.1	27.9	22.9	41.3	30.9	26.2	48.7	34.1	27.9
SL, pounds......	1.7	1.6	1.4	2.1	1.9	1.8	2.4	2.3	2.2

Sl, strong liquor; *Wl*, weak liquor; *SG*, lbs. of steam per hour per ton of refrigeration for the generator, *SL*, do. for the liquor pump. Pressures are in lbs. per sq. in., gauge.

The following table gives the steam consumption in lbs. per hour per ton of refrigeration, for engine-driven compressors and for absorption machines with liquor pump not exhausting into the generator at the suction and condenser pressures (gauge) given: *SC*, simple non-condensing engine, ***CC***. compound condensing engine, *A*, absorption machine.

	Condenser Pressures.								
	140			170			200		
	Suction Pressures.								
	0	15	30	0	15	30	0	15	30
SC..............	78.3	44.5	31.1	90.5	52.5	37.2	104.0	61.4	44.5
CC..............	42.0	23.8	16.6	48.4	28.0	19.0	55.6	32.7	23.9
A...............	31.8	29.5	24.3	43.4	32.8	28.0	51.1	36.4	30.1

The economy of the absorption machine is much better for all conditions than that of a simple non-condensing engine-driven compressor. At suction gauge pressures above 8 to 10 lbs. the economy of the compound condensing engine-driven compressor exceeds that of the absorption machine, the absorption machine giving the superior economy at suction pressures below 8 to 10 lbs.

Means for Applying the Cold. (M. C. Bannister, Liverpool Eng'g Soc'y, 1890.) — The most useful means for applying the cold to various uses is a saturated solution of brine or chloride of magnesium, which remains liquid at 5° Fahr. The brine is first cooled by being circulated in contact with the refrigerator-tubes, and then distributed through coils of pipes, arranged either in the substances requiring a reduction of temperature, or in the cold stores or rooms prepared for them; the air coming in contact with the cold tubes is immediately chilled, and the moisture in the air deposited on the pipes. It then falls, making room for warmer air, and so circulates until the whole room is at the temperature of the brine in the pipes.

The Direct Expansion Method consists in conveying the compressed cooled ammonia (or other refrigerating agent) directly to the room to be cooled, and then expanding it through an expansion cock into pipes in the room. Advantages of this system are its simplicity and its rapidity of action in cooling a room; disadvantages are the danger of leakage of the gas and the fact that the machine cannot be stopped without a rapid rise in the temperature of the room. With the brine system, with a large amount of cold brine in the tank, the machine may be stopped for a considerable time without serious heating of the room.

Air has also been used as the circulating medium. The ammonia-pipes refrigerate the air in a cooling-chamber, and large conduits are used to convey it to and return it from the rooms to be cooled. An advantage of this system is that by it a room may be refrigerated more quickly than by brine-coils. The returning air deposits its moisture on the ammonia-pipes, in the form of snow, which is removed by mechanical brushes.

ARTIFICIAL-ICE MANUFACTURE.

Under summer conditions, with condensing water at 70°, artificial-ice machines use ammonia at a condenser pressure, about 190 lbs. above the atmosphere and 15 lbs. suction-pressure.

In a compression type of machine the useful circulation of ammonia, allowing for the effect of cylinder-heating, is about 13 lbs. per hour per indicated horse-power of the steam-cylinder. This weight of ammonia produces about 32 lbs. of ice at 15° from water at 70°. If the ice is made from distilled water, as in the "can system," the amount of the latter supplied by the boilers is about 33% greater than the weight of ice obtained. This excess represents steam escaping to the atmosphere from the re-boiler and steam-condenser, to purify the distilled water, or free it from air; also, the loss through leaks and drips, and loss by melting of the ice in extracting it from the cans. The total steam consumed per horse-power is, therefore, about $32 \times 1.33 = 43.0$ lbs. About 7.0 lbs. of this covers the steam-consumption of the steam-engines driving the brine circulating-pumps, the several cold-water pumps, and leakage, drips, etc. Consequently, the main steam-engine must consume 36 lbs. of steam per hour per I.H.P., or else live steam must be condensed to supply the required amount of distilled water. There is, therefore, nothing to be gained by using steam at high rates of expansion in the steam-engines, in making artificial ice from distilled water. If the cooling water for the ammonia-coils and steam-condenser is not too hard for use in the boilers, it may enter the latter at about 175° F., by restricting the quantity to $1\frac{1}{2}$ gallons per minute per ton of ice. With good coal $8\frac{1}{2}$ lbs. of feed-water may then be evaporated, on the average, per lb. of coal.

The ice made per pound of coal will then be $32 \div (43.0 \div 8.5) = 6.0$ lbs. This corresponds with the results of average practice.

If ice is manufactured by the "plate system," no distilled water is used for freezing. Hence the water evaporated by the boiler may be reduced to the amount which will drive the steam-motors, and the latter may use steam expansively to any extent consistent with the power required to compress the ammonia, operate the feed and filter pumps, and the hoisting machinery. The latter may require about 15% of the power needed for compressing the ammonia.

If a compound condensing steam-engine is used for driving the compressors, the steam per indicated steam horse-power, or per 32 lbs. of net ice, may be 14 lbs. per hour. The other motors at 50 lbs. of steam per horse-power will use 7.5 lbs. per hour, making the total consumption per steam horse-power of the compressor 21.5 lbs. Taking the evaporation at 8 lbs., the feed-water temperature being limited to about 110°, the coal per horse-power is 2.7 lbs. per hour. The net ice per lb. of coal is then about $32 \div 2.7 = 11.8$ lbs. The best results with "plate-system" plants, using a compound steam-engine, have thus far afforded about $10\frac{1}{2}$ lbs. of ice per lb. of coal.

In the "plate system" the ice gradually forms, in from 8 to 10 days, to a thickness of about 14 inches, on the hollow plates, 10×14 feet in area, in which the cooling fluid circulates.

In the "can system" the water is frozen in blocks weighing about 300 lbs. each, and the freezing is completed in from 40 to 48 hours. The freezing-tank area occupied by the "plate system" is, therefore, about twelve times, and the cubic contents about four times, as much as required in the "can system."

The investment for the "plate" is about one-third greater than for the "can" system. In the latter system ice is being drawn throughout the

24 hours, and the hoisting is done by hand tackle. Some "can" plants are equipped with pneumatic hoists and on large hoists electric cranes are used to advantage. In the "plate system" the entire daily product is drawn, cut, and stored in a few hours, the hoisting being performed by power. The distribution of cost is as follows for the two systems, taking the cost for the "can" or distilled-water system as 100, which represents an actual cost of about $1.25 per net ton:

	Can System.	Plate System.
Hoisting and storing ice	14.2	2.8
Engineers, firemen, and coal-passer	15.0	13.9
Coal at $3.50 per gross ton	42.2	20.0
Water pumped directly from a natural source at 5 cts. per 1000 cubic feet	1.3	2.6
Interest and depreciation at 10%	24.6	32.7
Repairs	2.7	3.4
	100.00	75.4

A compound condensing engine is assumed to be used by the "plate system."

Test of the New York Hygeia Ice-making Plant. — (By Messrs. Hupfel, Griswold, and Mackenzie; *Stevens Indicator*, Jan., 1894.)

The final results of the tests were as follows:

Net ice made per pound of coal, in pounds	7.12
Pounds of net ice per hour per horse-power	37.8
Net ice manufactured per day (12 hours) in tons	97
Av. pressure of ammonia-gas at condenser, lbs. per sq. in. above atmos.	135.2
Average back pressure of amm.-gas, lbs. per sq. in. above atmos.	15.8
Average temperature of brine in freezing-tanks, degrees F.	19.7
Total number of cans filled per week	4389
Ratio of cooling-surface of coils in brine-tank to can-surface	7 to 10

An Absorption Evaporator Ice-making System, built by the Carbondale Machine Co. is in operation at the ice plant of the Richmond Ice Co., Clifton, Staten Island, N. Y., which produces the extra distilled water by an evaporator at practically no fuel cost, and thus about 10 tons of distilled water ice per ton of coal is obtained. Steam from the boiler at 100 lbs. pressure enters an evaporator, distilling off steam at 70 lbs., which operates the pumps and auxiliary machinery. These exhaust into the ice machine generator under 10 lbs. pressure, where the exhaust is condensed. In a 100-ton plant the evaporator will condense 43 tons of live steam, distilling off 40 tons of steam to operate the auxiliaries, which exhaust into the generator; 20 tons of live steam has to be added to this exhaust, making 60 tons in all, which is the amount required to operate the generator. The 60 tons of condensation from the generator and 43 tons from the evaporator go to the re-boiler, making 103 tons of distilled water to be frozen into ice. The total steam consumption is the 60 tons condensed in the generator plus 3 tons for radiation, or 63 tons in all. Hence if the boiler evaporates 6.6 lbs. water per pound of coal the economy of the plant will be 10 1/2 lbs. ice per pound of coal, a result which cannot be obtained even with compound condensing engines and compression machines.

Heat-exchanging coils, on the order of a closed feed-water heater, are used to heat the feed-water going to the boiler. The condensation leaving the generator and evaporator at a high temperature is utilized for this purpose; by this means securing a feed-water temperature considerably in excess of 212°.

Ice-Making with Exhaust Steam. — The exhaust steam from electric light plants is being utilized to manufacture ice on the absorption system. A 10-ton plant at the Holdredge Lighting Co., Holdredge, Neb., built by the Carbondale Machine Co., is described in *Elec. World*, April 7, 1910. Here 11 tons of ice were made per day with exhaust steam from the electric engines at 2 1/2 lbs. pressure, using 6 1/3 K.W., or 8 1/2 H.P., for driving the circulating pumps.

Tons of Ice per Ton of Coal. — From a long table by Mr. Voorhees, showing the net tons of plate ice that may be made in well-designed plants under a variety of conditions as to type of engine, the following figures are taken:

Compression, Simple Corliss engine, non-condensing.........	6.1 tons
Absorption liquor pump and auxiliaries not exhausting into generator, simple, non-condensing engine................	10.0
Compression, compound condensing engine.................	11.2
Compression triple-expansion condensing engine............	12.8
Absorption, pump and auxiliaries exhausting into generator, Corliss non-condensing engine..........................	13.3
Compression and absorption, compound engine, non-condensing	16.0
Compression, triple-expansion condensing engine, multiple effect	16.5
Compression and absorption, triple-expansion non-condensing engine, multiple effect................................	19.5

MARINE ENGINEERING.

Rules for Measuring Dimensions and Obtaining Tonnage of Vessels. (Record of American and Foreign Shipping. American Bureau of Shipping, N. Y., 1890.) — The dimensions to be measured as follows;

I. Length, *L*. — From the fore-side of stem to the after-side of stern-post measured at middle line on the upper deck of all vessels, except those having a continuous hurricane-deck extending right fore and aft, in which the length is to be measured on the range of deck immediately below the hurricane-deck.

Vessels having clipper heads, raking forward, or receding stems, or raking stern-posts, the length to be the distance of the fore-side of stem from aft-side of stern-post at the deep-load water-line measured at middle line. (The inner or propeller-post to be taken as stern-post in screw-steamers.)

II. Breadth, *B*. — To be measured over the widest frame at its widest part; in other words, the molded breadth.

III. Depth, *D*. — To be measured at the dead-flat frame and at middle line of vessel. It shall be the distance from the top of floor-plate to the upper side of upper deck-beam in all vessels except those having a continuous hurricane-deck, extending right fore and aft, and not intended for the American coasting trade, in which the depth is to be the distance from top of floor-plate to midway between top of hurricane deck-beam and the top of deck-beam of the deck immediately below hurricane-deck.

In vessels fitted with a continuous hurricane-deck, extending right fore and aft, and intended for the American coasting trade, the depth is to be the distance from top of floor-plate to top of deck-beam of deck immediately below hurricane-deck.

Rule for Obtaining Tonnage. — Multiply together the length, breadth, and depth, and their product by 0.75; divide the last product by 100; the quotient will be the tonnage. $L \times B \times D \times 0.75 \div 100 =$ tonnage.

The U. S. Custom-house Tonnage Law, May 6, 1864, provides that "the register tonnage of a vessel shall be her entire internal cubic capacity in tons of 100 cubic feet each." This measurement includes all the space between upper decks, however many there may be. Explicit directions for making the measurements are given in the law.

The Displacement of a Vessel (measured in tons of 2240 lbs.) is the weight of the volume of water which it displaces. For sea-water it is equal to the volume of the vessel beneath the water-line, in cubic feet, divided by 35, which figure is the number of cubic feet of sea-water at 60° F. in a ton of 2240 lbs. For fresh water the divisor is 35.93. The U. S. register tonnage will equal the displacement when the entire internal cubic capacity bears to the displacement the ratio of 100 to 35.

The displacement or gross tonnage is sometimes approximately estimated as follows: Let L denote the length in feet of the boat, B its extreme breadth in feet, and D the mean draught in feet; the product of these three dimensions will give the volume of a parallelopipedon in cubic feet. Putting V for this volume, we have $V = L \times B \times D$.

The volume of displacement may then be expressed as a *percentage* of the volume V, known as the "*block coefficient.*" This percentage varies for different classes of ships. In racing yachts with very deep keels it varies from 22 to 33; in modern merchantmen from 55 to 90; for ordinary small boats probably 50 will give a fair estimate. The volume of displacement in cubic feet divided by 35 gives the displacement in tons.

Coefficient of Fineness. — A term used to express the relation between the displacement of a ship and the volume of a rectangular prism or box whose lineal dimensions are the length, breadth, and draught.

Coefficient of fineness $= D \times 35 \div (L \times B \times W)$; D being the displacement in tons of 35 cubic feet of sea-water to the ton, L the length between perpendiculars, B the extreme breadth and W the mean draught, all in feet.

Coefficient of Water-lines. — An expression of the relation of the displacement to the volume of the prism whose section equals the midship section of the ship, and length equal to the length of the ship.

Coefficient of water-lines $= D \times 35 \div$ (area of immersed water section $\times L$).

Seaton gives the following values:

	Coefficient of Fineness.	Coefficient of Water-lines
Finely-shaped ships	0.55	0.63
Fairly-shaped ships	0.61	0.67
Ordinary merchant steamers 10 to 11 knots	0.65	0.72
Cargo steamers, 9 to 10 knots	0.70	0.76
Modern cargo steamers of large size	0.78	0.83

Resistance of Ships. — The resistance of a ship passing through water may vary from a number of causes, as speed, form of body, displacement, midship dimensions, character of wetted surface, fineness of lines, etc. The resistance of the water is twofold; 1st. That due to the displacement of the water at the bow and its replacement at the stern, with the consequent formation of waves. 2d. The friction between the wetted surface of the ship and the water, known as skin resistance. A common approximate formula for resistance of vessels is

Resistance = speed$^2 \times \sqrt[3]{\text{displacement}^2} \times$ a constant, or $R = S^2 D^{2/3} \times C$.

If D_1 = displacement in pounds, S_1 = speed in feet per minute, R resistance in pounds, $R = cS_1^2 D_1^{2/3}$. The work done in overcoming the resistance through a distance equal to S_1 is $R \times S_1 = cS_1^3 D_1^{2/3}$; and if E is the efficiency of the propeller and machinery combined, the indicated horse-power I.H.P. $= cS_1^3 D_1^{2/3} \div (E \times 33{,}000)$.

If S = speed in knots, D = displacement in tons, and C a constant which includes all the constants for form of vessel, efficiency of mechanism, etc., I.H.P. $= S^3 D^{2/3} \div C$.

The wetted surface varies as the cube root of the square of the displacement; thus, let L be the length of edge of a cube just immersed, whose displacement is D and wetted surface W. Then $D = L^3$ or $L = \sqrt[3]{D}$, and $W = 5 \times L^2 = 5 \times \left(\sqrt[3]{D}\right)^2$. That is, W varies as $D^{2/3}$.

Another approximate formula is

$$\text{I.H.P.} = \text{area of immersed midship section} \times S^3 \div K.$$

The usefulness of these two formulæ depends upon the accuracy of the so-called "constants" C and K, which vary with the size and form of the ship, and probably also with the speed. Seaton gives the following, which may be taken roughly as the values of C and K under the conditions expressed:

General Description of Ship.	Speed, knots.	Value of C.	Value of K.
Ships over 400 feet long, finely shaped	15 to 17	240	620
" 300 " "	15 " 17	190	500
" " "	13 " 15	240	650
" " "	11 " 13	260	700
Ships over 300 feet long, fairly shaped	11 " 13	240	650
" " "	9 " 11	260	700
Ships over 250 feet long, finely shaped	13 " 15	200	580
" " "	11 " 13	240	660
" " "	9 " 11	260	700
Ships over 250 feet long, fairly shaped	11 " 13	220	620
" " "	9 " 11	250	680
Ships over 200 feet long, finely shaped	11 " 12	220	600
" " "	9 " 11	240	640
Ships over 200 feet long, fairly shaped	9 " 11	220	620
Ships under 200 feet long, finely shaped	11 " 12	200	550
" " "	10 " 11	210	580
" " "	9 " 10	230	620
Ships under 200 feet long, fairly shaped	9 " 10	200	600

Coefficient of Performance of Vessels. — The quotient

$$\sqrt[3]{(\text{displacement})^2} \times (\text{speed in knots})^3 \div \text{ tons of coal in 24 hours}$$

gives a coefficient of performance which represents the comparative cost of propulsion in coal expended. Sixteen vessels with three-stage expansion-engines in 1890 gave an average coefficient of 14,810, the range being from 12,150 to 16,700.

In 1881 seventeen vessels with two-stage expansion-engines gave an average coefficient of 11,710. In 1881 the length of the vessels tested ranged from 260 to 320, and in 1890 from 295 to 400. The speed in knots divided by the square root of the length in feet in 1881 averaged 0.539; and in 1890, 0.579; ranging from 0.520 to 0.641. (*Proc. Inst. M. E.*, July, 1891, p. 329.)

Defects of the Common Formula for Resistance. — Modern experiments throw doubt upon the truth of the statement that the resistance varies as the square of the speed. (See Robt. Mansel's letters in *Engineering*, 1891; also his paper on The Mechanical Theory of Steamship Propulsion, read before Section G of the Engineering Congress, Chicago, 1893.)

Seaton says: In small steamers the chief resistance is the skin resistance. In very fine steamers at high speeds the amount of power required seems excessive when compared with that of ordinary steamers at ordinary speeds.

In torpedo-launches at certain high speeds the resistance increases at a lower rate than the square of the speed.

In ordinary sea-going and river steamers the reverse seems to be the case.

Rankine's Formula for total resistance of vessels of the "wave-line" type is:

$$R = ALBV^2\ (1 + 4 \sin^2 \theta + \sin^4 \theta),$$

in which equation θ is the mean angle of greatest obliquity of the stream-lines, A is a constant multiplier, B the mean wetted girth of the surface exposed to friction, L the length in feet, and V the speed in knots. The *power* demanded to impel a ship is thus the product of a constant to be determined by experiment, the area of the wetted surface, the *cube* of the speed, and the quantity in the parenthesis, which is known as the "coefficient of augmentation." In calculating the resistance of ships the last term of the coefficient may be neglected as too small to be practically important. In applying the formula, the mean of the squares of the sines of the angles of maximum obliquity of the water-lines is to be taken for $\sin^2 \theta$, and the rule will then read thus:

To obtain the resistance of a ship of good form, in pounds, multiply the length in feet by the mean immersed girth and by the coefficient of augmentation, and then take the product of this "augmented surface," as Rankine termed it, by the square of the speed in knots, and by the proper constant coefficient selected from the following:

For clean painted vessels, iron hulls.......	$A = 0.01$
For clean coppered vessels...............	$A = 0.009$ to 0.008
For moderately rough iron vessels........	$A = 0.011 +$

The net, or effective, horse-power demanded will be quite closely obtained by multiplying the resistance calculated, as above, by the speed in knots and dividing by 326. The gross, or indicated, power is obtained by multiplying the last quantity by the reciprocal of the efficiency of the machinery and propeller, which usually should be about 0.6. Rankine uses as a divisor in this case 200 to 260.

The form of the vessel, even when designed by skillful and experienced naval architects, will often vary to such an extent as to cause the above constant coefficients to vary somewhat: and the range of variation with good forms is found to be from 0.8 to 1.5 the figures given.

For well-shaped iron vessels, an approximate formula for the horse-power required is H.P. $= SV^3 \div 20{,}000$, in which S is the "augmented surface." The expression $SV^3 \div$ H.P. has been called by Rankine the *coefficient of propulsion.* In the Hudson River steamer "Mary Powell," according to Thurston, this coefficient was as high as 23,500.

The expression $D^{\frac{2}{3}}V^3 \div$ H.P. has been called the *locomotive performance.* (See Rankine's Treatise on Shipbuilding, 1864; Thurston's Manual of the Steam-engine, part ii, p. 16; also paper by F. T. Bowles, U. S. N., Proc. U. S. Naval Institute, 1883.)

Rankine's method for calculating the resistance is said by Seaton to give more accurate and reliable results than those obtained by the older rules, but it is criticised as being difficult and inconvenient of application.

Empirical Equations for Wetted Surface. (Peabody, Naval Architecture, page 411).—L = length, feet; B = beam; H = mean draught; D = displacement in tons; K = block coefficient.

Taylor Surface $= C\sqrt{DL}$. Values of C for different ratios $B \div H$ are:

$B \div H =$	2	2.2	2.4	2.6	2.8	3.0	3.2	3.4
$C =$	15.63	15.54	15.50	15.51	15.55	15.62	15.71	15.83

Normand Surface $= 1.52\ LH + (3.74 + 0.85\ K^2)\ LB$.
Mumford Surface $= L\ (1.74 + KB)$.

Errors of these approximate equations as applied to several types of vessels are shown by Professors Durand and McDermott (Trans. Soc. Nav. Archts. & Mar. Engrs., Vol. 2), as follows: Taylor -2.69 to $+2.52\%$; Normand, -1.55 to $+2.57\%$; Mumford, 0 to -0.95%, except one lake freight vessel, $L = 299$, $B = 40.9$, $D = 15.9$, $K = 0.825$, on which Mumford's formula was -12.55% in error.

E. R. Mumford's Method of Calculating Wetted Surfaces is given in a paper by Archibald Denny, *Eng'g*, Sept. 21, 1894. The following is his formula, which gives closely accurate results for medium draughts, beams, and finenesses;

$$S = (L \times D \times 1.7) + (L \times B \times C),$$

in which S = wetted surface in square feet; L = length between perpendiculars in feet; D = middle draught in feet; B = beam in feet; C = block coefficient.

The formula may also be expressed in the form $S = L(1.7\ D + BC)$.

In the case of twin-screw ships having projecting shaft-casings, or in the case of a ship having a deep keel or bilge keels, an addition must be made for such projections. The formula gives results which are in general much more accurate than those obtained by Kirk's method. It underestimates the surface when the beam, draught, or block coefficients are excessive; but the error is small except in the case of abnormal forms, such as stern-wheel steamers having very excessive beams (nearly one-fourth the length), and also very full block coefficients. The formula gives a surface about 6% too small for such forms.

The wetted surface of the block is nearly equal to that of the ship of the same length, beam and draught; usually 2% to 5% greater. In exceedingly fine hollow-line ships it may be 8% greater.

Area of bottom of block $= (F + M) \times B$;
Area of sides $= 2\ M \times H$.

$$\text{Area of sides of ends} = 4 \times \sqrt{F^2 + \left(\frac{B}{2}\right)^2} \times H;$$

Tangent of half angle of entrance $= \frac{1}{2}B/F = B/(2\ F)$.

From this, by a table of natural tangents, the angle of entrance may be obtained:

	Angle of Entrance of the Block Model.	Fore-body in parts of length.
Ocean-going steamers, 14 knots and upw'd	18° to 15°	0.3 to 0.36
" " 12 to 14 knots	21° to 18°	0.26 to 0.3
" cargo steamers, 10 to 12 knots..	30° to 22°	0.22 to 0.26

Dr. Kirk's Method. — This method is generally used on the Clyde. The general idea proposed by Dr. Kirk is to reduce all ships to so definite and simple a form that they may be easily compared; and the magnitude of certain features of this form shall determine the suitability of the ship for speed, etc.

The form consists of a middle body, which is a rectangular parallelopiped, and fore-body and after-body, prisms having isosceles triangles for bases, as shown in Fig. 225.

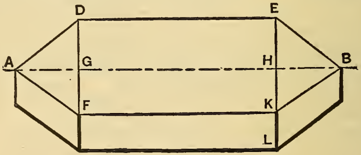

FIG. 225.

This is called a block model, and is such that its length is equal to that of the ship, the depth is equal to the mean draught, the capacity equal to the displacement volume, and its area of section equal to the area of immersed midship section. The dimensions of the block model may be obtained as follows: Let $AG = HB$ = length of fore- or after-body $= F$; GH = length of middle body $= M$; KL = mean draught $= H$; EK = area of immersed midship section $\div KL = B$. Volume of block $= (F + M) \times B \times H$; midship section $= B \times H$; displacement in tons = volume in cubic ft. $\div$ 35.

$$AH = AG + GH = F + M = \text{displacement} \times 35 \div (B \times H).$$

To find the Indicated Horse-power from the Wetted Surface. (Seaton.) — In ordinary cases the horse-power per 100 feet of wetted surface may be found by assuming that the rate for a speed of 10 knots is 5, and that the quantity varies as the cube of the speed. For example: To find the number of I.H.P. necessary to drive a ship at a speed of 15 knots, having a wetted skin of block model of 16,200 square feet:

The rate per 100 feet $= (15/10)^3 \times 5 = 16.875$.
Then I.H.P. required $= 16.875 \times 162 = 2734$.

When the ship is exeptionally well-proportioned, the bottom quite clean, and the efficiency of the machinery high, as low a rate as 4 I.H.P. per 100 feet of wetted skin of block model may be allowed.

The gross indicated horse-power includes the power necessary to overcome the friction and other resistance of the engine itself and the shafting, and also the power lost in the propeller. In other words, I.H.P. is no measure of the resistance of the ship, and can only be relied on as a means of deciding the size of engines for speed, so long as the efficiency of the engine and propeller is known definitely, or so long as similar engines and propellers are employed in ships to be compared. The former is difficult to obtain, and it is nearly impossible in practice to know how much of the power shown in the cylinders is employed usefully in overcoming the resistance of the ship. The following example is given to show the variation in the efficiency of propellers:

	Knots.		I.H.P.
H.M.S. "Amazon," with a 4-bladed screw, gave	12.064	with	1940
H.M.S. "Amazon," with a 2-bladed screw, increased pitch, and fewer revolutions per minute............	12.396	"	1663
H.M.S. "Iris," with a 4-bladed screw	16.577	"	7503
H.M.S. "Iris," with 2-bladed screw, increased pitch, fewer revolutions per knot......................	18.587	"	7556

Relative Horse-power Required for Different Speeds of Vessels. (Horse-power for 10 knots = 1.) — The horse-power is taken usually to vary as the cube of the speed, but in different vessels and at different speeds it may vary from the 2.8 power to the 3.5 power, depending upon the lines of the vessel and upon the efficiency of the engines, the propeller, etc. (The power may vary at a much higher rate than the 3.5 power of the speed when the speed is much less than normal, and the machinery is therefore working at less than its normal efficiency.)

EXAMPLE IN USE OF THE TABLE.—A certain vessel makes 14 knots speed with 587 I.H.P. and 16 knots with 900 I.H.P. What I.H.P. will be required at 18 knots, the rate of increase of horse-power with increase of speed remaining constant? The first step is to find the rate of increase, thus: $14^x : 16^x :: 587 : 900$.

$$x \log 16 - x \log 14 = \log 900 - \log 587;$$

$$x\,(0.204120 - 0.146128) = 2.954243 - 2.768638,$$

whence x (the exponent of S in formula H.P. $\propto S^x$) = 3.2.

From the table, for $S^{3.2}$ and 16 knots, the I.H.P. is 4.5 times the I.H.P. at 10 knots; $\therefore$ H.P. at 10 knots = 900 ÷ 4.5 = 200.

From the table for $S^{3.2}$ and 18 knots, the I.H.P. is 6.559 times the I.H.P. at 10 knots; $\therefore$ H.P. at 18 knots = 200 × 6.559 = 1312 H.P.

Resistance per Horse-power for Different Speeds. (One horse-power = 33.000 lbs. resistance overcome through 1 ft. in 1 min.)—The resistances per horse-power for various speeds are as follows: For a speed of 1 knot, or 6080 feet per hour = 101 1/3 ft. per min., 33,000 ÷ 101 1/3 = 325.658 lbs. per horse-power; and for any other speed 325.658 lbs. divided by the speed in knots; or for

1 knot	325.66 lbs.	8 knots	40.71 lbs.	15 knots	21.71 lbs.
2 knots	162.83 "	9 "	36.18 "	16 "	20.35 "
3 "	108.55 "	10 "	32.57 "	17 "	19.16 "
4 "	81.41 "	11 "	29.61 "	18 "	18.09 "
5 "	65.13 "	12 "	27.14 "	19 "	17.14 "
6 "	54.28 "	13 "	25.05 "	20 "	16.28 "
7 "	46.52 "	14 "	23.26 "		

More accurate methods than those above given for estimating the horse-power required for any proposed ship are: 1. Estimations calculated from the results of trials of "similar" vessels driven at "corresponding" speeds; "similar" vessels being those that have the same ratio of length to breadth and to draught, and the same coefficient of fineness, and "corresponding" speeds those which are proportional to the square roots of the lengths of the respective vessels. Froude found that the resistances of such vessels varied almost exactly as wetted surface × (speed)^2

2. The method employed by the British Admiralty and by some Clyde shipbuilders, viz., ascertaining the resistance of a model of the vessel, 12 to 20 ft. long, in a tank, and calculating the power from the results obtained.

Estimated Displacement, Horse-power, etc. — The table on the next page, calculated by the author, will be found convenient for making approximate estimates.

The figures in 7th column are calculated by the formula H.P. $= S^3 D^{\frac{2}{3}} \div c$ in which $c = 200$ for vessels under 200 ft. long when $C = 0.65$, and 210 when $C = 0.55$; $c = 200$ for vessels 200 to 400 ft. long when $C = 0.75$, 220 when $C = 0.65$, 240 when $C = 0.55$; $c = 230$ for vessels over 400 ft. long when $C = 0.75$, 250 when $C = 0.65$, 260 when $C = 0.55$.

The figures in the 8th column are based on 5 H.P. per 100 sq. ft. of wetted surface.

The diameters of screw in the 9th column are from formula $D = 3.31 \sqrt[5]{\text{I.H.P.}}$, and in the 10th column from formula $D = 2.71 \sqrt[5]{\text{I.H.P.}}$

To find the diameter of screw for any other speed than 10 knots, revolutions being 100 per minute, multiply the diameter given in the table by the 5th root of the cube of the given speed ÷ 10. For any other revolutions per minute than 100, divide by the revolutions and multiply by 100.

To find the approximate horse-power for any other speed than 10 knots, multiply the horse-power given in the table by the cube of the ratio of the given speed to 10, or by the relative figure from table on p. 1373.

F. E. Cardullo, *Mach'y*, April, 1907, gives the following formula as closely approximating the speed of modern types of hulls: $S = 6.35 \sqrt[3]{\frac{\text{I.H.P.}}{D^{2/3}}}$, in which S = speed in knots, D = displacement in tons. If we take $S = 10$ knots, then I.H.P. $\div D^{2/3} = 3.906$. Let $D = 10{,}000$, and $S = 10$, then H.P. $= 1813$. The table on page 1375 gives for a displacement of 10,400 tons and a coefficient of fineness 0.65, 1966 and 1760 H.P., averaging 1863 H.P.

Internal Combustion Marine Engines. — Linton Hope (*Eng'g*, April 8, 1910), in a paper on the application of internal combustion engines to fishing boats and fine-lined commercial vessels, gives a table showing the brake H.P. required to propel such vessels at various speeds. The following table is an abridgment. L = load water line; D = displacement in tons.

* Shaft horse-power.

Relation of Horse-Power to Speed.—If S_1 and S_2 are two successive speeds and P_1P_2 the corresponding horse-powers, then to find the value of the exponent x in the equation H.P. $\propto S^x$, we have

$$x = (\log P_2 - \log P_1) \div (\log S_2 - \log S_1).$$

Applying this formula to the horse-powers and speeds of the "Lusitania" we find that between 15.77 and 18 knots $x = 3.21$; between 18 and 21 knots $x = 3.09$; between 21 and 23 knots $x = 4.12$; between 23 and 25.4 knots $x = 3.63$.

THE SCREW-PROPELLER.

The "pitch" of a propeller is the distance which any point in a blade describing a helix will travel in the direction of the axis during one revolution, the point being assumed to move around the axis. The pitch of a propeller with a uniform pitch is equal to the distance a propeller will advance during one revolution, provided there is no slip. In a case of this kind, the term "pitch" is analogous to the term "pitch of the thread" of an ordinary single-threaded screw.

Let P = pitch of screw in feet, R = number of revolutions per second, V = velocity of stream from the propeller = $P \times R$, v = velocity of the ship in feet per second, $V - v$ = slip, A = area in square feet of section of stream from the screw, approximately the area of a circle of the same diameter, $A \times V$ = volume of water projected astern from the ship in cubic feet per second. Taking the weight of a cubic foot of sea-water at 64 lbs., and the force of gravity at 32, we have from the common formula for force of acceleration, viz.: $F = M\frac{v_1}{t} = \frac{W}{g}\frac{v_1}{t}$, or $F = \frac{W}{g}v_1$, when $t = 1$ second.

$$\text{Thrust of screw in pounds} = \frac{64\,AV}{32}(V - v) = 2\,AV(V - v).$$

Rankine (Rules, Tables, and Data, p. 275) gives the following: To calculate the thrust of a propelling instrument (jet, paddle, or screw) in pounds, multiply together the transverse sectional area, in square feet, of the stream driven astern by the propeller; the speed of the stream relatively to the ship in knots; the real slip, or part of that speed which is impressed on the stream by the propeller, also in knots; and the constant 5.66 for sea-water, or 5.5 for fresh water. If S = speed of the screw in knots, s = speed of ship in knots, A = area of the stream in square feet (of sea-water),

$$\text{Thrust in pounds} = A \times S\ (S - s) \times 5.66.$$

The real slip is the velocity (relative to water at rest) of the water projected sternward; *the apparent slip* is the difference between the speed of the ship and the speed of the screw; i.e., the product of the pitch of the screw by the number of revolutions.

This apparent slip is sometimes negative, due to the working of the screw in disturbed water which has a forward velocity, following the ship. Negative apparent slip is an indication that the propeller is not suited to the ship. The apparent slip should generally be about 8% to 10% at full speed in well-formed vessels with moderately fine lines; in bluff cargo boats it rarely exceeds 5%.

The effective area of a screw is the sectional area of the stream of water laid hold of by the propeller, and is generally, if not always, greater than the actual area, in a ratio which in good ordinary examples is 1.2 or thereabouts, and is sometimes as high as 1.4: a fact probably due to the stiffness of the water, which communicates motion laterally amongst its particles. (Rankine's Shipbuilding, p. 89.)

Prof. D. S. Jacobus, *Trans. A. S. M. E.*, xi, 1028, found the ratio of the effective to the actual disk area of the screws of different vessels to be as follows:

Tug-boat, with ordinary true-pitch screw		1.42
Tug-boat, with screw having blades projecting backward		0.57
Ferryboat "Bergen," with ordinary true-pitch screw	at speed of 12.09 stat. miles per hr.	1.53
	at speed of 13.4 stat. miles per hr.	1.48
Steamer "Homer Ramsdell," with ordinary true-pitch screw		1.20

Size of Screw. — Seaton says: The size of a screw depends on so many things that it is very difficult to lay down any rule for guidance, and much must always be left to the experience of the designer, to allow for all the circumstances of each particular case. The following rules are given for ordinary cases (Seaton and Rounthwaite's Pocket-book):

P = pitch of propeller in feet $= \frac{10133\,S}{R\,(100 - x)}$, in which S = speed in knots, R = revolutions per minute, and x = percentage of apparent slip. For a slip of 10%, pitch = $112.6\,S \div R$.

D = diameter of propeller $= K\sqrt{\dfrac{\text{I.H.P.}}{\left(\dfrac{P \times R}{100}\right)^3}}$, K being a coefficient given in the table below. If $K = 20$, $D = 20{,}000\sqrt{\text{I.H.P.} \div (P \times R)^3}$.

Total developed area of blades $= C\sqrt{\text{I.H.P.} \div R}$, in which C is a coefficient to be taken from the table.

Another formula for pitch, given in Seaton's Marine Engineering, is $P = \dfrac{C}{R}\sqrt[3]{\dfrac{\text{I.H.P.}}{D^2}}$, in which $C = 737$ for ordinary vessels, and 660 for slow-speed cargo vessels with full lines.

Thickness of blade at root $= \sqrt{\dfrac{d^3}{nb} \times k}$, in which d = diameter of tail shaft in inches, n = number of blades, b = breadth of blade in inches where it joins the boss, measured parallel to the shaft axis; $k = 4$ for cast iron, 1.5 for cast steel, 2 for gun-metal, 1.5 for high-class bronze.

Thickness of blade at tip: Cast iron $0.04\,D + 0.4$ in.; cast steel $0.03\,D + 0.4$ in.; gun-metal $0.03\,D + 0.2$ in.; high-class bronze $0.02\,D + 0.3$ in., where D = diameter of propeller in feet.

Propeller Coefficients.

Description of Vessel.	Approx. Speed, Knots.	No. of Screws.	No. of Blades per Screw	Values of K.	Values of C.	Usual Material of Blades.
Bluff cargo boats..........	8–10	One	4	17 –17.5	19 –17.5	Cast iron

C. I., cast iron; G. M., gun-metal; B., bronze; S., steel; F.S., forged steel.

From the formulæ $D = 20{,}000\sqrt{\dfrac{\text{I.H.P.}}{(P \times R)^3}}$ and $P = \sqrt{\dfrac{737\text{I.H.P.}}{R \quad D^2}}$, if $P = D$ and $R = 100$, we obtain $D = \sqrt[5]{400 \times \text{I.H.P.}} = 3.31\sqrt[5]{\text{I.H.P.}}$

If $P = 1.4\,D$ and $R = 100$, then $D = \sqrt[5]{145.8 \times \text{I.H.P.}} = 2.71\sqrt[5]{\text{I.H.P.}}$

From these two formulæ the figures for diameter of screw in the table on page 1375 have been calculated. They may be used as rough approximations to the correct diameter of screw for any given horse-power, for a speed of 10 knots and 100 revolutions per minute.

For any other number of revolutions per minute multiply the figures in the table by 100 and divide by the given number of revolutions. For any other speed than 10 knots, since the I.H.P. varies approximately as the cube of the speed, and the diameter of the screw as the 5th root of the I.H.P., multiply the diameter given for 10 knots by the 5th root of the cube of one-tenth of the given speed. Or, multiply by the following factors:

For speed of knots:	4	5	6	7	8	9	11	12	13	14	15	16
$\sqrt[5]{(S \div 10)^3} =$	0.577	0.660	0.736	0.807	0.875	0.939	1.059	1.116	1.170	1.224	1.275	1.327
Speed:	17	18	19	20	21	22	23	24	25	26	27	28
$\sqrt[5]{(S \div 10)^3} =$	1.375	1.423	1.470	1.515	1.561	1.605	1.648	1.691	1.733	1.774	1.815	1.855

For more accurate determinations of diameter and pitch of screw, the formulæ and coefficients given by Seaton, quoted above, should be used.

Efficiency of the Propeller. — According to Rankine, if the slip of the water be s, its weight W, the resistance R, and the speed of the ship v,

$$R = Ws \div g;\ Rv = Wsv \div g.$$

This impelling action must, to secure maximum efficiency of propeller, be effected by an instrument which takes hold of the fluid without shock or disturbance of the surrounding mass, and, by a steady acceleration, gives it the required final velocity of discharge. The velocity of the propeller overcoming the resistance R would then be

$$[v + (v + s)] \div 2 = v + s/2;$$

and the work performed would be

$$R\,(v + s/2) = Wvs \div g + Ws^2 \div 2g,$$

the first of the last two terms being useful, the second the minimum lost work; the latter being the wasted energy of the water thrown backward. The efficiency is $E = v \div (v + s/2)$; and this is the limit attainable with a perfect propelling instrument, which limit is approached the more nearly as the conditions above prescribed are the more nearly fulfilled. The efficiency of the propelling instrument is probably rarely much above 0.60, and never above 0.80.

In designing the screw-propeller, as was shown by Dr. Froude, the best angle for the surface is that of 45° with the plane of the disk; but as all parts of the blade cannot be given the same angle, it should, where practicable, be so proportioned that the "pitch-angle at the center of effort" should be made 45°. The maximum possible efficiency is then, according to Froude, 77%. In order that the water should be taken on without shock and discharged with maximum backward velocity, the screw must have an axially increasing pitch.

The true screw is the usual form of propeller in all steamers, both merchant and naval. (Thurston, Manual of the Steam-engine, part ii, p. 176.)

The combined efficiency of screw, shaft, engine, etc., is generally taken at 50%. In some cases it may reach 60% or 65%. Rankine takes the effective H.P. to equal the I.H.P. ÷ 1.63.

Results of Researches on the efficiency of screw-propellers are summarized by S. W. Barnaby, in a paper read before section G of the Engineering Congress, Chicago, 1893. He states that the following general principles have been established:

(*a*) There is a definite amount of real slip at which, and at which only, maximum efficiency can be obtained with a screw of any given type, and this amount varies with the pitch-ratio. The slip-ratio proper to a given ratio of pitch to diameter has been discovered and tabulated for a screw of a standard type, as below:

Pitch-ratio and Slip for Screws of Standard Form.

Pitch-ratio.	Real Slip of Screw.	Pitch-ratio.	Real Slip of Screw.	Pitch-ratio.	Real Slip of Screw.
0.8	15.55	1.4	19.5	2.0	22.9
0.9	16.22	1.5	20.1	2.1	23.5
1.0	16.88	1.6	20.7	2.2	24.0
1.1	17.55	1.7	21.3	2.3	24.5
1.2	18.2	1.8	21.8	2.4	25.0
1.3	18.8	1.9	22.4	2.5	25.4

(*b*) Screws of large pitch-ratio, besides being less efficient in themselves, add to the resistance of the hull by an amount bearing some proportion to their distance from it, and to the amount of rotation left in the race.

(*c*) The best pitch-ratio lies probably between 1.1 and 1.5.

(*d*) The fuller the lines of the vessel, the less the pitch-ratio should be.

(*e*) Coarse-pitched screws should be placed further from the stern than fine-pitched ones.

(*f*) Apparent negative slip is a natural result of abnormal proportions of propellers.

(*g*) Three blades are to be preferred for high-speed vessels, but when the diameter is unduly restricted, four or even more may be advantageously employed.

(*h*) An efficient form of blade is an ellipse having a minor axis equal to four-tenths the major axis.

(*i*) The pitch of wide-bladed screws should increase from forward to aft, but a uniform pitch gives satisfactory results when the blades are narrow, and the amount of the pitch variation should be a function of the width of the blade.

(*j*) A considerable inclination of screw-shaft produces vibration, and with right-handed twin-screws turning outwards, if the shafts are inclined at all, it should be upwards and outwards from the propellers.

For results of experiments with screw-propellers, see F. C. Marshall, *Proc. Inst. M. E.*, 1881; R. E. Froude, *Trans. Inst. Nav. Archs.*, 1886; G. A. Calvert, *Trans. Inst. Nav. Archs.*, 1887; S. W. Barnaby, *Proc. Inst. C. E.*, 1890, vol. cii, and D. W. Taylor's "Resistance of Ships and Screw Propulsion." Also Mr. Taylor's paper in Proc. Soc. Nav. Arch. & Marine Engrs., 1904. Mr. Taylor found the highest efficiencies, exceeding 70%, in propellers with pitch ratios from 1.0 to 1.5 ratio of width of blade to diameter of 1/8 to 1/5, and ratio of developed area of blade to disk area of 0.201 to 0.322.

One of the most important results deduced from experiments on model screws is that they appear to have practically equal efficiencies throughout a wide range both in pitch-ratio and in surface-ratio; so that great latitude is left to the designer in regard to the form of the propeller. Although these experiments are not a direct guide to the selection of the most efficient propeller for a particular ship, they supply the means of analyzing the performances of screws fitted to vessels, and of thus indirectly determining what are likely to be the best dimensions of screw for a vessel of a class whose results are known. (*Proc. Inst. M. E.*, July, 1891.)

Mr. Barnaby in *Proc. Inst. C. E.*, 1890, gives a table to be used in calculations for determining the best dimensions of screws for any given speed and H.P. from which the following table is abridged. It is deduced from Froude's experiments at Torquay. (*Trans. Inst. Nav. Archs.*, 1886.)

C_A = disk area in sq. ft. $\times V^3$/H.P. C_R = revs. per min. $\times D/V$. V = speed in knots, D = diam. of screw in ft. H.P. = effective H.P. on the screw shaft. Disk area = $0.7854\,D^2 = C_A \times$ I.H.P./V^3. Revs. per min. = $C_R \times V/D$. The constants C_A and C_R assume a standard value of the speed of the wake, equal to 10% of the speed of the ship. In a very full ship it may amount to 30%, therefore V should be reduced when using the constants by amounts varying from 20% to 0 as the form varies from "very full" to "fairly fine."

* Natural and forced draft respectively.

Summary of Results. (1891 to 1901).—Steam pressures have been increased in the merchant marine from 158 lbs. to 197 lbs. per sq. in., the maximum attained being 267 lbs. per sq. in., and 300 lbs. in the naval service. The piston speed of mercantile machinery has gone up from 529 to 654 ft. per minute, the maximum in merchant practice being about 900 ft., and in naval practice 960 ft. for large engines, and 1300 ft. in torpedo-boat destroyers. Boilers also yield a greater power for a given surface, and thus the average power per ton of machinery has gone up from an average of 6 to about 7 I.H.P., while ten years ago the highest sustained ocean speed was 20.7 knots, it is now 23.38 knots; the highest speed for large warships was 22 knots and is now 23 knots on a trial of double the duration; the maximum speed attained by any craft was 25 knots, as compared with 36.581 knots now, while the number of ships of over 20 knots was 8 in 1891, and is 58 now (1901).

Turbines and Boilers of the "Lusitania." (Thomas Bell, *Proc. Inst. Nav. Archts.*, 1908.)—Some of the principal dimensions of the turbines and boilers of the "Lusitania" are as follows:

Turbines.	Diameter of Rotor, Ins.	Length of Blades, Ins.	
		In First Expansion.	In Last Expansion.
H.P.	96	2 3/4	12 3/8
L.P.	140	8 1/4	22
Astern	104	2 1/4	8

Total cooling surface, main condensers, 82,800 sq. ft; area of exhaust inlet, 158 sq. ft; bore of circulating discharge pipes, 32 ins.

Boilers. — Working pressure, 195 lbs. per sq. in.; 23 double-ended boilers, 17 ft. 6 in. mean diameter by 22 ft. long; 2 single-ended boilers, 17 ft. 6 in. mean diameter by 11 ft. 4 in. long; total number of furnaces, 192; total grate surface, 4048 sq. ft.; total heating surface, 158,352 sq. ft.; total length of boiler-rooms, 336 ft.; total length of main and auxiliary engine rooms, 149 ft. 8 in.

The following are the weights of the various revolving parts, and the size of bearings and the pressure: Weight of one H.P. turbine rotor complete, 86 tons; one L.P. rotor, 120 tons; one astern rotor, 62 tons.

	Main Bearing Journals.		Pressure per Sq. In. of Bearing Surface.	At. 190 Revs. Surface Speed of Journal.
	Diameter.	Effective Length.		
H.P. rotor	27 1/8 in.	44 3/4 in.	80 lbs.	1350 ft. per min.
L.P. rotor	33 1/8 in.	56 1/2 in.	72 lbs.	1650 ft. per min.
Astern rotor	24 1/8 in.	34 3/4 in.	83 lbs.	1200 ft. per min.

Performance of the "Lusitania." (Thos. Bell, *Proc. Inst. Nav. Archts.*, 1908; *Power*, May 12, 1908.) — The following records were obtained in the official trials:

Speed in knots	15.77	18	21	23	25.4
Shaft horse-power	13,400	20,500	33,000	48,000	68,850
Steam cons. per shaft, H.P. hr.					
of turbines, lbs	21.23	17.24	14.91	13.92	12.77
of auxiliaries, lbs	5.3	3.72	2.6	2.01	1.69
total lbs	26.53	20.96	17.51	15.93	14 46
Temp. of feed-water, ° F.	200	200	199	179	165
Coal cons. lbs. per shaft H.P. hr	2.52	2.01	1.68	1.56	1.43

Estimated steam and coal consumption under service conditions, at same speeds:

Steam cons. of auxiliaries, per shaft H.P. hr., lbs.	6.97	4.92	3.41	2.65	2.17
Steam cons. of total per shaft H.P. hr., lbs	28.20	22.16	18.32	16.57	14.94
Coal cons., lbs. per shaft H.P. hr., lbs.	2.76	2.17	1.8	1.62	1.46
Est. coal cons., on a voyage of 3100 nautical miles, gross tons	3,270	3,440	3,930	4,700	5,490

The following figures are taken from the records of a voyage from

Dimensions and Performances of Notable Atlantic Steamers (*Eng'g*, Aug. 2, 1907).

* Between perpendiculars. † Thousands of tons.

Relative Economy of Turbines and Reciprocating Engine. (C. A. Parsons, *Trans. Inst. Nav. Archs.*, 1910.) — The "Vespasian," a cargo vessel 275 ft. long, 38 ft. 9 in. breadth, 19 ft. 8 in. mean loaded draught, 4350 tons displacement, was at first fitted with a triple-expansion engine, cylinders 22 1/4, 35 and 59 ins., 42-in. stroke; and afterwards with two Parsons turbines, high and low pressure, each connected by a flexible coupling to a 20-tooth pinion, the two pinions gearing into a wheel 8 ft. 3 in. pitch diam., with 398 double helical teeth, 20° angle, 24 in. face, the gear ratio being 19.9 to 1. The boilers, propeller, shafting and thrust block remained the same as with the reciprocating engine. Tests were made before and after the installation of the turbines with the following results: At a speed of 8.87 knots the reciprocating engine used 11,750 lbs. of water per hour, as against 10,750 lbs. taken by the turbines — a saving of 8.5%; at 9.55 knots the figures were 14,500 and 12,600, respectively — a saving of 13.0%; at 10.2 knots, 17,500 and 14,750 lbs., respectively — a saving of 16.0%.

Queenstown to Sandy Hook, 2781 nautical miles, Nov. 3-8, 1908, 4 days, 18 hrs., 40 m.: Averages: Steam pressure at boilers, 168 lbs.; temperature hot-well, 74.5°; feed-water, 197°; vacuum, 28.1 in.; speed, 24.25 knots; speed, best day, 24.8 knots; revolutions, 181.1; slip, 15.9%. Total coal, 4976 tons. Steam consumption: main turbines, 851,500 lbs., = 13.1 lbs. per shaft H.P. hr. (on a basis of 65,000 shaft H.P.); auxiliary machinery, 114,000 lbs., = 1.75 per H.P. hr.; evaporating plant and heating, 32,500 lbs., = 0.5 lb. per H.P. hr. Total, 998,000 lbs., = 15.35 lbs. per shaft H.P. hour. Average coal burned, 43½ tons per hour. Water evaporated per lb., coal 10.2 lbs. from feed at 196°, = 10.9 lbs. from and at 212°. Coal for all purposes per shaft H.P. hour, 1.5 lbs. Coal per sq. ft. of grate per hour, 24.1 lbs. The coal was half Yorkshire, half South Wales.

In September, 1909, the "Lusitania" made the westward passage, 2784 miles from Daunt's Rock near Queenstown to Ambrose Channel Lightship, off Sandy Hook, in 4 days 11 h. 42 m., averaging 25.85 knots for the entire passage. Four successive days runs, from noon to noon, were 650, 652, 651 and 674 miles.

Reciprocating Engines with a Low-Pressure Turbine. — The "Laurentic," built for the Canadian trade of the White Star Line, 14,000 tons gross register, is a triple-screw steamer, with the two outer screws driven by four-cylinder triple-expansion engines, and the central screw by a Parsons turbine. The steam, of 200 lbs. boiler pressure, first passes to the reciprocating engines, where it expands to from 14 to 17 lbs. absolute, and then passes to the turbine. For manœuvering the ship into and out of port the turbine is not used, and the steam passes directly from the engines to the condensers. During the trial trip the combined engine-turbine outfit developed 12,000 H.P., with a speed of 17½ knots, and showed a coal consumption of 1.1 lbs. and a water consumption of 11 lbs. per indicated horse-power hour. (*Power*, May 18, 1909.)

The "Kronprinzessin Cecilie" of the North German Lloyd Co., is probably the last high-speed transatlantic steamer of very great power that will be built with reciprocating engines. Its dimensions are: length, 706 ft.; beam, 72 ft.; depth, 44 ft. 2 in.; displacement, 26,000 tons. Four 12,000 H.P. engines, two on each shaft, in tandem. Cylinders, 37⅜, 49¼, 74⅞ and 112¼ ins., by 6 ft. stroke. Steam, 230 lbs., delivered from 19 cylindrical boilers, through four 17-in. steampipes. Coal used in 24 hours, 764 tons, in 124 furnaces; 1.4 lbs. per H.P. hour, including auxiliaries. Speed on trial trip on a 60-mile course, 24.02 knots. (*Sci. Am.*, Aug. 24, 1907.)

THE PADDLE-WHEEL.

Paddle-wheels with Radial Floats. (Seaton's Marine Engineering.) — The effective diameter of a radial wheel is usually taken from the centers of opposite floats; but it is difficult to say what is absolutely that diameter, as much depends on the form of float, the amount of dip, and the waves set in motion by the wheel. The slip of a radial wheel is from 15 to 30 per cent, depending on the size of float.

$$\text{Area of one float} = C \times \text{I.H.P.} \div D.$$

D is the effective diameter in feet, and C is a multiplier, varying from 0.25 in tugs to 0.175 in fast-running light steamers.

The breadth of the float is usually about ¼ its length, and its thickness about ⅛ its breadth. The number of floats varies directly with the diameter, and there should be one float for every foot of diameter.

(For a discussion of the action of the radial wheel, see Thurston, Manual of the Steam-engine, part ii, p. 182.)

Feathering Paddle-wheels. (Seaton.) — The diameter of a feathering-wheel is found as follows: The amount of slip varies from 12 to 20 per cent, although when the floats are small or the resistance great it is as high as 25 per cent; a well-designed wheel on a well-formed ship should not exceed 15 per cent under ordinary circumstances.

If K is the speed of the ship in knots, S the percentage of slip, and R the revolutions per minute,

$$\text{Diameter of wheel at centers} = K\ (100 + S) \div (3.14 \times R).$$

The diameter, however, must be such as will suit the structure of the ship, so that a modification may be necessary on this account, and the revolutions altered to suit it. The diameter will also depend on the amount of "dip" or immersion of float.

When a ship is working always in smooth water the immersion of the top edge should not exceed $1/8$ the breadth of the float; and for general service at sea an immersion of $1/2$ the breadth of the float is sufficient. If the ship is intended to carry cargo, the immersion when light need not be more than 2 or 3 inches, and should not be more than the breadth of float when at the deepest draught; indeed, the efficiency of the wheel falls off rapidly with the immersion of the wheel.

$$\text{Area of one float} = C \times \text{I.H.P.} \div D.$$

C is a multiplier, varying from 0.3 to 0.35; D is the diameter of the wheel to the float centers, in feet.

The number of floats $= 1/2\,(D + 2)$.
The breadth of the float $= 0.35 \times$ the length.
The thickness of floats $= 1/12$ the breadth.
Diameter of gudgeons $=$ thickness of float.

Seaton and Rounthwaite's Pocket-book gives:

$$\text{Number of floats} = 60 \div \sqrt{R},$$

where R is number of revolutions per minute.

$$\text{Area of one float (in square feet)} = \frac{\text{I.H.P.} \times 33{,}000 \times K}{N \times (D \times R)^3},$$

where N = number of floats in one wheel.

For vessels plying always in smooth water $K = 1200$. For sea-going steamers $K = 1400$. For tugs and such craft as require to stop and start frequently in a tide-way $K = 1600$.

It will be quite accurate enough if the last four figures of the cube $(D \times R)^3$ be taken as ciphers.

For illustrated description of the feathering paddle-wheel see Seaton's Marine Engineering, or Seaton and Rounthwaite's Pocket-book. The diameter of a feathering-wheel is about one-half that of a radial wheel for equal efficiency. (Thurston.)

Efficiency of Paddle-wheels. — Computations by Prof. Thurston of the efficiency of propulsion by paddle-wheels give for light river steamers with ratio of velocity of the vessel, v, to velocity of the paddle-float at center of pressure, V, or v/V, $= 3/4$, with a dip $= 3/20$ radius of the wheel and a slip of 25 per cent, an efficiency of 0.714; and for ocean steamers with the same slip and ratio of v/V, and a dip $= 1/3$ radius, an efficiency of 0.685.

JET-PROPULSION.

Numerous experiments have been made in driving a vessel by the reaction of a jet of water pumped through an orifice in the stern, but they have all resulted in commercial failure. Two-jet propulsion steamers, the "Waterwitch," 1100 tons, and the "Squirt," a small torpedo-boat, were built by the British Government. The former was tried in 1867, and gave an efficiency of apparatus of only 18 per cent. The latter gave a speed of 12 knots, as against 17 knots attained by a sister-ship having a screw and equal steam-power. The mathematical theory of the efficiency of the jet was discussed by Rankine in *The Engineer*, Jan. 11, 1867, and he showed that the greater the quantity of water operated on by a jet-propeller, the greater is the efficiency. In defiance both of the theory and of the results of earlier experiments, and also of the opinions of many naval engineers, more than $200,000 were spent in 1888–90 in New York upon two experimental boats, the "Prima Vista" and the "Evolution," in which the jet was made of very small size, in the latter case only $5/8$-inch diameter, and with a pressure of 2500 lbs. per square inch. As had been predicted, the vessel was a total failure. (See article by the author in *Mechanics*, March, 1891.)

The theory of the jet-propeller is similar to that of the screw-propeller. If A = the area of the jet in square feet, V its velocity with reference to the orifice, in feet per second, v = the velocity of the ship in reference to the earth, then the thrust of the jet (see Screw-propeller, *ante*) is $2\,AV(V - v)$. The work done on the vessel is $2\,AV(V - v)\,v$, and the work wasted on the rearward projection of the jet is $1/2 \times 2\,AV(V - v)^2$. The efficiency is $\frac{2\,AV(V-v)\,v}{2\,AV(V-v)\,v + AV(V-v)^2} = \frac{2\,v}{V+v}$. This expression equals unity when $V = v$, that is, when the velocity of the jet with reference to the earth, or $V - v$, $= 0$; but then the thrust of the propeller is also 0. The greater the value of V as compared with v, the less the efficiency. For $V = 20\,v$, as was proposed in the "Evolution," the efficiency of the jet would be less than 10 per cent, and this would be further reduced by the friction of the pumping mechanism and of the water in pipes.

The whole theory of propulsion may be summed up in Rankine's words: "That propeller is the best, other things being equal, which drives astern the largest body of water at the lowest velocity."

It is practically impossible to devise any system of hydraulic or jet propulsion which can compare favorably, under these conditions, with the screw or the paddle-wheel.

Reaction of a Jet. — If a jet of water issues horizontally from a vessel, the reaction on the side of the vessel opposite the orifice is equal to the weight of a column of water the section of which is the area of the orifice, and the height is twice the head.

The propelling force in jet-propulsion is the reaction of the stream issuing from the orifice, and it is the same whether the jet is discharged under water, in the open air, or against a solid wall. For proof, see account of trials by C. J. Everett, Jr., given by Prof. J. Burkitt Webb, *Trans. A. S. M. E.*, xii, 904.

CONSTRUCTION OF BUILDINGS.*

FOUNDATIONS.

Bearing Power of Soils. — Ira O. Baker, "Treatise on Masonry Construction."

Kind of Material.	Bearing Power in Tons per Square Foot.	
	Minimum.	Maximum.
Rock — the hardest — in thick layers, in native bed.	200	....
Rock equal to best ashlar masonry..................	25	30
Rock equal to best brick masonry..................	15	20
Rock equal to poor brick masonry..................	5	10
Clay on thick beds, always dry..................	4	6
Clay on thick beds, moderately dry..................	2	4
Clay, soft..................	1	2
Gravel and coarse sand, well cemented..................	8	10
Sand, compact, and well cemented..................	4	6
Sand, clean, dry..................	2	4
Quicksand, alluvial soils, etc..................	0.5	1

The building code of Greater New York specifies the following as the maximum permissible loads for different soils:

"Soft clay, one ton per square foot;
"Ordinary clay and sand together, in layers, wet and springy, two tons per square foot;
"Loam, clay or fine sand, firm and dry, three tons per square foot;
"Very firm coarse sand, stiff gravel or hard clay, four tons per square foot, or as otherwise determined by the Commissioner of Buildings having jurisdiction."

* The limitations of space forbid any extended treatment of this subject. Much valuable information upon it will be found in Trautwine's "Civil Engineers' Pocket-book," and in Kidder's "Architects' and Builders' Pocket-book." The latter in its preface mentions the following works of reference: "Notes on Building Construction," 3 vols., Rivingtons, publishers, London; "Building Superintendence," by T. M. Clark (J. R. Osgood & Co., Boston); "The American House Carpenter," and "The Theory of Transverse Strains," both by R. G. Hatfield; "Graphical Analysis of Roof-trusses," by Prof. C. E. Greene; "The Fire Protection of Mills," by C. J. H. Woodbury; "House Drainage and Water Service," by James C. Bayles; "The Builder's Guide and Estimator's Price-book," and "Plastering Mortars and Cements," by Fred. T. Hodgson; "Foundations and Concrete Works," and "Art of Building," by E. Dobson, Weale's Series, London.

Bearing Power of Piles. — *Engineering News* Formula: Safe load in tons $= 2\ Wh \div (S + 1)$. W = weight of hammer in tons, h = height of fall of hammer in feet, S = penetration under last blow, or the average under last five blows, in inches.

Safe Strength of Brick Piers, exceeding six diameters in height. (Kidder.)

Piers laid with rich lime mortar, lbs. per sq. in., $110 - 5\ H/D$.
Piers laid with 1 to 2 natural cement mortar, $140 - 5\frac{1}{2}\ H/D$.
Piers laid with 1 to 3 Portland cement mortar, $200 - 6\ H/D$.
H = height; D = least horizontal dimension, in feet.

Thickness of Foundation Walls. (Kidder.)

Height of Building.	Dwellings, Hotels, etc.		Warehouses.	
	Brick.	Stone.	Brick.	Stone.
	Inches.	Inches.	Inches.	Inches.
Two stories	12 or 16	20	16	20
Three stories	16	20	20	24
Four stories	20	24	24	28
Five stories	24	28	24	28
Six stories	28	32	28	32

MASONRY.

Allowable Pressures on Masonry in Tons per Square Foot. (Kidder.)

Different Cities.*	(1)	(2)	(3)	(4)	(5)	(6)	(7)

6 parts average gravel	99,900	234,475	385,612	265,550	406,700
6 parts coarse stone, no fine	....	....	234,475	220,350	266,300

Reinforced Concrete.—The building laws of New York, St. Louis, Cleveland and Buffalo, and the National Board of Fire Underwriters agree in prescribing the following as the maximum allowable working stresses:

Extreme fiber stress in compression in concrete	500	lbs. per sq. in.	
Shearing stress in concrete	50	"	"
Direct compression in concrete	350	"	"
Adhesion of steel to concrete	50	"	"
Tensile stress in steel	16,000	"	"
Shearing stress in steel	10,000	"	"

BEAMS AND GIRDERS.

Safe Loads on Beams. — Uniformly distributed load:

$$\text{Safe load in lbs.} = \frac{2 \times \text{breadth} \times \text{square of depth} \times A}{\text{span in feet}}.$$

$$\text{Breadth in inches} = \frac{\text{span in feet} \times \text{load}}{2 \times \text{square of depth} \times A}.$$

The depth is taken in inches. The coefficient A, is $1/18$ the maximum fiber stress for safe loads, and is the safe load for a beam 1 in. square, 1 ft. span. The following values of A are given by Kidder as one-third of the breaking weight of timber of the quality used in first-class buildings. The values for stones are based on a factor of safety of six.

VALUES FOR A. — COEFFICIENT FOR BEAMS.

Cast iron	308	Pine, Texas yellow	90
Wrought iron	666	Spruce	70
Steel	888	Whitewood (poplar)	65
American Woods:		Redwood (California)	60
Chestnut	60	Bluestone flagging (Hudson River)	25
Hemlock	55	Granite, average	17
Oak, white	75	Limestone	14
Pine, Georgia yellow	100	Marble	17
Pine, Oregon	90	Sandstone	8 to 11
Pine, red or Norway	70	Slate	50
Pine, white, Eastern	60		
Pine, white, Western	65		

Safe Loads in Tons, Uniformly Distributed, for White-oak Beams.

(In accordance with the Building Laws of Boston.)

Formula: $W = \frac{4\,PBD^2}{3\,L}$. W = safe load in pounds; P, extreme fiber-stress = 1000 lbs. per square inch, for white oak; B, breadth in inches; D, depth in inches; L, distance between supports in inches.

For other kinds of wood than white oak multiply the figures in the table by a figure selected from those given below (which represent the safe stress per square inch on beams of different kinds of wood according to the building laws of the cities named) and divide by 1000.

	Hemlock.	Spruce.	White Pine.	Oak.	Yellow Pine.
New York..............	800	900	900	1100	1100*
Boston..................	....	750	750	1000†	1250
Chicago.................	....	....	900	1080	1440

* Georgia pine. † White oak.

Maximum Permissible Stresses in Structural Materials used in Buildings. (Building Ordinances of the City of Chicago, 1893.) — Cast iron, crushing stress: For plates, 15,000 lbs. per square inch; for lintels, brackets, or corbels, compression 13,500 lbs. per square inch, and tension 3000 lbs. per square inch. For girders, beams, corbels, brackets, and trusses, 16,000 lbs. per square inch for steel and 12,000 lbs. for iron.

For plate girders:

Flange area = maximum bending moment in ft.-lbs. $\div (CD)$.

D = distance between center of gravity of flanges in feet.
C = 13,500 for steel, 10,000 for iron.
Web area = maximum shear $\div C$.
C = 10,000 for steel; 6,000 for iron.

For rivets in single shear per square inch of rivet area:

If shop-driven, steel, 9000 lbs., iron, 7500 lbs.; if field-driven, steel, 7500 lbs., iron, 6000 lbs.

For timber girders: $S = cbd^2 \div l$.

b = breadth of beam in inches, d = depth of beam in inches, l = length of beam in feet, c = 160 for long-leaf yellow pine, 120 for oak, 100 for white or Norway pine.

WALLS.

Thickness of Walls of Buildings. — Kidder gives the following general rule for mercantile buildings over four stories in height:

For brick equal to those used in Boston or Chicago, make the thickness of the three upper stories 16 ins., of the next three below 20 ins., the next three 24 ins., and the next three 28 ins. For a poorer quality of material make only the two upper stories 16 ins. thick, the next three 20 ins. and so on down.

In buildings less than five stories in height the top story may be 12 ins. in thickness.

Thickness of Walls in Inches, for Mercantile Buildings and for all Buildings over Five Stories in Height. (The figures show the range of the thicknesses required by the ordinances of eight different cities. — Condensed from Kidder.)

Stories High.	Stories.

(Extract from the Building Laws of the City of New York, 1893.)

Walls of Warehouses, Stores, Factories, and Stables. — 25 feet or less in width between walls, not less than 12 in. to height of 40 ft. If 40 to 60 ft. in height, not less than 16 in. to 40 ft., and 12 in. thence to top;

60 to 80 ft. in height, not less than 20 in. to 25 ft., and 16 in. thence to top;

75 to 85 ft. in height, not less than 24 in. to 20 ft.; 20 in. to 60 ft., and 16 in. to top;

85 to 100 ft. in height, not less than 28 in. to 25 ft.; 24 in. to 50 ft.; 20 in. to 75 ft., and 16 in. to top;

Over 100 ft. in height, each additional 25 ft. in height, or part thereof, next above the curb, shall be increased 4 inches in thickness, the upper 100 feet remaining the same as specified for a wall of that height.

If walls are over 25 feet apart, the bearing-walls shall be 4 inches thicker than above specified for every $12^1/_2$ feet or fraction thereof that said walls are more than 25 feet apart.

Strength of Floors, Roofs, and Supports.

	Floors calculated to bear safely per sq. ft., in addition to their own wt.
Floors of dwelling, tenement, apartment-house or hotel, not less than	70 lbs.
Floors of office-building, not less than	100 "
Floors of public-assembly building, not less than	120 "
Floors of store, factory, warehouse, etc., not less than	150 "
Roofs of all buildings, not less than	50 "

Every floor shall be of sufficient strength to bear safely the weight to be imposed thereon, in addition to the weight of the materials of which the floor is composed.

Columns and Posts. — The strength of all columns and posts shall be computed according to Gordon's formulæ, and the crushing weights in pounds, to the square inch of section, for the following-named materials, shall be taken as the coefficients in said formulæ, namely: Cast iron, 80,000; wrought or rolled iron, 40,000: rolled steel, 48,000; white pine and spruce, 3500; pitch or Georgia pine, 5000; American oak, 6000. The breaking strength of wooden beams and girders shall be computed according to the formulæ in which the constants for transverse strains for central load shall be as follows, namely: Hemlock, 400; white pine, 450; spruce, 450; pitch or Georgia pine, 550; American oak, 550; and for wooden beams and girders carrying a uniformly distributed load the constants will be doubled. The factors of safety shall be as one to four for all beams, girders, and other pieces subject to a transverse strain; as one to four for all posts, columns, and other vertical supports when of wrought iron or rolled steel; as one to five for other materials, subject to a compressive strain; as one to six for tie-rods, tie-beams, and other pieces subject to a tensile strain. Good, solid, natural earth shall be deemed to sustain safely a load of four tons to the superficial foot, or as otherwise determined by the superintendent of buildings, and the width of footing-courses shall be at least sufficient to meet this requirement. In computing the width of walls, a cubic foot of brickwork shall be deemed to weigh 115 lbs. Sandstone, white marble, granite, and other kinds of building-stone shall be deemed to weigh 160 lbs. per cubic foot. The safe-bearing load to apply to good brickwork shall be taken at 8 tons per superficial foot when good lime mortar is used, $11^1/_2$ tons per superficial foot when good lime and cement mortar mixed is used, and 15 tons per superficial foot when good cement mortar is used.

Fire-proof Buildings — Iron and Steel Columns. — All cast-iron, wrought-iron, or rolled-steel columns shall be made true and smooth at both ends, and shall rest on iron or steel bed-plates, and have iron or steel cap-plates, which shall also be made true. All iron or steel trimmer-beams, headers, and tail-beams shall be suitably framed and connected together, and the iron girders, columns, beams, trusses, and all other iron-work of all floors and roofs shall be strapped, bolted, anchored, and connected together, and to the walls, in a strong and substantial manner. Where beams are framed into headers, the angle-irons, which are bolted to the tail-beams, shall have at least two bolts for all beams over 7 inches in depth, and three bolts for all beams 12 inches and over in depth, and these bolts shall not be less than $^3/_4$ inch in diameter. Each one of such angles or knees, when bolted to girders, shall have the same number of bolts as stated for the other leg. The angle-iron in no case shall be less in thickness than the header or trimmer to which it is bolted, and the width of angle in no case shall be less than one third the depth of beam, excepting that no angle-knee shall be less than $2^1/_2$ inches wide, nor required to be more than 6 inches wide. All wrought-iron or rolled-steel beams 8 inches deep and under shall have bearings equal to their depth, if resting on a wall; 9 to 12 inch beams shall have a bearing of 10 inches, and all beams more than 12 inches in depth shall have bearings of not less than 12 inches if resting on a wall. Where beams rest on iron supports, and are properly tied to the same, no greater bearings shall be required than one third of the depth of the beams. Iron or steel floor-beams shall be so arranged as to spacing and length of beams that the load to be supported by them, together with the weights of the materials used in the construction of the said floors, shall not cause a deflection of the said beams of more than 1/30 of an inch per linear foot of span; and they shall be tied together at intervals of not more than eight times the depth of the beam.

Under the ends of all iron or steel beams, where they rest on the walls, a stone or cast-iron template shall be built into the walls. Said template shall be 8 inches wide in 12-inch walls, and in all walls of greater thickness said template shall be 12 inches wide; and such templates, if of stone, shall not be in any case less than $2^1/_2$ inches in thickness, and no template shall be less than 12 inches long.

No cast-iron post or columns shall be used in any building of a less average thickness of shaft than three quarters of an inch, nor shall it have an unsupported length of more than twenty times its least lateral dimensions or diameter. No wrought-iron or rolled-steel column shall have an unsupported length of more than thirty times its least lateral dimensions or diameter, nor shall its metal be less than one fourth of an inch in thickness.

Lintels, Bearings and Supports. — All iron or steel lintels shall have bearings proportionate to the weight to be imposed thereon, but no lintel used to span any opening more than 10 feet in width shall have a bearing less than 12 inches at each end, if resting on a wall; but if resting on an iron post, such lintel shall have a bearing of at least 6 inches at each end, by the thickness of the wall to be supported.

Strains on Girders and Rivets. — Rolled iron or steel beam girders, or riveted iron or steel plate girders used as lintels or as girders, carrying a wall or floor or both, shall be so proportioned that the loads which may come upon them shall not produce strains in tension or compression upon the flanges of more than 12,000 lbs. for iron, nor more than 15,000 lbs. for steel per square inch of the gross section of each of such flanges, nor a shearing strain upon the web-plate of more than 6000 lbs. per square inch of section of such web-plate, if of iron, nor more than 7000 pounds if of steel; but no web-plate shall be less than $^1/_4$ inch in thickness. Rivets in plate girders shall not be less than $^5/_8$ inch in diameter, and shall not be spaced more than 6 inches apart in any case. They shall be so spaced that their shearing strains shall not exceed 9000 lbs. per square inch, on their diameter, multiplied by the thickness of the plates through which they pass. The riveted plate girders shall be proportioned upon the supposition that the bending or chord strains are resisted entirely by the upper and lower flanges, and that the shearing strains are resisted entirely by the web-plate. No part of the web shall be estimated as flange area, nor more than one half of that portion of the angle-iron which lies against the web. The distance between the centers of gravity of the flange areas will be considered as the effective depth of the girder.

The building laws of the city of New York contain a great amount of detail in addition to the extracts above, and penalties are provided for violation. See An Act creating a Department of Buildings, etc., Chapter 275, Laws of 1892. Pamphlet copy published by Baker, Voorhies & Co., New York.

FLOORS.

Maximum Load on Floors. (*Eng'g*, Nov. 18, 1892, p. 644.) — Maximum load per square foot of floor surface due to the weight of a dense crowd. Considerable variation is apparent in the figures given by many authorities, as the following table shows:

Authorities.	Weight of Crowd, lbs. per sq. ft.
French practice, quoted by Trautwine and Stoney	41
Hatfield ("Transverse Strains," p. 80)	70
Mr. Page, London, quoted by Trautwine	84
Maximum load on American highway bridges according to Waddell's general specifications	100
Mr. Nash, architect of Buckingham Palace	120
Experiments by Prof. W. N. Kernot, at Melbourne	126 to 143.1
Experiments by Mr. B. B. Stoney ("On Stresses," p. 617)	147.4
Experiments by Prof. L. J. Johnson, *Eng. News*, April 14, 1904	134.2 to 156.9

The highest results were obtained by crowding a number of persons previously weighed into a small room, the men being tightly packed so as to resemble such a crowd as frequently occurs on the stairways and platforms of a theatre or other public building.

Safe Allowances for Floor Loads. (Kidder.) Lbs. per square foot.

For dwellings, sleeping and lodging rooms	40 lbs.
For schoolrooms	50 "
For offices, upper stories	60 "
For offices, first story	80 "
For stables and carriage houses	65 "
For banking rooms, churches and theaters	80 "
For assembly halls, dancing halls, and the corridors of all public buildings, including hotels	120 "
For drill rooms	150 "
For ordinary stores, light storage, and light manufacturing	120* "

* Also to sustain a concentrated load at any point of 4000 lbs.

STRENGTH OF FLOORS.

(From circular of the Boston Manufacturers' Mutual Insurance Co.)

The tables on p. 1393 were prepared by C. J. H. Woodbury, for determining safe loads on floors. Care should be observed to select the figure giving the greatest possible amount and concentration of load as the one which may be put upon any beam or set of floor-beams; and in no case should beams be subjected to greater loads than those specified, unless a lower factor of safety is warranted under the advice of a competent engineer. These tables are computed for beams one inch in width, because the strength of beams increases directly as the width when the beams are broad enough not to cripple.

Beams or heavy timbers used in the construction of a factory or warehouse should not be painted, varnished or oiled, filled or encased in impervious concrete, air-proof plastering, or metal for at least three years, lest fermentation should destroy them by what is called "dry rot."

It is, on the whole, safer to make floor-beams in two parts with a small open space between, so that proper ventilation may be secured.

These tables apply to distributed loads, but the first can be used in respect to floors which may carry concentrated loads by using half the figure given in the table, since a beam will bear twice as much load when evenly distributed over its length as it would if the load was concentrated in the center of the span.

The weight of the floor should be deducted from the figure given in the table, in order to ascertain the net load which may be placed upon any floor. The weight of spruce may be taken at 36 lbs. per cubic foot, and that of Southern pine at 48 lbs. per cubic foot.

Table I was computed upon a working modulus of rupture of Southern pine of 2160 lbs., using a factor of safety of six. It can also be applied to ascertaining the strength of spruce beams if the figures given in the table are multiplied by 0.78; or in designing a floor to be sustained by spruce beams, multiply the required load by 1.28, and use the dimensions as given by the table.

EXAMPLE.—Required the safe load per square foot of floor, which may be safely sustained by a floor on Southern pine 10 × 14 in. beams, 8 ft. on centers, and 20 ft. span. In Table I a 1 × 14 in. beam, 20 ft.

span, will sustain 118 lbs. per foot of span; and for a beam 10 ins. wide the load would be 1180 lbs. per foot of span, or 147 1/2 lbs. per sq. ft. of floor for Southern-pine beams. From this should be deducted the weight of the floor, 17 1/2 lbs. per sq. ft., leaving 130 lbs. per sq. ft. as a safe load. If the beams are of spruce, multiply 147 1/2 by 0.78, reducing the load to 115 lbs. Deducting the weight of the floor, 16 lbs., leaves the safe net load as 90 lbs. per sq. ft. for spruce beams.

Table II applies to floors whose strength must be in excess of that necessary to sustain the weight, in order to meet the conditions of delicate or rapidly moving machinery, to the end that the vibration or distortion of the floor may be reduced to the least practicable limit.

In the table the limit is that of a load which would cause a bending of the beams to a curve of which the average radius would be 1250 ft.

This table is based upon a modulus of elasticity obtained from observations upon the deflection of loaded storehouse floors, and is taken at 2,000,000 lbs. for Southern pine; the same table can be applied to spruce, whose modulus of elasticity is taken as 1,200,000 lbs., if six tenths of the load for Southern pine is taken as the proper load for spruce; or, in the matter of designing, the load should be increased one and two thirds times, and the dimension of timbers for this increased load as found in the table should be used for spruce.

It can also be applied to beams and floor-timbers supported at each end and in the middle, remembering that the deflection of a beam supported in that manner is only 0.4 that of a beam of equal span which rests at each end; that is to say, the floor-planks are 2 1/2 times as stiff, cut two bays in length, as they would be if cut only one bay in length. When a floor-plank two bays in length is evenly loaded, 3/16 of the load on the plank is sustained by the beam at each end of the plank, and 10/16 by the beam under the middle of the plank; so that for a completed floor 3/8 of the load would be sustained by the beams under the joints of the plank, and 5/8 of the load by the beams under the middle of the plank: this is the reason of the importance of breaking joints in a floor-plank every 3 ft. in order that each beam shall receive an identical load. If it were not so, 3/8 of the whole load upon the floor would be sustained by every other beam, and 5/8 of the load by the alternate beams.

Repeating the former example for the load on a mill floor on Southern-pine beams 10 × 14 ins., and 20 ft. span, 8 ft. centers: In Table II a 1 × 14 in. beam should receive 61 lbs. per foot of span, or 75 lbs. per sq. ft. of floor, for Southern-pine beams. Deducting the weight of the floor, 17 1/2 lbs. per sq. ft., 57 lbs. per sq. ft. is the advisable load.

If the beams are of spruce, the result of 75 lbs. should be multiplied by 0.6, reducing the load to 45 lbs. The weight of the floor, in this instance amounting to 16 lbs., would leave the net load as 29 lbs. for spruce beams.

If the beams were two spans in length, they could, under these conditions, support two and a half times as much load with an equal amount of deflection, unless such load should exceed the limit of safe load as found by Table I, as would be the case under the conditions of this problem.

Maximum Spans for 1, 2 and 3 Inch Plank. (*Am. Mach.*, Feb. 11, 1904.) — Let w = load per sq. ft.; l = length in ins.; $W = wl/12$; S = safe fiber stress, using a factor of safety of 10; b = width of plank; d = thickness; p = deflection, E = coefficient of elasticity, I = moment of inertia = $1/_{12}\, bd^3$.

Then $Wl/8 = Sbd^2/6$; $s = 5\, Wl^3 \div 384\, EI$. Taking S at 1200 lbs., E at 850,000 and $s = l \div 360$ for long-leaf yellow pine, the following figures for maximum span, in inches, are obtained:

Uniform load, lbs. per sq. ft.		40	60	80	100	150	200	250	300
1-in. plank	For strength	75	61	53	48	39	33	...	...
	For deflection	37	33	30	28	24	22	...	...
2-in. plank	For strength	151	123	107	96	78	67	60	55
	For deflection	75	66	60	55	48	44	41	38
3-in. plank	For strength	227	185	161	144	117	101	91	83
	For deflection	113	99	90	83	73	66	61	58

For white oak S may be taken at 1000 and E at 550,000; for Canadian spruce, S = 800, E = 600,000; for hemlock, S = 600, E = 450,000.

I. Safe Distributed Loads upon Southern-pine Beams One Inch in Width.

(C. J. H. Woodbury.)

(If the load is concentrated at the center of the span, the beams will sustain half the amount given in the table.)

Mill Columns.—Timber posts offer more resistance to fire than iron pillars, and have generally displaced them in millwork. Experiments at the U. S. Arsenal at Watertown, Mass., show that sound timber posts of the proportions customarily used in millwork yield by direct crushing, the strength being directly as the area at the smallest part. The columns yielded at about 4500 lbs. per sq. in., confirming the general practice of allowing 600 lbs. per sq. in. as a safe load. Square columns are one fourth stronger than round ones of the same diameter.

COST OF BUILDINGS.

Approximate Cost of Mill Buildings. — Chas. T. Main (*Eng. News*, Jan. 27, 1910) gives a series of diagrams of the cost in New England Jan., 1910, per sq. ft. of floor space of different sizes of brick mill buildings, one to six stories high, of the type known as "slow-burning," calculated for total floor loads of about 75 lbs. per sq. ft. Figures taken from the diagrams are given in the table below. The costs include ordinary foundations and plumbing, but no heating, sprinklers or lighting.

Cost of Brick Mill Buildings per sq. ft. of Floor Area.

Length, feet.	50	100	150	200	250	300	350	400	500
One Story.									
Width 25 ft.	$1.90	$1.66	$1.58	$1.54	$1.51	$1.49	$1.48	$1.47	$1.46
50	1.52	1.29	1.21	1.18	1.16	1.15	1.14	1.13	1.13
75	1.41	1.21	1.12	1.08	1.06	1.04	1.03	1.02	1.02
125	1.32	1.09	1.02	0.98	0.96	0.94	0.94	0.93	0.92
Two Stories.									
25	2.00	1.62	1.52	1.47	1.44	1.41	1.39	1.38	1.36
50	1.50	1.21	1.13	1.09	1.06	1.05	1.04	1.03	1.02
75	1.34	1.08	1.01	0.97	0.94	0.92	0.92	0.91	0.90
125	1.22	0.97	0.90	0.86	0.84	0.82	0.81	0.80	0.80
Three Stories.									
25	1.98	1.57	1 47	1.42	1.39	1.38	1.36	1.35	1.34
50	1.47	1.17	1.07	1.03	1.01	1.00	0.98	0.98	0.98
75	1.30	1.05	0.98	0.94	0.91	0.89	0.88	0.87	0.86
125	1.18	0.93	0.86	0.82	0.80	0.78	0.77	0.76	0.76
Four Stories.									
25	2.00	1.61	1.50	1.45	1.42	1.40	1.38	1.37	1.36
50	1.38	1.17	1.10	1.05	1.02	1.00	1.00	0.99	0.98
75	1.32	1.08	0 97	0.93	0.90	0.88	0.88	0.87	0.87
125	1.20	0.93	0.85	0.81	0.78	0.77	0.76	0.75	0.74
Six Stories.									
25	2.10	1.72	1.57	1.51	1.48	1.46	1.44	1.43	1.42
50	1.53	1.21	1.12	1.08	1.05	1.04	1.03	1.02	1.02
75	1.35	1.08	0.98	0.94	0.92	0.90	0.89	0.88	0.86
125	1.22	0.96	0.86	0.82	0.79	0.78	0.77	0.76	0.76

The cost per sq. ft. of a building 100 ft. wide will be about midway between that of one 75 ft. wide and one 125 ft. wide, and the cost of a five-story building about midway between the costs of a four- and a six-story. The data for estimating the above costs are as follows:

		Stories High.					
		1	2	3	4	5	6
Foundations, including excavations, cost per lin. ft.	Outside walls..	$2.00	$2.90	$3.80	$4.70	$5.60	$6.50
	Inside walls ...	1.75	2.25	2.80	3.40	3.90	4.50
Brick walls, cost per sq. ft. of surface...	Outside walls..	0.40	0.44	0.47	0.50	0.53	0.57
	Inside walls...	0.40	0.40	0.40	0.43	0.45	0.47

Columns, including piers and castings, cost each $15.

Assumed Height of Stories.—From ground to first floor, 3 ft. Buildings

25 ft. wide, stories 13 ft. high; 50 ft. wide, 14 ft. high; 75 ft. wide, 15 ft high; 100 ft. and 125 ft. wide, 16 ft. high.

Floors, 32 cts. per sq. ft. of gross floor space not including columns Columns included, 38 cts.

Roof, 25 cts. per sq. ft., not including columns. Columns included 30 cts. Roof to project 18 ins. all around buildings.

Stairways, including partitions, $100 each flight. Two stairways and one elevator tower for buildings up to 150 ft. long; two stairways and two elevator towers for buildings up to 300 ft. long. In buildings over two stories, three stairways and three elevator towers for buildings over 300 ft. long.

In buildings over two stories, plumbing $75 for each fixture including piping and partitions. Two fixtures on each floor up to 5000 sq. ft. of floor space and one fixture for each additional 5000 sq. ft. of floor or fraction thereof.

Modifications of the above Costs:

1. If the soil is poor or the conditions of the site are such as to require more than ordinary foundations, the cost will be increased.
2. If the building is to be used for ordinary storage purposes with low stories and no top floors, the cost will be decreased from about 10% for large low buildings to 25% for small high ones, about 20% usually being a fair allowance.
3. If the building is to be used for manufacturing and is substantially built of wood, the cost will be decreased from about 6% for large one-story buildings to 33% for high small buildings; 15% would usually be a fair allowance.
4. If the building is to be used for storage with low stories and built substantially of wood, the cost will be decreased from 13% for large one-story buildings to 50% for small high buildings; 30% would usually be a fair allowance.
5. If the total floor loads are more than 75 lbs. per sq. ft. the cost is increased.
6. For office buildings, the cost must be increased to cover architectural features on the outside and interior finish.

Reinforced-concrete buildings designed to carry floor loads of 100 lbs. per sq. ft. or less will cost about 25% more than the slow-burning type of mill construction.

ELECTRICAL ENGINEERING.*

STANDARDS OF MEASUREMENT.

C.G.S. (Centimeter, Gramme, Second) or "Absolute" System of Physical Measurements:

Unit of space or distance	= 1 centimeter, cm.;
Unit of mass	= 1 gramme, gm.;
Unit of time	= 1 second, sec.;
Unit of velocity = space ÷ time	= 1 centimeter in 1 second;

Unit of acceleration = change of 1 unit of velocity in 1 second;
Acceleration due to gravity, = 980.665 centimeters per sec. per sec.

$$\text{Unit of force} = 1 \text{ dyne} = \frac{1}{980.665}\text{ gm.} = \frac{0.00220462}{980.665}\text{ lb.} = 0.0000022481 \text{ lb.}$$

A dyne is that force which, acting on a mass of one gramme during one second, will give it a velocity of one centimeter per second. The weight of one gramme in latitude 40° to 45° is about 980 dynes, at the equator 973 dynes, and at the poles nearly 984 dynes. Taking the value of g, the acceleration due to gravity, in British measures at 32.1740 feet per second at lat. 45° at the sea level, and the meter = 39.37 inches, we have

$$1 \text{ gramme} = 32.174 \times 12 \div 0.3937 = 980.665 \text{ dynes.}$$

Unit of work = 1 erg = 1 dyne-centimeter = 0.000000073756 ft.-lb.;
Unit of power = 1 watt = 10 million ergs per second,
= 0.73756 foot-pound per second.

$$= \frac{0.73756}{550} = \frac{1}{745.7}\text{ horse-power} = 0.0013410 \text{ H.P.}$$

C.G.S. unit magnetic pole is one which reacts on an equal pole at a centimeter's distance with the force of 1 dyne.

C.G.S. unit of magnetic field strength, the *gauss*, is the intensity of field which surrounding unit pole acts on it with a force of 1 dyne.

C.G.S. unit of electro-motive force = the force produced by the cutting of a field of 1 gauss intensity at a velocity of 1 centimeter per second (in a direction normal to the field and to the conductor) by 1 centimeter of conductor. The *volt* is 100,000,000 times this unit.

C.G.S. unit of electrical current = the current in a conductor (located in a plane normal to the field) when each centimeter is urged across a magnetic field of 1 gauss intensity with a force of 1 dyne. One-tenth of this is the *ampere*.

The C.G.S. unit of quantity of electricity is that represented by the flow of 1 C.G.S. unit of current for 1 second. One-tenth of this is the *coulomb*.

The Practical Units used in Electrical Calculations are:

Ampere, the unit of current strength, or rate of flow, represented by I.
Volt, the unit of electro-motive force, electrical pressure, or difference of potential, represented by E.
Ohm, the unit of resistance, represented by R.
Coulomb (or ampere-second), the unit of quantity, Q.
Ampere-hour = 3600 coulombs, Q'.
Watt (volt-ampere), the unit of power, P.
Joule (or watt-second), the unit of energy or work, W.
Farad, the unit of electrostatic capacity, represented by C.
Henry, the unit of inductance, represented by L.

Using letters to represent the units, the relations between them may be expressed by the following formulæ, in which t represents one second and T one hour:

$$I = \frac{E}{R}, \quad Q = It, \quad Q' = IT, \quad C = \frac{Q}{E}, \quad W = QE, \quad P = IE.$$

As these relations contain no coefficient other than unity, the letters may represent any quantities given in terms of those units. For example, if E represents the number of volts electro-motive force, and R the number of ohms resistance in a circuit, then their ratio $E \div R$ will give the number of amperes current strength in that circuit.

The above six formulæ can be combined by substitution or elimination,

---

* In the revision of this chapter the author has had the assistance of Mr. David B. Rushmore.

so as to give the relations between any of the quantities. The most important of these are the following:

$$Q = \frac{E}{R}t, \quad C = \frac{I}{E}t, \quad W = IEt = \frac{E^2}{R}t = I^2Rt = Pt,$$

$$E = IR, \quad R = \frac{E}{I}, \quad P = \frac{E^2}{R} = I^2R = \frac{W}{t} = \frac{QE}{t}.$$

The definitions of these units as adopted at the International Electrical Congress at Chicago in 1893, and as established by Act of Congress of the United States, July 12, 1894, are as follows:

The *ohm* is substantially equal to 10^9 (or 1,000,000,000) units of resistance of the C.G.S. system, and is represented by the resistance offered to an unvarying electric current by a column of mercury at 32° F., 14.4521 grammes in mass, of a constant cross-sectional area, and of the length of 106.3 centimeters.

The *ampere* is $1/10$ of the unit of current of the C.G.S. system, and is the practical equivalent of the unvarying current which when passed through a solution of nitrate of silver in water in accordance with standard specifications deposits silver at the rate of 0.001118 gramme per second.

The *volt* is the electro-motive force that, steadily applied to a conductor whose resistance is one ohm, will produce a current of one ampere, and is practically equivalent to 1000/1434 (or 0.6974) of the electromotive force between the poles or electrodes of a Clark's cell at a temperature of 15° C., and prepared in the manner described in the standard specifications. [The e.m.f. of a Weston normal cell is 1.0183 volts at 20° C.]

The *coulomb* is the quantity of electricity transferred by a current of one ampere in one second.

The *farad* is the capacity of a condenser charged to a potential of one volt by one coulomb of electricity.

The *joule* is equal to 10,000,000 units of work in the C.G.S. system, and is practically equivalent to the energy expended in one second by an ampere in an ohm.

The *watt* is equal to 10,000,000 units of power in the C.G.S. system, and is practically equivalent to the work done at the rate of one joule per second.

The *henry* is the induction in a circuit when the electro-motive force induced in this circuit is one volt, while the inducing current varies at the rate of one ampere per second.

The ohm, volt, etc., as above defined, are called the "international" ohm, volt, etc., to distinguish them from the "legal" ohm, B.A. unit, etc.

The value of the ohm, determined by a committee of the British Association in 1863, called the B.A. unit, was the resistance of a certain piece of copper wire. The so-called "legal" ohm, as adopted at the International Congress of Electricians in Paris in 1884, was a correction of the B.A. unit, and was defined as the resistance of a column of mercury 1 square millimeter in section and 106 centimeters long, at a temperature of 32° F. 1 legal ohm = 1.0112 B.A. units; 1 international ohm = 1.0023 legal ohm; 1 legal ohm = 0.9977 int. ohm.

Derived Units.

1 megohm	= 1 million ohms;
1 microhm	= 1 millionth of an ohm;
1 milliampere	= $1/1000$ of an ampere;
1 micro-farad	= 1 millionth of a farad.

Relations of Various Units.

1 ampere..................	= 1 coulomb per second;
1 volt-ampere (direct current)	= 1 watt = 1 volt-coulomb per sec.;
1 watt....................	= 0.73756 foot-pound per second, = 0.00094859 heat-unit per sec. (Fahr.), = $1/745.7$ of one horse-power;
1 joule = 10^7 ergs...........	= 0.73756 foot-pound, = work done by one watt in one sec., = 0.00094859 heat-unit; = 0.23904 gram calories;
1 British thermal unit......	= 1054.2 joules; = 777.54 foot-pounds; = 25.200 gram calories;

1 mean gram calorie........	= 4.1834 × 10^7 ergs *; = 0.0039683 B. T. U.;
1 kilowatt, or 1000 watts....	= 1000/745.7 or 1.3410 horse-powers;
1 kilowatt-hour............ 1000 volt-ampere hours..... 1 British Board of Trade unit	= 1.3410 horse-power hours, = 2,655,220 foot-pounds, = 3415 heat-units;
1 horse-power..............	= 745.7 watts = 745.7 volt-amperes, = 33,000 foot-pounds per minute.

The ohm, ampere, and volt are defined in terms of one another as follows: Ohm, the resistance of a conductor through which a current of one ampere will pass when the electro-motive force is one volt. Ampere, the quantity of current which will flow through a resistance of one ohm when the electro-motive force is one volt. Volt, the electro-motive force required to cause one ampere to flow through a resistance of one ohm.

For Methods of Making Electrical Measurements, Testing, etc., see "American Handbook for Electrical Engineers"; Karapetoff's "Experimental Electrical Engineering"; Bedell's "Direct and Alternating Current Manual"; 1914 Standardization Rules of A. I. E. E.

Equivalent Electrical and Mechanical Units.—H. Ward Leonard published in *The Electrical Engineer*, Feb. 25, 1895, a table of useful equivalents of electrical and mechanical units, from which the table on page 1399 is taken, with some modifications.

Units of the Magnetic Circuit.

Unit magnetic pole is a pole of such strength that when placed at a distance of one centimeter from a similar pole of equal strength it repels it with a force of one dyne.

Magnetic Moment is the product of the strength of either pole into the distance between the two poles.

Intensity of Magnetization is the magnetic moment of a magnet divided by its volume.

Intensity of Magnetic Field is the force exerted by the field upon a unit magnetic pole. The unit is the gauss.

Gauss = unit of field strength, or density, symbol H is that intensity of field which acts on a unit pole with a force of one dyne, = one line of force per square centimeter. One gauss produces 1 dyne of force per centimeter length of conductor upon a current of 10 amperes, or an electro-motive force of 1/100,000,000 volt in a centimeter length of conductor when its velocity across the field is 1 centimeter per second. A field of H units is one which acts with H dynes on unit pole, or H lines per square centimeter. A unit magnetic pole has 4π lines of force proceeding from it.

Maxwell = unit of magnetic flux, is the amount of magnetism passing through a square centimeter of a field of unit density. Symbol, ϕ.

In non-magnetic materials a unit of intensity of flux is the same as unit intensity of field. The name maxwell is given to a unit quantity of flux, and one maxwell per square centimeter in non-magnetic materials is the same as the gauss. In magnetic materials the flux produced by the molecular magnets is added to the field (Norris).

Magnetic Flux, ϕ, is equal to the average field intensity multiplied by the cross-sectional area. The unit is the maxwell. Maxwells per square inch = gausses × 6.45.

Magnetic Induction, symbol B, is the flux or the number of magnetic lines per unit of area of cross-section of magnetized material, the area being at every point perpendicular to the direction of the flux. It is equal to the product of the field intensity, H, and the permeability, μ.

Gilbert = unit of magnetomotive force, is the amount of M.M.F. that would be produced by a coil of $10 \div 4\pi$ or 0.7958 ampere-turns. Symbol F.

The M.M.F. of a coil is equal to 1.2566 times the ampere-turns.

If a solenoid is wound with 100 turns of insulated wire carrying a current of 5 amperes, the M.M.F. exerted will be 500 ampere-turns × 1.2566 = 628.3 gilberts.

Oersted = unit of magnetic reluctance; a magnetic circuit has a reluctance of 1 oersted when unit m.m.f. produces unit flux. Symbol, R.

Reluctance is that quantity in a magnetic circuit which limits the flux

* Mean of the values of Reynolds and Moorby and of Barnes—Marks & Davis, Steam Tables, 1909.

Equivalent Values of Electrical, Mechanical and Heat Units

Unit.	Equivalent Value in Other Units.
1 K.W. Hour =	1,000 watt hours. 1.341 horse-power hours. 2,655,200 ft.-lbs. 3,600,000 joules. 3,415 heat-units. 367,100 kilogram meters. 0.234 lb. carbon oxidized with perfect efficiency. 3.52 lbs. water evap. from and at 212° F. 22.77 lbs. of water raised from 62° to 212° F.
1 H.P. Hour =	0.745.7 K.W. hour. 1,980,000 ft.-lbs. 2,546.5 heat-units. 273,740 k.g.m. 0.174 lb. carbon oxidized with perfect efficiency. 2.62 lbs. water evaporated from and at 212° F. 17.0 lbs. water raised from 62° F. to 212° F.
1 Kilo-watt =	1,000 watts. 1.3410 horse-power. 2,655,200 ft.-lbs. per hour. 44,254 ft.-lbs. per minute. 737.56 ft.-lbs. per second. 3,415 heat-units per hour. 56.92 heat-units per minute. 0.9486 heat-units per second. 0.234 lb. carbon oxidized per hour. 3.52 lbs. water evap. per hour from and at 212°.

Unit.	Equivalent Value in Other Units.
1 H.P. =	745.7 watts. 0.7457 K.W. 33,000 ft.-lbs. per minute. 550 ft.-lbs. per second. 2,546.5 heat-units per hour. 42.44 heat-units per minute. 0.707 heat-units per second. 0.174 lb. carbon oxidized per hour. 2.62 lbs. water evap. per hour from and at 212° F.
1 Joule =	1 watt second. 0.000000278 K.W. hour. 0.10197 k.g.m. 0.0009486 heat-units. 0.73756 ft.-lb.
1 Ft.-lb. =	1.3558 joules. 0.13826 k.g.m. 0.0000003766 K.W. hour. 0.0012861 heat-unit. 0.0000005 H.P. hour.
1 Watt =	1 joule per second. 0.001341 H.P. 3.415 heat-units per hour. 0.73756 ft.-lbs. per second. 0.0035 lb. water evap. per hr. 44.254 ft.-lbs. per minute.
1 Watt per sq. in. =	8.20 heat-units per sq. ft. per minute. 6,373 ft.-lbs. per sq. ft. per minute. 0.1931 H.P. per sq. ft.

Unit.	Equivalent Value in Other Units.
1 Heat-unit =	1,054.2 watt seconds. 777.54 ft.-lbs. 107.5 kilogram meters. 0.0002928 K.W. hour. 0.0003927 H.P. hour. 0.0000685 lb. carbon oxidized. 0.001030 lb. water evap. from and at 212° F.
1 Heat-unit per Sq. Ft. per min. =	0.1220 watt per sq. in. 0.01757 K.W. per sq. ft. 0.02356 H.P. per sq. ft.
1 Kilo-gram Meter =	7.233 ft.-lbs. 0.000003653 H.P. hour. 0.000002724 K.W. hour. 0.009302 heat-unit.
1 lb. Carbon Oxi-dized with perfect Effi-ciency =	14,600 heat-units. 1.11 lbs. Anth'cite coal ox. 2.5 lbs. dry wood oxidized. 22 cu.ft. illuminating-gas. 4.275 K.W. hours. 5.733 H.P. hours. 11,352,000 ft.-lbs. 15.05 lbs. of water evap. from and at 212° F.
1 lb. Water Evap. from and at 212° F. =	0.2841 K.W. hour. 0.3811 H.P. hour. 970.4 heat-units. 104,320 k.g.m. 1,023,000 joules. 754,525 ft.-lbs. 0.066466 lb. carbon oxidized.

under a given M.M.F. It corresponds to the resistance in the electric circuit.

Permeance is the reciprocal of reluctance.

The reluctivity of any medium is its specific reluctance, and in the C.G.S. system is the reluctance offered by a cubic centimeter of the body between opposed parallel faces. The reluctivity of nearly all substances, other than the magnetic metals, is sensibly that of vacuum, is equal to unity, and is independent of the flux density.

Permeability is the reciprocal of magnetic reluctivity. It is a number and the symbol is μ.

Materials differ in regard to the resistance they offer to the passage of lines of force; thus iron is more permeable than air. The permeability of a substance is expressed by a coefficient, μ, which denotes its relation to the permeability of air, which is taken as 1. If H = number of magnetic lines per square centimeter which will pass through an air-space between the poles of a magnet, and B the number of lines which will pass through a certain piece of iron in that space, then $\mu = B \div H$. The permeability varies with the quality of the iron, and the degree of saturation, reaching a practical limit for soft wrought iron when B = about 18,000 and for cast iron when B = about 10,000 C.G.S. lines per square centimeter.

The permeability of a number of materials may be determined by means of the table on page 1431.

ANALOGIES BETWEEN THE FLOW OF WATER AND ELECTRICITY.

Water.	Electricity.
Head, difference of level, in feet. Difference of pressure, lbs. per sq. in.	Volts; electro-motive force; difference of potential; E. or E.M.F.
Resistance of pipes, apertures, etc., increases with length of pipe, with contractions, roughness, etc.; decreases with increase of sectional area.	Ohms, resistance, R. Increases directly as the length of the conductor or wire and inversely as its sectional area, $R \propto l \div s$. It varies with the nature of the conductor.
Rate of flow, as cubic ft. per second, gallons per min., etc., or volume divided by the time. In the mining regions sometimes expressed in "miners' inches."	Amperes; current; current strength; intensity of current; rate of flow; 1 ampere = 1 coulomb per second. $\text{Amperes} = \frac{\text{volts}}{\text{ohms}}$; $I = \frac{E}{R}$; $E = IR$.
Quantity, usually measured in cubic ft. or gallons, but is also equivalent to rate of flow × time, as cu. ft. per second for so many hours.	Coulomb, unit of quantity, Q, = rate of flow × time, as ampere-seconds. 1 ampere-hour = 3600 coulombs.
Work, or energy, measured in foot-pounds; product of weight of falling water into height of fall; in pumping, product of quantity in cubic feet into the pressure in lbs. per square foot against which the water is pumped.	Joule, volt-coulomb, W, the unit of work, = product of quantity by the electro-motive force = volt-ampere-second. 1 joule = 0.7373 foot-pound. If I (amperes) = rate of flow, and E (volts) = difference of pressure between two points in a circuit, energy expended = IEt, = I^2Rt.
Power, rate of work. Horse-power = ft.-lbs. of work in 1 min. ÷ 33,000. In water flowing in pipes, rate of flow in cu. ft. per second × resistance to the flow in lbs. per sq. ft. ÷ 550.	Watt, unit of power, P, = volts × amperes, = current or rate of flow × difference of potential. 1 watt = 0.7373 foot-pound per sec. = 1/746 of a horse-power.

ELECTRICAL RESISTANCE.

Laws of Electrical Resistance. — The resistance, R, of any conductor varies directly as its length, l, and inversely as its sectional area, s, or $R \propto l \div s$.

If r = the resistance of a conductor 1 unit in length and 1 square unit in sectional area, $R = rl \div s$. The common unit of length for electrical calculations in English measure is the foot, and the unit of area of wires is the circular mil = the area of a circle 0.001 in. diameter. 1 mil-foot = 1 foot long 1 circ.-mil area.

Resistance of 1 mil-foot of soft copper wire at 51° F. = 10 international ohms.

EXAMPLE. — What is the resistance of a wire 1000 ft. long, 0.1 in. diam.? 0.1 in. diam. = 10,000 circ. mils.

$$R = rl \div s = 10 \times 1000 \div 10{,}000 = 1 \text{ ohm}.$$

Specific resistance, also called resistivity, is the resistance of a material of unit length and section as compared with the resistance of soft copper.

Conductivity is the reciprocal of specific resistance, or the relative conducting power compared with copper taken at 100.

Conductance is the reciprocal of resistance.

Relative Conductivities of Different Metals at 0° and 100° C.

(D) Dewar and Fleming; (M) Matthiessen.

Conductivity of Aluminum. — J. W. Richards (*Jour. Frank.. Inst.*, Mar., 1897) gives for hard-drawn aluminum of purity 98.5, 99.0, 99.5, and 99.75% respectively a conductivity of 55, 59, 61, and 63 to 64%, copper being 100%. The Pittsburg Reduction Co. claims that its purest aluminum has a conductivity of over 64.5%. (*Eng'g News*, Dec. 17, 1896.)

German Silver. —The resistance of German silver depends on its composition. Matthiessen gives it as nearly 13 times that of copper, with a temperature coefficient of 0.0004433 per degree C. Weston, however (*Proc. Electrical Congress*, 1893, p. 179), has found copper-nickel-zinc alloys (German silver) which had a resistance of nearly 28 times that of copper, and a temperature coefficient of about one-half that given by Matthiessen.

Conductors and Insulators in Order of Their Value.

CONDUCTORS.	INSULATORS (NON-CONDUCTORS).	
All metals	Dry air	Ebonite
Well-burned charcoal	Shellac	Gutta-percha
Plumbago	Paraffin	India-rubber
Acid solutions	Amber	Silk
Saline solutions	Resins	Dry paper
Metallic ores	Sulphur	Parchment
Animal fluids	Wax	Dry leather
Living vegetable substances	Jet	Porcelain
Moist earth	Glass	Oils
Water	Mica	

According to Culley, the resistance of distilled water is 6754 million times as great as that of copper. Impurities in water decrease its resistance.

Resistance Varies with Temperature.— For every degree Centigrade the resistance of copper increases about 0.4%, or for every degree F., 0.2222%. Thus a piece of copper wire having a resistance of 10 ohms at 32° would have a resistance of 11.11 ohms at 82° F.

The following table shows the amount of resistance of a few substances used for various electrical purposes by which 1 ohm is increased by a rise of temperature of 1° C.

Platinoid	0.00021	Gold, silver	0.00065
Platinum silver	0.00031	Cast iron	0.00080
German silver (see above)	0.00044	Copper	0.00400

Annealing.—Resistance is lessened by annealing. Matthiessen gives the following relative conductivities for copper and silver, the comparison being made with pure silver at 100° C.:

Metal.	Temp. C.	Hard.	Annealed.	Ratio.
Copper	11°	95.31	97.83	1 to 1.027
Silver	14.6°	95.36	103.33	1 to 1.084

Dr. Siemens compared the conductivities of copper, silver, and brass with the following results. Ratio of hard to annealed:

Copper....1 to 1.058 Silver....1 to 1.145 Brass....1 to 1.180

STANDARD VALUES FOR RESISTIVITY AND TEMPERATURE COEFFICIENT OF COPPER.

Bureau of Standards, 1914.

The Bureau of Standards made measurements of a large number of representative samples of copper and established standard values of resistivity and temperature coefficients, which have been adopted by the International Electrochemical Commission.

Conductivity of Copper.

The following rules of the International Electrical Commission have been adopted by the American Institute of Electrical Engineers.

The following shall be taken as normal values for standard annealed copper:

(1) At a temperature of 20° C. the resistance of a wire of standard annealed copper one meter in length and of a uniform section of 1 square millimeter is 1/58 ohm = 0.017241....ohm.

(2) At a temperature of 20° C. the density of standard annealed copper is 8.89 grams per cubic centimeter.

(3) At a temperature of 20° C. the "constant mass" temperature coefficient of resistance of standard annealed copper, measured between two potential points rigidly fixed to the wire, is 0.00393 = 1/254.45 ....per degree centigrade.

(4) As a consequence it follows from (1) and (2) that, at a temperature of 20° C. the resistance of a wire of standard annealed copper of uniform section, one meter in length and weighing one gram, is (1/58) $\times$ 8.89 = 0.15328......ohm.

Paragraphs (1) and (4) define what are sometimes called "volume resistivity" and "mass resistivity" respectively. This may be expressed in other units as follows: Volume resistivity = 1.7241 microhm-cm. (or microhms in a cm. cube) at 20° C. = 0.67879 microhm inch at 20° C. and mass resistivity = 875.20 ohms (mile, pound) at 20° C.

The new value is known as the International Annealed Copper Standard, and is equivalent to

0.017241 ohm (meter, mm^2) at 20° C.

The units of mass resistivity and volume resistivity are interrelated through the density; this was taken as 8.89 grams per cm^3 at 20° C. by the International Electrochemical Commission. The International Annealed Copper Standard, in various units of mass resistivity and volume resistivity, is:

0.15328	ohm (meter, gram) at 20° C.
875.20	ohms (mile, pound) at 20° C.
0.017241	ohm (meter, mm^2) at 20° C.
1.7241	microhm-cm. at 20° C.
0.67879	microhm-inch at 20° C.
10.371	ohms (mil, foot) at 20° C.

The Temperature Coefficient of Resistance of Copper.—The Bureau of Standards' investigation of the temperature coefficient showed that the coefficient varies with different samples, but that the relation of conductivity to temperature coefficient is substantially a simple proportionality.

The general law may be expressed by the following practical rule: The 20° C. temperature coefficient of a sample of copper is the product of the per cent. conductivity by 0.00393. There are sometimes cases when the temperature coefficient is more easily measured than the conductivity, and the conductivity can be computed from the relation: per cent. conductivity = 254.5 $\times$ temperature coefficient.

When a temperature coefficient of resistance must be assumed the best value to assume for good commercial annealed copper wire is that corresponding to 100 per cent. conductivity, viz.:

$$a_0 = 0.00427,\ a_{15} = 0.00401,\ a_{20} = 0.00393,\ a_{25} = 0.00385$$

$$\left(a_{20} = \frac{Rt - R_{20}}{R_{20}\ (t - 20)},\ \text{etc.}\right)$$

This value was adopted as standard by the International Electrochemical Commission in 1913. It would usually apply to instruments and machines, since they are generally wound with annealed wire. Experiment has shown that distortions such as those caused by winding and ordinary handling do not affect the temperature coefficient.

Similarly, when assumption is unavoidable, the temperature coefficient of good commercial hard-drawn copper wire may be taken as that corresponding to a conductivity of 97.3 per cent., viz.:

$$a_0 = 0.00414,\ a_{15} = 0.00390,\ a_{20} = 0.00382,\ a_{25} = 0.00375$$

Rule for reducing resistivity from one temperature to another: The change of resistivity of copper per degree C. is a constant, independent of the temperature of reference and of the sample of copper. This "resistivity-temperature constant" may be taken, for general purposes, as 0.00060 ohm (meter, gram), or 0.0068 microhm-cm. More exactly, it is:

0.000.597	ohm (meter, gram)
or, 0.000.0681	ohm (meter, mm^2)
or, 0.006.81	microhm-cm.
or, 3.41	ohms (mile, pound)
or, 0.002.68	microhm-inch,
or, 0.040.9	ohm (mil, foot).

Continued on p. 1406.

Resistivity of Hard-Drawn Copper Wires.—In general the resistivity of hard-drawn wires varies with the size of the wire, while the resistivity of annealed wires does not. The difference between the resistivity of annealed and hard-drawn wires increases as the diameter of the wire decreases. This general conclusion is, however, complicated in any particular case by the number of drawings between annealings, amount of reduction to each drawing, etc. For No. 12 A.W.G. (B. & S.), the conductivity of hard-drawn wires was found to be less than the conductivity of annealed wires by 2.7 per cent.

Density of Copper.—The international standard density for copper, at 20° C., is 8.89 grams per cubic centimeter. This is the value which has been used by the A.I.E.E., and most other authorities in the past. Recent measurements have indicated this value as a mean. This density, 8.89, at 20° C., corresponds to a density of 8.90 at 0° C. In English units, the density at 20° C. = 0.32117 pounds per cubic inch.

For a complete treatise on this subject, see Bulletin No. 31, Bureau of Standards.

Approximate Rules for the Resistance of Copper Wire.—The resistance of any copper wire at 20° C. or 68° F., according to Matthiessen's standard, is $R = \frac{10.35l}{d^2}$, in which R is the resistance in international ohms, l the length of the wire in feet, and d its diameter in mils. (1 mil = $^1/_{1000}$ inch.)

A No. 10 wire, A.W.G., 0.1019 in. diam (practically 0.1 in.), 1000 ft. in length, has a resistance of 1 ohm at 68° F. and weighs 31.4 lbs.

If a wire of a given length and size by the American or Brown & Sharpe gauge has a certain resistance, a wire of the same length and three numbers higher has twice the resistance, six numbers higher four times the resistance, etc.

DIRECT ELECTRIC CURRENTS.

Ohm's Law.—This law expresses the relation between the three fundamental units of resistance, electrical pressure, and current. It is:

$$\text{Current} = \frac{\text{electrical pressure}}{\text{resistance}};\ I = \frac{E}{R};\ \text{whence } E = I R, \text{ and } R = \frac{E}{I}.$$

In terms of the units of the three quantities,

$$\text{Amperes} = \frac{\text{volts}}{\text{ohms}};\ \text{volts} = \text{amperes} \times \text{ohms};\ \text{ohms} = \frac{\text{volts}}{\text{amperes}}.$$

EXAMPLES: *Simple Circuits.* — **1.** If the source has an effective electrical pressure of 100 volts, and the resistance is two ohms, what is the current?

$$I = \frac{E}{R} = \frac{100}{2} = 50 \text{ amperes.}$$

2. What pressure will give a current of 50 amperes through a resistance of 2 ohms? $E = IR = 50 \times 2 = 100$ volts.

3. What resistance is required to obtain a current of 50 amperes when the pressure is 100 volts? $R = E \div I = 100 \div 50 = 2$ ohms.

Ohm's law applies equally to a complete electrical circuit and to any part thereof.

Series Circuits. — If conductors are arranged one after the other they are said to be in series, and the total resistance of the circuit is the sum of the resistances of its several parts. Let A, Fig. 226, be a source of current, such as a battery or generator, producing a difference of potential or

E.M.F. of 120 volts, measured across ab, and let the circuit contain four conductors whose resistances, r_1, r_2, r_3, r_4, are 1 ohm each, and three other resistances, R_1, R_2, R_3, each 2 ohms. The total resistance is 10 ohms, and by Ohm's law the current $I = E \div R = 120 \div 10 = 12$ amperes. This current is constant throughout the circuit, and a series circuit is therefore one of *constant current*. The *drop* of potential in the whole circuit from a around to b is 120 volts, or $E = RI$. The drop in any portion depends on the resistance of that portion; thus from a to R_1 the resistance is 1 ohm, the constant current 12 amperes, and the drop $1 \times 12 = 12$ volts. The drop in passing through each of the resistance R_1, R_2, R_3 is $2 \times 12 = 24$ volts.

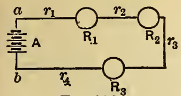

FIG. 226.

Parallel, Divided, or Multiple Circuits.— Let B, Fig. 227, be a generator producing an E.M.F. of 220 volts across the terminals ab. The current is divided, so that part flows through the main wires ac and part through the "shunt" s, having a resistance of 0.5 ohm. Also the current has three paths between c and d, viz., through the three resistances in parallel R_1, R_2, R_3, of 2 ohms each. Consider that the resistance of the wires is so small that it may be neglected. Let the conductances of the four paths be represented by C_s. C_1, C_2, C_3. The total conductance is $C_s + C_1 + C_2 + C_3 = C$ and the total resistance $R = 1 \div C$. The conductance of each path is the reciprocal of its resistance, the total conductance is the sum of the separate conductances, and the resistance of the combined or "parallel" paths is the reciprocal of the total conductance.

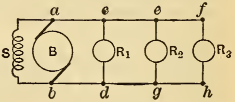

FIG. 227.

$$R = 1 \div \left(\frac{1}{0.5} + \frac{1}{2} + \frac{1}{2} + \frac{1}{2}\right) = 1 \div 3.5 = 0.286 \text{ ohm.}$$

The current $I = E \div R = 770$ amperes.

Conductors in Series and Parallel. — Let the resistances in parallel be the same as in Fig. 227, with the additional resistance of 0.1 ohm in each of the six sections of the main wires, ac, bd, etc., in series. The voltage across ab being 220 volts, determine the drop in voltage at the several points, the total current, and the current through each path. The problem is somewhat complicated. It may be solved as follows: Consider first the points eg; here there are two paths for the current, $efgh$ and eg. Find the resistance and the conductance of each and the total resistance (the reciprocal of the joint conductance) of the parallel paths. Next consider the points cd; here there are two paths — one through e and the other through cd. Find the total resistance as before. Finally consider the points ab; here there are two paths — one through c, the other through s. Find the conductances of each and their sum. The product of this sum and the voltage at ab will be the total amperes of current, and the current through any path will be proportional to the conductance of that path. The resistances, R, and conductances, C, of the several paths are as follows:

	R	C
R_a of $efR_3hg = 0.1 + 2 + 0.1$	$= 2.2$	0.4545
R_b of eR_2g	$= 2$	0.5
Joint R_c	$= 1.048$	0.9545
R_d of $ce + dg + R_c$	$= 1.248$	0.8013
R_e of cR_1d	$= 2$	0.5
Joint R_f	$= 0.7687$	1.3013

R_g of $ac + bd + R_f$	= 0.9687	1.0332
R_h of s	= 0.5	2
Joint $R_a + R_h$	= 0.330	3.0332

Total current = 220 × 3.0332 = 667.3 amperes.
Current through s = 220 × 2 = 440 amp.; through c = 227.3 amp.
" " cR_1d = 227.3 × 0.5 ÷ 1.3013 = 87.34 amp.
" " e = 227.3 × 0.8013 ÷ 1.3013 = 139.96 "
" " eR_2g = 139.96 × 0.5 ÷ 0.9545 = 73.31 "
" " fR_3 = 139.96 × 0.4545 ÷ 0.9545 = 66.65 "

The drop in voltage in any section of the line is found by the formula $E = RI$, R being the resistance of that section and I the current in it. As the R of each section is 0.1 ohm we find E for ac and bd each = 22.7 volts, for ce and dg each 14.0 volts, and for ef and gh each 6.67 volts. The voltage across cd is 220 − 2 × 22.7 = 174.6 volts; across eg, 174.6 − 2 × 14.0 = 146.6, and across fh 146.6 − 2 × 667 = 133.3 volts. Taking these voltages and the resistances R_1, R_2, R_3, each 2 ohms, we find from $I = E \div R$ the current through each of these resistances 87.3, 73.3, and 66.65 amperes as before.

Internal Resistance. — In a simple circuit we have two resistances, that of the circuit R and that of the internal parts of the source of electromotive force, called internal resistance, r. The formula of Ohm's law when the internal resistance is considered is $I = E \div (R + r)$.

Power of the Circuit. — The power, or rate of work, in watts = current in amperes × electro-motive force in volts = $I \times E$. Since $I = E \div R$, watts = $E^2 \div R$ = electro-motive force² ÷ resistance.

EXAMPLE. — What H.P. is required to supply 100 lamps of 40 ohms resistance each, requiring an electro-motive force of 60 volts?

The number of volt-amperes for each lamp is $\frac{E^2}{R} = \frac{60^2}{40}$, 1 volt-ampere = 0.00134 H.P.; therefore $\frac{60^2}{40} \times 100 \times 0.00134 = 12$ H.P. (electrical) very nearly.

Electrical, Brake, and Indicated Horse-power. — The power given by a dynamo = volts × amperes ÷ 1000 = kilowatts, kw. Volts × out amperes ÷ 746 = electrical horse-power, E.H.P. The power put into a dynamo shaft by a direct-connected engine or other prime mover is called the shaft or brake horse-power, B.H.P. If e_1 is the efficiency of the dynamo, B.H.P. = E.H.P. ÷ e_1. If e_2 is the mechanical efficiency of the engine, the indicated horse-power, I.H.P. = brake H.P. ÷ e_2 = E.H.P. ÷ $(e_1 \times e_2)$.

If e_1 and e_2 each = 91.5%, I.H.P. = E.H.P. × 1.194 = kw. × 1.60. In direct-connected units of 250 kw. or less the rated H.P. of the engine is commonly taken as 1.6 × the rated kw. of the generator.

Electric motors are rated at the H.P. given out at the pulley or belt. H.P. of motor = E.H.P. supplied × efficiency of motor.

Heat Generated by a Current. — Joule's law shows that the heat developed in a conductor is directly proportional, 1st, to its resistance; 2d, to the square of the current strength; and 3d, to the time during which the current flows, or $H = I^2Rt$. Since $I = E \div R$,

$$I^2Rt = \frac{E}{R} IRt = EIt = E\frac{E}{R}t = \frac{E^2t}{R}.$$

Or, heat = current² × resistance × time
= electro-motive force × current × time.
= electro-motive force² × time ÷ resistance.
Q = quantity of electricity flowing = It = $(Et \div R)$.
H = EQ; or heat = electro-motive force × quantity.

The electro-motive force here is that causing the flow, or the difference in potential between the ends of the conductor.

The electrical unit of heat, or "joule" = 10^7 ergs = heat generated in one second by a current of 1 ampere flowing through a resistance of one ohm = 0.239 gramme of water raised 1° C. $H = I^2Rt \times 0.239$ gramme calories = $I^2Rt \times 0.0009478$ British thermal units.

In electric lighting the energy of the current is converted into heat in the lamps. The resistance of the lamp is made great so that the required quantity of heat may be developed, while in the wire leading to and from the lamp the resistance is made as small as is commercially practicable, so that as little energy as possible may be wasted in heating the wire.

Heating of Conductors. (From Kapp's Electrical Transmission of Energy.) — It becomes a matter of great importance to determine beforehand what rise in temperature is to be expected in each given case, and if that rise should be found o be greater than appears safe, provision must be made to increase the rate at which heat is carried off. This can generally be done by increasing the superficial area of the conductor. Say we have one circular conductor of 1 square inch area, and find that with 1000 amperes flowing it would become too hot. Now by splitting up this conductor into 10 separate wires each one-tenth of a square inch cross-sectional area, we have not altered the total amount of energy transformed into heat, but we have increased the surface exposed to the cooling action of the surrounding air in the ratio of 1: $\sqrt{10}$, and therefore the ten thin wires can dissipate more than three times the heat, as compared with the single thick wire.

Prof. Forbes states that an insulated wire carries a greater current without overheating than a bare wire if the diameter be not too great. Assuming the diameter of the cable to be twice the diam. of the conductor, a greater current can be carried in insulated wires than in bare wires up to 1.9 inch diam. of conductor. If diam. of cable = 4 times diam. of conductor, this is the case up to 1.1 inch diam. of conductor.

Heating of Bare Wires. — The following formulæ are given by Kennelly:

$$T = \frac{I^2}{d^3} \times 90{,}000 + t; \quad d = 44.8 \sqrt[3]{\frac{I^2}{T - t}}.$$

T = temperature of the wire and t that of the air, in Fahrenheit degrees; I = current in amperes, d = diameter of the wire in mils.

If we take $T - t = 90°$ $F.$, $\sqrt{90} = 4.48$, then

$$d = 10 \sqrt[3]{I^2} \quad \text{and} \quad I = \sqrt{d^3 \div 1000}.$$

This latter formula gives for the carrying capacity in amperes of bare wires almost exactly the figures given for weather-proof wires in the Fire Underwriters' table, except in the case of Nos. 18 and 16, B. & S. gauge, for which the formula gives 8 and 11 amperes, respectively, instead of 5 and 8 amperes, given in the table.

Heating of Coils. — The rise of temperature in magnet coils due to the passage of current through the wire is approximately proportional to the watts lost in the coil per unit of effective radiating surface, thus:

$$t \propto \frac{I^2R}{S} \text{ or } t = \frac{I^2R}{kS},$$

t being the temperature rise in degrees Fahr.; S, the effective radiating surface; and k a coefficient which varies widely, according to condition. In electromagnet coils of small size and power, k may be as large as 0.015. Ordinarily it ranges from 0.012 down to 0.005; a fair average is 0.007. The more exposed the coil is to air circulation, the larger is the value of k; the larger the proportion of iron to copper, by weight, in the core and winding, the thinner the winding with relation to its dimension parallel with the magnet core, and the larger the "space factor" of the winding, the larger will be the value of k. The space factor is the ratio of the actual copper cross-section of the whole coil to the gross cross-section of copper, insulation, and interstices.

Fusion of Wires. — W. H. Preece gives a formula for the current required to fuse wires of different metals, viz., $I = ad^{3/2}$ in which d is the diameter in inches and a a coefficient whose value for different metals is as follows: Copper, 10,244; aluminum, 7585; platinum, 5172; German silver, 5230; platinoid, 4750; iron, 3148; tin, 1462; lead, 1379; alloy of 2 lead and 1 tin, 1318.

Allowable Carrying Capacity of Copper Wires.
(For inside wiring, National Board of Fire Underwriters' Rules.)

B. & S. Gauge.	Circular Mils.	Amperes.		Circular Mils.	Amperes.

000	167,800	177	262	1,800,000	970	1,550
0000	211,600	210	312	2,000,000	1,050	1,670

Wires smaller than No. 14 B. & S. gauge must not be used except in fixtures and pendant cords.

The lower limit is specified for rubber-covered wires to prevent deterioration of the insulation by the heat of the wires.

For insulated aluminum wire the safe-carrying capacity is 84 per cent of that of copper wire with the same insulation.

See pamphlets published by the National Board of Fire Underwriters, New York, for complete specifications and rules for wiring.

Underwriters' Insulation. — The thickness of insulation required by the rules of the National Board of Fire Underwriters varies with the size of the wire, the character of the insulation, and the voltage. The thickness of insulation on rubber-covered wires carrying voltages up to 600 varies from $1/32$ inch for a No. 18 B. & S. gauge wire to $1/8$ inch for a wire of 1,000,000 circular mils. Weather-proof insulation is required to be slightly thicker. For voltages of over 600 the insulation varies from $1/16$ inch for No. 14 B. & S. gage to $9/64$ inch for 1,000,000 C. M. and over.

ELECTRIC TRANSMISSION, DIRECT CURRENTS.

Cross-section of Wire Required for a Given Current.—

Let R = resistance of a given line of copper wire, in ohms;
r = " " 1 mil-foot of copper;
L = length of wire, in feet;
e = drop in voltage between the two ends;
I = current, in amperes;
A = sectional area of wire, in circular mils;

then $I = \frac{e}{R}$; $R = \frac{e}{I}$; $R = r\frac{L}{A}$; whence $A = \frac{rIL}{e}$.

The value of r for soft copper wire at 68° F. is 10.371 international ohms. For ordinary drawn copper wire the value of 10.8 is commonly taken, corresponding to a conductivity of 97.2 per cent.

For a circuit, going and return, the total length is $2L$, and the formula becomes $A = 21.6IL \div e$, L here being the distance from the point of supply to the point of delivery.

If E is the voltage at the generator and a the per cent of drop in the line, then $e = Ea \div 100$, and $A = 2160\ IL \div aE$.

If P = the power in watts, $= EI$, then $I = \frac{P}{E}$, and $A = \frac{2160\ PL}{aE^2}$.

If P_k = the power in kilowatts, $A = 2{,}160{,}000\ P_kL \div aE^2$.

If L_m = the distance in miles and A_c the area in circular inches, then

$A_c = 6405\ P_k L_m \div aE^2$. If A_s = area in square inches, $A_s = 5030\ P_k L_m \div aE^2$. When the area in circular mils has been determined by either of these formulæ reference should be made to the table of Allowable Capacity of Wires, to see if the calculated size is sufficient to avoid overheating. For all interior wiring the rules of the National Board of Fire Underwriters should be followed.

Weight of Copper for a Given Power. — Taking the weight of a mil-foot of copper at 0.000003027 lb., the weight of copper in a circuit of length $2L$ and cross-section A, in circ. mils, is $0.000006054\,LA$ lbs., $= W$. Substituting for A its value $2160\,PL \div aE^2$ we have

$W = 0.0130766\,PL^2 \div aE^2$; P in watts, L in ft.
$W = 13.0766\ P_k L^2 \div aE^2$; P_k in kilowatts, L in ft.
$W = 364{,}556{,}000\ P_k L^2_m \div aE^2$; P_k in kilowatts, L_m in miles.

The weight of copper required varies directly as the power transmitted; inversely as the percentage of drop or loss; directly as the square of the distance; and inversely as the square of the voltage.

From the last formula the following table has been calculated:

WEIGHT OF COPPER WIRE TO CARRY 1000 KILOWATTS WITH 10% LOSS.

Distance in Miles.	1	5	10	20	50	100
Volts.	Weight in Lbs.					
500	145,822	3,645,560	....	....	....	....
1,000	36,456	911,390	3,645,560	....	....	....
2,000	9,114	227,848	911,390	3,645,560	....	....
5,000	1,458	36,456	145,822	593,290	3,645,560	....
10,000	365	9,114	36,456	145,822	911,390	3,645,560
20,000	91	2,278	9,114	36,456	227,848	911,390
40,000	....	570	2,278	9,114	56,962	227,848
60,000	....	....	1,013	4,051	25,316	101,266

In calculating the distance, an addition of about 5 per cent should be made for sag of the wires.

Short-circuiting. — From the law $I = E/R$ it is seen that with any pressure E, the current I will become very great if R is made very small. In short-circuiting the resistance becomes small and the current therefore great. Hence the dangers of short-circuiting a current.

ECONOMY OF ELECTRIC TRANSMISSION.

The loss of power in a transmission line is ordinarily given in per cent of the total power consumed in the conductors at maximum load. Whatever the line pressure may be, the size of the conductors varies inversely with the percentage of loss. Consequently the maximum line loss which can be allowed is dependent on the most economical size of the line conductors.

In 1881 Lord Kelvin gave out a statement in regard to the most economical size of conductors. This statement, which is known as "Kelvin's law," was as follows:

"The most economical area of conductor will be that for which the annual interest on the capital outlay equals the annual cost of energy wasted."

According to this rule, the cheaper the cost of power, the less should be the capital outlay for the conductors, thus allowing a smaller size to be used. George Forbes states that the most economical section of the conductor is independent of the voltage and the distance, and is proportional to the current.

It is generally assumed that the cost of the pole line and the insulators is constant and not affected by the variation in the size of the line conductors.

If A = interest cost per year of conductors erected, in dollars, B = value of the line loss per year, in dollars; then for the most economical cross-section of the conductors

$$A = B.$$

If K = Cost per kilowatt-year of lost power, in dollars,
K_1 = Cost per pound of wires erected, in dollars,
L = Length of line in 1000 ft.,
D^2 = Cross-section of conductor in circular mils,
I = Line current in amperes,
p = per cent interest,

then $A = \frac{p}{100} \times K_1 \times 0.003 \times L \times D^2$,

$$B = K \times I^2 \times 10.5 \times \frac{L}{D^2}$$

$$\frac{p}{100} \times K_1 \times 0.003 \times L \times D^2 = K \times I^2 \times 10.5 \times \frac{L}{D^2}$$

$$D^2 = 592\ I \sqrt{\frac{K}{p\ K_1}}$$

D^2 is the cross-section, in circular mils, that will give the most economical line loss.

In the following, the above equation is worked out for three different rates of interest:

For 4%, $D^2 = 296\ I \sqrt{\frac{K}{K_1}}$; For 5%, $D^2 = 265\ I \sqrt{\frac{K}{K_1}}$;

For 6%, $D^2 = 242\ I \sqrt{\frac{K}{K_1}}$

In determining the value of I, care must be taken that the annual mean value of the current is used. The value of K must also be the one for which the power, representing the line loss, can be produced, and not that for which it can be sold.

Wire Tables. — The tables on the following page show the relation between load, distance, and "drop" or loss by voltage in a two-wire direct-current circuit of any standard size of wire. The tables are based on the formula

$$(21.6\ IL) \div A = \text{Drop in volts.}$$

I = current in amperes, L = distance in feet from point of supply to point of delivery, A = sectional area of wire in circular mils. The factors I and L are combined in the table, in the compound factor "ampere feet."

Examples in the Use of the Wire Tables. — 1. Required the maximum load in amperes at 220 volts that can be carried 95 feet by No. 6 wire without exceeding $1^1/_2$% drop.

Find No. 6 in the 220-volt column of Table I; opposite this in the $1^1/_2$% column is the number 4005, which is the ampere-feet. Dividing this by the required distance (95 feet) gives the load, 42.15 amperes.

Example 2. A 500-volt line is to carry 100 amperes 600 feet with a drop not exceeding 5%; what size of wire will be required?

The ampere-feet will be 100 × 600 = 60,000. Referring to the 5% column of Table II, the nearest number of ampere-feet is 60,750, which is opposite No. 3 wire in the 500-volt column.

These tables also show the percentage of the power delivered to a line that is lost in non-inductive alternating-current circuits. Such circuits are obtained when the load consists of incandescent lamps and the circuit wires lie only an inch or two apart, as in conduit wiring.

Efficiency of Electric Systems.—The efficiency of a system is the ratio of the power delivered by the electric motors at the distant end of the line to the power delivered to the dynamo-electric machines at the other end. The efficiency of a generator or motor varies with its load and with the size of the machine, ranging about as follows:

Average Full-load Efficiency of Generators:

K.W.	25	50	100	200	500	1000	2000	3000
Eff. %	88	90	91	92	93	94	94.5	95

Average Full-load Efficiency of Motors:

H.P.	1	2	5	10	25	50	100	200	500
Eff. %	80	82	85	87	88	90	91	92	93

The efficiency of both generators and motors decreases, at first very

Wire Table — Relation between Load, Distance, Loss, and Size of Conductor.

Note. — The numbers in the body of the tables are Ampere-Feet, i.e., Amperes × Distance (length of one wire). See examples below.

Table I. — 110-volt and 220-volt Two-wire Circuits.

Wire Sizes; B. & S. Gauge.		Line Loss in Percentage of the Rated Voltage; and Power Loss in Percentage of the Delivered Power.

14	....	....	950	1,425	1,900	2,375	2,850	3,800	4,750

slowly and then more rapidly, as the load decreases. Each machine has its "characteristic" curve of efficiency, showing the ratio of output to input at different loads. Roughly the decrease in efficiency for direct-current machines at half-load varies from 3% to 10% for the smallest sizes. The loss in transmission, due to fall in electrical pressure or "dop" in the line, is governed by the size of the wires, the other conditions remaining the same. For a long-distance transmission plant this will vary from 5% upwards.

With generator efficiency and motor efficiency each 90%, and transmission loss 5%, the combined efficiency is $0.90 \times 0.90 \times 0.95 = 76.95\%$.

Resistances of Pure Aluminum Wire.*

Conductivity 62 in the Matthiesen Standard Scale. Pure aluminum weighs 167.111 pounds per cubic foot.

* Calculated on the basis of Dr. Matthiessen's standard, viz.: The resistance of a pure soft copper wire 1 meter long, having a weight of 1 gram = 0.141729 International Ohm at 0° C.
(From Aluminum for Electrical Conductors; Pittsburgh Reduction Co.)

ELECTRIC RAILWAYS.

While 600 volts is still maintained as a standard for street railway systems, experience has shown that the most economical operation of high-speed suburban and interurban railroads can be obtained with 1200 to 1500 volts on the trolley. Steam railroad electrifications will, however, be accomplished most satisfactorily with 2400 or 3000 volts direct current.

Schedule Speeds, Miles per Hour.

City Service.

Max. Speed.	Stops per Mile. 1	2	3	4	5	6	7	8
15......	10.8	9.9	9.3	8.7	8.3	7.9	7.5	7.2
20......	13.7	12.1	11.1	10.3	9.6	9.0	8.6	8.1
25......	16.3	14.2	12.7	11.5	10.6	9.9	9.3	8.7
30......	18.5	15.6	13.8	12.4	11.3	10.5	9.8	9.2

INTERURBAN SERVICE.

Max. Speed.	Miles between Stops.								
	1/2	3/4	1	1.5	2	3	4	5	10
30......	14.0	15.5	16.7	18.5	19.7	21.0	22.0	22.5	23.9
40......	15.4	18.1	20.0	22.7	24.5	26.7	28.0	28.9	30.8
50......	16.2	19.5	21.9	25.6	27.9	31.0	32.9	34.2	37.2
60......	17.0	20.8	23.6	27.9	30.9	34.8	37.5	39.3	43.6

The figures in the above tables include stops of 5 seconds each for the city service and of 15 seconds for the interurban service, besides a 15% margin for line drop and traffic delays. The ratio of acceleration is approximately 1.5 miles per hour per second for the city service and 1.2 miles per hour per second for the interurban service, the braking being 1.5 miles per hour per second and the coasting approximately 10% of the running time exclusive of stop.

Train Resistance. (General Electric Co.)—The horse-power output at the rim of the wheels is equal to,

$$\text{H.P.} = \frac{T \times F \times \text{Feet}}{33{,}000 \times \text{Minutes}} = \frac{T \times F \times V}{375}.$$

When reduced to Kilowatts,

$$\text{Kw.} = \frac{T \times F \times V \times 746}{375 \times 1000} = \frac{2 \times T \times F \times V}{1000} \text{ approx.}$$

The kilowatt input to train is equal to,

$$\text{Kw.} = \frac{2 \times T \times F \times V}{1000 \times \text{Eff.}}$$

Where T = Total weight of train in tons.
F = Train resistance, including that due to grades and curves, in lbs. per ton.
V = Speed in miles per hour.
Eff = Efficiency of motors at speed V.

The train resistance may be found from the following formula:

$$F. = \frac{50}{\sqrt{T}} + 0.03\ V + \frac{0.002\ V^2}{T} A \left(1 + \frac{N-1}{10}\right)$$

Where F = Train resistance in lbs., per ton.
T = Total weight of train in tons.
V = Speed in miles per hour.
A = End cross-section in sq. ft.
N = Number of cars in train.
$\frac{50}{\sqrt{T}}$ is limited to a value of 3.5.

Tractive Resistance of a 28-ton Electric Car (Harold H. Dunn, Bull. 74, Univ'y of Ill. Expt. Station, April, 1914).—Mean of all tests:

Miles per hr..	5	10	15	20	25	30	35	40	45
Lb. per ton..	5.25	6.80	8.62	10.75	13.03	15.75	18.75	22.13	26.12

Two formulæ have been derived from the results:

$$R = 4 + 0.222\ S + 0.00582\ S^2.$$

$$R = 4 + 0.222\ S + 0.00181 \frac{A}{W} S^2.$$

A = cross-sectional area of the car in sq. ft. W = weight of the car in tons.

The formulæ should not be used beyond the limit of 45 miles per hour.

Rates of Acceleration.—Electric Locomotive Passenger Service, 0.3 to 0.6 mile per hour per second.

Electric Motor Cars, Interurban Service, 0.8 to 1.3 miles per hour per second.

Electric Motor Cars, City Service, 1.5 miles per hour per second.

Electric Motor Cars, Rapid Transit Service, 1.5 to 2.0 miles per hour per second.

Highest Practical Rate, 2.0 to 2.5 miles per hour per second.

Safe Maximum Speed on Curves.—

Radius of Curve, Ft.	10,000	5000	2000	1000	500	200	100	50
Speed, miles per hr.,	100	75	50	35	25	15	10	6

The above values apply only when full elevation is given the outer rail. For city service such elevation is not possible and the maximum speed will, therefore, be less under such conditions. The same restriction applies with steel wheel flanges of 3/4 inch or less.

Coefficient of Adhesion. — The following are the average values of the coefficient of adhesion between wheels and rails, based on a uniform torque:

Clean, dry rail,	30%.	
Wet rail,	18%;	with sand, 22%.
Rail covered with sleet,	15%;	with sand, 20%.
Rail covered with dry snow,	10%;	with sand, 15%.

Electrical Resistance of Steel Rails.—The resistance of steel rails varies considerably, due to the difference in chemical composition. Ordinary traction rails have a specific resistance averaging 12 times that of copper, while for contact rails (third rails) the average is only 8 times. The values given in the following table are in ohms at 75° F. and with no joints.

Weight of Rails, Lbs. per Yard.	Actual Area, Sq. In.	Actual Area in Circular Mils.	Resistance per Mile, 8 to 1 Ratio.	Resistance per Mile, 12 to 1 Ratio.
40	3.92	4,918,300	0.09118	0.13395
45	4.42	5,627,700	0.07915	0.11905
50	4.90	6,238,800	0.07135	0.10710
60	5.88	7,486,600	0.05955	0.08920
70	6.86	8,734,400	0.05105	0.07660
75	7.35	9,230,900	0.04780	0.07185
80	7.84	9,982,100	0.04465	0.06695
90	8.82	11,229,900	0.03975	0.05955
100	9.80	12,477,700	0.03750	0.05365

Resistance of Rail Bonds. — The resistance of bonded rails will vary, depending on the amount of contact made by the splice bars and rail ends, but in selecting bonds this element of the return circuit should be disregarded, as it is quite unreliable and frequently negligible.

Size of Conductor.	Diameter of Terminal, in Inches.	Resistance per In. of Conductor. 75° Fahr.	Carrying Capacity, Amp.
0	1/2	.00000829	210
00	5/8	.00000657	265

350,000 C. M.	1	.00000250	700
400,000 C. M.	1	.00000219	800
450,000 C. M.	1	.00000196	900
500,000 C. M.	1	.00000175	1000

Electric Locomotives.—In selecting an electric locomotive the principal points to be determined are the weight of the locomotive, the type and capacity of the equipment, and the mechanical features. The weight upon the drivers must be enough to pull the heaviest trains under the most adverse conditions. Therefore the weight of the heaviest train, the maximum grade and curvature must be ascertained. It must be known whether the locomotive is expected to start the train under these conditions, or whether it will start upon the level and only meet maximum grade conditions when running.

In order to determine the motor equipment all the data of the service conditions are required, such as the speed required under various conditions of load and grade. The maximum free-running speed will be approximately 50 to 75 per cent greater than the rated full load speed. Mechanical limitations must also be considered, such as track clearances, limiting weight on drivers, type of couplings, etc.

*"Continuous Rating," which means the rating which can be continually developed without overheating the motors.
†"Pounds Tractive Effort," in which the drawbar pull is measured.

Relative Efficiencies of Electric Railway Distributing Systems.—The table on p. 1417 shows the approximate all-day combined efficiencies from prime mover to train wheels for various methods of trunk line electrifications. The trains are supposed to be handled by electric locomotives, and in each instance a considerable length of line is contemplated, making it necessary to have a 100,000-volt high-tension primary distribution or a multiplicity of power sources.

Space will not permit a complete treatment of the subject of Electric Railways in this work. For further information consult: "American Handbook for Electrical Engineers"; Standard Handbook for Electrical Engineers"; "Foster's Electrical Engineer's Pocket Book"; Burch, "Electric Traction for Railway Trains"; Harding, "Electric Railway Engineering."

ELECTRIC WELDING.

Electric welding is divided into two general classes, arc heating and resistance heating.

Arc Welding.—In this process the heat of the arc is utilized to bring the metals to be welded to the melting temperature, when the joint is filled with molten metal, usually introduced in the form of a rod. This system is usually operated by direct current, and as the positive side of a direct current arc generates heat at a rate approximately three times that of the negative side, the positive side is used for performing the welding operation.

Two kinds of arcs may be used for this class of welding, the carbon arc and the metallic arc. The former requires an e. m. f. varying from 50 to 100 volts and the value of the current is varied over a range of 100 to 750 amperes, 300 being the average. The metallic arc, however, requires an e. m. f. of only from 15 to 30 volts, the length of the arc being very short as compared with the carbon arc.

The arc should be as stable as possible, and the current should, therefore, be of a constant value. The regulation may be accomplished by inserting resistance in series in the circuit, but this system is naturally very wasteful and greater economy may be obtained by providing motor-generator sets, with the generator of the variable voltage type.

The following costs, Table I (from *Electrical World*) were compiled from the records of an electric railway repair shop:

TABLE I.
Data on Electric Welding Repairs in Railway Shops.

	Time in Minutes.	Kw.	Average Costs.
Gear-case lugs	10	6	$0.07
Armature shaft (broken) 2-in.	60	20–30	0.80
Dowel-pin holes	5–12	4–8	0.07
Broken motor cases	150–200	75–90	4.98
Broken lugs on a compressor cover, doors and grease-cup hinges	2–5	1–3	0.03
Broken truck frames	30–60	20–35	0.63
Worn bolt holes in motors and trucks	5–10	3–5	0.05
Enlarged and elongated holes in brake levers	2–4	$1\frac{1}{2}$–3	0.03
Armature shafts, 2-in., worn in journals	120–180	60–90	3.75
Armature shafts, worn in keyways	10–15	7–12	0.10
Armature shaft, worn thread	20–30	10–15	0.24
Air-brake armature shafts (broken)	20–30	10–20	0.27
Leaking axle boxes	5–15	3–7	0.08

Resistance Welding. — Resistance welding is done by the heat developed by a large amperage carrying through the joining metals by means of a low voltage. Single-phase alternating current is generally used for the operation, which may be broadly divided into two classes—butt-welding and spot-welding. The former covers all work on which the ends or the sides of the material are welded together, while spot-welding is used for joining metal sheets together at any point by a spot the size of a rivet, without punching holes or using rivets.

For resistance welding a very low voltage is used, varying from 2 to 8 volts, the line voltage being stepped down by special transformers.

The current consumption, in amperes, varies with the work and the time taken to make the weld.

The following tables (from *Iron Trade Review*) give the cost of resistance welding. Table II gives the results obtained by butt-welding round stock ranging from 1/4 to 1 inch diameter, in the shortest and longest time possible. The difference in current consumption is very great and in most cases the shorter time in seconds was the most economical of the two, although neither is the most economical rate at which the material can be welded.

TABLE II.—Shortest and Longest Butt-welding Periods.

Size, In.	Time, Seconds.	Current Amperes.	Volts per Square Inch.	Size, In.	Time, Seconds.	Current Amperes.	Volts per Square Inch.
1/4	2.7	1960	39.5	5/8	3.5	9400	33.7
1/4	5	1645	35.5	5/8	10.85	5510	18.85
3/8	4	4330	45.5	3/4	4	10000	16.26
3/8	5.27	2190	19.7	3/4	22.2	9400	19.7
1/2	4	6600	36.6	7/8	7	11900	27.7
1/2	15.8	1800	13	7/8	17	10550	19.6
9/16	3.6	8400	8	1	33	7740	10.35
9/16	21.5	3400	12.25	1	114	4450	16.1

Table III contains the results of tests made to determine the cost of power for making electric butt welds on material ranging from 1/4 to 2 inches in diameter.

TABLE III.—Cost of Power.

Area, Sq. In.	Kw.	Welding Time, Seconds.	Cost per 1000 Welds*	Area, Sq. In.	Kw.	Welding Time, Seconds.	Cost per 1000 Welds*
0.05	5	5	$0.07	0.79	18	30	$1.50
0.11	7 1/2	6	0.13	0.99	20	30	1.66
0.20	8	10	0.22	1.23	26	40	2.89
0.31	10	12	0.33	1.77	40	60	6.67
0.44	12	15	0.50	2.41	45	70	8.75
0.60	15	20	0.83	3.14	56	80	12.44

Table IV gives the time, power and cost per 100 spot-welds, with current at 1/4 cent per Kw.-hr., for welding Nos. 10 to 28 gage sheets.

TABLE IV.—Cost of Welding.

Gage.	Kw.	Time in Seconds.	Cost per 1000 Welds, Cents.*	Gage.	Kw.	Time in Seconds.	Cost per 1000 Welds, Cents.

*Current at 1 cent per Kw.-hr.

ELECTRIC HEATERS.

Wherever a comparatively small amount of heat is desired to be automatically and uniformly maintained, and started or stopped on the instant without waste, there is the province of the electric heater.

The elementary form of heater is some form of resistance, such as coils of thin wire introduced into an electric circuit and surrounded with a substance which will permit the conduction and radiation of heat, and at the same time serve to electrically insulate the resistance.

This resistance should be proportional to the electro-motive force of the current used and to the equation of Joule's law:

$$H = I^2Rt \times 0.24,$$

where I is the current in amperes; R, the resistance in ohms; t, the time in seconds; and H, the heat in gram-centigrade units.

Since the resistance of metals increases as their temperature increases, a thin wire heated by current passing through it will resist more, and grow hotter and hotter until its rate of loss of heat by conduction and radiation equals the rate at which heat is supplied by the current. In a short wire, before heat enough can be dispelled for commercial purposes, fusion will begin; and in electric heaters it is necessary to use either long lengths of thin wire, or carbon, which alone of all conductors resists fusion. In the majority of heaters, coils of thin wire are used, separately embedded in some substance of poor electrical but good thermal conductivity.

Relative Efficiency of Electric and of Steam Heating. — Suppose that by the use of good coal, careful firing, well-designed boilers and triple-expansion engines we are able in daily practice to generate 1 H.P. at the fly-wheel with an expenditure of 2 1/2 lb. of coal per hour.

We have then to convert this energy into electricity, transmit it by wire to the heater, and convert it into heat by passing it through a resistance-coil. We may set the combined efficiency of the dynamo and line circuit at 85%, and will suppose that all the electricity is converted into heat in the resistance-coils of the radiator. Then 1 brake H.P. at the engine = 0.85 electrical H.P. at the resistance coil = 1,683,000 ft.-lb. energy per hour = 2180 heat-units. But since it required 2 1/2 lbs. of coal to develop 1 brake H.P., it follows that the heat given out at the radiator per pound of coal burned in the boiler furnace will be $2180 \div 2\,1/2 = 872$ H.U. An ordinary steam-heating system utilizes 9652 H.U. per lb. of coal for heating; hence the efficiency of the electric system is to the efficiency of the steam-heating system as 872 is to 9652, or about 1 to 11. (*Eng'g News*, Aug. 9, '90; Mar. 30, '92; May 15, '93.)

Heat Required to Warm and Ventilate a Room. — The heat required to raise the temperature of a given space or room to a certain value depends upon the ventilation, the character of the walls, the dimensions, proportions of the room, etc. One watt-hour of electrical energy will raise the temperature of one cubic foot of air (measured at 70°) 191° F., or 1 watt will raise the temperature of a cubic foot of air at the rate of 0.0531° F. per second, or approximately 3.2° per minute. In addition to raising the temperature of the air to the desired value, the loss of heat through conduction and ventilation must be supplied. (See Heating and Ventilation.)

Example. Assume a room of a capacity of 3000 cu. ft., in which the air is changed every 20 minutes, the temperature to be maintained 30° above the outside air.

$3000 \div 20 = 150$ cu. ft. per minute.

$(150 \times 30) \div 3.2 = 1406$ watts necessary to supply the ventilation loss. To begin with, to raise the air in the room 30° will require

$$(3000 \times 30) \div 191 = 471 \text{ watt-hours}$$

and therefore the total energy used during the first hour will be $1406 + 471 = 1877$ watt-hours or 1.88 Kw.-hours.

Domestic Heating. — Electric heating is extensively used for household cooking apparatus. The time taken to heat water in any quantity to any definite temperature not exceeding boiling point can be determined by the formula:

$$t = \frac{V\,(T_2 - T_1)\,1831}{P \times \text{Eff.}}$$

Where t = time in minutes, V = number of pints, T_1 = initial temperature, °F., T_2 = final temperature, °F., P = energy consumption in watts, Eff. = Efficiency of cooking utensil, per cent.

Example. To heat 1 pint of water 100° F. with a 220-watt heater with 50% efficiency, time = $(1 \times 100 \times 1831) \div (220 \times 50) = 16.6$ min.

The following table (compiled by the National Electric Light Association) gives the watts consumed and cost of operation of different domestic heating devices, the cost of current being at the rate of 5 cents per Kw.-hr.

Cost of Operation of Domestic Heating Appliances.

Apparatus.	Watts.	Cents per hr.
Broilers, 3 heat*	300 to 1200	1.5 to 6
Chafing dishes, 3 heat	200 to 500	1 to 2.5
Coffee percolators for 6-in. stove	100 to 440	0.5 to 2.2
Curling-iron heaters	60	0.3
Double boilers for 6-in., 3-heat stove	100 to 440	0.5 to 2.2
Flatiron (domestic size), 3 lb	275	1
Flatiron (domestic size), 4 lb	350	1.4
Flatiron (domestic size), 5 lb	400	2
Flatiron (domestic size), 6 lb	475	2.4
Flatiron (domestic size), 7.5 lb	540	2.7
Flatiron (domestic size), 9 lb	610	3.05
Frying kettles, 8 in. diameter	825	4.125
Griddle-cake cookers, 9 in. by 12 in., 3-heat	330 to 880	1.7 to 4.4
Griddle-cake cookers, 12 in. by 18 in., 3-heat	500 to 1500	2.5 to 7.5
Ornamental stoves	250 to 500	1.25 to 2.5
Ovens	1200 to 1500	6 to 7.5
Plate warmers	300	1.5
Radiators	700 to 6000	3.5 to 30
Ranges: 3-heat, 4 to 6 people	1000 to 4515	5 to 22
Ranges: 3-heat, 6 to 12 people	1100 to 5250	5.5 to 26
Ranges: 3-heat, 12 to 20 people	2000 to 7200	10 to 36
Toasters, 9 in. by 12 in., 3-heat	330 to 880	1.6 to 4.4
Urns, 1-gal., 3-heat	110 to 440	0.5 to 2.2
Urns, 2-gal., 3-heat	220 to 660	1.1 to 3.3

Experience has shown that 300 watt-hours per meal per person is a liberal allowance for electric cooking; or in a family of five, four kilowatt hours per day is an average.

ELECTRIC FURNACES.

In the combustion furnace, no matter what form of fuel is used, the temperature cannot exceed 2000° C. (3632° F.), and for higher temperatures the electric furnace must be used. The intensity of the heat in this type of furnace depends on the amount of current that passes, and as most substances are conductors when hot, the degree of intensity possible is theoretically unlimited. In practice, however, the conducting substance begins to fuse when heated to its melting point, and one is then confronted with the physical difficulty of keeping the conducting medium in place, or, if this be accomplished, the conducting medium ultimately vaporizes, the gaseous materials escape, and heat is thus carried away from the furnace as rapidly as it is supplied. The temperature of the electric arc, which is somewhere between 3600° and 4000° C. (6512° – 7232° F.), is perhaps the highest temperature attainable at present.

Electric furnaces may be divided in two broad classes, *arc furnaces* and *resistance furnaces*. In the former the heat is generated by passing an electric current through the space between the ends of two electrodes, forming the so-called arc. In the resistance furnace the heat is generated in the interior of a body due to its electrical resistance.

There are three typical forms of arc furnaces, their common feature being that most and sometimes all of the heat is transmitted to the material by radiation, which extends in all directions. In all the furnaces the arc must be started by a quick movement of the electrodes and afterwards these must be continuously fed together as they are consumed.

The chief characteristics of the three main types of arc furnaces are:

1. The direct-heating type, in which two or more electrodes are used and the heating is accomplished by conduction and radiation. The current passes from one electrode down through the slag, across through the bath and up through the slag to the other electrode. The Heroult furnace belongs to this type.

The Girod furnace is also of the direct-heating type, the current arcing from the electrodes, which are connected to one side of the circuit, to a fixed electrode in the bottom.

---

* The apparatus can be set at three different heats or temperatures.

2. The indirect-heating type. To this type belongs the Stassano furnace, in which the arc extends between two or more carbon electrodes above the charge, and therefore passes over but does not come in contact with the charge, the heating being accomplished by radiation.

3. The smothered type, in which the arc extends from the end of the upper electrode, which extends beneath the surface of the charge, to the lower fixed electrode in the bottom of the furnace.

The direct and indirect heating arc furnaces are extensively used for melting and refining metals, while examples of the smothered type are the ferro-silicon and calcium carbide furnaces.

Resistance furnaces may also be divided in two distinct types, those of direct and indirect heating.

1. Direct heating. In these the heat is produced in the material by its own resistance, and enters the material at the highest efficiency.

The material may be placed in a channel between two electrodes at the ends which lead the current to and from it, the charge being surrounded with insulating material to reduce the loss of heat. The Acheson graphite furnaces are of this type.

Under this classification also come the induction furnaces in which the terminal electrodes are eliminated and the heat generated solely by induction. The furnace consists essentially of an iron core, around one leg of which is wound a primary winding enclosed in a refractory case and usually cooled by means of forced draft. The annular hearth surrounds this primary coil and is separated from it by means of refractory material. This hearth contains the metal and acts as a secondary winding of one turn. The voltage induced in this turn is quite small so that the energy transformed from the primary coil results in a very large current in the secondary, which heats the metal and thus nearly all the electrical energy is converted into heat in the metal to be melted. The Kjellin and the Rochling-Rodenhauser furnaces belong to this type. They are extensively used for steel refining.

2. Indirect heating furnaces have the heat generated in an internal or external resistor and it is transferred to the charge by conduction and radiation. Such furnaces are used for small moderate temperature work.

Uses of Electric Furnaces.

Pig Iron. — When the electric furnace is used for smelting of iron ore it is only necessary to supply enough carbon for the reduction, this amount being approximately one-third of what is required in the ordinary blast furnace for both the heating and reduction. From repeated trial runs with electric smelting furnaces in Norway and Sweden it has been found that coke as a reducing agent does not give satisfactory results, and charcoal is therefore used exclusively.

The table on p. 1424 gives a summary of the most important figures relating to the economical results which were obtained with the electric iron ore furnaces in Sweden.

Steel Refining. — Electric furnaces are used in the manufacture of crucible quality steel, and the number is constantly increasing, both arc and induction furnaces being in general use.

The following data as to the cost of electric steel refining are taken from an article in *Stahl und Eisen*, April 10, 1913. This article gives the results which have been obtained in Germany by the Heroult furnace and it contains a discussion of electric steel production from a large-industry point of view.

The total refining cost must include many items as well as the cost of current; for example, the cost of fluxes (ore, lime, sand, etc.), the additions of ferro-alloys, relining, maintenance, and repairs, electrode consumption, wages, and, finally, interest and depreciation. The totals of these items and the cost of current, which is the largest item, are given below:

Total Refining Costs (Per Ton).

	5-ton		10-ton		15-ton		20-ton	
	Basic.	Acid.	Basic.	Acid.	Basic.	Acid.	Basic.	Acid.
Total costs....	$2.79	$1.79	$2.45	$1.45	$2.28	$1.34	$2.15	$1.25
Cost of current	1.19	0.77	1.07	0.59	1.01	0.54	0.95	0.48

The figures are based on prevailing market prices. Current is taken

* 1 hectoliter = 3.53 cu. ft. = 2.84 U. S. bushels.

at 0.595c. per Kw.-hr., which is a figure that should be easy of attainment for most steel plants. The time per heat is taken as 2 1/4 to 2 1/2 hours. Three-phase furnaces are considered, and in the installation cost of the plant must be included transformers, cables, and switchboards. The amount of current required is as follows:

Size of Furnace, Tons	1	2	5	10	25
Kilowatts...........	300–350	400–450	750–800	1000–1200	3000–3500

Ferro-Alloys. — The electric furnace has clearly demonstrated its advantages in the manufacture of ferro-alloys. The production of a ferro-alloy low in carbon or with a high percentage of the alloying element is limited in the blast furnace by three difficulties — first, the temperature is too low for the reduction of some of the oxides of the alloying metals; second, it is difficult to obtain an alloy containing a high percentage of the special metal; and third, it is impossible to produce a ferro-alloy low in carbon, because of the great excess of carbon in the charge. With the crucible, owing to the small scale of operation necessary, the process is expensive. Owing to the temperature limitation, certain oxides can not be reduced and metals of high melting point can not be melted; it is difficult to obtain an alloy with a high percentage of the special metal; and if a graphite crucible is used, the percentage of carbon tends to be high in the ferro-alloy.

Non-ferrous Metals. — In the metallurgy of non-ferrous metals the electric furnace has had a greater application for the treatment of zinc ores than in the metallurgy of any of the other non-ferrous metals except aluminum. Since 1885, when an electric furnace for the treatment of zinc ores was patented by the Cowles brothers, experimental work has been done on a very large scale. However, the process has not been applied to any great extent because of the difficulty of condensing the zinc vapor produced in smelting in the electric furnace, and so it may be said that the electric smelting of zinc ores is yet in the experimental stage.

Silundum, or silicified carbon, is a product obtained when carbon is heated in the vapor of silicon in an electric furnace. It is a form of carborundum, and has similar properties; it is very hard, resists high temperatures, and is acid-proof. It is a conductor of electricity, its resistance being about three times that of carbon. It can be heated in the air up to 1600° C. without showing any sign of oxidation. At about 1700°, however, the silicon leaves the carbon and combines with the oxygen of the air. Silundum can not be melted. The first use to which the material was applied was for electric cooking and heating. For heating purposes the silundum rods can be used single, in lengths up to 32 in., depending on the diameter, as solid, round, flat, or square rods or tubes, or in the form of a grid mounted in a frame and provided with contact wires.—(*El. Review*, London. *Eng. Digest*, Feb., 1909.)

PRIMARY BATTERIES.

Following is a partial list of some of the best known primary cells or batteries.

Name.	Elements. −	+	Electrolyte.	Depolarizer.	E.M.F. volts.
Daniell	Cu	Zn	Dilute H_2SO_4	Concent. $CuSO_4$	1.07
Gravity	Cu	Zn	$ZnSO_4$	Concent. $CuSO_4$	1.
Grove	Pt	Zn	Dilute H_2SO_4	HNO_3	1.9

Edison-Lalande	Cu	Zn	Conc. NaOH	CuO	0.7–0.9
Leclanche	C	Zn	NH_4Cl	MnO_2	1.4
Clark	Pt	Zn	$ZnSO_4$	Hg_2SO_4	1.44
Weston	Pt	Cd	$CdSO_4$	Hg_2SO_4	1.02
Dry battery	C	Zn	Various electrolyte pastes.		1–1.8

The gravity cell is used for telegraph work. It is suitable for closed circuits, and should not be used where it is to stand for a long time on open circuit.

The Fuller cell is adapted to telephones or any intermittent work. It can stand on open circuit for months without deterioration.

The Edison-Lalande cell is suitable for either closed or open circuits.

The Leclanche cell is adapted for open circuit intermittent work, such as bells, telephones, etc.

The Clark and Weston cells are used for electrical standards. The Weston cell has largely superseded the Clark.

Dry cells are in common use for house service, igniters for gas engines, etc.

Batteries are coupled in series of two or more to obtain an e.m.f. greater than that of one cell, and in multiple to obtain more amperes without change of e.m.f.

Spark coils, or induction coils, with interrupters, are used to obtain ignition sparks for gas engines, etc.

ELECTRIC ACCUMULATORS OR STORAGE BATTERIES.

Secondary or storage batteries may be divided in two general classes: viz., the lead battery and the Edison alkaline battery. They are composed of a number of cells connected in series or multiple. The voltage is independent of the size of the cell and is a function of the electro-chemical properties used for the electrodes and electrolytes, being approximately two volts per cell. The current, however, is approximately proportional to the surface of the electrodes that are submerged in the electrolyte.

Lead Batteries. — The lead battery consists of two electrodes, the positive and negative, immersed in the electrolyte. The two electrodes are sponge lead (Pb) for the negative, and peroxide of lead (PbO_2) for the positive, these forming the active couple, the electrolyte being dilute sulphuric acid. The two sets of electrodes are called an element, and they can be readily distinguished by their colors, the positive peroxide plate being of a velvety brown chocolate color and the negative lead sponge plate of a light gray.

Inside of the cell the current starts from the negative electrode toward the positive, and the positive electrode, therefore, is that portion of the battery from which the electric current passes out into the load circuit, this being termed "discharge," as compared to the storing of energy, which is termed "charge." When the cell gives out current, the elements gradually change in composition, becoming mixtures or compounds of lead and lead sulphate at the negative electrode, and lead peroxide and lead sulphate at the positive electrode, the chemical change caused by the giving out of electrical energy being a gradual formation of lead sulphate.

Lead batteries are made with two different types of plates, the "formed" or Planté plate, and the "pasted" or Faure plate. In the former, the active material is formed electro-chemically on the surface of the plate body, while in the latter it is first applied mechanically in the form of lead oxide and afterward| subjected to the forming process. As a rule the negative plates are always of the Faure type. Positive Planté plates have a long life, while the life of positive Faure plates is limited to a considerable extent by the number of charges. The latter, however, give a greater capacity for the same weight than the formed plate, and are, therefore, used where light weight is required, such as for electric vehicles. Positive plates have ordinarily a shorter life than negative.

The capacity of a storage battery is measured in ampere-hours, and varies with the discharge rate. An arbitrary standard of the 8-hour rate is now universally adopted, but if the rate is increased, the capacity is diminished. So, for example, at a one-hour discharge rate only about half the number of ampere-hours can be obtained from a cell that it can supply at the 8-hour rate. An 80-ampere-hour battery thus means one which will discharge 10 amperes continuously for eight hours without falling below the minimum allowable voltage.

When a battery is being discharged, the voltage sinks gradually and it should never be discharged below some fixed limit, because an excessive quantity of sulphate will then form, which may injure the plates both electrically and mechanically, tending to crack and loosen the active material. This condition is indicated by the deposit of white sulphate on the surfaces of the plates. The voltage at which a lead battery is assumed to be completely discharged depends on the discharge rate and may be computed from the formula

$$E = 1.66 + 0.0175\,t$$

where t = time of discharge in hours.

Thus for an 8-hour rate the discharge should be stopped when the voltage has dropped to 180, while for an 1-hour rate, it should be stopped when it has dropped to 168.

The voltage rises gradually during the charging from about 2.15 per cell at the beginning to about 2.55 at the end. The rate of charging is usually specified by the manufacturer. In certain instances it is equal to the 8-hour discharge rate, while in others the instructions may be to start the charge between the 3- and 5-hour rate, reducing the current to the 8-hour rate as soon as the plates gas freely. The time required for a charge will, of course, depend upon the amount of the previous discharge. If this has been two-thirds of the rated capacity of the battery, about three hours at the starting rate and an hour and a half or two hours at the finishing rate will be necessary; *i.e.*, from 10 to 15 per cent more charge than the amount taken out on the discharge is ordinarily required.

At regularly weekly or bi-weekly intervals the battery should be given an overcharge for the purpose of equalizing all cells, reducing all sulphate, and keeping the plates in good general condition. Such overcharge is a regular charge continued until the voltage does not show any rise for four or five consecutive readings 15 minutes apart, all cells then gasing freely. A charging voltage of 2.7 volts should be provided for such overcharges.

The specific gravity of the electrolyte, will reach a maximum in the same manner as the voltage, and readings of this in the various cells of the battery should be taken toward the end of the charge with a hydrometer. These readings will act as a check on those taken on the voltage, and while it may not be found practicable to do this every time the battery is charged, it is very important and should be done at least once a week. If batteries are used intermittently and allowed to stand some time without charge or discharge, the electrolyte should be of low density, not over 1.210.

Several different methods may be adopted for controlling the discharge voltage and maintaining a uniform pressure at the lights, viz.: (1) by connecting in additional or "end" cells one at a time, as the voltage drops, by means of an end cell switch; (2) by a rheostat, whose resistance is cut out step by step; (3) by counter electro-motive force cells, which, like a rheostat, cut down the battery voltage at the beginning of discharge, and are cut out of circuit one by one by means of an end cell switch.

Also, several methods may be employed for obtaining the necessary increase of voltage for charging, viz.; (1) by dividing the battery into two equal parts and charging these in parallel through a suitable resistance, the generator running at normal (lamp) voltage; (2) by raising the voltage of the generator sufficiently to charge all the cells in one series; (3) by means of a booster, whose voltage is added to that of the generator, and is varied to give the total required.

In a lead storage-cell, if the surface and quantity of active material be accurately proportioned, and if the discharge be commenced immediately after the termination of the charge, then a current efficiency of as much as 98% may be obtained, provided the rate of discharge is low and well regulated. Since the current efficiency decreases as the discharge rate increases, and since very low discharge rates are seldom used in practice, efficiencies as high as this are never obtained practically, the average being about 90%.

After a battery has been erected and all connections made and the current ready, the electrolyte may be poured into the jars, and as soon thereafter as possible the initial charging should commence. Never allow a battery to stand longer than two hours after the acid is put in, before starting the charge. This should be as continuous as possible, until all cells gas freely and the specific gravity and voltage show no rise over a period of 10 hours. The duration of such a charge may vary from 30 to 100 hours, and is always given by the manufacturer. The temperature in any one cell should not be permitted to go above 100° F.; if this occurs, the charging rate must be reduced or the charge temporarily stopped.

The level of the electrolyte should be kept above the top of the plates by adding pure fresh water. Addition of new electrolyte is seldom necessary and should be done only on advice from the manufacturer.

The sediment which collects in the bottom of the cells should always be removed before it touches the plates.

The battery room should be well ventilated, especially when charging, and great care taken not to bring an exposed flame near the cells when charging or shortly after.

Metals or impurities of any kind must not be allowed to get into the cells. If this should happen, the impurity should be removed at once, and if badly contaminated, the electrolyte replaced with new. If in doubt as to the purity of electrolyte or water, the manufacturers should be consulted.

To take cells out of commission, the electrolyte should be drawn off; the cells filled with water and allowed to stand for 12 or 15 hours. The water can then be drawn off and the plates allowed to dry. When putting into service again, the same procedure should be followed as with the initial charge.

Lead storage batteries are extensively used for the following applications:

Stand-by service in central stations.

Voltage regulation on D. C. distribution lines.

To carry peak loads of central stations.

Voltage regulation in isolated building plants.

To carry load of isolated plant, when the plant is shut down for the night.

To furnish country places with power where such places are off the line of central stations.

To furnish current for talking circuits in telephone service.
To furnish current for signal work.
To light trains in connection with a generator system.
To operate submarine torpedo boats.
For ignition, starting and lighting on gas cars.
To propel electric pleasure and commercial vehicles.
To regulate long distance transmission lines.

For a complete treatise on lead storage batteries see Lyndon, "Storage Battery Engineering."

Edison Alkaline Battery.—The Edison storage battery is considerably lighter, although not as efficient as the lead battery, and for that reason it is extensively used for vehicle service. Its weight varies from 14 to 18 watt-hours per pound.

The active materials of this battery are oxides of nickel and iron in the positive and negative grids respectively, the electrolyte being a solution of caustic potash in water with a small amount of lithium hydrate. The first charging of a cell reduces the iron oxide to metallic iron while converting the nickel hydrate to a very high oxide of nickel, black in color. On discharge, the metallic iron goes back to iron oxide and the high nickel oxide goes to a lower oxide, but not to its original form of green nickel hydrate, and every cycle thereafter during charging the positive changes to a high nickel oxide. Current passing in either direction (charge or discharge) decomposes the potassium hydrate of the electrolyte and the oxidation and the reduction at the electrodes are brought about by the action of its elements. An amount of potassium hydrate equal to that decomposed is always reformed at one of the electrodes by a secondary chemical reaction, and consequently there is none of it lost and its density remains constant. The eventual results of charging, therefore, are a transference of oxygen from the iron to the nickel electrode and that of discharging is a transference back again.

The density of the electrolyte does not change during charge or discharge and consequently hydrometer readings are unnecessary.

To give the best output and efficiency, the manufacturer gives the normal rate of charge as 7 hours and discharge as 5 hours. The rates are, however, optional, and may with certain restrictions be based on the operating conditions. The discharge starts at 1.44 volts per cell, falls rapidly for the first hour, and slowly for 4 1/2 hours. The voltage at the end of 5 hours, the normal discharge period, is 1.11 per cell.

The charge starts at 1.54 volts per cell, rises rapidly for three-quarters of an hour, and then slowly until it becomes practically constant at the end of 7 hours. The voltage is then 1.81 per cell.

ELECTROLYSIS.

Electrolysis is the separation of a chemical compound into its constituents by an electric current. Faraday gave the nomenclature of electrolysis. The compound to be decomposed is the electrolyte, and the process electrolysis. The plates or poles of the battery are electrodes. The plate where the greatest pressure exists is the anode, and the other pole is the cathode. The products of decomposition are ions.

Lord Rayleigh found that a current of one ampere will deposit 0.017253 grain, or 0.001118 gram of silver per second on one of the plates of a silver voltameter, the liquid employed being a solution of silver nitrate containing from 15% to 20% of the salt. The weight of hydrogen similarly set free by a current of one ampere is 0.00001038 gram per second.

Knowing the amount of hydrogen thus set free, and the chemical equivalents of the constituents of other substances, we can calculate what weight of their elements will be set free or deposited in a given time by a given current. Thus, the current that liberates 1 gram of hydrogen will liberate 8 grams of oxygen, or 107.7 grams of silver, the numbers 8 and 107.7 being the chemical equivalents for oxygen and silver respectively.

To find the weight of metal deposited by a given current in a given time, find the weight of hydrogen liberated by the given current in the given time, and multiply by the chemical equivalent of the metal.

The table below (from "Practical Electrical Engineering") is calculated upon Lord Rayleigh's determination of the electro-chemical equivalents and Roscoe's atomic weights.

*Valency is the atom-fixing or atom-replacing power of an element compared with hydrogen, whose valency is unity.

†Atomic weight is the weight of one atom of each element compared with hydrogen, whose atomic weight is unity.

‡Becquerel's extension of Faraday's law showed that the electro-chemical equivalent of an element is proportional to its chemical equivalent. The latter is equal to its combining weight, and not to atomic weight ÷ valency, as defined by Thompson, Hospitalier, and others who have copied their tables. For example, the ferric salt is an exception to Thompson's rule, as are sesqui-salts in general.

Thus: Weight of silver deposited in 10 seconds by a current of 10 amperes = weight of hydrogen liberated per second × number of seconds × current strength $\times 107.7 = 0.00001038 \times 10 \times 10 \times 107.7 = 0.11178$ gram.

Weight of copper deposited in 1 hour by a current of 10 amperes =

$$0.00001038 \times 3600 \times 10 \times 31.5 = 11.77 \text{ grams.}$$

Since 1 ampere per second liberates 0.00001038 gram of hydrogen, strength of current in amperes

$$= \text{weight in grams of H liberated per second} \div 0.00001038$$

$$= \frac{\text{weight of element liberated per second}}{0.00001038 \times \text{chemical equivalent of element}}.$$

THE MAGNETIC CIRCUIT.

For units of the magnetic circuit, see page 1398.

Lines and Loops of Force. — It is conventionally assumed that the attractions and repulsions shown by the action of a magnet or a conductor upon iron filings are due to "lines of force" surrounding the magnet or conductor. The "number of lines" indicates the magnitude of the forces acting. As the iron filings arrange themselves in concentric circles, we may assume that the forces may be represented by closed curves or "loops of force." The following assumptions are made concerning the loops of force in a conductive circuit:

1. That the lines or loops of force in the conductor are parallel to the axis of the conductor.
2. That the loops of force external to the conductor are proportonal in number to the current in the conductor, that is, a definite current generates a definite number of loops of force. These may be stated as the strength of field in proportion to the current.
3. That the radii of the loops of force are at right angles to the axis of the conductor.

The magnetic force proceeding from a point is equal at all points on the surface of an imaginary sphere described by a given radius about that point. A sphere of radius 1 cm. has a surface of 4π square centimeters If ϕ = total flux, expressed as the number of lines of force emanating from a magnetic pole having a strength M,

$$\phi = 4\pi M; \quad M = \phi \div 4\pi.$$

Magnetic moment of a magnet = product of strength of pole M and its length, or distance between its poles L. Magnetic moment $= \phi L \div 4\pi$.

If B = number of lines flowing through each square centimeter of cross-section of a bar-magnet, or the "specific induction," and A = cross-section

$$\text{Magnetic Moment} = LAB \div 4\pi.$$

If the bar-magnet be suspended in a magnetic field of density H and so placed that the lines of the field are all horizontal and at right angles to the axis of the bar, the north pole will be pulled forward, that is, in the direction in which the lines flow, and the south pole will be pulled in the opposite direction, the two forces producing a torsional moment or torque,

$$\text{Torque} = MLH = LABH \div 4\pi, \text{ in dyne-centimeters.}$$

Magnetic attraction or repulsion emanating from a point varies inversely as the square of the distance from that point. The law of inverse squares, however, is not true when the magnetism proceeds from a surface of appreciable extent, and the distances are small, as in dynamo-electric machines and ordinary electromagnets.

The Magnetic Circuit. — In the electric circuit

$$\text{Current} = \frac{\text{E.M.F.}}{\text{Resistance}}, \text{ or } I = \frac{E}{R}; \text{ Amperes} = \frac{\text{volts}}{\text{ohms}}$$

Similarly, in the magnetic circuit

$$\text{Flux} = \frac{\text{Magnetomotive Force}}{\text{Reluctance}}, \text{ or } \phi = \frac{F}{R}. \quad \text{Maxwells} = \frac{\text{Gilberts}}{\text{Oersteds}}.$$

Reluctance is the reciprocal of permeance, and permeance is equal to permeability × path area ÷ path length (metric measure); hence

$$\phi = F\mu a \div l.$$

One ampere-turn produces 1.257 gilberts of magnetomotive force and one inch equals 2.54 centimeters; hence, in inch measure,

$$\phi = (1.257A_t)\,\mu\, 6.45\, a \div 2.54\, l = 3.192\,\mu a A_t \div l.$$

The ampere-turns required to produce a given magnetic flux in a given path will be

$$A_t = \phi l \div 3.192\,\mu a = 0.3133\,\phi l \div \mu a.$$

Since magnetic flux ÷ area of path = magnetic density, the ampere-turn required to produce a density B, in lines of force per square inch of area of path, will be

$$A_t = 0.3133\, Bl \div \mu.$$

This formula is used in practical work, as the magnetic density must be predetermined in order to ascertain the permeability of the material under its working conditions. When a magnetic circuit includes several qualities of material, such as wrought iron, cast iron, and air, it is most direct to work in terms of ampere-turns per unit length of path. The ampere-turns for each material are determined separately, and the winding is designed to produce the sum of all the ampere-turns. The following table gives the average results from a number of tests made by Dr. Samuel Sheldon:

VALUES OF B AND H

H	Ampere-turns per centimeter length.	Ampere-turns per inch length.	Cast Iron.		Cast Steel.		Wrought Iron.		Sheet Metal.

H = 1.257 ampere-turns per cm. ≐ 0.495 ampere-turns per inch.

EXAMPLE.— A magnetic circuit consists of 12 ins. of cast steel of 8 sq. ins. cross-section; 4 ins. of cast iron of 22 sq. ins. cross-section; 3 ins. of sheet iron of 8 sq. ins. cross-section; and two air-gaps each $1/16$ in. long and of 12 sq. ins. area. Required, the ampere-turns to produce a flux of 768,000 maxwells, which is to be uniform throughout the magnetic circuit.

The flux density in the steel is $768{,}000 \div 8 = 96{,}000$ maxwells; the ampere-turns per inch of length, according to Sheldon's table, are 60.6, so that the 12 in. of steel will require 727.2 ampere-turns.

The density in the cast iron is $768{,}000 \div 22 = 34{,}900$; the ampere-turns $= 4 \times 40 = 160$.

The density in the sheet iron $= 768{,}000 \div 8 = 96{,}000$; ampere-turns per inch = 30; total ampere-turns for sheet iron = 90.

The air-gap density is $768{,}000 \div 12 = 64{,}000$; ampere-turns per in. $= 0.3133$B; ampere-turns required for air-gap $= 0.3133 \times 64{,}000 \div 8 = 2506.4$.

The entire circuit will require $727.2 + 160 + 90 + 2506.4 = 3483.6$ ampere-turns, assuming uniform flux throughout.

In practice there is considerable "leakage" of magnetic lines of force; that is, many of the lines stray away from the useful path, there being no material opaque to magnetism and therefore no means of restricting it to a given path. The amount of leakage is proportional to the permeance of the leakage paths available between two points in a magnetic circuit which are at different magnetic potentials, such as opposite ends of a magnet coil. It is seldom practicable to predetermine with any approach to accuracy the magnetic leakage that will occur under given conditions unless one has profuse data obtained experimentally under similar conditions. In dynamo-electric machines the leakage coefficient varies from 1.3 to 2.

Tractive or Lifting Force of a Magnet. — The lifting power or "pull" exerted by an electro-magnet upon an armature in actual contact with its pole-faces is given by the formula

$$\text{Lbs.} = B^2 a \div 72{,}134{,}000,$$

a being the area of contact in square inches and B the magnetic density over this area. If the armature is very close to the pole-faces this formula also applies with sufficient accuracy for all practical puposes, but a considerable air-gap renders it inapplicable.

The design of solenoids for the coil-and-plunger type of electro-magnets is described by C. R. Underhill in his book, "Solenoids, Electro-Magnets, and Electro-Magnetic Windings."

Various forms of magnetic chucks are illustrated and described by O. S. Walker, in *Am. Mach.*, Feb. 11, 1909.

For magnets used in hoisting, see page 1193.

Determining the Polarity of Electro-Magnets.—If a wire is wound around a magnet in a right-handed helix, the end at which the current flows into the helix is the south pole. If a wire is wound around an ordinary wood-screw, and the current flows around the helix in the direction from the head of the screw to the point, the head of the screw is the south pole. If a magnet is held so that the south pole is opposite the eye of the observer, the wire being wound a a right-handed helix around it, the current flows in a right-handed direction, with the hands of a clock.

Determining the Direction of a Current.—Place a wire carrying a current above and parallel to a pivoted magnetic needle. If the current be flowing along the wire from N. to S., it will cause the N.-seeking pole to turn to the eastward; if it be flowing from S. to N., the pole will turn to the westward. If the wire be below the needle, these motions will be reversed.

Maxwell's rule. The direction of the current and that of the resisting magnetic force are related to each other as are the rotation and the forward travel of an ordinary (right-handed) corkscrew.

DYNAMO-ELECTRIC MACHINES.

A dynamo-electric machine is a machine for converting mechanical energy into electrical energy, or *vice versa*. It may be either a direct current or an alternating current machine.

Rating.— The *A. I. E. E. Standardization Rules* (1914) recommend that in the case of Direct Current Generators, the rating shall be expressed in Kilowatts (Kw.) available at the terminals.

In the case of Alternators and Transformers, the rating shall be expressed in kilovolt-amperes (Kv.-a.) available at the terminals, at a specified power factor. The corresponding kilowatts should also preferably be stated.

In the case of Motors, it is recommended that the rating shall be expressed in kilowatts (Kw.) available at the shaft. Since the input of machinery of this class is measured in electrical units and since the output has a definite relation to the input, it is logical to measure the delivered power in the same units as are employed for the receiving power. However, on account of the prevailing practice of expressing mechanical output in horse-power, it is recommended that for machinery of this class the rating should, for the present, be expressed both in kilowatts and in horse-power; as follows:

Kw. ———— approx. equiv. h.p.————

The horse-power rating of a motor may, for practical purposes, be taken as $4/3$ of the kilowatt rating.

There are various kinds of ratings, such as:

Continuous Rating.—A machine rated for continuous service shall be able to operate continuously at its rated output, without exceeding any of the limitations specified.

Short-Time Rating.—A machine rated for short-time service (*i.e.*, service including runs alternating with stoppages of sufficient duration to ensure substantial cooling) shall be able to operate at its rated output during a limited period, to be specified in each case, without exceeding any of the limitations specified.

Nominal Ratings.—For railway motors and railway sub-station machinery, certain nominal ratings are employed.

Duty-Cycle Operation.—Many machines are operated on a cycle of duty which repeats itself with more or less regularity. For purposes of rating, either a continuous or a "short-time" "equivalent load" may be selected which shall simulate as nearly as possible the thermal conditions of the actual duty cycle.

Standard durations of equivalent tests shall be for machines operating under specified duty-cycles: 5 min., 10 min., 30 min., 60 min., 120 min., and continuous. Of these the first 5 are short-time ratings selected as being thermally equivalent to the specified duty cycle. When, for example, a short-time rating of 10 minutes' duration is adopted, and the thermally equivalent load is 25 kw. for that period, then such a machine shall be stated to have a 10-minute rating of 25 kw. In every case the equivalent short-time test shall commence only when the windings and other parts of the machine are within 5° C. of the ambient temperature at the time of starting the test. In the absence of any specification as to the kind of rating, the continuous rating shall be understood.

Temperature Limitations of the Capacity of Electrical Machinery.— The capacity, so far as relates to temperature, is usually limited by the maximum temperature at which the materials in the machine, especially those employed for insulation, may be operated for long periods without deterioration. When the safe limits are exceeded, deterioration is rapid. The insulating material becomes permanently damaged by excessive temperature, the damage increasing with the length of time that the excessive temperature is maintained, and with the amount of excess temperature, until finally the insulation breaks down.

Ambient Temperature of Reference for Air.—The standard ambient temperature of reference, when the cooling medium is air, shall be 40° C. (104° F.).

The permissible rises in temperature given in column 2 of the table on p. 1434 have been calculated on the basis of the standard ambient temperature of reference, by substracting 40° C. from the highest temperatures permissible, which are given in column 1 of the same table.

Altitude.—Increased altitude has the effect of increasing the temperature rise of some types of machinery. In the absence of information in regard to the height above sea level at which the machine is intended to work in ordinary service, this height is assumed not to exceed 1000 meters (3300 feet). For machinery operating at an altitude of 1000 meters or less, a test at any altitude less than 1000 meters is satisfactory, and no correction shall be applied to the observed temperatures. Machines intended for operation at higher altitudes shall be regarded as special. When a machine is intended for service at altitudes above 1000 meters (3300 feet) the permissible temperature rise at sea level, until more nearly accurate information is available, shall be reduced by 1 per cent for each 100 meters (130 ft.) by which the altitude exceeds 1000 meters. Water-cooled oil transformers are exempt from this reduction.

Ambient Temperature of Reference for Water-Cooled Machinery.—For water-cooled machinery, the standard temperature of reference for incoming cooling water shall be 25° C. (77° F.), measured at the intake of the machine.

Corrections for the Deviation of the Ambient Temperature, at the time of test, from the reference value of 40° *C.* — The effect on the temperature rise of the precise value of the ambient temperature at the time of test is small, obscure, and of doubtful direction. No correction shall be made for ambient temperature deviations from the standard value of 40° C. It is desirable, however, that tests should be conducted at ambient temperatures not lower than 25° C. Exception to this rule is made in the case of air-blast transformers, in which, if the ingoing air temperature during the test differs from 40° C., a correction on account of difference in resistance and difference in convection shall be made by changing the "observable" temperature rise of the windings by 0.5 per cent for each degree centigrade. Thus with a room temperature of 30° C. the "observable" rise of temperature shall be increased by 5 per cent, and with a room temperature of 15° C. the "observable" rise of temperature shall be increased by 12.5 per cent.

The actual temperatures attained in the different parts of a machine, and not the rises in temperature, affect the life of the insulation of the machine. The temperatures in the different parts of a machine which it is desired to ascertain, are the maximum temperatures reached in those parts.

As it is usually impossible to determine the maximum temperature attained in insulated windings, it is convenient to apply a correction to the observable temperature, to approximate the difference between the actual maximum temperature and the observable temperature by the method used. This correction or margin of security is provided to cover the errors due to fallibility in the location of the measuring devices, as well as inherent inaccuracies in measurement and methods.

Methods of Determining the Temperature of Different Parts of a Machine.—Three methods will be considered. One or other of these methods will usually be appropriate for commercial measurements on any particular type of machine.

No. 1. *Thermometer Method.*—This method consists in the determination of the temperature by mercury or alcohol thermometers, by resistance thermometers, or by thermo-couples, applied to the hottest accessible part of the completed machine, as distinguished from the thermo-couples or resistance coils imbedded in the machine as described under Method No. 3. When Method No. 1 is used, the hottest-spot temperature for windings shall be estimated by adding a hottest-spot correction of 15° C. to the highest temperature observed, in order to allow for the impossibility of locating any of the thermometers at the hottest spot.

Exception. In cases where the thermometer is applied directly to the surfaces of a bare winding, such as an edgewise strip conductor, or a cast copper winding, a hottest-spot correction of 5° C. instead of 15° C. shall be made. For bare metallic surfaces not forming part of a winding, no correction is to be applied.

No. 2. *Resistance Method.* This method consists in the measurement of the temperature of windings by their increase in resistance, corrected to the instant of shut-down when necessary. In the application of this method thermometer measurements must also be made whenever practicable without disassembling the machine, in order to increase the probability of revealing the highest observable temperature. Whichever method yields the higher temperature, that temperature shall be taken as the "highest observable" temperature and a hottest-spot correction of 10° C. added thereto.

In the case of resistance measurements, the temperature coefficient of copper shall be deduced from the formula $1/(234.5 + t)$. Thus, at an initial temperature $t = 40°$ C., the temperature coefficient or increase in resistance per degree centigrade rise is $1/(274.5) = 0.00364$.

No. 3. *Imbedded Temperature-Detector Method.* Thermo-couples or resistance coils, located as nearly as possible at the estimated hottest spot. This method is only to be used with coils placed in slots.

Temperature Limits.—In the following table column 1 gives the permissible limits for the hottest-spot temperatures of insulations, and column 2 the highest permissible temperature rise of the hottest spot above 40° C. permitted under rated-load conditions, for the purpose of fixing the Institute rating. The rise of temperature observed must never exceed the limits in column 2 of the table. The highest temperatures attained in any machine corresponding to the output for which it is rated must not exceed the values indicated in column 1 of the table and the clauses following:

Hottest-Spot Temperatures and Corresponding Permissible Temperature Rises.

Class.	Insulation.	Col. 1.	Col. 2.
A 1	Cotton, silk, paper, and other fibrous materials, not so treated as to increase the thermal limit..........	95° C.	55° C.
A 2	Similar to A 1, but treated or impregnated and including enameled wire........................	105° C.	65° C.
B	Mica, asbestos, or other material capable of resisting high temperatures, in which any Class A material or binder, if used, is for structural purposes only, and may be destroyed without impairing the insulating or mechanical qualities..................	125° C.	85° C.
C	Fireproof and refractory materials................	No limit specified.	

Summary of the Temperature Conditions under the Three Methods of Measurement for Insulations of Classes A_1, A_2, and B.

Class.	Hottest Spot Temp.	Thermometer only.		Resistance.*		Imbedded Thermo-couples or Resistance Coils.						
						Double-layer Windings. All voltages.		Single-layer Windings. 5000 volts or less.		Single-layer Windings above 5000 volts.		
		a	b	a	b	a	b	a	b	Hottest Spot Correction.	Limiting Observable Temperat'r	Limiting Observable Temp. Rise above 40°.
A_1	95°	15	80	10	85	5	90	10	85	10+(E-5)†	85 − (E-5)	45 − (E-5)
A_2	105°	15	90	10	95	5	100	10	95	10+(E-5)	95 − (E-5)	55 − (E-5)
B	125°	15	110	10	115	5	120	10	115	10+(E-5)	115 − (E-5)	75 − (E-5)

* With thermometer check when practicable.

a Hottest-spot correction. *b* Limiting observable temperature. The limit of the observable temperature rise above 40° always = (b −40°).

† In this formula E represents the rated pressure between terminals in kilovolts. Thus for a three-phase machine with single-layer winding of 11 kilovolts between terminals, the hottest spot correction to be added to the maximum observable temperature will be 16° C.

Special Cases of Temperature Limits. — *Temperature of Oil.* The oil in which apparatus is immersed shall in no part have an observable temperature in excess of 90° C.

Water-cooled Transformers. The hottest-spot temperature shall not exceed 85° C.

Commutators. The observable temperature shall in no case be permitted to exceed the values given in the table for the insulation employed, either in the commutator or in any insulation whose temperature would be affected by the heat of the commutator.

For commutators so constructed that no difficulties from expansion can occur, the following temperature limits are suggested:

Current per Brush Arm.	Maximum Permissible Temp.
200 amperes or less.	130° C.
200 to 900 amperes.	130° C. less 5 deg. for each 100 amperes increase above 200.
900 amperes and over.	95° C.

Moving Force of a Dynamo-electric Machine. — A wire through which a current passes has, when placed in a magnetic field, a tendency to move perpendicular to itself and at right angles to the lines of the field. The force producing this tendency is $P = lBI$ dynes, in which l = length of the wire, I = the current in C.G.S. units, and B = the induction, or flux density, in the field in gausses or lines per square centimeter.

If the current I is taken in amperes, $P = lBI \div 10 = lBI \times 10^{-1}$.

If P_k is taken in kilograms,

$$P_k = lBI \div 9{,}810{,}000 = 10.1937\ lBI \times 10^{-8} \text{ kilograms.}$$

Example.—The mean strength of field, B, of a dynamo is 5000 C.G.S. lines; a current of 100 amperes flows through a wire; the force acts upon 10 centimeters of the wire = $10.1937 \times 10 \times 100 \times 5000 \times 10^{-8} = 0.5097$ kilograms.

Torque of an Armature. — The torque of an armature is the moment tending to turn it. In a generator it is the moment which must be applied to the armature to turn it in order to produce current. In a motor it is the turning moment which the armature gives to the pulley.

Let I = current in the armature in amperes, E = the electromotive force in volts, T = the torque in pound-feet, ϕ = the flux through the armature in maxwells, N = the number of conductors around the armature, and n = the number of revolutions per second. Then

$$\text{Watts} = IE = 2\pi nT \times 1.356.*$$

In any machine if the flux be constant, E is directly proportional to the speed and $= \phi Nn \div 10^8$; whence

$$\phi NI \div 10^8 = 2\pi T \times 1.356;$$

$$T = \frac{\phi NI}{10^8 \times 2\pi \times 1.356} = \frac{\phi NI}{8.52 \times 10^8} \text{ pound-feet.}$$

Let l = length of armature in inches, d = diameter of armature in inches, B = flux density in maxwells per square inch, and let m = the ratio of the conductors under the influence of the pole-pieces to the whole number of conductors on the armature. Then

$$\phi = \tfrac{1}{2}\pi d \times l \times B \times m.$$

These formulæ apply to both generators and motors. They show that torque is independent of the speed and varies directly with the current and the flux. The total peripheral force is obtained by dividing the torque by the radius (in feet) of the armature, and the drag on each conductor is obtained by dividing the total peripheral force by the number of conductors under the influence of the pole-pieces at one time.

Example.—Given an armature of length l = 20 inches, diameter d = 12 inches, number of conductors N = 120, of which 80 are under the influence of the pole-pieces at one time; let the flux density B = 30,000 maxwells per sq. in. and the current I = 400 amperes.

$$\phi = \frac{12\pi}{2} \times 20 \times 30{,}000 \times \frac{80}{120} = 7{,}540{,}000.$$

$$T = \frac{7{,}540{,}000 \times 120 \times 400}{8.52 \times 100{,}000{,}000} = 424.8 \text{ pound-feet.}$$

Total peripheral force = 424.8 ÷ 0.5 = 849.6 lbs.
Drag per conductor = 849.6 ÷ 120 = 7.08 lbs.
The work done in one revolution = torque × circumference of a circle of 1 foot radius = 424.8 × 6.28 = 2670 foot-pounds.
Let the revolutions per minute equal 500, then the horse-power

$$= \frac{2670 \times 500}{33000} = 40.5 \text{ H.P.}$$

Torque, Horse-power and Revolutions. — T = torque in pound-feet, H.P. = T × Rpm. × 6.2832 ÷ 33,000 = IE ÷ 745.7. Whence Torque = 7.0432 EI ÷ Rpm. or 7 times the watts ÷ the revs. per min. nearly.

Electromotive Force of the Armature Circuit. — From the horse-power, calculated as above, together with the amperes, we can obtain the E.M.F., IE = H.P. × 745.7, whence E M F. or E = H.P. × 745.7 ÷ I.

If H.P., as above, = 40.5, and I = 400, $E = \dfrac{40.5 \times 745.7}{400} = 75.5$ volts.

The E.M.F. may also be calculated by the following formulæ:

I = Total current through armature;
e_a = E.M.F. in armature in volts;
N = Number of active conductors counted all around armature;
p = Number of pairs of poles (p = 1 in a two-pole machine);
n = Speed in revolutions per minute;
ϕ = Total flux in maxwells.

Electromotive force:
$$\begin{cases} e_a = \phi N \dfrac{n}{60} 10^{-8} & \text{for two-pole machines.} \\ e_a = \dfrac{p\phi N}{10^8}\,\dfrac{n}{60} & \text{for multipolar machines with series-wound armature} \end{cases}$$

Strength of the Magnetic Field. — Let I = current in amperes. N = number of turns in the coil. A = area of the cross-section of the core in

* 1 ft.-lb. per second = 1.356 watts.

square centimeters, $l =$ length of core in centimeters, μ the permeability of the core, and $\phi =$ flux in maxwells. Then

$$\phi = \frac{\text{Magnetomotive Force}}{\text{Reluctance}} = \frac{1.257\,NI}{(l \div A\mu)}.$$

In a dynamo-electric machine the reluctance will be made up of three separate quantities, viz.: that of the field magnet cores, that of the air spaces between the field magnet pole-pieces and the armature, and that of the armature. The total reluctance is the sum of the three. Let L_1, L_2, L_2 be the length of the path of magnetic lines in the field magnet cores,* in the air-gaps, and in the armature respectively; and let A_1, A_2, A_3 be the areas of the cross-sections perpendicular to the path of the magnetic lines in the field magnet cores, the air-gaps, and the armature respectively. Let the permeability of the field magnet cores be μ_1, and of the armature μ_3. The permeability of the air-gaps is taken as unity. Then the total reluctance of the machine will be

$$\frac{L_1}{A_1\mu_1} + \frac{L_2}{A_2} + \frac{L_3}{A_3\mu_3}.$$

$$\text{The flux}, \phi = \frac{1.257\,NI}{(L_1 \div A_1\mu_1) + (L_2 \div A_2) + (L_3 \div A_3\mu_3)}.$$

The ampere-turns necessary to create a given flux in a machine may be found by the formula,

$$NI = \phi\,\frac{[(L_1 \div A_1\mu_1) + (L_2 \div A_2) + (L_3 \div A_3\mu_3)]}{1.257}.$$

But the total flux generated by the field coils is not available to produce current in the armature. There is a leakage between the field magnets, and this must be allowed for in calculations. The leakage coefficient varies from 1.3 to 2 in different machines. The meaning of the coefficient is that if a flux of say 100 maxwells per square cm. are desired in the field coils, it will be necessary to provide ampere turns for $1.3 \times 100 = 130$ maxwells, if the leakage coefficient be 1.3.

Another method of calculating the ampere-turns necessary to produce a given flux is to calculate the magnetomotive force required in each portion of the machine, separately, introducing the leakage coefficient in the calculation for the field magnets, and dividing the sum of the magnetomotive forces by 1.257.

In the ordinary type of multipolar machine there are as many magnetic circuits as there are poles. Each winding energizes part of two circuits. The calculation is made in the same manner as for a single magnetic circuit.

DIRECT-CURRENT GENERATORS.

Direct-current generators may be separately excited, in which case the field magnets are excited or magnetized from some external source, as, for instance, a storage battery or another continuous-current dynamo. Such generators are used to some extent in connection with regulating sets, but as a rule almost all direct-current generators are self-excited, in which case the magnetizing current for the field-coils is furnished by the dynamo itself.

Direct-current generators (as well as motors) may be classified according to the manner of the field-winding into:

1. *Series-wound Dynamo.*—The field-winding and the external circuit are connected in series with the armature-winding, so that the entire armature current must pass through the field-coils.

Since in a series-wound dynamo the armature-coils, the field, and the external circuit are in series, any increase in the resistance of the external circuit will decrease the electro-motive force from the decrease in the magnetizing currents. A decrease in the resistance of the external cir-

---

* The length of the path in the field-magnet cores L_1 includes that portion of the path which lies in the piece joining the cores of the various field-magnets.

cuit will, in a like manner, increase the electro-motive force from the increase in the magnetizing current. The use of a regulator avoids these changes in the electro-motive force.

2. *Shunt-wound Dynamo.*—The field-magnet coils are placed in a shunt to the armature circuit, so that only a portion of the current generated passes through the field-magnet coils, but all the difference of potential of the armature acts at the terminals of the field-circuit.

In a shunt-wound dynamo an increase in the resistance of the external circuit increases the electro-motive force, and a decrease in the resistance of the external circuit decreases the electro-motive force. This is just the reverse of the series-wound dynamo.

In a shunt-wound dynamo a continuous balancing of the current occurs, the current dividing at the brushes between the field and the external circuit in the inverse proportion to the resistance of these circuits. If the resistance of the external circuit becomes greater, a proportionately greater current passes through the field magnets, and so causes the electro-motive force to become greater. If, on the contrary, the resistance of the external circuit decreases, less current passes through the field, and the electro-motive force is proportionately decreased.

3. *Compound-wound Dynamo.* — The field magnets are wound with two separate sets of coils, one of which is in series with the armature and the external circuit, and the other in shunt with the armature or the external circuit.

A compound generator is made for the purpose of delivering current at constant potential either at the terminals of the machine or at some distant receiving point on the line. In the former case the machine is flat-compounded, the ideal being the same terminal voltage at full load as at no load, giving a practically horizontal voltage characteristic. In the latter case the machine is over-compounded, giving a terminal voltage which rises from no load to full load to compensate for line drop, so that at the receiving end of the line the voltage will be constant at all loads.

The standard voltages for ordinary light and power service are 125 and 250 volts, while for railway service they have been built for voltages as high as 1200, and in one particular installation two such machines are connected in series furnishing a supply voltage of 2400 volts.

Many direct-current generators are provided with commutating poles, and such machines may be operated over an extremely wide range of load and voltage with fixed brush positions and sparkless commutation. The commutating winding produces a magnetic field which is in a direction to assist the reversal of current in the coil undergoing commutation and also directly opposed to the field generated by armature reaction which tends to retard the reversal of current in this coil. The commutating field thus completely nullifies the distortive effect of armature reaction on the main field flux in the commutating zone, and generates an e.m.f. which helps the brush to commutate the current without sparking, and with a consequent increased life of the commutator and brushes.

Commutating poles are placed between the main poles of direct-current generators and motors. They are used for the purpose of nullifying the effect of the armature reaction upon the magnetic field adjacent to the neutral point. The armature reaction tends to move the neutral point from its proper mechanical position, and it is obvious that a number of ampere turns setting up magnetic lines of force equal to and opposing the directions of those set up by the armature ampere turns will nullify that effect on the neutral occasioned by the armature reaction.

The commutating pole winding is connected in series with the armature and has a number of turns per pole sufficient to give a magnetic strength that will not only counteract the armature reaction above referred to, but will actually reverse the current in the coil when it is in the commutating zone.

The commutating zone is the region over which the brushes may have to be moved in order to obtain good commutation between no load and full load. With commutating pole machines no such movement is necessary and the reversal takes place in the coils short circuited under the brushes.

Inasmuch as the commutating windings are directly in series with the armature, their strength varies directly with the armature current and provides the correct rectifying effect for proper reversal of current in the coils at all loads. Hence it is unnecessary to shift the brushes as the load changes.

Parallel Operation.—The first requisite for satisfactory parallel operation of direct current generators is that they have the same characteristics. They must have the same degree of compounding for any percentage of their rated load. The resistance of series fields with their shunt resistances and cable connections to the bus-bar should furthermore be inversely proportional to the capacities of the machines; *i.e.*, no matter what size cables are used, the resistances of the two connections must be so proportioned that the drop will be the same for both machines between the equalizer junction and the main bus-bar when each machine is delivering its full-load current.

Three-Wire System.—The chief advantage of the Edison three-wire system over the ordinary two-wire installation is that of economy in distribution. In a two-wire system with a given load and a given percentage of voltage drop, the distribution at 250 volts requires only one-quarter the weight of copper required for a distribution at 125 volts. A neutral wire in the three-wire system will, however, modify this proportion of copper, the final saving depending on the size of the neutral. In well-designed systems, the maximum unbalanced current carried by the neutral will be about 25 per cent of the full load. Therefore the size of the neutral need not be larger than 25 per cent of the capacity of the outside mains, and the weight of the copper in this case would be $9/32$ of that used in distributing the same power by a two-wire system.

The practical methods available for operating direct-current three-wire systems are: 1. Two generators. 2. One generator with balancer set. 3. One generator with storage battery. 4. One generator with balancing coil. 5. Three-wire generator.

ALTERNATING CURRENTS.*

The advantages of alternating over direct currents are: 1. Greater simplicity of dynamos and motors, no commutators being required; 2. The feasibility of obtaining high voltages, by means of static transformers, for cheapening the cost of transmission; 3. The facility of transforming from one voltage to another, either higher or lower, for different purposes.

A direct current is uniform in strength and direction, while an alternating current rapidly rises from zero to a maximum, falls to zero, reverses its direction, attains a maximum in the new direction, and again returns to zero. This series of changes can best be represented by a curve the abscissas of which represent time and the ordinates either current or electro-motive force (e.m.f.). The curve usually chosen for this purpose is the sine curve, Fig. 228; the best forms of alternators give a curve that is a very close approximation to the sine curve, and all calculations and deductions of formulæ are based on it. The equation of the sine curve is $y = \sin x$, in which y is any ordinate, and x is the angle passed over by a moving radius vector.

After the flow of a direct current has been once established, the only opposition to the flow is the resistance offered by the conductor to the passage of current through it. This resistance of the conductor, in treating of alternating currents, is sometimes spoken of as *ohmic resistance*. The word resistance, used alone, always means the ohmic resistance. In alternating currents, in addition to the resistance, sev-

---

* Only a very brief treatment of the subject of alternating currents can be given in this book. The following works are recommended as valuable for reference: Steinmetz, "Theoretical Elements of Electrical Engineering. Alternating Current Phenomena"; Cohen, "Formulæ and Tables for the Calculation of Alternating Current Problems"; Jackson, "Alternating Currents and Alternating Current Machinery"; Bedell, "Direct and Alternating Current Manual": Timbie, "Alternating Currents."

eral other quantities, which affect the flow of current, must be taken into consideration. These quantities are inductance, capacity, and skin effect. They are discussed under separate headings.

The current and the e.m.f. may be in phase with each other, that is, they may attain their maximum strength at the same instant, or they may not, depending on the character of the circuit. In a circuit containing only resistance, the current and e.m.f. are in phase; in a current containing inductance the e.m.f. attains its maximum value before the current, or leads the current. In a circuit containing capacity the current leads the e.m.f. If both capacity and inductance are present in a circuit, they will tend to neutralize each other.

Maximum, Average, and Effective Values.—The strength and the e.m.f. of an alternating current being constantly varied, the maximum value of either is attained only for an instant in each period. The maximum values are little used in calculations, except in deducing formulæ and for proportioning insulation, which must stand the maximum pressure. The average value is obtained by averaging the ordinates of the sine curve representing the current, and is $2 \div \pi$ or 0.637 of the maximum value.

The value of greatest importance is the effective, or "square root of the mean square," value. It is obtained by taking the square root of the mean of the squares of the ordinates of the sine curve. The effective value is the value shown on alternating-current measuring instruments. The product of the square of the effective value of the current and the resistance of the circuit is the heat lost in the circuit.

The relation of the maximum, average, and effective values is:

$$E_{\text{Effec.}} = E_{\text{Max.}} \times 0.707; \quad E_{\text{Aver.}} = E_{\text{Max.}} \times 0.637; \quad E_{\text{Max.}} = 1.41 \times E_{\text{Effec.}}$$

Frequency.—The time required for an alternating current to pass through one complete cycle, as from one maximum point to the next (*a* and *b*, Fig. 228), is termed the period. The number of periods in a second is termed the frequency of the current. Since the current changes its direction twice in each period, the number of reversals or alternations is double the frequency. A current of 120 alternations per second has a period of $1/60$ and a frequency of 60. The frequency of a current is equal to one-half the number of poles on the generator, multiplied by the number of revolutions per second. Frequency is denoted by the letter *f*.

The frequencies most generally used in the United States are 25, 40, 60, 125, and 133 cycles per second. The Standardization Report of the A I.E.E. recommends the adoption of three frequencies, viz. 25, 60 and 120.

With the higher frequencies both transformers and conductors will be less costly in a circuit of a given resistance but the capacity and inductance effects in each will be increased, and these tend to increase the cost. With high frequencies it also becomes difficult to operate alternators in parallel.

A low frequency current cannot be used on lighting circuits, as the lights will flicker when the frequency drops below a certain figure. For arc lights the frequency should not be less than 40. For incandescent lamps it should not be less than 25. If the circuit is to supply both power and light a frequency of 60 is usually desirable. For power transmission to long distances a low frequency, say 25, is considered desirable, in order to lessen the capacity effects. If the alternating current is to be converted into direct current for lighting purposes a low frequency may be used, as the frequency will then have no effect on the lights.

Inductance.—Inductance is that property of an electrical circuit by which it resists a change in the current. A current flowing through a conductor produces a magnetic flux around the conductor. If the current be changed in strength or direction, the flux is also changed, producing in the conductor an e.m.f. whose direction is opposed to that of the current in the conductor. This counter e.m.f. is the *counter e.m.f. of inductance*. It is proportional to the rate of change of current, provided that the permeability of the medium around the conductor remains constant. The unit of

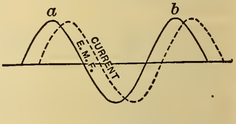

FIG. 228.

inductance is the *henry*, symbol L. A circuit has an inductance of one henry if a uniform variation of current at the rate of one ampere per second produces a counter e.m.f. of one volt.

The effect of inductance on the circuit is to cause the current to lag behind the e.m.f. as shown in Fig. 228, in which abscissas represents time, and ordinates represent e.m.f. and current strengths respectively.

Capacity.—Any insulated conductor has the power of holding a quantity of static electricity. This power is termed the *capacity* of the body. The capacity of a circuit is measured by the quantity of electricity in it when at unit potential. It may be increased by means of a condenser. A condenser consists of two parallel conductors, insulated from each other by a non-conductor. The conductors are usually in sheet form.

The unit of capacity is a *farad*, symbol C. A condenser has a capacity of one farad when one coulomb of electricity contained in it produces a difference of potential of one volt, or when a rate of change of pressure of one volt per second produces a current of one ampere. The farad is too large a unit to be conveniently used in practice, and the micro-farad or one-millionth of a farad is used instead. The effect of capacity on a circuit is to cause the e.m.f. to lag behind the current. Both inductance and capacity may be measured with a Wheatstone bridge by substituting for a standard resistance a standard of inductance or a standard of capacity.

Power Factor.—In direct-current work the power, measured in watts, is the product of the volts and amperes in the circuit. In alternating-current work this is only true when the current and e.m.f. are in phase. If the current either lags or leads, the values shown on the volt and ammeters will not be true simultaneous values. Referring to Fig. 228, it will be seen that the product of the ordinates of current and e.m.f. at any particular instant will not be equal to the product of the effective values which are shown on the instruments. The power in the circuit at any instant is the product of the simultaneous values of current and e.m.f., and the volts and amperes shown on the recording instruments must be multiplied together and their product multiplied by a power factor before the true watts are obtained. This power factor, which is the ratio of the volt-amperes to the watts, is also the cosine of the angle of lag or lead of the current. Thus

$$P = I \times E \times \textit{power factor} = I \times E \times \cos \theta,$$

where θ is the angle of lag or lead of the current.

A watt-meter, however, gives the true power in a circuit directly. The method of obtaining the angle of lag is shown on p. 1442.

Reactance, Impedance, Admittance.—In addition to the ohmic resistance of a circuit there are also resistances due to inductance, capacity, and skin effect. The virtual resistance due to inductance and capacity is termed the reactance of the circuit. If inductance only be present in circuit, the reactance will vary directly as the inductance. If capacity only be present, the reactance will vary inversely as the capacity.

$$\text{Inductive reactance} = 2\pi f L; \quad \text{Condensive reactance} = \frac{1}{2\pi f C}.$$

The total apparent resistance of the circuit, due to both the ohmic resistance and the total reactance, is termed the impedance, and is equal to the square root of the sum of the squares of the resistance and the reactance.

$$\text{Impedance} = Z = \sqrt{R^2 + (2\pi f L)^2} \text{ when inductance is present in the circuit.}$$

$$\text{Impedance} = Z = \sqrt{R^2 + \left(\frac{1}{2\pi f C}\right)^2} \text{ when capacity is present in the circuit.}$$

Admittance is the reciprocal of impedance, $= 1 \div Z$.

If both inductance and capacity are present in the circuit, the reactance of one tends to balance that of the other; the total reactance is the algebraic sum of the two reactances; thus,

$$\text{Total reactance} = X = 2\pi f L - \frac{1}{2\pi f C}; \quad Z = \sqrt{R^2 + \left(2\pi f L - \frac{1}{2\pi f C}\right)^2}.$$

In all cases the tangent of the angle of lag or lead is the reactance divided by the resistance. In the last case

$$\tan \theta = \frac{2\pi f L - \frac{1}{2\pi f C}}{R}.$$

Skin Effect.—Alternating currents tend to have a greater density at the surface than at the axis of a conductor. The effect of this is to make the virtual resistance of a wire greater than its true ohmic resistance. With low frequencies and small wires the skin effect is small, but it becomes quite important with high frequencies and large wires. With magnetic material it is much higher than with non-magnetic.

The skin effect factor, by which the ohmic resistance is to be multiplied to obtain the virtual resistance is given by Berg in the following approximate formula:

$$C_S = \frac{1 + \sqrt{1 + \left(\frac{k}{\delta}\right)^2}}{2}$$

For Copper Cable: $\left(\frac{k}{\delta}\right) = 0.0105\, d^2 f$; for Aluminum Cable: $\left(\frac{k}{\delta}\right) = 0.0063\, d^2 f$, where d = diameter of cable, and f = frequency.

For the same per cent increase, due to skin effect, a cable can have 13% larger diameter than a solid wire; in other words, the skin effect is the same as long as the ohmic resistance is the same, whether a solid wire or a cable is used.

Ohm's Law applied to Alternating-Current Circuits.—To apply Ohm's law to alternating-current circuits a slight change is necessary in the expression of the law. Impedance is substituted for resistance. The law should read

$$I = \frac{E}{\sqrt{R^2 + X^2}} = \frac{E}{Z}.$$

Impedance Polygons.—1. *Series Circuits.*—The impedance of a circuit can be determined graphically as follows: Suppose a circuit to contain a resistance R and an inductance L, and to carry a current I of frequency f. In Fig. 229 draw the line ab proportional to R, and representing the direction of current. At b erect bc perpendicular to ab and proportional to $2\,\pi f L$. Join a and c. The line ac represents the impedance of the circuit. The angle θ between ab and ac is the angle of lag of the current behind the e.m.f., and the power factor of the circuit is cosine θ. The e.m.f. of the circuit is $E = IZ$.

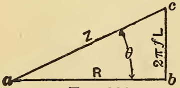

FIG. 229.

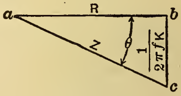

FIG. 230.

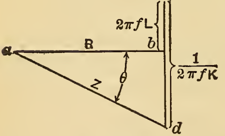

FIG. 231.

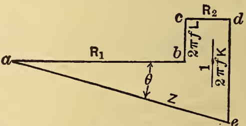

FIG. 232.

If the above circuit contained, instead of the inductance L, a capacity C, then would the polygon be drawn as in Fig. 230. The line bc would be proportional to $\frac{1}{2\,\pi f C}$ and would be drawn in a direction opposite to that of bc in Fig. 229. The impedance would again be Z, the e.m.f. would be $Z \times I$, but the current would lead the e.m.f. by the angle θ.

Suppose the circuit to contain resistance, inductance, and capacity, the lines of the impedance polygon would then be laid off as in Fig. 231. The impedance of the circuit would be represented by ad, and the angle of lag by θ. If the capacity of the circuit had been such that cd was less than bc, then would the e.m.f. have led the current.

If between the inductance and capacity in the circuit in the previous examples there be interposed another resistance, the impedance polygon will take the form of Fig. 232. The lines representing either resistances, inductances, or capacities in the circuit follow each other in all cases as do the resistances, inductances, and capacities in the circuit, each line having its appropriate direction and magnitude.

EXAMPLE.—A circuit (Fig. 233) contains a resistance, R_1, of 15 ohms, a capacity, C_1, of 100 microfarads (0.000100 farad), a resistance, R_2, of 12

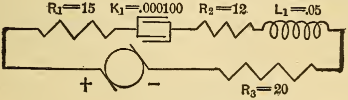

FIG. 233.

ohms. and inductance of L_1, of 0.05 henry, and a resistance R_3, of 20 ohms. Find the impedance and electromotive force when a current of 2 amperes is sent through the circuit, and the current when e.m.f. of 120 volts is impressed on the circuit, frequency being taken as 60. Also find the angle of lag, the power factor, and the power in the circuit when 120 volts are impressed.

The resistance is represented in Fig. 234 by the horizontal line ab, 15 units long. The capacity is represented by the line bc, drawn downwards from b and whose length is

$$\frac{1}{2\pi f C_1} = \frac{1}{2 \times 3.1416 \times 60 \times 0.0001} = 26.55.$$

From the point c a horizontal line cd, 12 units long, is drawn to represent R_2. From the point d the line de is drawn vertically upwards to represent the inductance L_1. Its length is

$$2\pi f L_1 = 2 \times 3.1416 \times 60 \times 0.05 = 18.85.$$

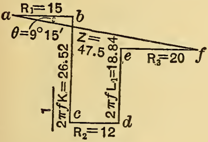

FIG. 234.

From the point e a horizontal line ef, 20 units long, is drawn to represent R_3. The line adjoining a and f will represent the impedance of the circuit in ohms. The angle θ, between ab and af, is the angle of lag of the e.m.f. behind the current. The impedance in this case is 47.5 ohms, and the angle of lag is 9° 15′.

The e.m.f. when a current of 2 amperes is sent through is

$$IZ = E = 2 \times 47.5 = 95 \text{ volts}.$$

If an e.m.f. of 120 volts be impressed on the circuit, the current flowing through will be

$$I = \frac{120}{Z} = \frac{120}{47.5} = 2.53 \text{ amperes}.$$

The power factor $= \cos\theta = \cos 9° \, 15' = 0.987$.

The power in the circuit at 120 volts is

$$I \times E \times \cos\theta = 2.53 \times 120 \times 0.987 = 299.6 \text{ watts}.$$

2. *Parallel Circuits.*—If two circuits be arranged in parallel, the current flowing in each circuit will be inversely proportional to the impedance of that circuit. The e.m.f. of each circuit is the e.m.f. across the terminals at either end of the main circuit, where the various branches separate. Consider a circuit, Fig. 235, consisting of two branches. The first branch contains a resistance R, and an inductance L_1 in series with it. The second

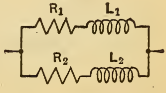

FIG. 235.

branch contains a resistance R_2 in series with an inductance L_2. The impedance of the circuit may be determined by treating each of the two branches as a separate series circuit, and drawing the impedance polygon for each branch on that assumption. Having found the impedance the current flowing in either branch will be the reciprocal of the impedance multiplied by the e.m.f. across the terminals. The current in the entire circuit is the geometrical sum of the current in the two branches.

The admittance of the equivalent simple circuit may be obtained by drawing a parallelogram, two of whose adjoining sides are made parallel to the impedance lines of each branch and equal to the two admittances respectively.

The diagonal of the parallelogram will represent the admittance of the equivalent simple circuit. The admittance multiplied by the e.m.f. gives the total current in the circuit.

EXAMPLE.—Given the circuit in Fig. 236, consisting of two branches. Branch 1 consists of a resistance $R_1 = 12$ ohms, an inductance $L_1 = 0.05$ henry, a resistance $R_2 = 4$ ohms, and a capacity $C_1 = 120$ microfarads (0.00012 farad). Branch 2 consists of an inductance $L_2 = 0.015$ henry, a resistance $R_3 = 10$ ohms, and an inductance $L_3 = 0.03$ henry. An e.m.f. of 100 volts is impressed on the circuit at a frequency of 60. Find the admittance of the entire circuit, the current, the power factor, and the power

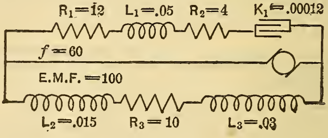

FIG. 236.

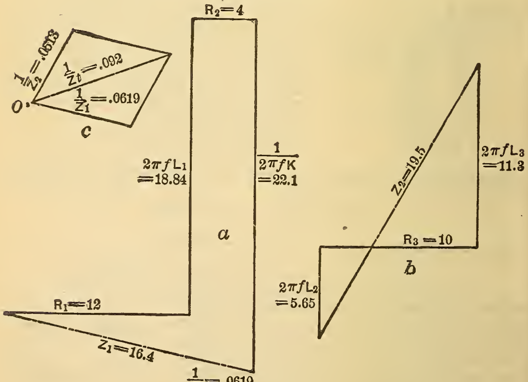

FIG. 237.

in the circuit. Construct the impedance polygons for the two branches separately as shown in Fig. 237, a and b. The impedance in branch 1 is 16.4 ohms, and the current is $(1/16.4) \times 100 = 6.19$ amperes. The angle of lead of the current is 1° 45′. The impedance in branch 2 is 19.5 ohms and the current is $(1/19.5) \times 100 = 5.13$ amperes. The angle of lag of the current is 61°.

The current in the entire circuit is found by taking the admittances of the two branches, and drawing them from the point o, in Fig. 237 c, parallel to the impedance lines in their respective polygons. The diagonal from o is the admittance of the entire circuit,and in this case is equal to 0.092. The current in the circuit is $0.092 \times 100 = 9.2$ amperes. The power factor is 0.944 and the power in the circuit is $100 \times 0.944 \times 9.2 = 868.48$ watts.

Self-Inductance of Lines and Circuits. — The following formulæ and table, taken from Crocker's "Electric Lighting," give a method of calculating the self-inductance of two parallel aerial wires forming part of the same circuit and composed of copper, or other non-magnetic material:

$$L \text{ per foot } = \left(15.24 + 140.3 \log \frac{2A}{d}\right) 10^{-9}.$$

$$L \text{ per mile } = \left(80.5 + 740 \log \frac{2A}{d}\right) 10^{-6}.$$

in which L is the inductance in henrys of each wire, A is the interaxial distance between the two wires, and d is the diameter of each, both in inches. If the circuit is of iron wire, the formulæ become

$$L \text{ per foot } = \left(2286 + 140.3 \log \frac{2A}{d}\right) 10^{-9}.$$

$$L \text{ per mile } = \left(12070 + 740 \log \frac{2A}{d}\right) 10^{-6}.$$

INDUCTANCE, IN MILLIHENRYS PER MILE, FOR EACH OF TWO PARALLEL COPPER WIRES.

Interaxial Distance, Ins.	American Wire Gauge Number.											
	0000	000	00	0	1	2	3	4	6	8	10	12
6	1.130	1.168	1.205	1.242	1.280	1.317	1.354	1.392	1.466	1.540	1.615	1.690
12	1.353	1.391	1.428	1.465	1.502	1.540	1.577	1.614	1.689	1.764	1.838	1.913
24	1.576	1.614	1.651	1.688	1.725	1.764	1.800	1.838	1.912	1.986	2.061	2.135
36	1.707	1.745	1.784	1.818	1.856	1.893	1.931	1.968	2.043	2.117	2.192	2.266
60	1.871	1.909	1.946	1.982	2.023	2.058	2.095	2.132	2.208	2.282	2.356	2.432
96	2.023	2.059	2.097	2.134	2.172	2.210	2.246	2.283	2.358	2.433	2.507	2.582

Capacity of Conductors. — All conductors are included in three classes, viz.: 1. Insulated conductors with metallic protection; 2. Single aerial conductor with earth return; 3. Metallic circuit consisting of two parallel aerial wires. The capacity of the lines may be calculated by means of the following formulæ taken from Crocker's "Electric Lighting."

Class 1. $C \text{ per foot } = \dfrac{7361\,k\,10^{-15}}{\log (D \div d)}$, $C \text{ per mile} = \dfrac{38.83\,k\,10^{-9}}{\log (D \div d)}$.

Class 2. $C \text{ per foot } = \dfrac{7361 \times 10^{-15}}{\log (4h \div d)}$, $C \text{ per mile} = \dfrac{38.83 \times 10^{-9}}{\log (4h \div d)}$

$$\text{Class 3.} \begin{cases} C \text{ per foot of each wire} = \dfrac{3681 \times 10^{-15}}{\log (2A \div d)}, \\ C \text{ per mile of each wire} = \dfrac{19.42 \times 10^{-9}}{\log (2A \div d)}. \end{cases}$$

In which C is the capacity in farads, D the internal diameter of the metallic covering, d the diameter of the conductor, h the height of the conductor above the ground, and A the interaxial distance between two parallel wires all in inches; k is a dielectric constant which for air is equal to 1 and for pure rubber is equal to 2.5. The formulæ in classes 2 and 3 assume the wires to be bare. If they are insulated, k must be introduced in the numerator and given a value slightly greater than 1.

Single-phase and Polyphase Currents. — A single-phase current is a simple alternating current carried on a single pair of wires and is generated on a machine having a single armature winding. It is represented by a single sine curve.

Polyphase currents are known as two-phase, three-phase, six-phase, or any other number, and are represented by a corresponding number of sine curves. The most commonly used systems are the two-phase and three-phase.

1. *Two-phase Currents.*—In a two-phase system there are two single-phase alternating currents bearing a definite time relation to each other and represented by two sine curves (Fig. 238). The two separate currents may be generated by the same or by separate machines. If by separate machines, the armatures of the two should be positively coupled together. Two-phase currents are usually generated by a machine with two armature windings, each winding terminating in two collector rings. The two windings are so related that the two currents will be 90° apart. For this reason two phase-currents are also called "quarter-phase" currents.

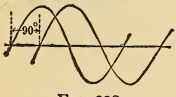

FIG. 238.

Two-phase currents may be distributed on either three or four wires. The three-wire system of distribution is shown in Fig. 239. One of the return wires is dispensed with, connection being made across to the other as shown. The common return wire should be made 1.41 times the area of either of the other two wires, these two being equal in size.

The four-wire system of distribution is shown in Fig. 240. The two phases are entirely independent, and for lighting purposes may be operated as two single-phase circuits.

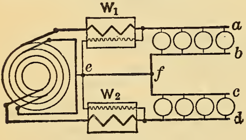

FIG. 239.

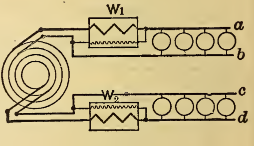

FIG. 240.

2. *Three-phase Currents.*—Three-phase currents consist of three alternating currents, differing in phase by 120°, and represented by three sine curves, as in Fig. 241. They may be distributed by three or six wires. If distributed by the six-wire system, it is analogous to the four-wire, two-phase system, and is equivalent to three single-phase circuits. In the three-wire system of distribution the circuits may be connected in two different ways, known respectively as the Y or star connection, and the Δ (delta) or mesh connection.

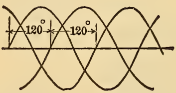

FIG. 241.

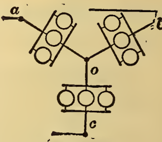

FIG. 242.

The Y connection is shown in Fig. 242. The three circuits are joined at the point o, known as the neutral point, and the three wires carrying the current are connected at the points a, b, and c, respectively. If the three circuits ao, bo, and co are composed of lights, they must be equally loaded or the lights will fluctuate. If the three circuits are perfectly balanced, the lights will remain steady. In this form of connection each wire may be considered as the return wire for the other two. If the three circuits are unbalanced, a return wire may be run from the neutral point *o* to the neutral point of the armature winding on the generator. The system will then be four-wire, and will work properly with unbalanced circuits.

The Δ connection is shown in Fig. 243. Each of the three circuits *ab*, *ac*, *bc*, receives the current due to a separate coil in the armature winding. This form of connection will work properly even if the circuits are unbalanced; and if the circuit contains lamps, they will not fluctuate when the circuit changes from a balanced to an unbalanced condition, or *vice versa*.

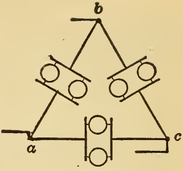

FIG. 243.

Measurement of Power in Polyphase Circuits.— 1. *Two-phase Circuits.*—The power of two-phase currents distributed by four wires may be measured by two wattmeters introduced into the circuit as shown in Fig. 240. The sum of the readings of the two instruments is the total power. If but one wattmeter is available, it should be introduced first in one circuit, and then in the other. If the current or e.m.f. does not vary during the operation, the result will be correct. If the circuits are perfectly balanced, twice the reading of one wattmeter will be the total power.

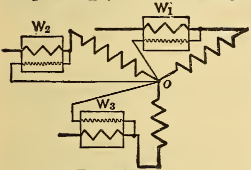

FIG. 244.

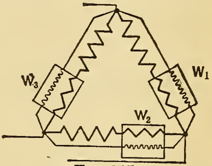

FIG. 245.

The power of two-phase currents distributed by three wires may be measured by two wattmeters as shown in Fig. 239. The sum of the two readings is the total power. If but one wattmeter is available, the coarse-wire coil should be connected in series with the wire *ef* and one extremity of the pressure-coil should be connected to some point on *ef*. The other end should be connected first to the wire *a* and then to the wire *d*, a reading being taken in each position of the wire. The sum of the readings gives the power in the circuits.

2. *Three-phase Circuits.*—The power in a three-phase circuit may be measured by three wattmeters, connected as in Fig. 244 if the system is Y-connected, and as in Fig. 245 if the system is Δ-connected. The sum of the wattmeter readings gives the power in the system. If the circuits are perfectly balanced, three times the reading of one wattmeter is the total power.

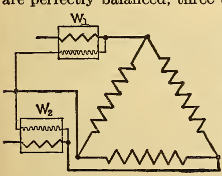

FIG. 246.

The power in a Δ-connected system may be measured by two watt-meters, as shown in Fig. 246. If the power factor of the system is greater than 0.50, the arithmetical sum of the readings is the power in the circuit. If the power factor is less than 0.50, the arithmetical difference of the readings is the power. Whether the power factor is greater or less than 0.50 may be discovered by interchanging the wattmeters without disturbing the relative connection of their coarse- and fine-wire coils. If the deflections of the needles are reversed, the difference of the readings is the power. If the needles are deflected in the same direction as at first, the sum of the readings is the power.

ALTERNATING-CURRENT GENERATORS.

Synchronous Generators.—The function of the alternating-current synchronous generator is to transform mechanical energy into electrical energy, either single-phase or polyphase. It comprises a comparatively constant magnetic field and an armature generating electro-motive forces and delivering currents in synchronism with the motion of the machine.

Alternating-current generators are generally designed to operate at normal load and 80% power factor without exceeding a specified temperature rise, and should such a machine have to be operated with a load of lower power factor, its rating will be reduced, when based on the same temperature guarantee.

Synchronous generators are almost always of the revolving field type, and may be either of a horizontal or vertical design.

Rating. — The normal full-load rating is usually based on continuous operation with a certain rated voltage, current, power factor, frequency and speed. The overload guarantees should refer to the normal conditions of operation, and an overload capacity of 25% for two hours has generally been accepted as standard, although in several instances a 50% two-hour overload is required. Of late (1915), however, generators are often given a maximum continuous rating with a temperature rise not exceeding 50° C. (122° F.).

The rated full-load current is that current which, with rated terminal voltage, gives the rated kilowatts or rated kilovolt-amperes. In machines in which the rated voltage differs from the no-load voltage, the rated current should refer to the former. The rated output may be determined as follows:

If E = full-load terminal voltage and I = rated current, then for a single-phase generator, K.V.A. $= \frac{EI}{1000}$.

For a two-phase generator the total output is equal to the output of the two single-phase circuits, and if I, in this case, is the rated current per circuit, the output for a two-phase generator is, K.V.A. $= \frac{2\,E\,I}{1000}$.

For a three-phase generator there are three circuits to be considered, whether the machine is star or delta connected. If E is the terminal voltage and I the line current, then for a three-phase generator,

$$\text{K.V.A.} = \frac{\sqrt{3} \times EI}{1000}.$$

The capacity of a polyphase generator, whether operating two- or three-phase, is always the same, while, if operating under the same conditions single-phase, in which case one phase is ineffective, the rating is only about 71% of what it would be if operated as a polyphase generator. This relation, however, does not hold true for a machine which is initially built for single-phase service, and in such a case the distribution of the winding can be made such as to increase the capacity somewhat. The inherent regulation is generally made poorer thereby, but by the use of massive damping devices it can be materially improved.

Efficiency.—The efficiency of a generator is the ratio of the power output to the power input, the difference between these two quantities being equal to the losses. The method commonly and most readily used for obtaining the efficiency is to determine these losses and then compute the efficiency by dividing the power output by the sum of the power output plus the losses.

The guaranteed efficiency should always refer to the energy load (the energy load is the load doing useful work, and is equal to the total K.V.A. × the power factor of the load), and it is most important that the power factor of the load is also given. In certain cases the guaranteed efficiency is based on a K.V.A. output, but the inconsistency of such a method is apparent, as the following example will illustrate:

Assume a generator rated 100 K.V.A. (100 Kw. at unity power-factor) or 100 K.V.A. (80 Kw. 0.8 P.F.), and that the losses at unity and 80% power factors are 10 and 11 Kw. respectively, the efficiency is then:

Based on 100 Kw. 1.0 P.F.,

$$\text{Eff.} = \frac{100}{100 + 10} = 91\%.$$

Based on 80 Kw. 0.8 P.F.,

$$\text{Eff.} = \frac{80}{80 + 11} = 88\%.$$

Based on 100 K.V.A. 0.8 P.F.,

$$\text{Eff.} = \frac{100}{100 + 11} = 90\%.$$

From the last two values it is seen that for 80% power-factor if based on the K.V.A., a 2% greater efficiency guarantee can be made, although this value has no meaning, as it is based on apparent power.

The losses in the generator consist of: The copper losses in the armature and field, proportional to the square of the armature and field currents respectively; the core loss, slightly increasing from no-load to full-load; the load loss, having a value approximately one-third of the short-circuiting core loss; and finally, the friction and windage losses, which are practically constant.

Regulation. — Such a close inherent voltage regulation as was formerly required is not any longer desirable, since a good voltage regulation may readily be accomplished by means of automatic voltage regulators, which perform their function whether the fluctuations are due to a change of load, speed, or power factor.

A close inherent regulation would require a low reactance generator, which means an expensive machine. A low reactance machine also, in case of short circuits, would allow a very large current to flow through the machine and through any other apparatus that may be within the circuit enclosed by the short-circuit. These short-circuit currents reach enormous values in large central stations, and in order to reduce the currents to safe values large reactances are necessary. It is, however, not possible to design high-speed turbo-generators for the necessary reactance, and external reactances must usually be inserted in the generator leads or between the bus-sections. By so limiting the abnormal flow of current the generating system is relieved from the disastrous effects of such short circuits.

Rating of a Generating Unit.—In determining the proper rating and capacity of the generators for a power station, the generator and the prime mover must of necessity be treated together as a combination so as to secure the highest operating efficiency. With steam-engines the ratings are usually such that the engine is working under its most economical load at the rating of the electrical generator. With gas engines, however, the efficiency increases with the load beyond the capacity of the engine, and for this reason the rating of such an engine is generally made as nearly as possible to its maximum capacity with only a small margin for regulating purposes. With steam turbines the efficiency curve is very flat so that it is the desirable overload capacity which limits the rating of the turbine. In the water-wheel unit, the efficiency usually falls off rapidly above and below the maximum point, so that the rating of the generator should correspond to the point of maximum efficiency of the wheel.

The effect of the power factor should also be considered when determining the prime mover as well as the generator capacity, and many mistakes have been made in this respect. The generator may, for example, have been designed and rated on the basis of unity power factor operation with a prime mover having a corresponding capacity. After installation it is, however, found that the actual operating power factor is 0.80, with the result that only 80 per cent of the prime mover capacity can be utilized without overloading the generator.

Windings.—The greatest number of all alternating-current generators are wound three-phase with the armature windings connected in star. This is preferable to delta connection, as a smaller number of conductors is required for a given voltage, while on the other hand the danger of the circulation of triple-frequency currents in the closed armature winding is avoided.

Voltages.—Standard generator voltages for all frequencies are 240, 480, 600, 1150, 2300, 4000, 6600, with the corresponding motor voltages 220, 440, 550, 1040, 2090, 6000. There is no motor voltage corresponding to 4000 volts, since this is only used on lighting three-phase, four-wire distributing systems. In addition 11,000 volts is also standard for 60 cycles, and 13,200 volts for 25 cycles.

Parallel Operation. — In order that an alternating-current generator shall be able to carry a load, a current must flow corresponding to this load. The e.m.f. required to generate this current is the resultant of the terminal and the induced e.m.f.'s of the generator, the displacement between these e.m.f.'s being due to the impulse of the prime mover. In the same manner when two or more generators are operating in parallel the division in load between the different units is entirely dependent on the turning efforts of the prime movers, and a change in the field excitation, as with direct-current generators, will have no effect whatsoever.

For a satisfactory parallel operation it is important that the e.m.f.'s and frequencies of the generators be the same, as, if this is not the case, cross currents will flow between the units. These cross currents may be either wattless or they may represent a transfer of energy, depending on whether they are caused by a difference in the e.m.f. or in the frequency of the machines.

Exciters (E. A. Lof, in *Coal Age*).—Synchronous generators as well as synchronous motors are dependent on a direct-current excitation for their operation, and the energy for the excitation is generally obtained from direct-current generators, termed "exciters." These should have a capacity sufficient to excite all of the synchronous apparatus in the station when these machines are operating at their maximum load and true operating power factor. It is not enough to provide for the excitation when operating at unity power factor, because the excitation which is required at lower power factors is considerably higher than at unity power factor.

For small and medium size plants a 125-volt exciter pressure is generally chosen, while for larger installations a 250-volt excitation will prove more economical.

There are many different ways of driving exciters. They may be direct-connected to the main units if these are of moderate speed. Such an arrangement may prove satisfactory for two or three units, but when the number of units is higher the system becomes rather complicated. Another objection is that in case of trouble with an exciter, the whole generating unit will have to be shut down. When two direct-connected units are used, they should each have a capacity sufficiently large to excite both the generators, and with three units the capacity of either exciter should preferably be such that it can excite two of the generators. For four or more units it should only be necessary to give each exciter a capacity sufficient for one generator, and if necessary a motor-driven exciter unit can be installed as a reserve.

The system, however, which seems to be the most widely used and which offers the greatest reliability, is that in which the excitation is obtained from a common source, consisting of as few exciters as possible. One or two units are then generally provided for normal excitation, depending on the size of the station, a third unit being installed as a reserve. It is also common practice to have the regular units driven by prime movers, such as steam-engines or water-wheels, while the reserve unit is motor-driven.

Still another system which is becoming common is to install low-voltage generators, driven either by a non-condensing steam turbine in case of a steam-plant or a water-wheel in a hydro-electric plant. The exciters are then motor-driven, current for driving them being obtained from the low voltage generator. The steam from the turbines would then, of course, be taken to the feed-water heaters, and in addition to the exciters, all the other auxiliaries, such as the circulating pumps, etc., would also be motor-driven.

In order to insure a close voltage regulation of the system, automatic regulators are commonly installed in connection with the exciters, their principle being to automatically increase or decrease the excitation by rapidly opening or closing a shunt circuit across the exciter-field rheostat, and thus keep a constant bus-bar voltage regardless of the load.

TRANSFORMERS.

A transformer consists essentially of two coils of wire, one coarse and one fine, wound upon an iron core. Its function is to transform electrical energy from one potential to another, although it may also be used for phase transformation. If the transformer causes a change from high to low voltage, it is known as a "step-down" transformer; if from low to high voltage, it is known as a "step-up" transformer.

Primary and Secondary.—In regard to the use of the terms high-voltage, low-voltage, primary and secondary, the A.I.E.E. Standardization Rules read as follows:

"The terms 'high-voltage' and 'low-voltage' are used to distinguish the winding having the greater from that having the lesser number of turns. The terms 'primary' and 'secondary' serve to distinguish the windings in regard to energy flow, the primary being that which receives the energy from the supply circuit, and the secondary that which receives the energy by induction from the primary."

The terms primary and secondary are, however, often confused, and in order to avoid any misunderstanding, it is preferable that the terms high-voltage and low-voltage be used instead of primary and secondary.

Voltage Ratio.—The A.I.E.E. Standardization Rules also state that "*The voltage ratio* of a transformer is the ratio of the r.m.s. (square root of mean square) primary terminal voltage to the r.m.s. secondary terminal voltage under specified conditions of load." It also defines "The *ratio of a transformer*, unless otherwise specified, as the ratio of the number of turns in the high-voltage winding to that in the low-voltage winding: i.e., the *turn-ratio*."

The two ratios are equal when one of the windings is open and the transformer does not carry any load. When loaded, the resistance and inductance of the windings cause a drop in the voltage, thus modifying the ratio of transformation slightly.

Rating.—A transformer should be rated by its kilovolt-ampere (K.V.A.) output. It is equal to the product of the voltage and current, and is, therefore, the same whether the different coils are connected in series or parallel. If the load is of unity power factor, the kilowatt output is the same as the kilovolt-ampere output, but if the power factor is less, the kilowatt output will be correspondingly less. For example, a 100 K.V.A. transformer will have a full-load rating of 100 K.W. at 100% power factor, 90 K.W. at 90% power factor, etc.

Efficiency.—There are two sources of loss in the transformer, viz., the copper loss and the iron loss. The copper loss is proportional to the square of the current, being the $I^2 R$ loss due to heat. If I_1, R_1, be the current and resistance respectively of the primary, and I_2, R_2, the current and resistance respectively of the secondary, then the total copper loss is $W_c = I_1^2 R_1 + I_2^2 R_2$ and the percentage of copper loss is $\dfrac{I_1^2 R_1 + I_2^2 R_2}{W_p}$, where W_p is the energy delivered to the primary. The iron loss is constant at all loads, and is due to hysteresis and eddy currents.

The efficiency of a transformer is the ratio of the output in watts at the secondary terminals to the input at the primary terminals. At full load the output is equal to the input less the iron and copper losses. The full-load efficiency of a transformer is usually very high, being from 92 per cent to 98 per cent. As the copper loss varies as the square of the load, the efficiency of a transformer varies considerably at different loads. Transformers on lighting circuits usually operate at full load but a very small part of the day, though they use some current all the time to supply the iron losses. For transformers operated only a part of the time, the "all-day" efficiency is more important than the full-load efficiency. It is computed by comparing the watt-hours output to the watt-hours input.

The all-day efficiency of a 10-Kw. transformer, whose copper and iron losses at full load are each 1.5 per cent, and which operates 3 hours at full load, 2 hours at half load, and 19 hours at no load, is computed as follows:

Iron loss, all loads = $10 \times 0.015 = 0.15$ K.W.
Copper loss, full load = $10 \times 0.015 = 0.15$ K.W.

Copper loss, $1/2$ load $= 0.15 \times (1/2)^2 = 0.0375$ K.W.
Iron loss, K.W. hours $= 0.15 \times 24 = 3.6$.
Copper loss, full load, K.W. hours $= 0.15 \times 3 = 0.45$.
Copper loss, $1/2$ load, K.W. hours $= 0.0375 \times 2 = 0.075$.

Output, K.W. hours $= \left\{ (10 \times 3) + (5 \times 2) \right\} = 40$.

Input, K.W. hours $= 40 + 3.6 + 0.45 + 0.075 = 44.125$.
All-day efficiency $= 40 \div 44.125 = 0.907$.

Connections.—Among the great variety of transformer manipulations in power and general distribution work, either for straight voltage transformation or for phase transformation, the following are the most generally used:

Voltage Transformation:
- Single-phase.
- Two-phase.
- Three-phase, delta-delta.
- Three-phase, delta-star, and *vice versa.*
- Three-phase, star-star.
- Three-phase, open-delta.
- Three-phase, Tee.

Phase Transformation:
- Two- or three-phase to single-phase.
- Two-phase to six-phase.
- Three-phase to two-phase.
- Three-phase to six-phase.

The transformer connections mostly used are delta-delta or delta-star with neutral grounded.

For moderate voltage systems, the isolated delta connection is to be preferred, although for high-tension systems with very high voltages practice has proved that the high-tension winding star connected and the neutral grounded will give a more satisfactory operation.

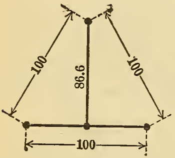

FIG. 247.

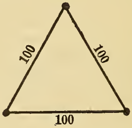

FIG. 248.

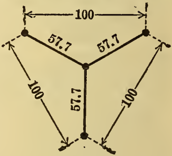

FIG. 249.

Tee-Connection.—(Fig. 247.)—T-connection requires only two single transformers of which one is provided with a 50 per cent tap to which the other is connected. The latter may be designed for only 86.6% of the line or main transformer voltage, but generally it is made identical with the main transformer and operated at reduced flux density.

Delta-Connection.—(Fig. 248.)—The e.m.f. between the mains is the same as that in any one transformer measured between terminals, and each transformer must, therefore, be wound for the full line voltage, but only for $\frac{1}{\sqrt{3}}$ or 57.7 per cent of the line current.

Star-Connection.—(Fig. 249.)—In the star-connection each transformer has one terminal connected to a common junction, or neutral point. Each transformer is wound for only 57.7 per cent of the line voltage, but for the full line current.

Reactance.—In order to obtain a good voltage regulation, it has been the custom to design the transformers with a reactance as low as $1\frac{1}{2}$ to 2 per cent. Recent experience has, however, shown that in high power systems such transformers are unsafe, owing to the enormous mechanical strain produced on the transformer and system by the excessive short-circuit currents permitted by such low impedance transformers.

A 2 per cent reactance means that at full load current, 2 per cent or 1/50 of the supply voltage is consumed by the reactance. At short circuit the total voltage would have to be consumed by the transformer reactance, and the short-circuit current at full voltage is then fifty times full load current. Safety thus requires that in high power systems the transformers should be designed for a much higher reactance and the present practice (1915) is, therefore, to design such transformers for 6 to 8 per cent reactance, and sometimes even for as high as 10 per cent.

Cooling.—According to the method used in dissipating the heat generated by the losses, transformers may be classified as: 1. Oil cooled. 2. Water cooled. 3. Air blast.

Parallel Operation.—In order that two or more transformers or groups of transformers shall operate successfully in parallel, it is necessary that their polarity be the same, that their voltages and voltage ratios be identical, and that their impedances be inversely proportional to the ratings.

Auto Transformers.—Auto transformers may be used where the required voltage change is small. Their action is similar to that of ordinary transformers, the essential difference between the two being that in the transformer the high-voltage and low-voltage windings are separate and insulated from each other while in the auto-transformer a portion of the winding is common to both the high and low voltage circuits.

The high- and low-voltage currents in both types of transformers are in opposite direction to each other, and thus in an auto-transformer a portion of the winding carries only the difference between the two currents.

Auto transformers are extensively used for alternating current motor starters, and also to some extent in moderate voltage generating stations.

Constant-Current Transformers.—The transformers heretofore discussed are constant-potential transformers and operate at a constant voltage with a variable current. For the operation of lamps in series a constant-current transformer is required. There are a number of types of this transformer. That manufactured by the General Electric Co. operates by causing the primary and secondary coils to approach or to separate on any change in the current.

SYNCHRONOUS CONVERTERS.

A synchronous converter is essentially a continuous-current generator, which, in addition to its commutator, is supplied with two or more collector rings connected to suitable points in the armature winding. If such a machine be driven by mechanical power, it will evidently deliver either alternating or direct current, and, conversely, if supplied with electric power, it will operate either as a synchronous motor, as a direct-current motor, or as a synchronous converter. When operated as a converter, the alternating current enters the armature winding through the collector rings, and after being rectified by the commutator, is delivered as direct current, or *vice versa*.

The alternating and direct current e.m.f. stand in a certain relation or ratio to each other, and this depends upon the number of phases and frequency of the system used, and also upon the ratio of maximum to the square root of the mean square value of the impressed e.m.f. (that is, the e.m.f. of the supply circuit). It also depends upon the load of the machine, the ohmic armature losses, the position of the direct-current brushes on the commutator, the excitation, the ratio of pole arc to pole pitch, and upon the operating conditions, that is, whether the machine is used to convert from alternating to direct current or *vice versa*. Synchronous converters for 60 cycles, which usually have a lower ratio of pole arc to pole pitch than 25 cycle converters, have, as a rule, a higher voltage ratio and, when used as inverted converters, a lower voltage ratio than corresponding 25 cycle machines.

In the two-ring or single-phase converter, the two collector rings are connected to armature conductors with the same angular distance apart as commutator bars under adjacent sets of brushes. At this instant the e.m.f. between the collector rings is at its maximum value and equal to the e.m.f. between the direct-current brushes. Therefore, the direct-current e.m.f. (E) of a two-ring single-phase synchronous converter is equal to the maximum value ($\sqrt{2} \times E_2$) of the sine wave e.m.f. between the two collector rings. Therefore,

$$E_2 = \frac{E}{\sqrt{2}}$$

in which E_2 is the effective value of the single-phase alternating e.m.f.

The effective e.m.f. between the two collector rings, which are connected to the armature winding at points 120 electrical degrees apart, that is, between any two rings of a three-ring three-phase converter, is represented by that chord of a polygon which subtends an angle of 120 degrees. Likewise, the e.m.f. between two rings which are connected to the armature winding at points 90 electrical degrees apart, as between two adjacent rings in a four-ring quarter-phase converter, is represented by the chord which subtends an angle of 90 electrical degrees; and the chord which subtends an angle of 60 electrical degrees represents the e.m.f. between two adjacent rings of a six-ring six-phase synchronous converter.

In general, the effective e.m.f., E_1, between adjacent rings of an n-ring converter, is represented by that chord of a polygon which subtends an angle of $\frac{360°}{n}$ or $\frac{2\pi}{n}$. Therefore,

$$E_1 = \frac{E}{\sqrt{2}} \sin \frac{180°}{n}$$

This gives the following *theoretical* values of the effective alternating e.m.f. between *adjacent* collector rings of a two-ring, three-ring, four-ring and six-ring synchronous converter, expressed in terms of the e.m.f., E, between the direct-current brushes:

For single-phase $\quad E_1 = \frac{E}{\sqrt{2}} = 0.707\,E,$

For three-phase $\quad E_1 = \frac{\sqrt{3}\,E}{2\sqrt{2}} = 0.612\,E,$

For quarter-phase $\quad E_1 = \frac{E}{2} = 0.500\,E,$

For six-phase $\quad E_1 = \frac{E}{2\sqrt{2}} = 0.354\,E.$

The above ratios represent, as before stated, the effective alternating e.m.f. between two *adjacent* collector rings. For quarter- and six-phase converters the different phases of the supply circuit, however, are not connected as a rule to adjacent rings and the ratios given above are not the ones to be used for determining the alternating supply voltage for these types of synchronous converters.

For the four-ring quarter-phase converter, each phase of the supply circuit is generally connected to diametrically opposite points of the armature winding and the ratio will, under such conditions, be equal to the ratio for the two-ring single-phase converters, that is, for quarter-phase $E_1 = \frac{E}{\sqrt{2}} = 0.707\,E.$

For six-phase synchronous converters two different arrangements of the connections are generally used. One is called the "double delta" connection and the other the "diametrical" connection. In the first case, the voltage ratio is the same as for the three-phase synchronous converter and simpfy consists of two "delta" systems. The transformers can also be connected in "double-star," and in such a case the ratio between the three-phase voltage between the terminals of each star and the direct voltage will be the same as for "double-delta," while the voltage of each transformer coil, or voltage to neutral, is $\frac{1}{\sqrt{3}}$ times as much. With the diametrical connection the ratio is the same as for the two-ring single-phase converter, it being analogous to three such systems. Therefore

Six-phase double-delta, $E_1 = \frac{\sqrt{3}\,E}{2\sqrt{2}} = 0.612\ E.$

Six-phase diametrical, $E_1 = \frac{E}{\sqrt{2}} = 0.707\ E.$

The ratio of the effective e.m.f., E_0, between any collector ring and the neutral point is always

$$E_0 = \frac{E}{2\sqrt{2}} = 0.354\ E.$$

The given voltage ratios are, as stated, only *theoretical*, as the losses in the winding have been neglected and the assumption has been made that both the impressed and the counter generated converter e.m.f. has a sine wave shape. The ratio between the alternating and direct terminal voltages is somewhat different from the theoretical ratio due to the voltage drop in the armature and to the wave shapes of the e.m.f.'s. The exact ratios are always furnished by the manufacturer.

Synchronous converters may be either of the shunt- or compound-wound type, the choice depending on the character of the service for which they are to be used. In the majority of installations, especially for power purposes, compound-wound converters are generally used because they automatically regulate for a comparatively constant direct-current voltage.

In order to change the direct voltage in the ordinary type of synchronous converter with constant voltage ratio, it is necessary to provide means for changing the applied alternating voltage correspondingly. This can be done in several ways, one of which is to provide taps on the step-down transformers and adjust the ratio of transformation by means of a dial switch. A much better method, however, is the use of an induction regulator between the transformer secondary terminals and the synchronous converter. This regulator consists of a stationary series winding and a movable potential winding, which can be turned through a certain angle, and at each angular position will raise or lower the voltage at the collector rings a certain amount, through the mutual action of the current and potential windings. This method of control is generally used with shunt-wound synchronous converters in order to keep the voltage constant, when the line drop is excessive. The induction regulator is either hand-operated by means of chain or motor drive, or the control can be made automatic by using a contact-making voltmeter and relay, which will automatically control the regulator motor.

The voltage regulation can also be accomplished by taking advantage of the fact that an alternating current passing over an inductive circuit will decrease in potential if lagging, and increase if leading. By providing the synchronous converter with a series field winding in addition to the shunt field, the excitation can be automatically regulated as the load comes on. The inductance of the supply circuit and step-down transformers is, however, frequently not sufficient to cause the required boost in the voltage, and in such a case it becomes necessary to insert extra reactance coils in the line or provide the step-down transformers with extra high reactance.

There are three feasible methods of starting synchronous converters: First, the application of alternating current at reduced voltage to the collection rings; second, the application of direct current to the commutator and starting the machine as a direct-current motor; third, the use of an auxiliary starting motor mechanically connected.

The alternating current starting method has many advantages over the other methods. It is self-synchronizing, and, therefore, entirely eliminates the difficulty of accurately adjusting the speed. When the speed of the prime movers is liable to be variable, the ability to start a machine quickly and get it on the line in the shortest possible time is a great advantage inherent to this method of starting. It is possible for the converter to drop into step with its direct-current voltage reversed from that of the bus to which the machine is to be connected, but the machine can easily be made to drop back a pole by a self-exciting field reversing switch on the machine frame. This method of starting makes the operation of the machine so simple that the liability of confusion and mistakes by operators is greatly reduced.

If several synchronous converters are to supply the same direct-current system, they can be connected in parallel in the same manner as shunt- or compound-wound generators, and they are even frequently operated in parallel with such generators and storage batteries. The different converters will divide the load according to their direct-current voltages, and these can be regulated by changing the applied alternating current. It is evidently necessary that all of the machines operating in parallel should have the same voltage regulation from no-load to full-load, and if a battery is also operated in parallel the voltage drop should be sufficiently large so as to cause the battery to take the excessive loads. Synchronous converters operated in parallel should not be connected to the same transformer secondaries. Such a connection would form a closed local circuit in which heavy cross-currents would flow when any difference in the operating conditions of the machine occurs, as, for example, if the brushes of one of the machines were slightly displaced relative to the other.

Compound-wound converters for parallel operation should be provided with equalizer switches. For connecting a compound-wound converter in parallel with one already running, the equalizer switch is closed first, so as to energize the series field from the running machine. Next, the shunt field circuit is closed and the field adjusted so that the voltage will correspond to that of the first machine, and finally the main switch is closed. The load can then be transferred from the first to the second converter by weakening the shunt field of the former and strengthening that of the latter.

MOTOR-GENERATORS.

Motor-generator sets may be divided into three general classes:

1. Direct current to direct current sets, including balancing sets for three-wire lighting systems, and for variable speed motor work, boosters for storage battery charging and railway or lighting feeders.

2. Alternating current to direct current sets or *vice versa*. These are used for excitation purposes and for supply of lighting, railway or power systems. The sets may be driven either with synchronous or induction motors, the former being equipped with an auxiliary squirrel cage winding on the fields so as to be self-starting at reduced voltage.

3. Alternating current to alternating current sets between the two periodicities; commonly called "frequency changers."

Balancers.—The balancer set, a form of direct-current compensator, is a variation of the regular motor-generator set, in that the units of which it is composed may be, alternately, motor or generator, and the secondary circuit is interconnected with the primary. On account of the latter feature, the efficiency of transformation is higher and a larger output is obtainable from a given amount of material than in the straight motor-generator set.

Balancer sets are widely used to provide the neutral of Edison three-wire lighting systems. They are also installed for power service in connection with the use of 250-volt motors on a 500-volt service or 125-volt motors on a 250-volt service.

The potential of the system being given, the capacity of a three-wire balancer set is fixed by the maximum current the neutral wire is required to carry. This figure is a more definite specification of capacity than a statement in per cent of unbalanced load.

As designed for power work and generally for lighting service, the brushes of each machine are set at the neutral point in order to get the best results for operating alternately either as a generator or motor. Where the changes of balance are so gradual as to permit of hand adjustment, if desired, a considerable increase in output is obtainable.

Boosters.—Boosters are extensively used in railway stations to raise the potential of the feeders extending to distant points of the system; for storage-battery charging and regulation; and in connection with the Edison three-wire lighting system. The design of the various sets is closely dependent upon their application.

Booster sets are constructed in either series- or shunt-wound types, and they may be arranged for either automatic or hand regulation, depending on the nature of the service required.

Where there are a number of lighting feeders connected and run at full load for only a short time each day it will generally be economical to install boosters rather than to invest in additional feeder copper. It is important, however, to consider each case where the question of installing a booster arises, as a separate problem, and to determine if the value of the power lost represents an amount lower than the interest charge on the extra copper necessary to deliver the same potential without the use of a booster.

Dynamotors. — A dynamotor is a machine for reducing a direct-current voltage, and it is extensively used in connection with high voltage railway equipments for obtaining a moderate voltage for the control. It has two armature windings and commutators on one drum, with the field between them. The control current is taken midway between the armatures and is returned to the ground side of the dynamotor. This insures that the maximum potential on the control circuit, under normal conditions, will be approximately one-half of the line voltage, and the potential to grounded parts no greater than when operated directly on a line voltage of one-half the amount.

Frequency Changers.—A periodicity of 25 cycles has been quite generally selected for railway service. Also in certain large cities, current of the same frequency is generated in central stations and distributed to substations in which are installed rotary converters supplying an Edison three-wire network.

Inasmuch as the periodicity of 60 cycles is more favorable than 25 cycles for alternating current lighting, frequency changers, similar to that shown above, are installed to furnish high tension 60-cycle current for distribution to outlying districts beyond the reach of the three-wire system.

In the design of frequency changers speeds must be selected that are common to the two periodicities of the system upon which they are to be used; since 300 r.p.m. is the highest speed common to 25 and 60 cycles, at which speed small sets are expensive per kilowatt, a line of sets with 4 or 8 pole motors and 10 or 20 pole generators has been developed, giving 62 1/2 cycles from 25 cycles or 60 cycles from 24 cycles.

Where parallel operation is required between synchronous motor-driven frequency changers, a mechanical adjustment is necessary between the fields or armatures of the generator and motor to obtain equal division of the load. The adjustment is best obtained by the cradle construction. The stator of one machine is bolted to a cradle fastened to the base, and by taking out the bolts the frame can be turned around through a small angle relatively to the cradle, and therefore to the stator field of the other machine, where the bolts can be replaced.

The Mercury Arc Rectifier consists of a mercury vapor arc enclosed in an exhausted glass vessel into which are sealed two terminal anodes connected to the two wires of an alternating-current circuit. A third terminal, at the bottom of the vessel, is a mercury cathode. When an arc is operating, it is a good conductor from either anode to the cathode. but practically an insulator in the other direction. The two anodes connected across the terminals of the alternating-current line become alternately positive and negative. While either anode is positive, there is an arc carrying the current between it and the cathode. When the polarity of the alternating-current reverses, the arc passes from the other anode to the mercury cathode, which is always negative. The current leading out from the mercury cathode is uni-directional. By means of reactances, the pulsations are smoothed out and the current at the cathode becomes a true direct current with pulsations of small amplitude.

ALTERNATING-CURRENT CIRCUITS.

Calculation of Alternating-current Circuits.—The following formulæ and tables are issued by the General Electric Co. They afford a convenient method of calculating the sizes of conductors for, and determining the losses in, alternating-current circuits. They apply only to circuits in which the conductors are spaced 18 inches apart, but a slight increase or decrease in this distance does not alter the figures appreciably. If the conductors are less than 18 inches apart, the loss of voltage is decreased, and *vice versa*.

Let W = total power delivered in watts;
D = distance of transmission (one way) in feet;
P^* = per cent loss of *delivered* power (W);
E = voltage between main conductors at consumer's end of circuit;
K = a constant; for continuous current = 2160;
T = a variable depending on the system and nature of the load; for continuous current = 1;
M = a variable, depending on the size of wire and frequency; for continuous current = 1;
A = a factor; for continuous current = 6.04.

Area of conductor, circular mills $= \dfrac{D \times W \times K}{P \times E^2}$;

Current in main conductors $= W \times T \div E$;

Volts lost in lines $= P \times E \times M \div 100$;

Pounds copper $= \dfrac{D^2 \times W \times K \times A}{P \times E^2 \times 1{,}000{,}000}$.

The value of M is found from the formula: $M = \left(1 + \dfrac{X}{R} \tan a\right) \cos^2 a$.

$$X = 0.000882 f \left[\log_{10}\left(\frac{d}{r}\right) + 0.109\right]$$

X = Reactance.
R = Resistance, ohms per 1000 ft., at 60° F. (Wire 100% Matthiessen's standard.)
d = inches between wires.
r = radius of wire, inches.
f = cycles per second.

Per cent of Power Factor.	Value of K.				Value of T.				Value of A.
	100	95	85	80	100	95	85	80	
System:									
Single-phase..................	2160	2400	3000	3380	1.00	1.05	1.17	1.25	6.04
Two-phase, 4-wire............	1080	1200	1500	1690	0.50	0.53	0.59	0.62	12.08
Three-phase, 3-wire...........	1080	1200	1500	1690	0.58	0.61	0.68	0.72	9.06

* P should be expressed as a whole number, not as a decimal; thus a 5 per cent loss should be written 5, not .05.

† As corrected by Harold Pender, see *Elect. World*, July 1, 1905. The formula for M is approximate, and gives values correct within 2% for any case likely to arise in practice.

Relative Weight of Copper Required in Different Systems for Equal Effective Voltages.

Direct current, ordinary two-wire system.................. 1.000
" " three-wire system, all wires same size........... 0.375
" " " " " neutral one-half size........ 0.313
Alternating current, single-phase two-wire, and two-phase four-wire 1.000
Two-phase three-wire, voltage between outer and middle wire same as in single-phase two-wire...... 0.729
" " voltage between two outer wires same... 1.457
Three-phase three-wire.................................. 0.750
" " four-wire...................................... 0.333

The weight of copper is inversely proportional to the squares of the voltages, other things being equal. The maximum value of an alternating e.m.f. is 1.41 times its effective rating. For derivation of the above figures see Crocker's "Electric Lighting," vol. ii.

Approximate Rule for Size of Wires for Three-Phase Transmission Lines. (General Electric Co.)

The table given below is for use in making rough estimates for the sizes of wires for three-phase transmission, as in the following example.

Required.—The size of wires to deliver 500 Kw. at 6000 volts, at the end of a three-phase line 12 miles long, allowing an energy loss of 10% and a power factor of 85%. If the example called for the transmission of 100 Kw. (on which the table is based), we should look in the 6000-volt column for the nearest figure to the given distance, and take the size of wire corresponding. But the example calls for the transmission of five times this amount of power, and the size of wire varies directly as the distance, which in this case is 12 miles. Therefore we look for the product $5 \times 12 = 60$ in the 6000-volt column of the table. The nearest value is 60.44 and the size of wire corresponding is No. 00, which is, therefore, the size capable of transmitting 100 Kw. over a line 60.44 miles long, or 500 Kw. over a line 12 miles long, as required by the example.

If it is desired to ascertain the size of wire which will given an energy loss of 5%, or one-half the loss for which the table is computed, it is only necessary to multiply the value obtained by 2, since the area varies inversely as the per cent energy loss.

Distances to which 100 Kw. Three-phase Current can be Transmitted Over Different Sizes of Wires at Different Potentials, Assuming an Energy Loss of 10% and a Power Factor of 85%.

Number B. & S.	Area in Circular Mils.	Distance of Transmission for Various Potentials at Receiving End, in Miles.								
		2,000	4,000	6,000	8,000	10,000	15,000	20,000	25,000	30,000

Notes on High-tension Transmission.—The cross-sectional area and, consequently, weight of conductors vary inversely as the square of the voltage for a given power transmission. The cost of conductors is therefore reduced 75% every time the voltage is doubled. The cost of other apparatus and appliances increases with increasing voltage. For long-distance lines the saving in copper with the highest practicable voltages is so great that the other expenses are rendered practically negligible. In the shorter lines, however, the most suitable voltage must be determined in each individual case. The voltages in the following table will serve as a guide.

VOLTAGES ADVISABLE FOR VARIOUS LINE LENGTHS.

Miles.	Volts.	Miles.	Volts.	Miles.	Volts.
1	500–1000	3–10	6600–13,200	20–40	44,000– 66,000
1–2	1000–2300	10–15	13,200–22,000	40–60	66,000– 88,000
2–3	2300–6600	15–20	22,000–44,000	60–100	88,000–110,000

Standard machinery is made for 2300, 6600, 13,200, 22,000, 33,000, 44,000, 66,000, 88,000 and 110,000 volts, and standard generators are made for the above voltages up to and including 13,200 volts. When the line voltage is higher than 13,200, step-up transformers must be employed. In a given case the saving in cost of conductor by using the higher voltage may be more than offset by the cost of transformers, and the question of voltage must be determined for each case.

Line Spacing.—Line conductors should be so spaced as to lessen the tendency to leakage and to prevent the wires from swinging together or against the towers. With suspended disk insulators the radius of free movement is increased, and special account should be taken of spacing when these insulators are used. The spacing should be only sufficient for safety, since increased spacing increases the self-induction of the line, and while it lessens the capacity, it does so only in a slight degree. The following spacing is in accordance with average practice.

CONDUCTOR SPACING ADVISABLE FOR VARIOUS VOLTAGES.

Volts.	Spacing.	Volts.	Spacing.
33,000	3 feet.	88,000	8 feet.
44,000	4 feet.	110,000	10 feet.
66,000	6 feet.	140,000	12 feet.

Aluminum Conductors.—The conductivity of aluminum is generally taken at 63.3%, that of hard-drawn copper of the same cross-sectional area. The weight of Al is 30.2% that of copper, and therefore an Al conductor of the same length and conductivity as a given copper conductor weighs 47.7% as much. The cost of Al must therefore be 2.097 times that of hard-drawn copper to give equal cost for the same length and conductivity. Owing to the mechanical unreliability of solid Al conductors, stranded conductors are used in all sizes, including even the smallest.

The Size of the Line Conductors depends on both economical and electrical considerations, except where the length of the span is the governing feature. With expensive steel towers it becomes necessary to string the conductors for higher stresses so as to reduce the sags and consequently the height of the towers as much as possible. It has, therefore, become a general practice to erect the conductors so that the stress at the worst load conditions equals one-half the ultimate strength of the conductor material, which gives a factor of safety of two. The load to which a line conductor is subjected, besides its own weight and ice, is acting in a vertical direction, the pressure imposed by the wind acting in a horizontal direction. It is also evident that the stress will be greater in extremely cold weather because of the contraction of the wires, and it is generally agreed that the worst load condition would occur at 0° F. with an actual wind velocity of 56 miles per hour (8 pounds pressure per square foot projected area) and with an ice covering one-half inch thick. The maximum temperature is considered to be 130° F., and the cables should be so supported that at this temperature the sag does not become excessive, but allows a clearance between the lowest conductor and ground of from 25 to 30 feet.

Line conductors may be either of copper or aluminum. It is advisable for mechanical reasons in spans of 200 to 300 feet never to use smaller cable than No. 5 B. & S. copper, or No. 1. B. & S. aluminum (equivalent of No. 3 copper). For spans greater than 300 feet, the minimum sizes of cable allowable are those which will give a reasonable sag at the most severe climatic conditions assumed. Frequently the size of conductors, determined by electrical considerations, limits the length of spans to a smaller value than is economical. This may occur even with moderately long spans—500 to 600 feet—when the character of the country is such as to make transportation costly or when expensive foundations must be used. In such cases it will often be found that a saving can be made by increasing the size of conductor, thereby allowing an increase in the length of span and the use of fewer towers of approximately the same height and not greatly increased weight.

The sag or deflection at the center of a span can be figured by the formula:

$$D = \frac{S^2 \times W}{8\,T},$$

where D = deflection in feet; S = length of span in feet; W = resultant of weight and wind in lbs. per foot of cable; T = tension on cable in lbs.

A 135,000-Volt Three-phase Transmission System from Cook Falls, Mich., to Flint, Mich., 125 miles distant, is described in *Power*, Aug. 9, 1910. The generating equipment comprises three 3000-K.W. 60-cycle alternators, mounted on horizontal shafts driven by water-wheels. The available head of water is 40 ft., and the flow averages 1100 cu. ft. per second. The transmission line consists of three No. 0 copper wires carried on suspension-type insulators hung from the cross-arms of 55-ft. tripod steel towers. The wires are at the angles of an isosceles triangle with a 12-ft. base and 17-ft. sides, the lowest wire 40 ft. above the ground. The insulators have eight disks linked in series, each disk having been tested to withstand continuously 75,000 volts, and subjected to 100,000 volts for a brief period.

ELECTRIC MOTORS.

Classification.—Motors may be classified according to type, speed, and mechanical features. The first cover:

Direct Current—1. Series. 2. Shunt. 3. Compound.

Alternating Current (single-phase and polyphase) — 1. Synchronous. 2. Synchronous Induction. 3. Induction. 3a. Phase-wound. 3b. Squirrel-Cage. 4. Commutator.

According to their speed, they are classified as—

Constant Speed: covering cases where the speed is constant or varies slightly.

Adjustable Speed: covering cases where the speed may be varied over a considerable range, but when once fixed remains at this value independent of the load changes.

Varying Speed: covering cases where the speed changes with the load, usually decreasing as the load increases.

Multi-Speed: covering cases where several distinct speeds may be obtained by changing the connections of the windings or by other means.

According to their mechanical features motors may be classified as: (1) Open. (2) Mechanically Protected. (3) Semi-Enclosed. (4) Totally Enclosed. (5) Enclosed, Externally Ventilated. (6) Enclosed, Self-Ventilated. (7) Moisture Proof. (8) Splash and Water Proof. (9) Submergible. (10) Acid Proof. (11) Explosion Proof.

Limitations.—The principal limitations in the ratings of motors are: (1) Mechanical Strength. (2) Heating. (3) Commutation. (4) Regulation. (5) Efficiency.

CHARACTERISTICS OF MOTORS AFFECTING THEIR APPLICATIONS.

(D. B. Rushmore, "American Handbook for Electrical Engineers.")

Series Motor.—This motor is used when a powerful starting torque and rapid acceleration are required, without an excessive instantaneous demand of energy. The torque is practically independent of the voltage and at low-flux densities varies directly as the square of the current, but as the magnetization approaches saturation it becomes more nearly proportional to the first power of the current. The maximum torque exists at low speed, this being the most valuable feature of the series motor. Dangerously high speeds may be attained by the armature with very light loads, and series motors should for this reason be either geared or direct connected to the load.

Speed Control of Series Motor.—The speed of a series motor on constant potential varies automatically with the load, increasing as the load decreases. The speed may, however, be adjusted if some means of varying the impressed voltage is provided. As the work required of a series motor is very often intermittent in character, the insertion of resistance in the armature circuit to reduce the speed is permissible from an economic standpoint in such cases. In others, such as railway work, where two or four motors are used, reduced voltage is most readily and economically obtained by connecting the motors in series or in series parallel.

Shunt Motor.—This motor has good starting characteristics and a practically constant speed, varying only slightly with load changes. The speed can, however, be adjusted, either by changing the e.m.f. impressed on the armature or by changing the field flux.

Speed Adjustment by Armature-voltage Control, *i.e.*, by changing the e.m.f. impressed on the armature, does not change the full-load torque which the motor is capable of exerting, since the rated torque depends only upon field flux and rated armature current. These methods are therefore constant-torque methods and are properly adapted to loads in which the torque remains constant regardless of speed. The method most generally used for varying the impressed e.m.f. with a single-voltage system is by means of inserting resistance in series with the armature. The efficiency with this method is, of course, very low at slow speeds. The speed regulation with varying loads may also be very poor.

There are several systems of controlling the motor speeds by applying different voltages, such as by the use of three-wire generators or two-wire generators with balancer sets or by the Ward Leonard system. This latter system, which is the most practical, consists of a constant-speed motor driving a generator which supplies current to the motor whose speed is to be adjusted. This arrangement is very satisfactory, but on account of the expense of providing three full-sized machines instead of one to perform the work, the cost may be prohibitive except with very large motors, such as for hoists, etc.

Speed Adjustment by Shunt-field Control, *i.e.*, by inserting resistance in the shunt-field circuit, is the simplest of all methods of speed variation, but with ordinary shunt motors the range of speed variation by this means is small. Where a variation of more than from 20 to 30 per cent is desired, a motor of modified design and of a certain increased size is generally required, because the field must be more powerful with respect to the armature than in the case of standard single-speed motors. Variable-speed motors of the field-weakening type are not constant torque, but constant-output motors, i.e., the torque falls proportionally as the speed increases.

A speed variation up to 3 to 1 meets, as a rule, all requirements, and such motors can readily be obtained in commercial sizes. Should a greater speed variation be desired, say 4 to 1 or 5 to 1, it is possible to accomplish this by the commutating-pole shunt motor with field control only. A combined field and armature control would, however, be a better method.

Compound Motor.—This motor is provided with both a series and a shunt field. The two fields are usually connected so that they act in the same direction, in which case the motor is called a "cumulative" compound motor. "Differential" compound motors, with the two fields opposing, are sometimes employed for special services. The cumulative, or ordinary, compound motor combines the characteristics of the shunt and series motors, having a speed not extremely variable under load changes, but developing a powerful starting torque and an increasing torque with increasing load. Motors having a comparatively weak series field are employed extensively in shop practice where the motor may be required to start under heavy load, but must maintain an approximately constant speed after starting, or when the load is removed. The heavily compounded motor is used where powerful starting torque and rapid acceleration are necessary, with a speed not varying too widely under load changes, such as for rolling mills, etc.

The speed control employed with compound motors may be any of the various methods explained in connection with the shunt motor. For certain service the control may be entirely rheostatic, the series winding being cut out after the motor has come up to speed.

Induction Motor.—The induction motor is essentially a constant-speed machine, although the speed may be varied either by varying the applied stator frequency or by introducing resistance in the rotor circuit. It is built in two distinct types, namely, the squirrel-cage and the phase-wound.

Squirrel-cage Motor.—The squirrel-cage type is used for constant-speed service with infrequent starting. It has a relatively small starting torque per ampere and draws a large starting current from the line. By increasing the resistance of the rotor, it may, however, also be built in the smaller sizes for a high starting torque, rapid acceleration and frequent starting, for such applications as sugar and laundry centrifugals, etc., where simplicity of control is desirable. They are also used for operating punches, shears, etc., where a fly-wheel is provided for storing the energy.

Induction Motor with Wound Rotor.—For service requiring high starting torque combined with moderate starting current a motor with the wound type of rotor is best adapted. A motor with the resistance mounted inside the rotor should not be used to operate machinery having large inertia or excessive static friction, since full starting current may be required for a long period before the apparatus attains full speed, and, as the capacity of the internal resistance is small, excessive temperatures may result. This type of motor is, as a rule, not built above 200 horse-power, due to mechanical difficulties involved in connection with the internal resistance.

A motor with external resistance should be used for moderate and large sizes. The rotor must then be provided with collector rings and brushes. The contact resistance of these as well as the leads and the controller fingers, which are in the circuit all the time, may impair the efficiency and regulation of the motor, especially if the controller and the resistance are located some distance from the motor. The phase-wound induction motor with an external variable-rotor resistance is best adapted for a variable-speed service, as the losses necessary to obtain reduced speeds are external to the motor itself.

Multi-speed Induction Motors.—It often happens that the service is such that two or three speeds will be satisfactory for the operation of the machinery and that these speeds must be independent of the load. Under such conditions multi-speed motors can frequently be used. In these motors the different synchronous speeds are produced by changing the number of poles in the magnetic circuit. Each of these speeds is fixed, if no resistance is used in the secondary circuit. With multi-speed motors, as with single-speed motors, however, resistance may be used in the secondary circuit for varying the speed.

A change of the number of poles may be made in any of the following ways:

1. By the use of single magnetic and electric circuits, changing the number of poles by re-grouping the coils. 2. By the use of single magnetic circuits and independent electric circuits. 3. By means of separate magnetic and electric circuits, the so-called Cascade connection.

Synchronous Motor.—The speed of a synchronous motor is constant, being fixed by the number of poles and the frequency of the applied voltage. The single-phase type is not self-starting and the polyphase type has in itself a very poor starting torque. They may, however, be made self-starting in the same manner as squirrel-cage induction motors, by the use of an amortisseur or cage-winding, similar in construction to that used for induction motors.

The speed-torque curve of a synchronous motor is similar to that of an induction motor except that the torque values are lower for a given resistance of rotor winding on account of the construction of the machine. The starting winding must be designed with both the load at start and the load at synchronous speed in mind, because too great a slip may cause the motor to shut down when the field is put on. It is, however, seldom that the same motor will be called upon to start a heavy load and at the same time synchronize a heavy load, as the load usually consists principally of either static friction, as in the use of motor-generator sets, line shafting, etc., or it comes up with the speed as in the case of a fan blower or centrifugal pump. The former case would be met by a high-resistance squirrel-cage winding and the latter would require a low resistance.

Single-phase Series Motor.—This type of commutator motor has a very powerful starting torque, high power factor, and relatively high efficiency. It is most generally used for traction work, the speed being controlled by varying the applied voltage which can most readily be done by means of an auto-transformer with a number of taps.

Repulsion Induction Motor.—This type of commutator motor has a limited speed and an increase of torque with decrease in speed. The action of the compensating field insures a power factor approximately unity at full load and closely approaching unity over a wide range in load. In addition, it serves to restrict the maximum no-load speed and also permits, where varying speed service is involved, an increase over the synchronous speed.

Starting of Repulsion Motors.—A repulsion motor, if started by directly closing the line switch, will develop about $2\frac{1}{2}$ times full-load torque. The starting current corresponding to full-load starting torque is from 2 to $2\frac{1}{4}$ times full-load running current. As a general rule, starting boxes are not required up to and including 2-horse-power rating. From 2 to 5 horse-power the use of a rheostat is optional, dependent upon the degree and care to be exercised in maintaining voltage regulation. Starting boxes should, however, preferably be used on sizes above 5 horse-power, especially where light and power circuits are combined.

Reversible Repulsion Motors.— The repulsion motor may be designed for reversible service. This is accomplished by adding an auxiliary reversing winding spaced 90° from the main field winding and connected in series with it. By reversing the relative polarity of the two windings, the direction of rotation is changed in a simpler manner than by mechanical shifting of the brush holder yoke. Instant reversal may be effected from full speed in one direction to full speed in the other, about 200 per cent of normal running torque being developed at the moment of speed reversal in either direction.

Variable-speed Repulsion Motors.—In addition to the constant-speed repulsion motor, two other types are also available, one for constant-torque and variable-speed service, the other for adjustable speed independent of torque. In general, variable-speed repulsion motors are not applicable to lathes, boring mills, or similar machines where the service requires adjustable speed and constant horse-power at all speeds below and above normal. When a certain amount of variable speed is required at approximately constant torque, such as in driving fans, blowers, printing presses, etc., the repulsion motor successfully meets a wide field of application.

MOTOR APPLICATIONS.

Pumps (E. A. Lof, in *Coal Age*).—Pumps are either of the reciprocating or centrifugal type. In the former the volume of water can be varied either by changing the speed or by the use of a by-pass valve. The latter method is, of course, less economical, and speed variation is, therefore, preferable. In starting large pumps the water may, however, be delivered through a by-pass until the motor is up to speed, when this passage is gradually closed and the water delivered into the pipe system. The load at starting, therefore, only consists of the friction losses, and usually does not exceed 25 per cent of the full-load torque.

Either direct- or alternating-current motors may be used for driving reciprocating pumps. When of the former class, the compound-wound type is generally selected for single-acting pumps on account of their rather pulsating load, while for duplex and triplex pumps, having steadier characteristics of power demand, the shunt-wound motor is used to advantage. Both squirrel-cage and phase-wound induction motors are suitable, the latter as a rule being selected where it is desirable to reduce the starting current to a minimum or where a somewhat variable speed is required.

Synchronous motors may also be used for driving large pumps of moderate speed, and are admirably adapted for such service, while their characteristics are such that by over-exciting their fields they may be made to considerably improve the power factor of the system. By-pass valves should preferably be provided on the pumps, when this type of motor is employed, so as to reduce the starting current as much as possible.

In selecting the motor equipment for a centrifugal pump, its characteristics as affected by the service conditions must be carefully predetermined, and in some respects the operating features of this type of water lift are entirely opposite to those of reciprocating pumps.

With constant speed an increase of the resistance against which the reciprocating pump operates increases the water pressure and, therefore, the load on the motor, while with the centrifugal pump an increase of the resistance reduces the load. The volume of water delivered by a reciprocating pump is not affected by the reduction of the head, but the required power is lessened. A reduction of the head with a centrifugal pump, however, increases the volume of water, and as the efficiency at the same time goes down rapidly, the load increases. It is, therefore, of importance to know what this overload, caused by a reduction of the head, amounts to, and the duration of the overload; and the capacity of the motor should, as a rule, be governed by the low- and not the high-head conditions.

The starting condition must be given careful consideration in selecting the motors. In starting a centrifugal pump the discharge valve may be entirely closed until the motor comes up to speed, so that the latter may start as nearly light as possible. As the machine accelerates, the water is churned around in the casing, causing the motor to load up as it approaches full speed, when, with pumps of the usual design, it takes from 40 to 50 per cent of full-load torque to drive it even though pumping no water.

Shunt-wound, direct-current motors and either squirrel-cage or phase-wound induction motors are well adapted for this type of pump and will readily meet the above conditions. A synchronous motor may lead to difficulties unless precautions are taken in designing the squirrel-cage starting winding with a sufficiently low resistance so that it will develop enough torque to pull the motor into synchronism. When this is done, however, the starting current is increased and a compromise must usually be made.

Fans.—Either direct- or alternating-current motors can be used for driving fans. Where the air-supply must be regulated, such as in mines, the motors must be of the adjustable-speed type. Direct-current motors may be either of the shunt- or compound-wound type, the speed regulation being accompanied by field control. Shunt-wound motors are generally used, but compound-wound motors are preferable for very large fans requiring a great starting torque.

With an alternating-current system, the phase-wound induction motor should be used, the speed regulation being accomplished by inserting resistance in the secondary rotor circuit.

Air Compressors.—Air compressors may be divided in two classes, centrifugal and reciprocating. The former require a high speed for their operation, while the speed of the latter is comparatively low.

Shunt-wound, direct-current motors and both squirrel-cage and phase-wound induction motors are used for driving them, the phase-wound type being preferable for larger units, where a low starting current is desirable.

With direct-current systems, shunt-wound motors are usually used for centrifugal compressors and compound-wound for the reciprocating type.

Hoists (E. A. Lof, in *Coal Age*).—The two principal classes of electric mine-hoist equipments are: The direct-current motor operated from its own motor-generator set by generator field control, and the induction motor. The direct-current motor lends itself well to direct connection, as the characteristics of slow-speed motors of this type are excellent. The cost of a direct-connected motor will, in practically all cases, be higher than that of a geared motor, but in some instances this is largely offset by the saving in gearing, etc. Where, however, a considerable saving can be made by using a geared motor, and where the mechanical advantages of a direct-connected hoist are not an important consideration, a geared direct-current motor should be employed. Such a motor should be separately excited and shunt-wound, and the current should be obtained from a separately excited generator of similar type, both machines being driven by a direct-coupled induction motor where the source of supply is alternating current, as is almost invariably the case.

The control of the hoist motor is effected by regulating and reversing the exciting current of the direct-current generator, thus varying the voltage impressed upon the motor terminals. The current for the motor and dynamo fields is supplied from the direct-connected exciter, and in the case of the motor it is maintained constant. As the rapidity of hoisting is practically proportional to the voltage impressed upon the motor armature, the controlling gear is arranged so that the speed will be directly proportional to the distance by which the controlling lever is moved away from the neutral position. This system of hoisting has the great advantage that the rheostatic losses are reduced to a minimum and that the operator has perfect control over the motor.

In many cases it is highly desirable to reduce the instantaneous peak loads and equalize the current input to the hoist. This is especially true where the power charge is based wholly or partly on the maximum demand, and any practicable method, therefore, by which energy may be taken from the line and stored during periods of light load and discharged when the hoist load is heavy, makes it possible to greatly reduce the maximum input and consequently the charge for power.

The simplest method of effecting this is by adding a fly-wheel to the motor-generator set, previously described. In order to permit the fly-wheel to take care of the peaks, and equalize the load, the speed of the set must be varied according to the demand for power. This is accomplished by an automatic slip regulator connected in the secondary circuit of the induction motor, which, in this case, must be of the phase-wound type.

The second important class of electric hoisting systems is, as previously stated, driven by induction motors. Excessive low-speed motors of this type and of moderate capacities do not show particularly good electrical characteristics. For large-capacity hoists at high-rope speeds, using as small a drum diameter as is consistent with good practice, a direct-connected induction motor is, in some instances, entirely feasible, and a number of such equipments are in actual operation abroad. However, the great majority of induction-motor-driven hoists now in use and which will be installed in the future are and will continue to be of the geared type.

The induction motor must be of the phase-wound type, and the speed control is accomplished by cutting in or out resistance in the secondary circuit. Drum controllers with grid resistances are used up to about 200 horse-power, while between this and 400 horse-power it is customary to provide a complete magnetic-contactor control. Above 400 horse-power the liquid rheostat is usually employed as a secondary resistance and control.

For equalizing the load taken by an induction-motor-driven hoist, a fly-wheel motor balancer may be used. This consists of a shunt-wound or compound-wound direct-current motor, connected to a heavy fly-wheel and carrying a direct-connected exciter. The motor balancer is floated indirectly across the incoming line circuit, being tied in by means of a rotary converter or motor-generator set. A regulator actuated by the line current controls the direct-current motor field, so that when the power taken by the hoist drops below the average, the field is automatically reduced, causing the fly-wheel set to speed up and absorb power from the supply system and store it in the fly-wheel. When the load on the hoist motor exceeds the average, the operation is reversed, the fly-wheel set slows down, and power is returned to the system through the rotary converter.

Machine Tools (Abstracted from C. Fair, *General Electric Review*, 1914).—In general, the most satisfactory electrical equipment for machine shops, using a large number of motors, would be one having available both A.C. and D.C. distribution; A.C. for all constant speed machines and D.C. for adjustable speed machines.

In the smaller shops, with rare exceptions, the choice of motors would depend upon the current available, which in the majority of cases would be alternating current. The size and product of the small factory make a proper layout a comparatively simple matter, while in larger factories skill and ingenuity are essential to obtain the most advantageous equipment. The standard motor of to-day will answer for the majority of the machine tools, although special motors are in some cases necessary.

When equipping tools with individual drives, the controlling apparatus as well as the motor should be attached directly to the tool whenever possible. In the case of portable tools this, of course, is a necessity.

A graphic recording wattmeter in circuit with a tool is of value in efficient management, as it not only tells the actual power consumed by the machine, showing whether or not the tool is properly motored, but it also shows whether the tool is operating at its maximum rate, by registering the time of unproductive cycles or the length of time the tool is idle. By analysis, the cause of the lost time may be discovered and a change of operating conditions can be made with a corresponding increase in production.

* Squirrel cage rotor.
† Squirrel cage rotor—high starting torque.
‡ Slip ring induction motor with external rotor resistance.
§ Does not apply to reversing motors.
** D. C. series motor.

The table on p. 1467 will, in a general way, aid in the choice of motors. The great variety and size of tools of the same name make it necessary in a general list, such as this, to double-check a number of tools. It must be kept in mind, however, that various circumstances, such as size and roughness of work, and fly-wheel capacity, etc., may call for radical departures in the choice of motors, this list being compiled to meet average conditions.

Shunt motors, for instance, are used in the following cases: When work is of a fairly steady nature, when considerable range of adjustment of speed is required, as on lathes and boring mills, and on group and line-shaft drives, etc.

Compound-wound motors are used where there are sudden calls for excessive power of short duration, as on planers without reversing motor drives, punch presses, bending rolls, etc.

Series motors should be used where speed regulation is not essential, and where excessive starting torque is required, as, for instance, in moving carriages of large lathes, in raising and lowering the cross rails of planers and boring mills, and for operating cranes, etc., but not where the motor can be run without load, through the opening of a clutch, or by a belt leaving its pulley, as the motor would run away if the operator failed to shut off the power.

When in doubt as to the choice of compound or series motors of small horse-power, the choice might be determined by the simplicity of control in favor of the series motor.

The alternating-current motor of the squirrel-cage rotor type corresponds to the constant-speed, shunt, direct-current motor; but with a high-resistance rotor it approaches more closely the characteristics of a compound, direct-current motor. It is understood that the variable-speed machines checked in the table above under the alternating-current squirrel-cage rotor column have the necessary mechanical speed changes.

The slip-ring induction motor with external rotor resistance would be used for variable speed, but this must not be construed to mean that it corresponds to a direct-current, adjustable-speed motor, as it has the characteristics of a direct-current shunt motor with armature control.

The self-contained, rotor resistance type could be used for lineshaft drives, and for groups when of sufficient size.

Multi-speed, alternating-current motors are those giving a number of definite speeds, usually 600 and 1200, or 600, 900, 1200, and 1800 r.p.m., and are made for both constant power and constant torque. These motors would be used where alternating current only was available, and where the speed ranges of the motor, together with one or two change gears, would give the required speeds. These motors should, however, be used with discretion, especially on sizes above six horse-power.

The adjustable speed, A.C., commutator brush-shifting type of motor with shunt characteristics would, on account of high cost, be used mostly where an adjustable speed motor was highly desirable and where A.C. only was available and where there were not enough machines calling for adjustable speed drive to warrant putting in a motor-generator set.

ILLUMINATION—ELECTRIC AND GAS LIGHTING.*

Illumination.—Some writers distinguish "lighting" and "illumination." Lighting refers to the character of the lights themselves, as dazzling, brilliant, or soft and pleasing, and illumination to the quantity of light reflected from objects, by which they are rendered visible. If the objects in a room are clearly seen, then the room is well illuminated.

The quantity of light is estimated in candle-power per square foot of area or per cubic foot of space. The amount of illumination given by one candle at a distance of 1 ft. is known as a foot-candle. Since the illumination varies inversely as the square of the distance, one foot-candle is given by a 16-candle-power lamp at a distance of 4 ft., or by a 25-c.-p. lamp at a distance of 5 ft.

Terms, Units, Definitions.—Quantity of light proceeding from a source of light, measured in units of luminous flux, or lumens.

Intensity with which the flux is emitted from a radiant in a single direction, called candle-power.

Illumination, density of the light flux incident upon an area.

* Contributed by Prof. W. H. Timbie.

Luminosity, brightness of surface; flux emitted per unit area of surface.

Candle-power, the unit of luminous intensity. A spermaceti candle burning at the rate of 120 grains per hour is the old standard used in the gas industry. It is very unsatisfactory as a standard and is being displaced by others.

The hefner lamp, burning amyl acetate, is the legal standard in Germany. The unit of luminous intensity produced by this lamp when constructed and operated as prescribed is called a *hefner*. The standard laboratories of Great Britain, France, and America have agreed upon the following relative values of the units used in the several countries: 1 International Candle = 1 Pentane Candle = 1 Bougie Decimale = 1 American Candle = 1.11 Hefners = 0.104 Carcel unit. 1 Hefner = 0.90 International Candle.

Intrinsic Brilliancy of a source of light = candle-power per square inch of surface exposed in a given direction.

Lumen, the unit of luminous flux, is the quantity of light included in a unit solid angle and radiated from a source of unit intensity. A unit solid angle is the angular space subtended at the surface of a sphere by an area equal to the square of the radius, or by $1 \div 4\pi$, or 1/12.5664 of the surface of the sphere. The light of a source whose average intensity in all directions is 1 candle-power, or one mean spherical candle-power, has a total flux of 12.5664 lumens.

Foot-candle, the unit of illumination, = 1 lumen per square foot; the illumination received by a surface every point of which is distant one foot from a source of one candle-power.

Lux, or meter-candle, 1 lumen per square meter; 1 foot-candle = 10.76 meter-candles.

Law of Inverse Squares.—The illumination of any surface is inversely proportional to the square of its distance from the source of light. This is strictly true when the source of light is a point, and is very nearly true in all cases when the distance is more than ten times the greatest dimension of the light-giving surface.

Law of Cosines.—When a surface is illuminated by a beam of light striking it at an angle other than a right angle, the illumination is proportional to the cosine of the angle the beam makes with a normal to the surface.

If E = the illumination at any point in a surface, I the intensity of light coming from a source, θ the angle of deviation of the direction of the beam from a normal to the surface, and l the distance from the source, then $E = I \cos \theta \div l^2$.

Relative Color Values of Various Illuminants.—The light proceeding from any source may be analyzed in terms of the elementary color elements, red, green and blue, by means of the spectroscope, or by a colorimeter. The following relative values have been obtained by the Ives colorimeter (*Trans. Ill., Eng. Soc.*, iii, 631). In all cases the red rays in the light are taken as 100, and the two figures given are respectively the proportions of green and blue relative to 100 red.

Average daylight, 100,100. Blue sky, 106,120. Overcast sky, 92, 85. Afternoon sunlight, 91, 56. Direct-current carbon arc, 64, 39. Mercury arc (red 100), 130, 190. Relation of Illumination to Vision.—Wickenden gives the following summary of the principles of effective vision:

1. The eye works with approximately normal efficiency upon surfaces possessing an effective luminosity of one foot-candle or more.
2. Excessive illumination and inadequate illumination strain and fatigue the eye in an effort to secure sharp perception.
3. Intrinsic brilliancy of more than 5 c.-p. per sq. in. should be reduced by a diffusing medium when the rays enter the eye at an angle below 60° with the horizontal.

4. Flickering, unsteady, and streaky illumination strains the retina in the effort to maintain uniform vision.
5. True color values are obtained only from light possessing all the elements of diffused daylight in approximately equivalent proportions.
6. An excess of ultra-violet rays is to be avoided for hygienic reasons.
7. Æsthetic considerations commend light of a faint reddish tint as warm and cheerful in comparison with the cold effects of the green tints, although the latter are more effective in revealing fine detail.

Types of Electric Lamps.—The carbon arc lamp is now rapidly disappearing on account of the cost of maintenance of the open type and the low efficiency of the enclosed type. Gas-filled tungsten lamps now operate at less cost on the same circuits on which these arcs formerly burned.

The Flaming Arc.—The carbons are impregnated with calcium fluoride or other luminescent salts. The current is usually 8 to 12 amperes and the voltage per lamp 35 to 60. The regenerative flame arc is a highly efficient variety of the flame arc.

The Magnetite Arc has for a cathode a thin iron tube packed with a mixture of magnetite, Fe_3O_4, and titanium and chromium oxides. The anode consists of copper or brass. It is well adapted to series operation with low currents. The 4-ampere lamp, using 80 volts per lamp, is highly successful for street illumination.

The Tungsten Incandescent (*vacuum*) depends upon the heating of a drawn tungsten filament to incandescence in a vacuum. They are made in sizes for 25, 40, 60, 100, 150, 250, 400, 500, 750, and 1000 watts and average about 1 candle-power for each watt, with a life of 1000 hours, before the candle-power falls below 80% at rated voltage.

The Tungsten Incandescent (*gas-filled*) has the advantage of having longer life and being smaller than the vacuum lamp of the same wattage. They are filled with an inert gas, generally nitrogen or argon, and have an efficiency of 2 candle-power per watt in the larger sizes (the average being about 1.7 candle-power per watt), with a life of 1300 hours.

The Mercury Vapor Lamp is an arc of luminous mercury vapor contained in a glass tube from which the air has been exhausted. A small quantity of mercury is contained in the tube, and platinum wires are inserted in each end. When the tube is placed in a horizontal position so that a thin thread of mercury lies along it, making electrical connection with the wires, and a current is passed through it, part of the mercury is vaporized, and on the tube being inclined so that the liquid mercury remains at one end, an electric arc is formed in the vapor throughout the tube. The tubes are made about one inch in diameter and of different lengths, as below. The mercury vapor lamp is very efficient, ranging from 1.9 c.-p. per watt for the 900 c.-p. size to 1.55 c.-p. per watt for the 300 c.-p. size. The color of the light is unsatisfactory, being deficient in red rays, but it possesses a very penetrating quality which makes it valuable in drafting rooms and wherever a light is needed to bring small details out sharply. The spectrum consists of three bands, of yellow, green, and violet, respectively. The intrinsic brilliancy of the lamp is very moderate, about 17 c.-p. per sq. in. Commercial lamps are made of the sizes given below. The lamp is essentially a direct-current lamp, but it may be adapted to alternating-current by use of the principle of the mercury-arc rectifier. The tubes have a life ordinarily of about 1000 hours.

The Quartz-Tube Mercury-Arc Lamp operates at a higher voltage and gives much nearer a white light. Owing to the injurious ultraviolet rays given out by this form, it must always be enclosed in a globe of clear glass. The efficiency ranges from 2.4 to 3.3 c.-p. per watt and the life averages 3000 hours. It is made in sizes from 1000 to 3500 c.-p.

Street Lighting.—Street lighting may be divided into three classes:
(a) "White-Way" or display illumination.
(b) Main road illumination.
(c) Residence district lighting.

The object of "White-Way" illumination is generally advertising and many more lights are used than are necessary for proper road illumination. The lamps generally used are the titanium arc, the magnetite arc, the yellow flaming arc, and the white flaming arc of over 1000 c.-p. See last column of Table VI.

In "Main-road" illumination the purpose is to illuminate the road appreciably for night automobile travel. The lamps generally used are some type of the 300-watt flaming arc, the magnetite arc, or the titanium arc of Table IV. These are usually placed from 200 to 300 ft. apart at heights varying from 15 to 18 ft.

For Residential-district Lighting, where vehicle travel is infrequent and slow, the smaller sizes (40 to 100 c.-p.) of tungsten lamps are used spaced from 100 to 200 ft. at height varying from 15 to 18 ft. according to shading of the road by the foliage. Tungsten lamps of the higher candle-powers of 200 to 450 are also used with spacings of 200 ft. and over, with reflectors designed to give the best distribution of the light.

Illumination by Arc Lamps at Different Distances.—Several diagrams and curves showing the light distribution in a vertical plane and the illumination at different distances of different types of lamps are given by Wickenden. From the latter are taken the approximate figures in the table below. The carbon and the magnetite lamps were 25 ft. high, the flame arcs 21 ft.

TABLE I.—Illumination by Arc Lamps.

Horizontal Distance from Lamp, Feet.	20	30	40	50	100	150	200	250
Kind of Lamp.	Foot-candles, normal illumination.							
A. Open carbon arc, D.C., 6.6 amp.	....	0.40	0.29	0.20	.032	.014	.006	.002

E. Magnetite arc, 6.6 "	....	1.00	0.69	0.51	.15	.075	.045	.025
F. Magnetite arc, 4 "	0.47	0.40	0.30	0.21	.07	.035	.022	.018

A. 6.6 amp., D.C., open arc, clear globe.

B. 6.6 amp., A.C., enclosed arc, opal inner and clear outer globe, small reflector.

C. 10 amp., flame arc, vertical electrodes; 50 volts, 1520 M.H.C.-P.*; 0.33 watt per M.L.H.C.-P.*; 10 hours per trim.

D. 7 amp., regenerative flame arc, 70 volts, 2440 M.L.H.C.-P., 0.2 watt per M.L.H.C.-P., 70 hours per trim.

E. 6.6 amp., D.C. series magnetite arc, 79 volts, 510 watts, 1450 M.L.H.C.-P. 75 to 100 hours per trim.

F. 4 amp., D.C. series magnetite arc, 80 volts, 320 watts, 575 M.L.H. C.-P., 150 to 200 hours per trim.

TABLE II.—Data of Some Arc Lamps.

Type of Lamp.	Hours per Trim.	Amperes.	Terminal Volts.	Terminal Watts.	Watts per M.L.H. C.-P.
D.C. series carbon, open	9 to 12	9.6	50	480	0.6
D.C. series carbon, enclosed	100 to 150	6.6	72	475	0.9
A.C. series carbon, enclosed	70 to 100	7.5	75	480	1.25
D.C. multiple carbon, enclosed	100 to 150	5.0	110	550	2.25
A.C. multiple carbon, enclosed	70 to 100	6.0	110	430	2.40
D.C. flame arcs, open	10 to 16	10	55	440	0.45
Regenerative, semi-enclosed	70	5	70	350	0.26
A.C. flame arcs, open	10 to 16	10	55	467	0.55
Magnetite, open	70 to 100	6.6	80	528	0.45

Values of watts per M.L.H.C.-P. approximate for open carbon arcs and magnetite arcs with clear globes, enclosed arcs with opalescent inner and clear outer globes, and for flame and regenerative arcs with opal globes.

*M.H.C.-P. = mean horizontal candle-power;
M.L.H.C.-P. = mean lower hemispherical candle-power.

Relative Efficiency of Illuminants.—The advent of the gas-filled tungsten incandescent lamp of high efficiency and high candle-power has driven the less efficient arc lamps from the field. At present (1915) the incandescent lamp of the 200- or 300-watt size is more efficient than the arc lamp of the same candle-power. On the other hand, the 1000-c.-p. arcs are more efficient than the incandescent lamps of the same size. The field for the arc lamp seems to be in the higher candle-power sizes. Dr. Steinmetz in *The General Electric Review* for March, 1914, gives the following tables.

TABLE III.—Relative Efficiency of Illuminants.

(Irrespective of Size, in Available Mean Spherical C.-P. per Watt).

TABLE V.—Efficiency of 500-Watt Illuminants.

	Available Mean Spherical C.-P. per Watt.	Available Mean Spherical C.-P.
A.C. series enclosed carbon arc	0.42	210
Mazda lamp (1 watt per h. c.-p.)	0.64	320
D.C. series enclosed carbon arc	0.65	325
Gas-filled mazda lamp (0.5 watt per h. c.-p.)	1.28	640
Standard 6.6 amp. d.c. magnetite arc	1.5	750
Special 6.6 amp. d.c. magnetite arc	1.7	850
White flame carbon arc, best	1.95	975
Quartz mercury lamp	2.0	1000
Yellow flame carbon arc, best	3.1	1550
A.C. titanium arc	3.6	1800

Characteristics of Tungsten Lamps. Vacuum Type.—The accompanying Table VII refers to tungsten lamps of the 25, 60, and 100 watt size. They show the changes which take place in the candle-power, watts, watts per candle-power and life when used at the various voltages. It is to be noted that a 4% increase in voltage above the normal (100%) increases the candle-power 15%, the efficiency 6%, but decreases the life 38%.

TABLE VI.—Relative Efficiency of Various C-P. of Illuminants.

200 Mean Spherical C.-P.		300 Mean Spherical C.-P.		400 Mean Spherical C.-P.		500 Mean Spherical C.-P.		1000 Mean Spherical C.-P.

Interior Illumination.—There are three systems for artificially lighting interiors. All three are easily adapted for the use of either gas or electricity or both: (1) Direct lighting; (2) indirect lighting; (3) semi-indirect lighting.

(1) *Direct Lighting.*—When the room is illuminated almost entirely by the light which comes directly from the lamps without reflection from walls and ceilings, it is said to be illuminated by direct lighting. This is the usual form of lighting.

(2) *Indirect Lighting.*—When a room is illuminated by the light of concealed lamps which is reflected from the walls and ceiling, the system of illumination is said to be indirect. The ceiling and walls must be light-colored. There is an entire lack of shadows in a room thus lighted.

(3) *Semi-indirect Lighting.*—When a room is illuminated mostly by light reflected from the walls and ceiling but still receives 15 or 20% directly from the lamps, the system of illumination is said to be semi-indirect. This system produces particularly pleasing effects.

The Quantity of Electricity and Gas Necessary to Illuminate Various Rooms.—Practically all modern illumination is done either by tungsten incandescent electric lamps or gas lamps with incandescent mantles.

The following table of electricity and gas necessary to light rooms used for given purposes is based on the fact that in the modern mazda lamps 1.1 watt produces 1 c.-p., and in the best gas lamps with incandescent mantles, 0.04 cu. ft. per hour of gas produces 1 c.-p. Inasmuch as there are no bright spots in the room to fatigue the eye, when indirect and semi-indirect systems are used, a lower degree of illumination is sufficient to enable objects to be clearly seen. Hence, although the indirect and semi-indirect systems are less efficient, the following table applies to all these methods:

TABLE VIII.—Electricity or Gas Necessary to Sufficiently Illuminate Rooms.

Use of Rooms.	Watts per Sq. Ft. of Working Plane.	Cu. Ft. per Hour per Sq. Ft. of Working Plane.	Use of Rooms.	Watts per Sq. Ft. of Working Plane.	Cu. Ft. per Hour per Sq. Ft. of Working Plane.

Library (public reading room)...	1.4-1.5	0.055-0.06			

For gas-filled tungsten and Welsbach "Kinetic" use 0.6 of above values. Data on gas furnished by F. R. Pierce, Welsbach Co.

Example of Use of Table VIII.

Specify the proper lighting arrangements for a banking office 25 ft. × 40 ft. with a 13-ft. ceiling.

The four-lamp fixture is an efficient and pleasing arrangement of lamps. It does not give quite as uniform distribution of light as individual lamps uniformly spaced, but the effect is much more pleasing and the distribution is very satisfactory.

Using Electricity.—

Watts per sq. ft. needed = 1.5 – 1.6 (Table VIII).
Total watts needed = 1.5 × 40 × 25.
= 1500 watts.

Using four-lamp fixtures, we shall need six fixtures, as in Fig. 250, in two rows of 3 each.

$$\text{Watts per fixture} = \frac{1500}{6} = 250.$$

$$\text{Watts per lamp} = \frac{250}{4} = 62.5.$$

On consulting Table IX we find we can use 60-watt lamps as the standard lamp nearest the size computed. If at any place more light is needed, 100-watt lamps may be substituted in the nearest fixture.

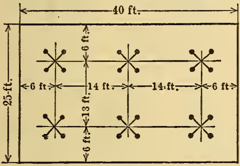

Fig. 250.

Using Gas.—To use gas with the same number of similar fixtures, we would have to use lamps which correspond to the 60-watt mazda. Allowing 25 watts to the cu. ft. per hour of gas, we would need a lamp which would burn $\frac{60}{25}$ or 2 1/2 cu. ft. per hour of gas. By Table IX, we see that this is a standard size.

The foregoing rules are merely intended to serve as a guide for planning correct illumination. They are not intended to take the place of judgment and intelligence. The details of each lighting project differ slightly from the details of every other lighting project and due weight should be given to ways in which these details affect the application of general rules.

Cost of Electric Lighting. (A. A. Wohlauer, *El. World*, May 16, 1908, corrected, July, 1915.)—The following table shows the relative cost of 1000 candle-hours of illumination by lamps of different kinds, based on costs of 2, 4 and 10 cents per Kw.-hour for electric energy. The life, K, is that of the lamp for incandescent lamps, of the electrode for arc lamps, and of the vapor tube for vapor lamps.

L_s = mean spherical candle-power.
S_s = watts per mean spherical candle.
P = renewal cost per trim or life, cents.
K = life in hours.
$C_r = 1000\,P/(KL_s)$.
$C_t = (S_s \times R) + C_r$ = cost per 1000 candle-hours.
R = rate in cts. per K.W. hour.

Illuminant.	Amp.	Volts.	L_s	S_s	P	K	C_r	Rating.	$C_t = (S_s \times R) + C_r$
